Previous biohemical and electrophysiological studies of Hermissenda photoreceptors (Heldman et al., J. Neurophysiol. 42, 153, 1979) have implicated acetylcholine (ACh) as a neurotransmitter mediating their inhibitory interactions. Isolated Hermissenda eyes synthesized and accumulated ACh but not other neurotransmitters. Carbachol (CCh) applications produced potential changes which mimicked naturally evoked inhibitory postsynaptic potentials (IPSP's) and shared the same reversal potential. Histochemical staining revealed the presence of acetylcholinesterase in the photoreceptor endings where synaptic interactions occur; and physostigmine blocked the IPSP's. Evidence was obtained by histochemical techniques that adrenergic substance-(s) are also endogenous to the Hermissenda visual system, specifically within a cluster of 2nd order neurons called optic ganglion cells. Other results suggested that an excitatory synaptic feedback from 2nd order visual cell(s) onto the type B cell is mediated by an adrenergic agonist. There was no indication of other endogenous neurotransmitters anywhere in the Hermissenda visual system (Sakakibara et al., J.Neurochem, 48:405, 1987). In the present experiments we investigated the effects of cholinergic agonists on the same soma membrane ionic currents and the possible interactions of these cholinergic substances with α_2 adrenergic agonists.Isolated medial type B photoreceptors of Hermissenda were impaled with 2 microelectrodes and voltage clamped at -60mV in darkness. Bath application of CCh (1mM) induced an increase of I_A of 10% ± 3.2 (N=5) and I_C of 20% ± 2.7 (N=5) at step commands to 0mV. This effect was clear and sustained after 5 min. of drug application. A voltage - dependent inward sustained calcium current $I_{Ca}2+$ was also measured at 0mV with elevated extracellular K^+ concentration (300mM). Applications of CCh (1mM) also induced an increase of $I_{Ca}2+$ with the same time course of the changes in I_A and I_C. The simultaneous applications of CCh (1mM) and the α_2 adrenergic agonist clonidine (1mM) largely prevented any effect of CCh on I_A and I_C. Serotonin at 1 mM induced a transient increase of I_A and I_C, which reversed spontaneously after 10 min. The results here indicate that modulation of Type B ionic currents could interact with other physiologic conditions (e.g. prolonged depolarization and elevation of intracellular Ca^{2+}) to generate long lasting changes in excitability during classical conditioning. We suggest that the role of endogenous neurotransmitters (both cholinergic and adrenergic) may have more relevance for classical conditioning mechanisms than substances not demonstrated to function in physiologic contexts.

111.6 PKC CLOSES SINGLE VOLTAGE DEPENDENT K CHANNELS IN HERMISSENDA TYPE B PHOTORECEPTORS. J. Farley, D. Resnick*, and S. Auerbach. Prog. in Neurosci., Princeton Univ., Princeton, NJ 08544.

Previous results (Farley & Auerbach, Nature, 1986) have demonstrated that injection of exogenous PKC into Type B cells, as well as activation of endogenous PKC by phorbol esters, mimic the increase in the steady-state depolarizing generator potential and resting input resistance that results from associative training. Conventional two micro-electrode voltage clamp analysis revealed that PKC activation reduced two K^+ currents (I_A and I_{K-Ca}) and enhanced a calcium current (I_{Ca}).

Recently, (Farley, Neurosci. Letter 1987, in press) it has been shown that an intermediate-sized (∿110 pS), calcium- and voltage-dependent K^+ channel, which is TEA- and 4-AP resistant, is likely to underlie the macroscopic I_{K-Ca} current recorded in previous voltage-clamp studies. Here, this channel was studied in ripped-off patches in a bath which contained (in mM): 300 KCl, 10 NaCl, CaCl, 0.15 EGTA, 170 sucrose, 2 Mg-ATP [free calcium was 0.85 mM; ph=7.6]. In the absence of the PKC-activator diacylglycerol (DiG), purified PKC resulted in a transient closure of the intermediate-sized (∿95 pS) K^+ channel in 4 of 4 separate experiments. The duration of PKC's closure, defined as the time required for single-channel activity to return to >50% of the pre-PKC baseline level, was 3.74 ± 4.06 min. In the presence of DiG, PKC addition produced a complete closure of channels in 5 of 5 separate experiments. The average duration of channel closure was 12.25 ± 8.06 min. DiG addition (without PKC) was without consistent effect, although in 3 of 5 experiments a clear closure of channels was observed.

We also observed that PKC consistently closed a smaller (∿ 23 pS) voltage-dependent K^+ channel, whose calcium-, 4-AP, and TEA sensitivities have not yet been determined. In contrast, a large (> 220 pS) calcium-dependent K^+ channel, seen infrequently in B cells, was not affected by PKC. In summary, PKC activation is sufficient to reduce the activity of single calcium-dependent K^+ channels in Type B photoreceptors. The results suggest that these effects are mediated by protein phosphorylation, and that the phosphorylation site is closely associated with the channel itself.

111.7 A PKC-INHIBITOR PREVENTS IN VITRO CONDITIONING-PRODUCED CHANGES IN HERMISSENDA TYPE B PHOTORECEPTORS. E.M. Schuman and J.Farley, Program in Neuroscience and Behavior, Princeton University, Princeton, N.J.,08544.

It has been suggested that training-produced increases in intracellular calcium might play a causal role in both short- and long-term changes in Hermissenda Type B photoreceptor excitability. It has further been proposed that these effects of calcium are mediated by the activation of calcium-dependent phosphorylation pathways. In the present experiments we have assessed the respective roles of two distinct Ca2+-dependent phosphorylation pathways as mediators of short-term neural correlates of learning in Type B photoreceptors during in vitro conditioning. The two pathways are Ca2+/calmodulin-dependent protein kinase (Ca2+/CAM PK) pathway(s), and a calcium-dependent phospholipid-sensitive protein kinase (PKC) pathway.

We have injected relatively specific inhibitors of each pathway (trifluoperazine,TFP, for Ca2+/CAM PK; imipramine for PKC) into Type B photoreceptors and have assessed the effects of the inhibitor upon in vitro conditioning produced changes in B cell excitability. In control experiments, pairings of light and intracellular current stimulation of a statocyst caudal hair cell (in vitro conditioning) resulted in a cumulative depolarization and increased input resistance of Type B photoreceptors (Table 1). Ionophoresis of imipramine into a Type B photoreceptor, prior to in vitro conditioning, prevented these changes. Ionophoresis of TFP failed to affect the in vitro conditioning-produced cumulative depolarization and increased input resistances of Type B cells. Neither imipramine nor TFP had any discernible effects on B cell membrane excitability or light response prior to in vitro conditioning. Biochemical analysis confirmed previous suggestions that imipramine is a more potent inhibitor of PKC than TFP, over the concentration range of 10^{-5} to 10^{-4} M. These results suggest that activation of PKC -- not a Ca2+/CAM-dependent PK -- is of primary importance in mediating the changes in Type B cell membrane excitability which result from associative training.

Table 1

Condition	n	Cumulative depolarization(mV) (sec post-conditioning) 30	60	90	120	Input resistance (% increase)
control	6	5.3*	4.9*	4.3*	3.9*	+25.0
imipr.	6	-0.7	-1.3	-1.7	-1.5*	-02.3
TFP	6	6.2	5.3	5.2	5.2	+15.6

111.8 INHIBITION OF PROTEIN SYNTHESIS BLOCKS LONG TERM PLASTICITY IN IDENTIFIED B-PHOTORECEPTORS IN HERMISSENDA. T. Crow and J. Forrester*. Dept. of Physiology, Univ. of Pittsburgh School of Medicine, Pittsburgh, PA 15261.

Pairing light with direct application of 5-HT to the exposed nervous system of otherwise intact Hermissenda produces a long-term reduction in normal positive phototactic behavior (Crow and Forrester, 1986). Control groups that received unpaired light and 5-HT do not exhibit a significant change in phototactic behavior. Associated with the light-5-HT application are both short-term and long-term changes in the light evoked generator potentials of identified medial and lateral type B-photoreceptors. Previous results suggest that short-term and long-term memory show differential effects of the inhibition of protein synthesis. Protein synthesis appears to be essential in the formation of long-term memory in mammals (Davis and Squire, 1984). Research in Aplysia has indicated that inhibitors of protein synthesis blocked long-term facilitation but not short-term facilitation (Montarolo et al., 1986). In order to determine if short-term and long-term plasticity intrinsic to B-photoreceptors depends upon protein synthesis, we examined the effects of the protein synthesis inhibitor anisomycin on light responses of medial and lateral B-photoreceptors at two different times (1 hr & 24 hrs) following the paired and unpaired application of light & 5-HT.

Anisomycin did not block the short-term enhancement in the generator potentials of medial and lateral B-photoreceptors produced by paired and unpaired light and 5-HT. Surgically isolated lateral and medial B-photoreceptors from the paired group (N=11) and the unpaired group (N=11) exhibited a significantly larger generator potential at the end of a 2 min light step compared to controls that received anisomycin without 5-HT application (N=7) (paired X=28.1mV, unpaired X=28.7mV, anisomycin control X=23.9mV; P < .05). Light responses were examined 1 hr after the application of light and 5-HT in the presence of anisomycin (10^{-6}M). The anisomycin was added to the chamber 30 min before the application of light and 5-HT and was washed out 30 min after the conclusion of the light-5-HT session. In contrast to the results from the short-term experiments, anisomycin blocked the long-term enhancement of the light responses of lateral B-photoreceptors observed 24 hrs after pairing light and 5-HT. Delaying the application of anisomycin 1 hr following the pairing of light and 5-HT or applying a derivative of anisomycin (deacetylanisomycin) (10^{-6}M) that does not inhibit protein synthesis, did not block the enhanced light response produced by paired light and 5-HT (paired & deacetylanisomycin X=29.4mV; paired & delayed anisomycin X=30.1mV; paired & anisomycin X=25mV; P < .01).

Thus short-term plasticity produced by pairing light with 5-HT does not depend upon protein synthesis for its expression. However, the long-term changes in the light response of lateral B-photoreceptors produced by pairing light with 5-HT depends upon protein synthesis. The formation of long-term plasticity in B-photoreceptors appears to have a narrow time window for protein synthesis since delaying the application of anisomycin by 1 hr resulted in the full expression of the enhanced generator potential.

111.9 cAMP LEADS TO LONG-TERM (24HR) CHANGES IN MEMBRANE CURRENT IN APLYSIA TAIL SENSORY NEURONS: A POSSIBLE MECHANISM FOR LONG-TERM SENSITIZATION. K.P. Scholz and J.H. Byrne. Dept. of Neurobiology and Anatomy, Univ. of Texas Med. Sch., Houston, TX 77225.

Sensory neurons that innervate the tail of Aplysia undergo a long-term (24 hr) reduction in net outward currents following sensitization of the animal (Scholz and Byrne, 1986, 1987). This modulation of membrane current appears to contribute to the storage and read-out of long-term memory. In an earlier study, Ocorr et al (1986) found that sensitizing stimuli caused a rapid elevation of cAMP within these same neurons. Since cAMP has been implicated in the regulation of gene expression in other cells, it seemed possible that its transient elevation by sensitizing stimuli might lead to the induction of the membrane effects associated with long-term sensitization. In the present study, we tested this hypothesis by examining the membrane currents of sensory neurons 24 hrs after injecting them with cAMP.

Sensory neurons in the pleural ganglion were impaled with one microelectrode that contained 30 mM fast-green and 200 mM of either cAMP or 5'-AMP. The compounds were injected by passing hyperpolarizing current into the cell (1 nA; five 20 sec trains and one 420 sec pulse). The ganglion was then placed in organ-culture. One day after injection, the same cells were voltage-clamped and their current-voltage relationship obtained over a range of membrane potentials from -80 to +25 mV. The cells injected with cAMP showed significantly less net outward currents at depolarized potentials compared to the cells which had been injected with 5'-AMP (10 ganglia, 36 cells).

The properties of the outward current that was reduced 24 hrs after injection of cAMP were studied by digital subtraction of experimental from control traces. The cAMP-sensitive current was only mildly voltage-dependent and had kinetics and an I-V relationship very similar to the S-current (a current that is regulated in the short-term by cAMP-dependent phosphorylation). Furthermore, outward tail-currents measured at -50 and -80 mV following depolarizing pulses indicated that the cAMP-sensitive current reverses near E_K. There appeared to be no modulation of the delayed K current. Finally, in both kinetics and voltage sensitivity, the currents modulated 24 hrs after injection of cAMP were nearly identical to those modulated 24 hrs after sensitizing stimulation. These results parallel findings in cultured sensory neurons where there is a 5-HT- and protein synthesis-dependent long-term enhancement of transmitter release and excitability (Montarolo et al, 1986, Dale et al, 1986).

Thus, cAMP-induced long-term regulation of a K current appears to be involved in the storage of long-term memory for sensitization in Aplysia.

111.10 EXOGENOUS CYCLIC AMP ANALOG PRODUCES LONG-TERM FACILITATION OF APLYSIA SENSORIMOTOR SYNAPSES IN CULTURE THAT IS BLOCKED BY THE PROTEIN SYNTHESIS INHIBITOR ANISOMYCIN. S. Schacher, V.F. Castellucci and E.R. Kandel. Ctr. for Neurobiol. & Behav. and HHMI, Columbia Univ., College of P&S, and NYS Psychiatric Institute, NY, NY 10032.

Both short-term and long-term sensitization of the gill and siphon withdrawal reflex in Aplysia are associated with an increase in efficacy of sensory neuron excitatory postsynaptic potentials (EPSPs) on follower cells. Short-term facilitation of sensory neuron synapses is primarily due to a transmitter mediated increase in cyclic AMP (cAMP) levels within the sensory cells. A single application of serotonin (5-HT), a transmitter that increases cAMP levels in sensory cells, can evoke short-term facilitation. When applied repeatedly over a 1.5 hour period, 5-HT can also produce long-term synaptic facilitation of sensorimotor synapses in culture (Montarolo et al., 1986). To determine whether this long-lasting facilitation produced by 5-HT is mediated by a cAMP-dependent mechanism, we examined the long-term effects of exogenous cAMP analog 8-benzylthio 3'-5' cAMP on sensory neuron-motor neuron EPSPs.

Single L7 motor cells were co-cultured with one to three sensory cells for five days. We then measured the amplitude of the EPSPs before exposing the cultures for two hours to 10^{-4} M cAMP in the presence of 5×10^{-4} M IBMX (a phosphodiesterase inhibitor). When these cultures (n = 5) were reexamined 24 hours later, we found a significant increase of 52% $\pm$ 5 ($p < .001$) in the amplitude of the EPSPs compared to a change of -8% $\pm$ 4 in untreated control cultures (n = 5), and a change of -9% $\pm$ 8 in cultures treated with IBMX alone (n = 5).

Since the long-term facilitation induced by 5-HT, but not the short-term, is blocked when 5-HT is applied in the presence of protein synthesis inhibitors (Montarolo et al., 1986), we examined the effects of cAMP analog in the presence of anisomycin, a reversible protein synthesis inhibitor. After measuring the amplitude of the EPSPs, the cultures were treated for three hours with 10^{-5} M anisomycin starting 15 minutes before incubation with cAMP-IMBX until 45 minutes after the two-hour exposure to cAMP-IBMX. Whereas cAMP-IBMX treatment of a second group of cultures (n = 5) evoked a significant increase of 44% $\pm$ 18 ($p < .01$) in the amplitude of the EPSPs measured 24 hours later, cultures exposed to cAMP-IBMX in presence of anisomycin failed to show an increase in synaptic strength; -8% $\pm$ 7 (n = 5). Cultures exposed to anisomycin alone for three hours showed a similar change of -9% $\pm$ 8 (n = 5).

These results are consistent with the idea that the induction of long-term facilitation of sensorimotor synapses by 5-HT may involve the same intracellular second messenger system that mediates short-term facilitation. However, unlike short-term facilitation, which utilizes cAMP-dependent mechanisms to modify pre-existing macromolecules (Kandel and Schwartz, 1982), the role of cAMP in the long-term increase in synaptic strength may reflect some regulatory processes in the synthesis of necessary macromolecules.

111.11 LEARNING ASSOCIATED PROTEINS (LAPs) FOLLOWING LONG-TERM SENSITIZATION OF THE GILL AND SIPHON WITHDRAWAL REFLEX IN APLYSIA. V.F. Castellucci, E.R. Kandel, T.E. Kennedy and P. Goelet*. HHMI, Columbia P&S, NY, NY 10032.

Long-term memory for sensitization of the withdrawal reflex in Aplysia, produced by 4 days of training, is associated with an increased synaptic efficacy of the connection between the sensory and motor neurons (Frost et al., 1985). This training is also accompanied by neuronal growth; there is an increase in the number of synaptic varicosities per sensory neuron, and in the number of active zones (Bailey and Chen, 1985, 1986). Such structural changes may require increased synthesis of certain proteins. In addition, a simplified five-trial one-day protocol in isolated reflex preparation or in dissociated cell culture, given over a 2-hour period, also produces long-term sensitization and synaptic facilitation when assayed 24 hrs later. Long-term sensitization and synaptic facilitation in these cases are blocked by inhibitors of protein synthesis if they are applied during the training period. By contrast, short-term sensitization and synaptic facilitation are unaffected (Montarolo et al., 1986). These results suggest that long-term memory for sensitization requires the expression of proteins and genes not required for the short-term memory.

We therefore searched for proteins whose rates of synthesis were altered during either the acquisition or maintenance phase of long-term memory for sensitization by using computer-assisted quantitative two-dimensional gel analysis (PROTEIN DATABASES, INC., NY). These methods have not allowed us, as yet, to detect significant changes during the 2 hr acquisition phase, but they have allowed us to identify proteins whose rates of synthesis were altered in the maintenance phase as assayed 24 hrs after either one day or four days of training. We focus here on a comparison of animals trained for four days to produce maximal long-term sensitization (n=11) and a control group (n=11). One day after training, we labeled abdominal ganglia from the sensitized and control group for 2 hrs with ^{35}S-methionine. We dissected out the region of the sensory and motor neurons and prepared protein extracts from each animal for high resolution two-dimensional gel electrophoresis.

We initially found changes in about 20 proteins, but focused on four candidates whose relative rates of synthesis were both significantly increased in the sensitized animals compared to controls and whose positions on the gels were relatively easy to distinguish from surrounding protein spots. The approximate molecular weight, isoelectric point, and the magnitude of the increase for these four proteins were: LAP A, 15.8 Kd, pI 5.3, 24-fold increase; LAP B, 16.2 Kd, pI 7.3, 3.5-fold increase; LAP-C, 79.4 Kd, pI 5.2, 2-fold increase; LAP D, 56.4 Kd, pI 4.7, 2-fold increase. By mixing these labeled samples with protein extracts from the total nervous system, we found, by silver staining, that these proteins are present at levels that may permit their isolation and characterization in molecular and behavioral terms.

111.12 SEROTONIN PRODUCES LONG-TERM FACILITATION AT PERIPHERAL SYNAPSES WHEN APPLIED SELECTIVELY TO SYNAPTIC REGIONS OF APLYSIA SIPHON SENSORY CELLS. G.A. Clark and E.R. Kandel. HHMI; Ctr. for Neurobio. & Behav., Columbia Univ.; & NYS Psych. Instit., NY, NY 10032.

RNA and protein synthesis inhibitors selectively block long-term but not short-term presynaptic facilitation at central connections of siphon sensory neurons in dissociated cell culture and in the semi-intact preparation, suggesting that certain gene products are required for the long-term but not the short-term process. We now ask: Must serotonin act directly on presynaptic somatic regions, which contain the RNA and protein synthetic machinery, to produce long-term facilitation? Or can it act when application is restricted to synaptic regions, either via retrograde transport of an intracellular signal, or through local and/or postsynaptic processes? To address this question, we have examined long-term facilitation at peripheral synapses of siphon sensory cells. In contrast to the central sensory neuron synapses in the abdominal ganglion, these peripheral synapses are located approximately 3 cm from the sensory neuron cell body, so it is possible to apply serotonin selectively onto synaptic regions of the sensory cell without applying it onto somatic regions. We previously found that bath application of serotonin onto both central (somatic) and peripheral (synaptic) regions produces long-term facilitation at peripheral synapses, relative to untreated controls. We now report that application of serotonin restricted to synaptic regions can also produce long-term facilitation at these distant synapses.

The abdominal ganglion and attached siphon nerve with associated peripheral siphon motoneurons were dissected from Aplysia and maintained in organ culture. The synaptic potentials from several different siphon sensory cells onto peripheral siphon motoneurons were then tested to establish a pre-serotonin baseline. Serotonin (20-50 uM) was then bath-applied onto the peripheral nervous system (containing the synaptic regions of the sensory cells, as well as the postsynaptic peripheral siphon motoneurons). Serotonin treatment consisted of 5 applications of 5 min duration, separated by a 15 min washout period. When the same synaptic connections were retested the following day, preparations that had received peripheral (synaptic) applications of serotonin exhibited significant facilitation at peripheral synapses (+52%; $p < .02$). These findings indicate that application of serotonin onto the synaptic cellular regions is sufficient to produce long-term synaptic facilitation.

We now plan to ask whether long-term changes induced by serotonin at these distant synapses are blocked by central (somatic) or by peripheral (synaptic and postsynaptic) application of protein synthesis inhibitors. In addition, we plan to compare effects of central and peripheral application of serotonin to determine whether long-term changes are synapse-specific.

111.13 LONG-TERM HETEROSYNAPTIC DEPRESSION OF APLYSIA SENSORIMOTOR SYNAPSES IN CULTURE IS PRODUCED BY THE PEPTIDE FMRF-AMIDE. P.G. Montarolo*, E.R. Kandel and S. Schacher. (SPON: E. Holtzman) Ctr. for Neurobiol. & Behav. and HHMI, Columbia Univ., College of P&S, and NYS Psychiat. Instit., NY, NY 10032.

The sensorimotor synapses of the gill- and siphon-withdrawal reflex in Aplysia can undergo heterosynaptic facilitation or depression both in-vivo and in-vitro. In culture, a single application of serotonin (5-HT) produces facilitation lasting minutes, while repeated applications of 5-HT causes facilitation lasting more than 24 hours (Montarolo et al. 1986). Short-term depression of sensory cell synapses can be evoked by a single application of either dopamine or the peptide FMRF-amide (Abrams et al., 1984; Belardetti et al., 1987). We have now examined whether repeated applications of FMRF-amide (10^{-7} M) or dopamine (10^{-6} M) can produce long-term heterosynaptic depression of sensorimotor synapses in culture.

After measuring the strength of the connections and the extent of short-term depression produced by the first 5-minute application of the inhibitory transmitters, the cells were exposed to 3 additional applications lasting 5 minutes, separated by 30 minutes of washing. The repeated applications of FMRF-amide caused a significant decrease ($p < .01$) of $-31 \pm 6\%$ ($n = 6$) in synaptic strength when measured 24 hours later. In contrast, dopamine, which can depress connections for a short duration, failed to reduce synaptic strength 24 hours later; $5 \pm 10\%$ ($n = 5$).

Since sensorimotor synapses can be depressed with low frequency stimulation of the sensory cells, we examined whether long-term depression can also be evoked by homosynaptic mechanisms. Sensory cells were given 10 stimuli at 30-second intervals during four sessions separated by either 30-minute or 90-minute rest intervals. The decrease in EPSP amplitude during each session and the extent of recovery with each rest interval was comparable to that observed in the intact nervous system. When the connections were retested 24 hours later, they were not changed significantly from their initial values from the previous day: $-7 \pm 6\%$, $n = 5$ and $-8 \pm 8\%$, $n = 5$ for the groups separated by 30- and 90-minute rest intervals, respectively. These changes were also not significantly different from the change obtained for control cells that received a single stimulus on the first day; $-2 \pm 11\%$, $n = 7$.

The results on long-term depression of sensory synapses with FMRF-amide, coupled with those on long-term facilitation with 5-HT, suggest that long-term heterosynaptic modulation can be produced in both directions by means of specific modulatory neurotransmitters. The inability to produce long-term homosynaptic depression in culture with stimulation protocols analogous to those used to evoke long-term habituation of the gill-withdrawal reflex (Carew et al., 1972) suggests the possibility that long-term habituation, unlike the short-term, may require heterosynaptic modulatory influences perhaps produced by transmitters such as FMRF-amide. To test this idea, one needs to identify the appropriate modulatory neurons that produce synaptic depression and see whether these cells are activated during long-term habituation training.

111.14 INDIVIDUAL APLYSIA SENSORY NEURONS VISUALIZED OVER TIME IN CELL CULTURE: ATTEMPTS TO CORRELATE LONG-TERM SYNAPTIC AND MORPHOLOGICAL CHANGES. D.L. Glanzman, E.R. Kandel and S. Schacher. HHMI, Ctr. for Neurobiol. & Behav., Columbia Univ., College of P&S, and NYS Psychiat. Instit., NY, NY 10032.

Studies on the nervous systems of vertebrates and invertebrates suggest that long-term synaptic changes during both development and learning are mediated, in part, by morphological changes. To determine whether synaptic changes that occur during learning and development share common mechanisms and whether they require interaction between the presynaptic cell and its postsynaptic target, we have applied to sensory neurons of Aplysia in dissociated cell culture the methodology for visualizing the structure of a single neuron over the course of days recently developed by Kater and Hadley (1982) and Purves and Hadley (1985).

We chose the Aplysia in-vitro culture system since sensory neurons can form stable synaptic connections with identified motor cells over a period of 4 days. Moreover, once stable, these connections can undergo long-lasting facilitation following repeated applications of serotonin (Montarolo et al., 1986). Sensory neurons were placed into culture either alone or together with motor cell L7. After 2-5 days in culture, synaptic strength was assayed electrophysiologically, and sensory neurons were stained with intracellular injections of the fluorescent dye 5(6)-carboxyfluorescein and viewed with a fluorescence microscope coupled to a low-light level video camera. In some experiments, the same sensory cells were reinjected with dye 24 hrs later.

We found that when sensory neurons were cultured alone, they were much less complex structurally than when they were co-cultured and formed synapses with the motor cell L7. The co-cultured sensory neurons had more processes and more varicosities than sensory neurons cultured alone. These data suggest that some interaction with the motor neuron regulates the growth of the sensory neurons' processes. Consistent with this correlation, there were concomitant increases in the complexity of the processes of sensory neurons as synaptic strength increased during the first 4 days. Specifically, there was elongation of sensory neuron branches and an increase in the number of varicosities. By contrast, after four days in culture, when the strength of the sensorimotor connections had stabilized, there were only minor morphological changes in sensory neurons over the next 24 hrs. In these stable cultures, there was a rough correlation between the complexity of a sensory neuron's processes and the strength of its synaptic connection. We have begun attempts to determine whether repeated applications of serotonin, which produce long-term facilitation of stable sensorimotor connections, can also produce morphological changes like those seen in developing sensorimotor cultures. In addition, we plan to examine whether such changes are cell autonomous or require the presence of the motor cell.

MOTOR SYSTEMS AND SENSORIMOTOR INTEGRATION: OCULOMOTOR SYSTEM II

112.1 SUPPRESSION OF OKN WITHOUT RETINAL ERROR SIGNALS: EFFECTS OF ATTENTIONAL MODE AND STIMULUS FREQUENCY J. Pola, H. J. Wyatt and M. Lustgarten. Schnurmacher Institute for Vision Research, SUNY State College of Optometry, 100 East 24th St., N.Y., N.Y. 10010.

We can suppress OKN by looking at a target. It is usually thought that such suppression depends on the pursuit system holding the eye on target against the influence of an optokinetic background. In recent studies we showed that this is not necessarily so, since viewing a target stabilized at the fovea (no retinal slip) results in suppression of OKN (Vis Res '84). Furthermore, the characteristics of this suppression depend on how subjects attend to the target (Neurosci Abstr '86).

We have now explored the influence of attending to a target on suppression of OKN over a wide range of frequencies of sinusoidal background field motion. As in previous studies we stabilized the target at the fovea to eliminate effects of target retinal slip. There were three conditions: "gaze", "look" and "hold". In the "gaze" condition, subjects regarded the target without attending to it; in the "look", subjects actively attended to the target; and in the "hold", subjects attempted to maintain the target at a location directly in front of them. In all three conditions, the frequency of field motion varied from 1/32 to 2 Hz. (Using field alone, we also studied OKN at these frequencies.)

Regardless of condition there was substantial suppression of OKN. In the "gaze" condition, the eyes moved roughly in phase with field motion at all frequencies, but much less than during OKN when viewing the field alone. In the "look" condition, the eyes moved counterphase to the field motion (what we call "hyper-suppression"), with amplitude of counterphase motion increasing and then decreasing over frequency, peak amplitude occurring at about 0.5 Hz. For the "hold" condition, the eyes remained relatively stationary across all frequencies.

We also asked subjects to imagine a target and to "hold" it at a fixed position in front of them against the field motion. In this case we did not find suppression of OKN at any frequency.

In summary, these findings show that the mode of attending determines how OKN is suppressed over a wide frequency range. The "hold" (no target) condition, however, indicates that the presence of a target is essential. Since there was no retinal slip in these experiments, it would seem that the presence of a target and attending to it are primary in modulating the optokinetic effect of the field on the oculomotor system. This may involve attenuating (as in "gaze") or even eliminating (as in "look" or "hold") the influence of the field.

(Supported by NSF BSN-85-19267)

112.2 THE ROLE OF THE NUCLEUS OF THE OPTIC TRACT IN PRODUCTION OF OPTOKINETIC NYSTAGMUS (OKN) AND AFTER-NYSTAGMUS (OKAN) IN THE MONKEY. D.Schiff*, B.Cohen & J.Buettner-Ennever* (SPON: H. Krieger). Depts. of Neurol, Mt Sinai Sch of Med, CUNY & Neuropath, Univ of Munich.

The pretectal nucleus of the optic tract (NOT) processes retinal slip information that leads to OKN and OKAN in the cat, rat and rabbit. The purpose of this study was to determine if this was also true in the monkey. Eye positions were recorded with a magnetic scleral search coil. The region of NOT was monopolarly stimulated through tungsten microelectrodes with 0.5 ms, 30-40 microamp pulses, delivered over 10 to 40 s, at frequencies of 50 to 500 Hz. Horizontal nystagmus with ipsilateral slow phases was elicited in darkness but not in light. Eye velocity rose slowly to a steady state level and was followed by after-nystagmus at the end of stimulation. The time constant of rise of the nystagmus was similar to the slow rise of slow phase eye velocity during OKN and to the charge of OKAN. The saturation velocity of the induced nystagmus was statistically the same as that of OKAN, and the after-nystagmus declined over the same time course. Activity induced by NOT stimulation could enhance, prolong or block the slow component of OKN and OKAN depending whether slow phases were to the same or opposite side and interacted with vestibular nystagmus as would OKN and OKAN. Interpreted in terms of the model of OKN and OKAN (Cohen et al. 1977), these data indicate that the stimulus had activated the velocity storage mechanism in the vestibular system through the indirect pathway to produce the slow component of OKN and OKAN.

Positive stimulation sites for inducing nystagmus were located in regions of NOT that were interstitial to fibers in the brachium of the superior colliculus, from the dorsal terminal nucleus (DTN) and from a fiber bundle in the pulvinar that extends from the cortex to NOT. Muscimol injections into NOT caused spontaneous nystagmus with contralateral slow phases and attenuated the slow rise in ipsilateral slow phases of OKN and OKAN. Kainic acid injections into NOT and DTN had the same effect. After lesions the slow rise in OKN with ipsilateral slow phases and the corresponding OKAN were lost. The rapid rise in OKN and vestibular nystagmus were unaffected. Ocular pursuit appeared intact. Partial electrolytic lesions of the cortico-pretectal tract resulted in a reduction of peak velocity of OKN and a longer rising time constant.

The lesion data suggest that after NOT lesions the velocity storage integrator could no longer be activated by retinal slip to produce ipsilateral slow phases. This indicates that the direct and indirect pathways for producing OKN and OKAN are separate at the level of NOT, and that NOT is part of the anatomical substrate for the indirect pathway for horizontal OKN and OKAN in the monkey as in cat, rat and rabbit. These data also indicate that inhibition in NOT is mediated by GABA, acting through GABA-A receptors.

112.3 VISUALLY INDUCED ADAPTIVE CHANGES IN POST-SACCADIC DRIFT IN NORMAL HUMANS. Z. Kapoula*, L. M. Optican* & D. A. Robinson. Lab. of Sensorimotor Res., National Eye Institute, Bethesda, MD 20892, Johns Hopkins Hospital, Dept. of Ophthalmol., Baltimore, MD, USA.

Post-saccadic ocular drift occurs when the brain fails to program the correct level of innervation to hold the eyes in their new final position. Such drifts are evident in cases of extraocular muscle weakness, and can be corrected by a cerebellar-dependent adaptive mechanism (Kommerell et al., Invest. Ophthalmol. 15:657, 1976; Optican and Robinson, J. Neurophysiol. 44:1058, 1980). This adaptation can be elicited optically in normal monkeys, and depends on the time constant of the adapting stimulus (Optican and Miles, J. Neurophysiol. 54:940, 1985). We examined the ability of normal humans to adapt to optically-induced post-saccadic retinal slip.

Four subjects sat in front of a white hemisphere (2 m diam) onto which a random dot pattern (180 x 60 deg) was projected. A computer detected the end of spontaneous saccades (within ±3 ms) and drifted the visual display by 25% of the horizontal component of that saccade. The scene could drift in the same direction as, or opposite to, the saccade, with a time constant of 25, 50 or 100 ms, depending on the experiment. Subjects were exposed to this visual experience for 3 hrs, producing 10,000-16,000 saccades. During training, eye movements were monitored with an EOG. Pre- and post-training binocular recordings were made with the magnetic-field/search-coil method. At first, the subjects followed the drift of the visual scene with a delay of 40-100 ms. After 1 - 3 hrs of training all 4 subjects developed consistent, zero-latency, compensatory ocular drifts, even after spontaneous saccades in the dark. The drift waveform was roughly exponential. The amount of drift was 15-20% in the presence of the adapting stimulus and 6-10% in the dark. The time constant of the ocular drift in the dark varied with subjects (52-149 ms) and was not influenced by the time constant of the stimulus used to train the subject. There were no significant differences in the adaptive changes in drift between the two eyes. However, significant differences were found between abductions and adductions: subjects trained to backward drift developed compensatory drift mostly in the abducting eye while subjects trained to onward drift developed drift mostly in the adducting eye. This asymmetry between the two eyes was evident mainly in the dark; in the light the drift was more conjugate.

The persistence of ocular drifts in the dark, and their exponential waveform, suggest that central readjustment of the basic saccadic innervation had occurred. The asymmetry present in the dark suggests that the adaptive mechanism is able to adjust the saccadic neural signals differently for each eye.

112.4 EFFECTS OF MONOCULAR AND BINOCULAR PATCHING UPON OCULAR ALIGNMENT AND SACCADE METRICS IN RHESUS MONKEYS. T. Suzuki*, S. Das* and D.S. Zee. Johns Hopkins University, Baltimore, Md 21205.

We investigated ocular alignment and postsaccadic gaze stability in monkeys after patching of one or both eyes. We measured the position of both eyes using search coils. Ocular alignment was assessed by measuring the phoria: the relative position of the two eyes with one fixing the target and the other under cover. Postsaccadic drift was inferred from the ratio (P:S) of the rapid portion of the saccade, the pulse (P), and the final resting position of the eye, the step (S). P:S of both eyes were measured under bi- (BV) and monocular (MV) viewing. Four paradigms were used: 10 days, right eye patched (REP), left eye patched (LEP), patch alternated daily (AP), and 5 days both eyes patched (BEP).

Phoria: Prior to patching both animals had < 0.35 deg of phoria but after each patching paradigm they developed an esophoria (2.0-2.25 and 0.6-2.05 deg for animals 1 and 2, respectively). Animal 1 also developed a left hyperphoria (.7-1.1 deg.) after LEP and REP.

Postsaccadic drift: Prior to patching, animal 1 had no postsaccadic drift (0.99 < P:S > 1.01). After either LEP or REP postsaccadic drift appeared with a duration < 100ms. The P:S of the habitually-patched eye decreased (0.95) for abducting saccades and increased (1.04) for adducting saccades; horizontal saccades were always followed by temporally-directed drift. During MV the habitually-viewing eye also showed postsaccadic drift (P:S = 0.98 for abduction and 1.03 for adduction) when it was the eye under cover but not when it was the fixing eye. Following BEP, P:S decreased (0.97-0.98) for saccades in both directions causing onward drift after horizontal saccades. For vertical saccades P:S of the habitually-patched eye increased (1.05) for down saccades and decreased (0.97) for up saccades so that postsaccadic drift was always upwards. No changes in vertical P:S were noted after BEP. For animal 2, prepatch, there was backward drift (P:S, 1.06) after horizontal saccades by the left eye. Postpatch the changes in P:S for horizontal saccades for REP and BEP were similar to those of animal 1 but little change was seen after LEP. For vertical saccades onward drift developed (P:S, 0.94-0.97) for upward saccades only, primarily after REP and primarily in the right eye when it was under cover.

Our results indicate that simultaneous binocular visual inputs are necessary to maintain ocular alignment. Absence of visual inputs also leads to postsaccadic drift, but the pattern of drift cannot be attributed solely to the associated phoria. Important, too, is whether one or both eyes had been patched and which eye viewed the target during testing. Since the drift was brief and immediately followed the saccade, we infer that mechanisms other than immediate visual feedback account for the decrease in postsaccadic drift when the eye is viewing rather than covered.

112.5 **EFFECT OF PERIPHERAL VISUAL FIELD ON VESTIBULO-OCULAR REFLEX (VOR) GAIN PLASTICITY AND VISUAL-VESTIBULAR INTERACTION.** J. L. Demer, J. Goldberg, F. I. Porter*, and K. Schmidt*. Cullen Eye Institute and Clayton Neurotology Laboratory, Baylor College of Medicine, Houston, Texas. 77030

When telescopes are mounted in spectacles for use as aids for the visually impaired, only the central visual field is magnified and the periphery is unmagnified. To maintain retinal image stability during head movements in this situation, the *gain* (eye velocity/head velocity) of compensatory eye movements required in central vision is equal to telescope magnification, while the required gain for the periphery is 1.0. We investigated the effect of this telescopic spectacle configuration on VOR gain plasticity and visual-vestibular interaction in 8 subjects, selected for high VOR gain plasticity from a group of 35 normally sighted subjects.

Eye movements were recorded by digitally sampled electro-oculography during sinusoidal whole-body rotation in a servo driven chair in darkness (**VOR**) and in light (visually augmented VOR, **VVOR**). Gains were measured for 0.1 Hz rotations (amplitude 30°/s in light, 60°/s in dark) as subjects wore 4X binocular telescopic spectacles having a magnified visual field of 10°. The peripheral field was either occluded or unobstructed. After initial measurements, subjects underwent training by sinusoidal rotation (0.1 Hz, amplitude 20°/s) for 15 min while viewing a distant video display. Gain measurements were then repeated.

Initial VOR gains were 0.65±0.08 (mean±SD, n=8) with the periphery occluded and 0.67±0.05 without occlusion. After plasticity training, each subject exhibited a significant ($p<0.05$) VOR gain increase with the periphery occluded, so that VOR gains increased on average by 21% to 0.78±0.07. Without occlusion of the periphery, only 5 subjects exhibited a significant VOR gain increase, so that the VOR gain for all subjects after plasticity training was 0.71±0.05; the mean gain increase was 7%. With peripheral occlusion, mean initial VVOR gain was 1.93±0.30, significantly greater than the value of 1.27±0.30 measured without occlusion. VVOR gain was not significantly changed after training for either condition.

These results indicate that the unmagnified peripheral field inhibits VOR gain plasticity and immediate modification of VVOR gain by magnified central vision. This finding supports a role for peripheral retinal slip in inducing VOR gain plasticity in humans.

112.6 DIRECTIONAL TUNING OF BURST NEURONS IN THE riMLF OF ALERT MONKEYS IN RESPONSE TO VESTIBULAR AND VISUAL STIMULATION. V. Henn and K. Hepp*. Neurology Dept. University and Physics Dept. ETH, 8091 Zürich, Switzerland.

Rapid eye movements have 3 degrees of freedom in the context of vestibular and optokinetic nystagmus when the head is rotated about arbitrary axes in 3-dimensional space. With the head erect and stationary, visually elicited saccades obey Listing's law and have 2 degrees of freedom. Bilateral lesions of the riMLF lead to a syndrome in which rapid eye movement generation is confined to the horizontal plane only. We conjectured that the riMLF constitutes an interface in synergy with the PPRF between the 3-dimensional vestibular input, the 2-dimensional visual input, and the 3-dimensional oculomotor output for rapid eye movement generation.

The riMLF contains predominantly burst neurons which we systematically studied during visual and vestibular stimulation in alert monkeys. Eye movements were measured with two orthogonally implanted search coils, unit activity was recorded with varnished tungsten electrodes. Animals were placed in a gimbal system which allowed rotation in 3 dimensions.

Rapid eye movements were analyzed in terms of 3-dimensional rotation vectors which are the linear approximation to a description in terms of rotation matrices. This description is independent of the initial eye position and was found adequate in the peri-primary range. In first approximation saccade trajectories in 3-dimensional space can be described as straight lines with the duration determined by the movement amplitude.

Burst neurons were either of short- or long-lead type. Analysis was performed to obtain 3-dimensional tuning curves. On-directions of neurons were closely aligned to canal and muscle planes, and activity attenuated in other directions according to a cosine function. The firing patterns of burst neurons could be interpreted in the sense that they were excited by ipsilateral canal input and excitatory on ipsilateral motoneurons. Thus, the basic input-output organization was found to be similar to horizontal burst neurons in the PPRF. Saccades in Listing's plane, or rapid phases of nystagmus along specific canal planes, or pure torsional nystagmus (about the line of sight) involved the same burst neurons which were activated in different ratios according to the specific movement direction.

Burst neurons in the riMLF with on-directions along vertical canal planes together with horizontal burst neurons in the PPRF constitute the final common pathway for saccade generation in 3 dimensions.

112.7 THE EFFECT OF IBOTENIC ACID LESIONS OF THE OMNIPUASE NEURONS ON SACCADIC EYE MOVEMENTS IN THE MONKEY. C.R.S. Kaneko and A.F. Fuchs. Reg. Primate Research Center and Department of Physiol. & Biophysics, University of Washington, Seattle, WA 98115.

In the mid 1970's, D.A. Robinson and D.S. Zee and colleagues formulated the "local feedback model" of the neuronal circuits that generate saccades. This model and several more recent variations have been difficult to evaluate because of the tight coupling of their cellular components and the consequent inability to affect them independently. The development of techniques to produce small, axon-sparing chemical lesions and the localization of a critical element, the omnipause neurons (OPNs), to a morphologically distinct pontine nucleus have made it possible to attack this problem. Specifically, we wanted to test which of the alternatives of the local feedback models best predicted the effect of loss of OPN activity: would OPN lesions produce saccades of increased duration and decreased velocity (Scudder, J. Neurophysiol., in press) or ocular flutter and opsoclonus (Zee & Robinson Ann. Neurol. 5:405-414, 1979).

Two rhesus monkeys were trained to track a back-projected spot for food reward. OPNs were located by their distinctive discharge in relation to saccades and their extent was mapped and marked by bracketing electrolytic lesions. Ibotenic acid was injected via a 30 gauge stainless cannula in concentrations of 15 µg/µl while OPNs were recorded via an attached microelectrode.

In the first animal, a 1.0 µl injection destroyed cells from 200 µm to the right of the midline to the rootlets of the left 6th nerve and from just rostral to the abducens nucleus 1.5 mm rostrad. Virtually the entire OPN nucleus was destroyed with some damage to adjacent areas but there was no apparent damage to the rootlets or any of the nearby fiber tracts. The second animal has had a single 0.2 µl injection and its histology is not yet available as other small injections are planned.

Both animals showed qualitatively similar deficits but those of the first animal were more severe. The saccade duration increased by an average of 500% and recovered to 300% of the original value as indicated by the slope of the regression line relating the saccade duration to its amplitude. Recovery was more complete for vertical components or vertical saccades averaging only 114% increase at 3 weeks post-lesion. Likewise, the peak velocity (i.e. the slope of the peak velocity/saccade amplitude relation) decreased, on average 73% and recovered to only 76% of the original value. The range of saccadic amplitudes decreased transiently but recovered for all but the horizontal direction in the animal with the large lesion in which it shrank from 38° left and 47° rightward to 6° left and 11° rightward.

In general, our results support the Scudder variation of the local feedback model. Simulations are being conducted to test the model's ability to predict, in detail, our lesion results.

112.8 RETICULAR PRESACCADIC INPUT TO THE PRIMATE SUPERIOR COLLICULUS. A.K. Moschovakis, A.B. Karabelas and S.M. Highstein, Dept. of Otolaryngology, Washington University, and the McDonnell Center for Studies of Higher Brain Function, St. Louis, Missouri 63110.

Intraaxonal recording and HRP injection were employed in alert naive, squirrel monkeys to identify superior colliculus (SC) neurons carrying presaccadic signals. In addition to tectal long lead burst neurons (TLLBs), (Moschovakis et al., Soc. Neurosci. Ab. 12:1185, '86), our sample includes axons of mesencephalic reticular formation (MRF) cells that project to the SC.

In contrast to TLLBs, that are active before saccades within a movement field of limited size, reticulotectal long-lead burst neurons (RTLLBs) discharge before most contraversive and some ipsiversive saccades. The latency of the high frequency portion of RTLLB presaccadic activity (1-46msec, x=18.75, S.D.=7.97) is statistically indistinguishable from that of TLLBs. There is a significant correlation ($0.50 < r < 0.84$, $p<0.01$) between the number of spikes in a burst (N_b) and the cosine of the angle between saccade vector and on-direction of the cell as well as between N_b and the amplitude of the saccadic component in the on-direction of the cell (approximately horizontal contraversive). The cell bodies of RTLLBs are located in the MRF, bordering the rostral 1mm of the SC dorsally, the periaqueductal gray medially, and the interstitial nucleus of Cajal ventrally. This area of the MRF has been shown to contain cells firing before contraversive rapid eye movements and its electrical stimulation elicits contraversive saccades (Cohen et al., Progr. Brain Res. 64:243, '86).

RTLLB axons emerge from the cell body and turn dorsally towards the deeper layers of the SC, where they ramify extensively, mainly in the stratum griseum intermedium but also in the stratum opticum, i.e. in the layers of the SC that contain the cell bodies of TLLBs. They then cross the midline in the intertectal commissure to terminate in the deeper layers of the contralateral SC. Terminal fields of RTLLBs are distributed to progressively more rostral and medial portions of the ipsilateral SC, as the cell body of origin is located more dorsally and the on-direction of the neuron is upward biased. RTLLBs may be both presynaptic and postsynaptic to TLLBs. (Supported by NEI EY-05433).

112.9 TECTO-RETICULO-SPINAL-NEURONS HAVE DISCHARGES CODING THE VELOCITY PROFILES OF EYE AND HEAD ORIENTING MOVEMENTS. D.P. Munoz and D. Guitton, Dept. Neurol.& Neurosurg. McGill Univ. Montreal, Canada.

Tecto-reticulo-spinal neurons (TRSNs) form a major descending projection from the superior colliculus (SC) to contralateral brainstem and spinal cord premotor areas involved in the control of eye and head movements. These neurons mediate the SC's influence in controlling orienting behaviour. We have already provided preliminary evidence that the velocity of gaze shifts and the intensity of TRSN phasic bursts covary and depend on the behavioral context within which the orienting movement is made (Brain Res. 398 185-190, 1986). In this abstract we provide further evidence on this unexpected result. TRSNs were studied in alert head-free or fixed cats trained to orient to targets that were either visible or whose location could be predicted based on knowledge gained from previous trials. RESULTS: The peak velocities of the eye, head, and therefore gaze movements were fastest and the durations shortest, when the cat oriented to visible targets. In the visible target condition the gaze velocity profle had a symmetrical, bell-shaped appearance. In the predicted target condition the gaze velocity profile was somewhat irregular, almost trapezoid-like in appearance. The instantaneous firing frequency profile of a TRSN, averaged over several trials, roughly approximated the mean gaze velocity profile in both target conditions. The target sometimes appeared immediately before the onset of an orienting movement to the predicted target. The shape of the initial part of the eye, head and gaze movement trajectories was characteristic of movements to the predicted target. However, there was a sudden acceleration of the eye and head during the course of these movements and the gaze velocity profile assumed a new shape more characteristic of movements to a visible target. Modification in the trajectory of the head movement occurred 20 ms after the reacceleration of the eye. TRSNs burst 10 ms and 30 ms before the increase in eye and head acceleration respectively. Microstimulation of the SC was used to mimic the effect of TRSN discharge on movement trajectory. Movements triggered by a high frequency train had greater peak velocities than identical amplitude movements triggered by low frequency stimulation. On some trials in which the low frequency train had evoked a movement, a superimposed high frequency train was introduced during the course of the gaze movement. The high frequency train triggered a reacceleration of the eye and head at latencies of 10 ms and 27 ms respectively. These results suggest that TRSN discharges can control both eye and head movements; and, in contrast to classical models of SC function, suggest that characteristics of TRSN burst activity predict the shape of the associated gaze trajectories.

112.10 THE OPTIC TECTUM ENCODES SACCADE MAGNITUDE IN A PUSH-PULL FASHION IN THE BARN OWL. S. du Lac and E.I. Knudsen. Dept. of Neurobiology, Stanford University School of Medicine, Stanford, CA 94305.

Single unit studies and focal electrical stimulation have demonstrated that the superior colliculus contains a map of orienting movement vector. However, the mechanisms by which place coded activity in the colliculus determines the size and direction of saccadic orienting movements have not been resolved. Current models of saccade generation assume that saccade size is specified by the topographically weighted sum of excitatory drives from collicular neurons. If this assumption is true, then simultaneous stimulation of two collicular sites should produce a saccade with a magnitude that is the sum of those elicited by stimulating each site alone. Alternatively, the colliculus could specify saccade size in a push-pull fashion by a ratio of excitatory and inhibitory influence on the saccade generator, the value of which varies topographically. This hypothesis predicts that simultaneous stimulation of two collicular sites would produce a saccade with a magnitude intermediate to the magnitudes encoded by each site.

We sought to distinguish between these alternatives by electrically stimulating the optic tectum in barn owls. (Although barn owls make saccadic head movements instead of saccadic eye movements, the role of the tectum in specifying the metrics of head movements appears to be similar to that of the superior colliculus in encoding orienting eye movements.) Pairs of monopolar stimulating microelectrodes were implanted in the optic tecta of anesthetized owls, and sensory receptive fields were mapped. The following day, electrodes were stimulated singly and simultaneously in the alert owl. Stimulation at the visual representations of 8° and of 60° contralateral elicited saccadic head movements of $8° \pm 2°$ and $63° \pm 3°$, respectively. Simultaneous stimulation elicited a head movement of $40° \pm 2°$. The experiment was repeated for 10 additional pairs of electrode sites in 3 owls. In all cases, the size of the resulting saccade was intermediate to the saccade sizes elicited from stimulation of each site alone. (Similar results were reported by Robinson in monkeys: Vis. Res., 1970.) However, the initial velocity of the saccade (first 10-20 msec) always matched that of the saccade elicited from the caudalmost site (in barn owls, the elicited saccade velocity increases from rostral to caudal). These results support the hypothesis that the tectum specifies saccade size in a push-pull fashion and that initial velocity is specified separately from saccade size.

112.11 EFFECTS OF FOCAL INACTIVATION OF SUPERIOR COLLICULUS ON SACCADES: SUPPORT FOR THE HYPOTHESIS OF VECTOR AVERAGING OF NEURONAL POPULATION RESPONSE. C. Lee, W. H. Rohrer* and D. L. Sparks. Dept. of Physiology and Biophysics, University of Alabama, Birmingham, AL 35294.

Cells in the deep layers of the superior colliculus discharge before saccadic eye movements with a gradient of response strength within a range of amplitudes and directions (Sparks, Holland and Guthrie, *Brain Res.*, 113:21, 1976). Since this range of movement (movement field) is broad, a large number of cells are active for any given saccade. We hypothesized that the amplitude and direction of a saccade are determined by the average drive of this active neuronal population, not by the drive of a single or a few cells with the strongest activity. To test this idea, we tried to manipulate the activity profile of the population response, and we measured the effect on saccades.

Three rhesus monkeys were prepared for chronic recording and for measurement of eye movements with the scleral search coil technique (Fuchs and Robinson, *J. Appl. Physiol.*, 21:1068, 1966). The monkeys were then trained on a saccadic task where the reward was contingent on successive acquisitions of a fixation target and a saccade target. Targets were selected from an array of LED's on a tangent screen. A metal-coated glass pipette (Malpeli and Schiller, *J. Neurosci. Methods*, 1:143, 1979), filled with lidocaine hydrochloride (2%), was placed in the deep layers of the superior colliculus. The movement associated with the strongest neuronal activity ("best movement" of the recorded site) was estimated by an on-line analysis of the number of action potentials associated with each saccade, and by movements triggered by electrical stimulation of the superior colliculus. After establishing normal saccades around the "best movement", we ejected 100 nl of lidocaine from the tip of the recording pipette into the recorded site.

As predicted, the nature of saccadic dysmetria following the lidocaine injection was target-specific. Saccades to targets with the same direction as the "best movement" but with smaller eccentricities fell short, while those with larger eccentricities overshot the target. Saccades to targets of the same amplitude as the "best movement" but in different directions deviated away from both the target and the "best movement". The amplitude and direction of saccades to the target of the "best movement" often remained the same. Thus, the pattern of saccadic errors was to shift the saccadic trajectory away from the "best movement". These changes are explained by modified profiles of population activity after focal inactivation which shift the average vector of population response toward directions corresponding to the observed saccadic errors.

These results indicate that the amplitude and the direction of a saccade are coded as the vector average of the population activity in the superior colliculus. The accuracy of a saccade is ensured by the contribution of a large number of active neurons that are broadly tuned, not by a few neurons that exibit the strongest activity. (Supported by NIH EY01189).

112.12 MEMORY CONTINGENT RESPONSES OF SUPERIOR COLLICULUS MOVEMENT CELLS D. M. Waitzman, T. P. Ma, L. M. Optican, and R. H. Wurtz. Lab. of Sensorimotor Res., National Eye Inst., Bethesda, MD 20892, USA.

Cells whose firing changed following the presentation of a flashed visual stimulus, to which monkeys would subsequently make a saccade, have been described in the substantia nigra pars reticulata (SNr) by Hikosaka and Wurtz (J. Neurophysiol. 49:1268-1301, 1983). These cells were termed memory contingent and many of them project to the superior colliculus (SC). The current experiments examined the response of intermediate and deep layer SC cells under similar memory contingent behavioral conditions.

We studied memory guided saccades by requiring the monkey to fixate a small spot of light in the primary position of gaze and indicated the location to be remembered by flashing a peripheral target for 50 ms. Eye position was maintained within a window (determined by the magnetic search coil technique) until the fixation point went off at a random time 500 to 1000 ms later. This offset signaled the monkey to look toward the location of the previously flashed target. Saccade responses were recorded to a set of locations which covered the movement field of the cell. Memory trials were randomly interspersed with trials which examined the discharge of the cell to visual stimuli without subsequent saccades, visually guided saccades, and spontaneous saccades.

Memory related activity was comprised of three parts: a phasic visual response, a sustained discharge, and a phasic movement discharge just before the remembered saccade. Cells had various combinations of these three parts. The phasic visual response to the flashed target had about 50 ms latency to onset and 50-100 ms duration. The peak activity either equaled or was less than the phasic response seen following a continuously presented visual stimulus. The sustained memory discharge began about 100 ms after the flashed stimulus and could continue until the monkey made a saccade to the target. The phasic movement discharge preceded the saccade by at least 50 ms. Those cells which discharged prior to remembered saccades also had phasic discharges preceding comparably sized visually guided saccades. Half of the cells with phasic movement activity discharged before spontaneous saccades made in total darkness.

These results indicate that there is a subset of saccade related neurons in the SC whose firing is complementary to the inhibition of the cells of SNr. The sustained memory discharges appear similar to those of the quasi-visual (QV) cells described by Mays and Sparks (J. Neurophysiol. 43:207-232, 1980). Moreover, as with the QV cells, both the sustained and phasic saccade related activity of memory cells could signal the change in eye position for intended eye movement in the absence of a visual target.

REGENERATION: SPINAL CORD I

113.1 THE SEVERITY OF LESION INDUCED HIND LIMB BEHAVIORAL DEFICITS AFTER CERVICAL FASICULUS GRACILIS ABLATION ARE AMELIORATED BY FETAL SPINAL CORD HOMOGRAFTS J.J. Bernstein and W.J. Goldberg. Laboratory of Central Nervous System Injury and Regeneration, Veterans Administration Medical Center, Washington, DC, 20422 and Departments of Physiology and Neurosurgery, George Washington University School of Medicine, Washington, DC.

Fetal spinal cord grafts survive for long periods of time in host spinal cord. Transplanted neurons express peptides and transmitters with limited axonal growth into the host. Astrocytes also mature and express GFAP. The present study explores the ability of fetal spinal cord grafts into C3 fasiculus gracilis (FG) to influence the expected deterioration of hindlimb performance following this lesion. Ten adult Sprague-Dawley rats were placed on a schedule of 23-h off and 1-h on water schedule. These subjects were then trained to traverse a narrow platform for a water reward. Criterion was established as 10 trials/day, completed in 15-s a trial, for two consecutive days. Animals were ranked for hind and fore limb performance utilizing slips, recovery and manner of traversing the platform. In a triple blind experimental design the animals numbers were coded and laminectomy performed at C3. The FG was bilaterally sectioned at the rostral and caudal borders of the segment and the FG aspirated. Five of the subjects were chosen at random for the implantation of two, one mm segments of E14 spinal cord from fetuses of timed pregnant Sprague-Dawley dams. Coded, lesion only and lesion-transplanted animals were then tested at 21,30,45,60 and 90 days later until criterion or for 4 days. Average ranked scores were coded and statistically analyzed by the non-parametric Friedman two-way analysis of variance a priori and the Mann-Whitney U test a posteriori. Hind limb performance of the lesion-only (ANOVA X^2=13.04, df=5; $p<0.05$) and lesion-transplant groups (ANOVA X^2=11.82, df=5; $p<0.05$) showed that the C3 fetal transplants significantly decreased ($p<0.05$) the severity of hind limb deficit at 21 days post lesion and significantly decreased ($p<0.05$) the expected foot slips and limb recovery to the platform that was expected and did develop in lesion-only animals at 90 days. There were no deficits in fore limb performance (ANOVAs $p>0.05$). There were a few small caliber nerve fibers in the FG at the level of C1. For this reason the transplant induced decreased severity of deficit is discussed stressing the trophic and tropic aspects of the transplant and the astrocytes that are known to migrate for centimeters from the site of transplantation in adult host spinal cord and cortex.

Supported by the Veterans Administration.

113.2 CULTURED FETAL SPINAL CORD ASTROCYTES MIGRATE INTO ADULT HOST CERVICAL CORD AND MEDULLA FOLLOWING TRANSPLANTATION INTO THORACIC SPINAL CORD. W.J. Goldberg and J.J. Bernstein. Laboratory of Central Nervous System Injury and Regeneration, Veterans Administration Medical Center and Departments of Physiology and Neurosurgery, George Washington University School of Medicine, Washington D.C.

We have previously demonstrated astrocytic migration from pressure-injected minced-piece transplants. Astrocytes migrated at a rate of 0.76 mm/day after a 14 day delay [Goldberg and Bernstein, J. Neurosci. Res. 17(4):in press]. In the presents experiments cell suspensions from 14-day gestation rat spinal cord, which had previously been soaked for 1 hour in a 2 ug/ml solution of Phaseolus vulgaris leucoagglutinin (PHAL), were cultured on collagen gels containing laminin for two weeks, at a density of 1500-2000 cells/mm^2. Pieces of the gel (0.5 mm^2) and attached cells (about 875) were then transplanted into the dorsal column of adult host thoracic spinal cord [Bernstein and Goldberg, Brain Res. 377(1986):403-406]. At 1, 2 and 3 months post implantation (MPI) animals were sacrificed and the spinal cords removed, embedded in paraffin and sectioned at 8 um for immunohistochemistry at the light microscopic level. Sections were double labeled for PHAL, utilized as a marker for transplant derived cells, and glial fibrillary acidic protein (GFAP), a specific marker for astrocytes. Transplant-derived astrocytes (PHAL-GFAP positive cells) migrated from the transplantation site both rostral and caudal and were observed within the host dorsal column ipsilateral to to transplantation site. At 2 months, lateral migration into the contralateral dorsal column and ipsilateral dorsal horn was observed. At 3 MPI transplant-derived astrocytes were observed in host nucleus gracilis, a distance of approximately 55 mm from the implantation site. This calculates into a migration rate of 0.72 mm/day, assuming a 14 day delay occurred as was observed with pressure-injected transplants. Astrocytes represent approximately 30% of the total cell population in this culture system, or about 260 cells. If these 260 astrocytes were evenly distributed over the 7 cm of lumbar to cervical spinal cord we would expect a final density of ca 4 astrocytes/mm, assuming that all of the astrocytes migrated in a single line. A single 8 um section may contain 15 or more astrocytes spread throughout the dorsal columns at 2 months post implantation, indicating that a significant number of cell divisions must have occurred. Since astrocytes in the original culture do not divide due to a lack of mitogens there must be factors present in the host dorsal column following the transplantation procedure which induce the division of astrocytes.

113.3 SOME DORSAL ROOT AXONS REGENERATE INTO THE ADULT RAT SPINAL CORD. AN HRP STUDY. F.J. Liuzzi and R.J. Lasek. Bio-architectonics Ctr., Case Western Res. Univ. Sch.of Med., Cleveland, OH 44106.

It has been known since the time of Cajal that many regenerating adult mammalian dorsal root axons are stopped at the dorsal root transitional zone where the cellular environment changes from one of Schwann cells and collagen to one of oligodendroglia and astrocytic processes. EM of this zone has shown that the axons end among the reactive astrocytic processes. Indeed, our studies of this region in adult rats after dorsal root crush indicate that reactive astrocytes block axonal growth by activating a physiological stop pathway which is extant in all axons (Liuzzi and Lasek, Soc. Neurosci. Abst. 12:697, 1986 and in press). The questions remained, however, of whether any regenerating dorsal root axons get past the astrocytes and, if so, whether any reach the gray matter to arborize and synapse. We have used anterograde injury-filling of regenerating dorsal root axons with HRP to demonstrate the reinnervation of the adult frog spinal cord (Liuzzi and Lasek, J. Comp. Neurol., 232:456, 1985) and are now using the same technique to answer the above questions in the adult rat.

For these studies, the L5 dorsal root was crushed twice, 10 sec each, with a #5 Dumont, approximately 10mm from the cord. After survival times up to 60 days, the root was reexposed and cut 5mm from cord. The proximal stump of the root was isolated and chips of dried concentrated HRP (Sigma type VI) were applied. After one hour, excess HRP was flushed from the area, the wound was closed and the animal was allowed to survive for 24 hours. Following perfusion with 1.0% glut. and 3.0% para. in phosphate buffer, the cord was removed, fixed for 6 hours and stored overnight in phosphate buffered sucrose (30%). Sixty micron-thick, transverse, vibratome sections were processed for HRP visualization using the same protocol that had been used in the frog studies.

Examination of cresyl-violet counterstained sections consistently revealed a very small number of HRP-labelled axons in the spinal cord. In the white matter, a few labelled axons were seen, particularly at the edge of the cord. Deeper in the markedly gliotic dorsal funiculus, there were many fewer, tortuous axons. In the gray matter, some very small diameter axons (<1.0um) were seen. Some of these axons, which were confined to the dorsal horn, meandered through the gray matter and appeared to branch infrequently. Others grew fairly straight. Although these regenerated axons have not been examined at the EM level, many were punctuated by en passant varicosities suggesting that they have the capacity to reform synaptic contacts with targets in the gray matter. This work was supported by a grant to F.J.L. from the S.C.R.F. of the Paralyzed Veterans of America.

113.4 A CELLULAR MATRIX FOR STUDYING AXONAL REGROWTH IN ADULT RAT SPINAL CORD INDUCED BY CONTROLLED FREEZING OF THE DORSAL COLUMN. N.R. West and G.H. Collins. Departments of Pathology and Anatomy, S.U.N.Y. Health Science Center at Syracuse, Syracuse, New York 13210.

Mature axons of the mammalian central nervous system will regenerate when provided with an appropriate matrix. Previous experience with cryogenic injury in rat spinal cord has shown that a cellular matrix does develop into which axonal regrowth occurs (Collins, West, et al. J. Neuropath. Exp. Neurol. 45:742, 1986). The rostral limit of the matrix occurs approximately at the junction of the injury zone with the Wallerian zone and the amount of axonal regrowth beyond this point is severely limited. The purpose of these studies has been, therefore, to develop a matrix of greater length so as to provide a model of spinal cord injury in which the following can be studied: 1) Axonal elongation over an extended distance (1.0 cm.), 2) Sequence of cellular and molecular events associated with this growth (West and Collins, unpublished observations), and 3) The effects of experimental manipulation upon the process of regrowth.

In studies involving 10 animals we have found that temperatures and times varying from -5°C for 60 minutes to -7°C for 15 minutes when applied by a cryode measuring 0.4 x 7.0 mm through an atraumatic laminectomy at T7-T9 will produce a lesion in which nearly all axons are destroyed and a cellular matrix forms. The area of injury extends laterally into the dorsal horns and ventrally encroaches upon the corticospinal tract, thus being approximately 1.0 mm in depth, 1.5 mm in width and 1.0 cm in length. Within this area phagocytic cells remove breakdown products of axons and myelin sheaths so that by 10 days following the injury, most of the degeneration has been cleared and the macrophages sequestered in the dorsal region where the matrix is less compact and contains cells with a spindly configuration. A variable amount of cellular proliferation is present around blood vessels and beneath the pia mater. Based upon previous studies, this matrix is the site where axons will regrow in association with Schwann cell ensheathment. Ventrally, a broad band of matrix develops consisting of cells which have a glial morphology, plus large immature cells. We conclude that this matrix, which is identical to that which has been shown to support axonal regrowth and central type myelination, has the capacity to support the regrowth of axons over an extended distance and will thereby constitute a model for the study of axonal growth in adult mammalian central nervous tissue.

113.5 GROWTH OF BLOOD VESSELS AND NEURITES INTO A COLLAGEN MATRIX PLACED BETWEEN THE CUT ENDS OF TRANSECTED RAT SPINAL CORD. J.B. Gelderd, Department of Anatomy, College of Medicine, Texas A&M University, College Station, TX 77843.

The purpose of this study was to evaluate the capability of a sterile, cell-free, bovine, collagen matrix (Collagen Corp., Palo Alto, CA) to support ingrowth of blood vessels and neurites following spinal cord transection in rats.

Using an operating microscope, adult Long-Evans hooded rats underwent laminectomy at the T_8-T_{10} vertebral level. The dura mater was split longitudinally and the spinal cord transected with a scalpel. Using gentle suction and iridectomy scissors, spinal cord and meninges were removed to form a gap of 3-4 mm between the rostral and caudal stumps of spinal cord. Following hemostasis, the gap was filled with collagen matrix and the musculature and skin sutured shut in layers. Some animals were killed at weekly intervals from 2 through 6 weeks postimplantation. The implantation site was serially sectioned horizontally and processed for light microscopy (Bodian silver, Gomori's trichrome) or separated into quadrants and processed for electron microscopy. Other implanted animals underwent surgery at 6 weeks to expose the implantation site. Using an operating microscope, the rostro-caudal center of the collagen implant was identified and transected with a scalpel. A piece of filter paper impregnated with HRP (Sigma, Type VI) was placed in the transection site and the incision closed. Forty-eight hours later, animals were killed by intracardiac perfusion with fixatives. Brain, spinal cord and all dorsal root ganglia located within 3 spinal segments of the implantation site were processed for HRP visualization, using the TMB reaction method.

The implantation site revealed typical cavitation formation in the neuropil adjacent to the lesion. A well-vascularized, connective tissue capsule surrounded the collagen implant and the stumps of spinal cord. Many blood vessels and fibroblasts penetrated the implant from this capsule. In addition, small numbers of axons could be seen within the connective tissue capsule and the collagen implant. Within the implant, axons typically were seen near blood vessels and appeared as single entities or as small, tightly-packed fascicles. A few HRP labelled cells were found predominantly within lamina 7-9 from upper cervical through lower lumbar spinal cord. In addition, a small number of HRP labelled cells were seen in brain stem reticular formation and red nucleus. No HRP labelling was seen in any other areas of the brain or in dorsal root ganglia adjacent to the implantation site. Supported by Texas A&M grant #15707.

113.6 THE EFFECT OF AN APPLIED DIRECT CURRENT FIELD ON RECOVERY AFTER SPINAL CORD INJURY: A BEHAVIORAL, ELECTROPHYSIOLOGICAL AND ANATOMICAL STUDY M.G. Fehlings*, C.H. Tator, R.D. Linden* Div. of Neurosurgery and Playfair Neuroscience Unit, Toronto Western Hospital, Univ. of Toronto, Toronto,Ont, M5T 2S8.

Recent work has indicated that direct current (DC) fields may promote the regeneration of transected mammalian spinal axons. In the present experiment, the therapeutic value of an applied DC field was studied in 40 rats with clip compression injuries of the cord at T1. The rats were randomly allocated to one of 4 groups of 10 rats each: two groups received a 17 g cord injury, and two groups a 53 g injury. One group at each injury severity received a treatment (14 μA) DC stimulator and the other group a control (0 μA) stimulator. Clinical neurological function was assessed weekly by the inclined plane technique. At 8 weeks after injury, motor and somatosensory evoked potentials (MEP and SSEP) were performed, and the axonal tracer horseradish peroxidase (HRP) was introduced into the cord at T6. The total number of HRP-labelled cells was counted in every sixth coronal section through the brainstem and motor cortex. All outcome parameters were assessed blindly.

In the 17 g group, there were no significant differences in any outcome measure between control and treated rats. In contrast, in the 53 g group, the inclined plane scores, the amplitude of the MEPs and the numbers of labelled cells in the red nucleus, raphé nuclei, and vestibular nuclei were greater in treated than control rats. These data strongly indicate that an applied DC field can produce functional neurological and anatomical improvement in rats with acute spinal cord injuries.

113.7 REINNERVATION OF SKELETAL MUSCLE VIA VENTRAL ROOTS REPLANTED INTO THE LATERAL COLUMN OF THE RAT SPINAL CORD. J.K. Terzis[1], K.J. Smith[2], M. Eramus[3], and K.A. Carson[4], Depts. of Microsurgery[1], Anatomy[2], & Neurosurgery[3], Eastern Virginia Medical School, Norfolk Virginia 23501

Spinal cord injury often results in a lifetime of dependency due to paralysis of the muscles below the level of the lesion. We have examined the possibility of reinnervating the affected muscles by the direct implantation of ventral roots into the lateral columns.

Sprague-Dawley rats were anesthetized (Nembutal and halothane) and the spinal cord exposed beneath lamina T_{13} by a lateral approach. In 17 rats the L_2 or L_3 ventral root was severed near its exit from the spinal cord and the distal stump replanted into the lateral column via a stab wound. The site of replantation was 3-4 mm caudal to the original position of root exit. In 10 control rats the cord was stabbed, but the distal end of the severed root was displaced from the proximal stump and left free in the cerebrospinal fluid. Eight to twelve months later the affected roots were pale and translucent, the replanted roots were white. Electrical stimulation of thd distal stump of divided replanted roots routinely evoked a prominent contraction of the appropriate muscles, whereas stimulation of non-replanted roots evoked a much smaller contraction. Where anesthetic depth permitted a slight pinch withdrawal reflex, pinching the hindpaws routinely evoked efferent activity in the proximal stump of the replanted root, just as it did in the contralateral control root. In some preparations, light stroking of the ipsilateral hindlimb or tail evoked centrifugal, seemingly somatosensory, discharges in the proximal stump of replanted (but not normal) ventral roots. Stimulation of the proximal stump of replanted roots sometimes activated time-locked units in more caudal ventral roots, and vice versa. Replanted roots were found to contain many regenerated myelinated nerve fibers upon histological examination, while non-replanted roots contained few nerve fibers. Horseradish peroxidase applied to the proximal stump of replanted roots (acutely severed) heavily labeled motoneurons located within 1-2 mm from the replanted site. The results suggest that axons regenerated from the CNS to establish functional contacts with the denervated skeletal muscle. The results may be of value in the reinnervation of muscles below a site of transection or damage of the spinal cord.

113.8 CNS AXONS REGENERATE INTO INTRASPINAL FETAL SPINAL CORD GRAFTS THROUGH CO-GRAFTS OF PERIPHERAL NERVE J. D. Houle Depts. of Neurological Surgery and Neuroscience, Univ. of Florida, Gainesville, FL 32610

Axonal integration between the injured adult central nervous system (CNS) and intraspinal grafts of fetal spinal cord (FSC) tissue often appears limited by glial scarring at the interface between graft and host tissue. The present study examined whether peripheral nerve grafts could be used to circumvent the scar and thereby facilitate the regeneration and interaction of spinal axons with co-grafted FSC tissue.

Both ends of a pre-degenerated segment (2 cm) of autologous tibial nerve were apposed to intermediate gray regions of the adult rat thoraco-lumbar spinal cord. After 2-8 months a spinal hemisection cavity was prepared between the two ends of the PNS graft, the PNS graft was cut at its midpoint and the two new ends were apposed to a suspension of FSC tissue grafted into the cavity. PNS bridges were re-exposed 2-12 months later, cut at their midpoint and all ends soaked in horseradish peroxidase (HRP). Animals were sacrificed after 48 hrs. and the entire spinal cord processed by either the DAB or TMB histochemical reaction. Portions of the PNS grafts were fixed and processed for Epon embedding.

Retrogradely filled spinal neurons (X per animal=650) in Laminae IV-VII were found up to 3 cm away from each PNS graft insertion site into the host spinal cord. Injury-filled host axons extended beyond the PNS graft interface with the FSC transplant to spread throughout the dorsal half of the FSC grafts. Large and small caliber axons grew in a straight course of up to 2 mm within the graft and were mostly unbranched, although a few displayed an extensive arborization that included terminal bouton formation. Neurons in dorsal root ganglia whose roots entered near these sites were also labeled with HRP (X=525), while only a few retrogradely labeled neurons (X=4) were found in the matured FSC tissue. These results indicate that the ingrowth of regenerating host axons into FSC grafts can be promoted by the diversion of these fibers around scars at the graft-host interface by a piece of PNS tissue. The co-grafting paradigm described here provides a model for future study of the dynamics of host axon interaction with FSC grafts from both anatomical and functional perspectives. This work was supported by NIH Grant NS 22316.

113.9 USE OF NATURAL HYDROGELS TO REPAIR THE INJURED RAT SPINAL CORD. S. Woerly, R. Marchand and L. Bertrand, Laboratoire de Neurobiologie, Hôpital de l'Enfant-Jésus, Qué., Canada, G1J 1Z4

Anatomical repair of the transected adult mammalian spinal cord with the aid of biomaterials (tissular or non tissular) requires that the implant material fulfills two essential functions (i) it must provide a bridge that will reestablish a physical continuity between the stumps of the severed spinal cord (ii) it must provide a terrain, mechanically and chemically favorable to the growth of regenerating neurites from the injured ends of the cord. To achieve this issue, we used natural hydrogels as biomaterials replacing lost spinal tissue. Hemiresection cavities and the gap between the stumps of transected thoracic spinal cords of adult rats were infiltrated immediately after injury, either with an ice-cold neutral prepolymerised type I collagen solution (concentration 2.4 mg/ml, Vitrogen, Collagen Corp.) alone or mixed with basement membrane Matrigel (Collaborative Res. Inc.), a biomatrix derived from the EHS mouse sarcoma. In a few cases, fetal rat spinal cord microfragments (E13) were also incorporated in the semi-fluid bioimplants prior to their implantation. Implant recipients were sacrificed one week to 2½ months later and tissues were processed for Gomori trichrome, Luxol-PAS, cholinesterase (Karnowsky and Roots) and immunocytochemistry for neurofilaments. Our results show 1) that self-assembly of collagen fibrils occurs in situ at the temperature of the tissue and results in the formation of a gel-like material. The collagen-matrigel mix forms a denser material 2) the gel completely fills the space offered by the premade cavities and fuses tightly with the healthy spinal tissue yielding an anastomosis between the two extremities of the transected spinal cords 3) the gel is invaded by (i) mesenchymatous cells, astrocytes and a few macrophages, (ii) capillaries and blood vessels (iii) in a few cases, cholinesterase- and/or neurofilament-rich processes from the host tissue extends along the fibrillar structures of the matrices 4) when present, the fetal implants survive within the gel and are intensely stained for cholinesterase 5) after 2½ months, the bioimplants are still well tolerated by the host tissue, and compared to sham, there is no cystic degeneration at the level of the transection and in most cases no scar formation. Hence, the hydrogel-derived collagen polymers that set in situ fulfills the requirements for a suitable material for implantation into the cord since it has the capacity (i) to anchor to the healthy tissue and to bridge resection cavities (ii) to support the growth of both neural elements and blood vessels across the gap of transection. Moreover, such a hydrophylic gel resembles the neural tissue by its consistency. (Supported by the MRC and FRSQ).

113.10 QUAIL-CHICK SPINAL CORD CHIMERAS TREATED WITH ORAL CYCLOSPORINE: 2 CASES. B.G. Uzman, G.M. Villegas, and K. Suzuki. Nerve Structure Research Lab., V.A. Medical Center, Memphis, TN 38104 Inst. de Estud. Avanz., Caracas, Vz. 1015A and U. North Carolina, Chapel Hill, NC 27514

Two quail-chick chimeras (0-1, 0-2) were treated with daily oral administration, not intraperitoneal injection, of Cyclosporin A (Csp) (Sandimmune, oral solution 15 mg/kg) beginning on the 54th post-hatching day (phd). Compared to a series reported by Kinutani and Le Douarin[1] in which 20 of 21 chimeras died with signs of acute spinal cord rejection before 65 phd, with 1 of the 21 surviving 113 phd, the survivals to 106 (0-1) phd and 200 (0-2) dph of the oral Csp-treated chimeras represent significant extensions of expected longevity. In addition, in the series reported by Kinutani and Le Douarin, the first neurologic signs of rejection appeared at 36 phd ± 3 d and inability to stand at 46 phd ± 3 d.[1] Chimera 0-1, initially without detectable motor defects, exhibited drooping of wings at 97 dph and, thereafter, a rapidly deteriorating neurologic course, similar to the Kinutani and Le Douarin chimeras [1,2]. Chimera 0-2 exhibited difficulty in standing and ambulation at hatching and within 12 days could not stand, apparently due to an imperfect graft. At 80 phd 0-2 exhibited a remitting neurologic picture of trembling and difficulty eating (requiring dropper and hand feeding) with recurrence approximately every 20 days for 4-6 day periods. Simultaneously recurring tonic/clonic "seizures" were first noted at 104 phd. Light and electron micrographs of central and peripheral nervous systems of 0-1 and 0-2 show differing degrees and types of cellular infiltration as well as differences in spinal cord fiber tract degeneration. Similarities to and differences from experimental allergic encephalomyelitis or neuritis and multiple sclerosis are notable.

3. The authors acknowledge the assistance of Mary Melvin and Donna Hall; and extend thanks to Prof. Le Douarin and Dr. M. Aimée Teillet for valuable discussions and instruction in quail/chick spinal cord chimera preparation, and to Dr. William Winter, Sandoz, Ltd, East Hanover, N.J. for a generous gift of Csp.

113.11 EFFECT OF DORSAL ROOT GANGLION NEURON PLUS SCHWANN CELL IMPLANTS ON GROWTH OF CORTICOSPINAL FIBERS AFTER SPINAL CORD INJURY IN NEONATAL RATS. K.R. Kuhlengel*, R.P. Bunge, H. Burton and M.B. Bunge (SPON: S. Goldring), Depts. Anat./Neurobiol. & Neurosurg., Washington Univ., St. Louis, MO 63110.

Injury sites were created in the dorsal thoracolumbar spinal cord of neonatal rats to interrupt the pathway of the developing corticospinal tract (CST). These lesioned cavities were filled with explants composed of rat dorsal root ganglion neurons and Schwann cells with or without vascular leptomeningeal cells prepared in tissue culture. The purpose of these implants was to facilitate axonal growth across the spinal injury site. Two surgical protocols were utilized. In one case, implants were placed at the time of lesioning at two days of age; in the second case, lesions were created on the first day of life and the implant was placed four to five days later. Implants placed at the time of surgery survived in 77.4% (48/62) of cases, whereas implants placed at the later time survived in 58.3% (35/60) of cases. Specimens were examined with light and electron microscopy and immunocytochemistry with antibodies against GFAP and laminin. These studies demonstrated that Schwann cells did not migrate into the host parenchyma but that astrocytes invaded the implants diffusely.

Studies were then performed using WGA-HRP to trace the CST and study the effects of these implants on the growth of this tract. In cases in which no implants were placed, CST fibers were either not seen distal to the lesion or were diffusely distributed throughout the gray matter caudally and did not return to their normal pathway in the ventral portion of the dorsal columns. In cases receiving implants at the time of surgery, diffuse labeling was present in the gray matter, with a fasciculated fiber pattern subjacent to the implant; this fasciculated fiber grouping continued caudally beyond the lesion in a corresponding gray matter location subjacent to the ventral portion of the dorsal columns. No fibers were seen passing through the implant. In cases of delayed implantation, a variable effect was seen in which in some cases there was mild fasciculation adjacent to the implant which persisted in this location caudally. In other cases, however, there was diffuse nonfasciculated fiber growth in the gray matter caudally, similar to that seen in non-implanted lesion controls. Thus, these implants did not function as tissue bridges, but appeared to influence the adjacent spinal cord parenchyma (dominated by astrocyte processes) to permit CST fiber fasciculation and passage beyond the lesion site. The effect of these implants was more marked if they were placed at the time of lesioning rather than later. One possible explanation for the accumulation of fasciculated fibers below the implant is the production of Schwann cell trophic factors which diffuse into the adjacent host cord and influence the expression of macromolecules in the glial border. (NIH grants NS09923, NS15070; NS07205.)

NEUROETHOLOGY I

114.1 NEURONAL AND HORMONAL CONTROL OF EGG LAYING BEHAVIORS IN THE POND SNAIL. G.P. Ferguson, A.W. Pieneman* and A. ter Maat*. Department of Biology, Free University, PO Box 7161, 1007 MC, Amsterdam, The Netherlands.

The freshwater pulmonate, *Lymnaea stagnalis* provides a useful model system for analysis of the neuronal and hormonal control of egg laying behaviors. In *Lymnaea* the critical event that determines when egg laying occurs is the discharge of the neurosecretory Caudo Dorsal Cells (CDCs). During this discharge the CDCs fire synchronously and release neuroactive peptides into the blood. One of these peptides is Caudo Dorsal Cell Hormone (CDCH), which causes ovulation of ripe oocytes from the ovotestis.

In the laboratory, egg laying occurs when the CDCs fire "spontaneously", or can be induced by either transferring animals into clean water, or using a fine wire electrode implanted on the CDCs to stimulate them electrically (in the intact animal) and selectively elicit a discharge. Under these conditions the overt egg laying behaviors have four distinct phases. During the first phase (resting phase), locomotion stops (for about 25 min) and the animal assumes a posture with the tentacles curved downwards, the foot contracted and the shell over the head. This is followed by the turning phase, the most active phase of egg laying. During this phase the animal cleans the area where the egg mass will be deposited by performing three appetitive behaviors simultaneously. There is clockwise bending and movement of the head-foot, counterclockwise rotation of the shell and an increase in the number of rasping movements made by the buccal mass. The subsequent oviposition phase (approx 12 min) is the consummatory egg laying behavior, the egg mass leaves the genital pore and is pressed onto the substrate by the mantle edge and pneumostome. Finally, the snail enters the inspection phase and brushes the egg mass with its lips and tentacles.

When ovulation was induced by injections of purified CDCH, the subsequent egg laying behaviors were found to differ from those following CDC discharges. Animals showed no resting phase. Instead, they continued locomotion and then entered directly into the turning phase. This indicates that the presence of only CDCH within the blood is not sufficient to produce the full complement of egg laying behaviors and suggests that the resting phase of egg laying may be dependent on the local action of CDC releasate within the CNS. The other egg laying behaviors of animals with CDCH injections were similar to those which occur after CDC discharges. The neural networks that control movements of the shell, foot and buccal mass of *Lymnaea* have been identified previously and studies are now in progress to determine how these networks are activated by CDC releasate and input from the eggs to produce coordinated egg laying behaviors.

114.2 SPECIALIZED VISUAL RECEPTORS RESPOND TO MAGNETIC FIELD ALIGNMENT IN THE BLOWFLY (CALLIPHORA VICINA). John B. Phillips* (SPON: J. Rosenbaum), Dept. of Biology, Indiana Univ., Bloomington, IN 47405

The optical-pumping model of magnetoreception (Leask 1977, Nature 267: 144) postulates that the magnetic field influences the response of a specialized visual receptor by changing the efficiency of energy transfer from an "antenna" pigment to the photopigment following excitation of the antenna pigment by light. Retinula 1-6 cells of the blowfly (Calliphora vicina) contain an antenna pigment that absorbs near-UV light and transfers energy by a radiationless process to a visual pigment absorbing at longer wavelengths. To determine whether energy transfer in R1-6 cells is influenced by an external magnetic field, the response to a standard flash of light was recorded intracellularly while varying the horizontal alignment of a 1.0 gauss magnetic field. In cells stimulated with 370 nm light (absorbed preferentially by the antenna pigment), responses that showed a slight decrement when compared to "zero field" control responses were consistently associated with alignments of the magnetic field that formed a bimodal or quadramodal pattern. Both patterns are axially-symmetrical (i.e., independent of the polarity of the magnetic field) which is a requirement of the optical-pumping model. In contrast, when R1-6 cells were stimulated with wavelengths of light absorbed by the photopigment directly, there was no consistent pattern of response. These findings suggest that the alignment of a 1.0 gauss magnetic field has a weak, but reproducible, effect on energy transfer in R1-6 cells. Similar bimodal or quadramodal patterns of response have been found in behavioral studies of magnetic orientation in several insects.

Under natural conditions, small changes in energy transfer efficiency would not be detectable in R1-6 cells because of masking due to direct excitation of the photopigment by light. However, in the R7(y) cell, also containing a UV-absorbing antenna pigment, sensitivity of the blue-absorbing photopigment to direct absorption of light is greatly reduced by an optically-dense screening pigment. Thus, the R7(y) photopigment is primarily sensitive to energy transfer from the antenna pigment. UV-sensitive R7(p) and blue-sensitive R8(p) cells provide additional inputs necessary to determine the proportion of UV light absorbed by the R7(y) antenna pigment that is transferred to the photopigment, and to factor out the component of R7(y) response due to direct excitation of the photopigment by light bypassing the screening pigment. These three cells are proposed to form a specialized receptor system that is responsible for magnetoreception in the blowfly, detecting small changes in the efficiency of energy transfer in R7(y) that indicate the relative alignment of the earth's magnetic field.

114.3 CHANGES IN WING PARAMETERS IN TELEOGRYLLUS OCEANICUS DUE TO ULTRASONIC STIMULI. Michael L. May and Peter D. Brodfuehrer. Section of Neurobiology and Behavior, Cornell University, Ithaca, NY 14853.

This work describes three wing-related effects in the Australian field cricket (Teleogryllus oceanicus) in response to an ultrasonic stimulus. While previous work on the effects of ultrasound, delivered during flight, showed negative phonotaxis with emphasis on the abdominal "rudder," this study reveals characteristic changes in the movements of both fore and hindwings: 1) a lift (i.e., increased angle of elevation) in the forewing ipsilateral to the stimulus; 2) a drop in the forewing contralateral to the stimulus; and 3) a "hitch" or momentarily decreased beating frequency in the hindwings. Each of these responses is consistent with the hypothesis that negative phonotaxis represents an escape behavior from echolocating bats.

Both forewing lift and drop are linearly related to the sound level intensity as determined from photographs of flying crickets tethered upright although the lift is larger in magnitude than the drop. To the best of our knowledge, wing lift has only been described as a steering movement in a mantis species (Yager, D.D.and Hoy, R.R., Soc. Neurosci. Abstr. 12:202, 1986). The contralateral forewing drop is of a relatively small magnitude and may, therefore, be due largely to pronation. Such pronation in turning has been described in the locust (Dugard, J.J., J. Insect Physiol. 13:1055-1063, 1967) and suggested in T. oceanicus (Pollack, G.S. and Hoy, R., J. Insect Physiol. 27:41-45, 1981).

The hindwing hitch was observed via both a light detector method and electromyographic recordings from muscle # 129. Further, it is a bilateral event. In a flying tethered cricket beating its wings at approximately 25 Hz, an ultrasonic stimulus induces a momentary drop in beating frequency to about 10 Hz. Within 2-3 wing cycles, the original frequency is recovered. As this response habituates rather quickly with multiple stimuli, it may be a startle response.

These responses further substantiate the potential of negative phonotaxis as a bat avoidance behavior. A startle response, such as the hindwing hitch, is not uncommon in an animal presented with a noxious stimulus. Further, the forewing responses would likely induce a turn away from the source of the sound stimulus. Although it is presently undetermined, the linearity of the forewing responses is likely to produce a turn which is also graded with sound level intensity. (Supported by NIH Grant #5T32GM07469.)

114.4 Non-Synaptic Regulation of Sensory Feedback During Movement Ronald S. Goldstein*, Frederic Libersat*, Jeffrey M. Camhi Dept. Zoology, Hebrew University, Jerusalem, Israel (SPON: M. Devor)

Movements of an animal produce sensory feedback, not all of which is useful. Potentially perturbing feedback is sometimes inhibited synaptically, either peripherally or centrally.

In cockroaches, flying produces strong wind feedback to the cerci, paired wind-responsive sensory appendages. When not flying, the cockroach uses its cerci to evoke well studied escape responses to very gentle air currents generated by approaching predators. The wind feedback during flight could therefore habituate the escape response. While flying, the cockroach moves its cerci by 45-60° about their joint with the body, and this cercal displacement reduces the sensory response to wind, by a novel, apparently non-synaptic mechanism (Libersat et al., this volume). This abstract describes the effect of this sensory reduction on wind-responsive interneurons, some of which mediate the escape response.

Controlled wind puffs from the front, presented when the cerci were in their rest position, elicited repeatable responses from the medial cercal nerve, the nerve containing wind-sensitive afferents from the cercus. However, when the cercus was displaced by 45-60° and held parallel to the body, and the wind stimulator was rotated to retain the same angle of stimulation, the wind-evoked response was reduced. The reduction, a mean of 34% occured in each of the nine animals tested. This reduction was repeatable within the same animal for as long as was tested (3 hours) as determined by repeatedly displacing and releasing the cercus.

In order to determine the effect of this sensory reduction on wind-sensitive interneurons, we recorded from these interneurons simultaneously with the sensory axons. When the cercus was displaced and produced typical sensory reduction, the wind-evoked interneuron response was reduced by 40% (six animals).

We examined the possible contribution to the depression of the interneuron response from two other sources besides the displacement-induced reduction of sensory activity. First, a chordotonal organ sensitive to lateral cercal displacements can apparently produce large IPSP's in some of the wind-sensitive interneurons (Bernard J. et al J. Comp. Phys. 153:377). This sensory structure could therefore contribute to depression of the interneuronal wind response when the cercus is displaced. Second, some information about the cercal displacement may ascend the nerve cord and elicit known descending inhibitory signals (Daley D. and Delcomyn F. J. Comp. Phys. 138:231) reducing the interneuronal response. We tested these two possibilities by: 1) cutting the lateral cercal nerve containing the afferent fibers from the chordotonal organ, and 2) cutting the nerve cord above the abdominal ganglia to prevent descending inhibition. No significant changes in the reduction of either sensory activity or interneuronal activity were found with cutting these nerves in any combination.

It appears, therefore, that the non-synaptic suppression of sensory activity produced by cercal displacement can account for the entire reduction of wind-evoked activity in the nerve cord that occurs in the interneurons. We are now examining the possibility that this reduction serves to protect the escape response from habituation.

114.5 MECHANISM OF NON-SYNAPTIC REGULATION OF SENSORY ACTIVITY DURING MOVEMENT Frederic Libersat*, Ronald S. Goldstein*, Jeffrey M. Camhi (SPON:A.F.Mirsky). Dept. Zoology, Hebrew University, Jerusalem, Israel

When a cockroach flies, it generates strong winds. Such winds could habituate the escape circuitry, normally excited in a non-flying cockroach by gentle wind gusts. These escape-inducing stimuli are detected by the cerci, two sensory organs located in the posterior abdominal region. However, during flight, the cockroach displaces the cerci, a movement that causes a reduction in the sensory response to wind (Goldstein et al., this volume). This abstract examines the mechanism of this sensory reduction.

Controlled wind puffs from the front, presented when the cerci are in their rest position, elicit very repeatable responses of the wind-sensory cells. We moved a cercus in a manner resembling its movement during flight and rotated the wind-tube to retain the same angle of stimulation. Now the wind-evoked reponse was reduced by a mean of 34% or 48% (extra-cellular and intra-cellular recordings repectively).

The same reduction in sensory activity occured when the animal displaced its cerci in reponse to stimulation of the motor axons in the lateral cercal nerve. Moreover, when semi-intact preparations made rhytmic wing movements, accompanied by cercal displacement, the same reduction of sensory activity occurred.

The sensory reduction did not result from displacement of the cercus to a position where the wind was blocked by other body parts or by the recording apparatus; when a pin was placed medial to the cercus, preventing its movement upon stimulation of the lateral nerve, the same reduction still occured.

Inhibition emanating from the central nervous system can be ruled out as the source of the reduction in sensory activity; cutting near the last abdominal ganglion the two nerves that provide the only innervation of the cercus and surrounding tissues leaves the reduction unaffected.

Two experiments demonstrate that the reduction takes place near the point where the sensory nerve emerges from the cercus. First, recordings from the nerve within the cercus near its base show no significant reduction upon cercal displacement, while simultaneous recordings from the nerve inside the body cavity show a typical reduction. Second, when the cercal nerve was dissected free from its surrounding tissues near the cercal joint, the wind response recorded central to the joint was not reduced by displacing the cercus.

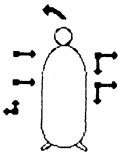
In order to test the possible role of "en-passant" synaptic inhibition on to the sensory axons, we recorded sensory activity using 0 Ca++ saline. In each of six experiments, this saline did not block the displacement-induced sensory reduction; yet, as a control, this saline did block sensory-to-giant interneuron synapses.

Intracellular recordings from sensory axons indicate that when the cercus is displaced, that the axonal core resistance and/or the extracellular resistance increase in the region of the cercal joint. This could contribute to the the blockage of sensory action potentials, and thereby to the observed sensory reduction.

In summary, this mechanism of sensory reduction is entirely peripheral, and apparently non-synaptic, being based upon mechanical stress on the sensory nerve that blocks some action potentials at the joint of the cercus with the body. The raises the possibility that body movements in general might impose similar stress on peripheral nerves, and thereby alter impulse traffic.

114.6 LEG MOVEMENTS AND THEIR CONTROL IN THE ESCAPE TURNS OF COCKROACHES J.M. Camhi and A. Levy*. Dept. Zoology, Hebrew University, Jerusalem, Israel.

Cockroaches respond to the minute wind gust made by the approach of a predator by turning rapidly away and then running. In spite of intensive work on the sensory and central control of this escape behavior, relatively little is known about the actual leg movements that produce the turn. We have filmed at 250 frames/sec turning responses of cockroaches to controlled wind stimuli, and carried out a computer graphics, frame-by-frame analysis of the movements. Our program calculates for each frame: 1) The body angle relative to wind direction; 2) for each leg, whether the tarsus is stationary or moving relative to the ground, (defining stance vs swing phases, respectively); 3) the vectorial anterior-posterior (A-P), and 4) medial-lateral (M-L) components of each leg's movement relative to the body.



Right front wind stimuli initially elicit usually a swing phase in the right hind leg and a stance phase in all five remaining legs. This differs from running, in which three legs are in stance and three in swing at any moment. This running pattern is established by the second or third step of the turn. The mean A-P and M-L movement vectors for each leg in stance during the starts of left turns evoked by wind from the right is shown in the figure.

These data suggest, first, that the initial movements of the hind legs (right leg swing, left leg small movements) contribute little to the strong left turn. This turn appears to result mainly from an inward pull by the left, and an outward push by the right, front and middle legs. In fact, if one computes the body angle that would result from only the M-L component of the front and middle legs, this accounts for over 75% of the angle of the turn. The left hind leg's action may serve to provide a pivot point, as is further suggested by this leg's remaining in stance for the first few stepping cycles of the other legs. The posterior movement of the right front and middle legs may represent largely a by-product of a left turn about a posterior pivot point, rather than a posteriorly directed force by these legs.

We have found that essentially the same initial leg movements and body turn are made in response to wind by cockroaches whose posterior abdomen is pinned in place and whose legs are free to move on a slick surface. This permits physiological recordings to be made during turning behavior carried out in place. However, dissected preparations show weak or no behavioral responses to wind stimuli. Therefore, we have developed techniques for implanting cuff electrodes around both abdominal and thoracic connectives and re-closing the body. In this way we record apparently normal interneuronal activity during turning behavior. In the thoracic connectives, the axon diameters of the much studied giant interneurons are small, permitting their small action potentials to be discriminated from larger action potentials of larger interneurons. Some of these latter are excited by the giant interneruons and may comprise a command for coordinated movement of all the legs. These studies are helping to define and analyze this command.

114.7 NEURAL CONTROL OF FLEXIBLE BODY DYNAMICS DURING THE C-START. R. DiDomenico*, J. Nissanov*, and R. C. Eaton. Department of Biology, EPO Box 334, Univ. of Colorado, Boulder, CO 80309.

This study continues our functional analysis of a pair of identified medial reticulospinal neurons, the Mauthner cells (M-cells) in the brain stem of teleost fishes. These cells are involved in producing a rapid escape response (the C-start) to predatory attacks. In this study we used a matrix camera, a high-speed digital imaging device for rapid acquisition and quantification of multiple behavioral trials. Bilateral EMG recordings were taken from the body musculature as an indication of the neural commands underlying the production of the behavior in response to a displacement stimulus.

Our study shows that the following features are required for an adequate neural explanation of the C-start: 1) inherent flexibility of the behavior pattern, which is expressed by the variety of possible trajectories and response strengths, and 2) invariant coupling between the various mechanical stages of the movement pattern. There are minimally two neural signals to be considered. These are revealed by their EMGs. The first of these signals triggers the initial C-like contraction of the response known as Stage 1. When the M-cell is present, it seems to participate in the production of the Stage 1 signal but we know from previous studies in which the M-cell has been lesioned that it is not indispensible for this component. The Stage 1 EMG is variable in duration and provides a sustained impulse that seems to code for turning angle of Stage 1. A second signal appears later in time on the side opposite the initial contraction and appears to code for the onset of the propulsive component of the behavior, Stage 2. Of the Stage 1 and 2 signals, the M-cell is included in the first, but Stage 1 does not occur in isolation from Stage 2 in freely-behaving animals. Instead, the two signals are inextricably linked in the production of the behavioral response. This is the minimal naturally occurring unit of the behavior, and our study shows that it requires complex neural processing in addition to that triggered only by the M-cell.

Two hypotheses have been suggested for the role of the M-cell in the C-start. One view [Hackett and Greenfield (1986) Behav. & Brain Sci. 9:729-730] implies that the behavior is mediated by a rigidly stereotypic system that produces an invariant output. In contrast, the present paper suggests a dynamic regulatory process that tunes the continuity of the motor performance to a variable stimulus environment. [Supported by NIH grant NS22621]

114.8 A SEXUALLY DIMORPHIC SONIC (ACOUSTIC) MOTOR SYSTEM IN A TELEOST FISH: PERIPHERAL AND CENTRAL ELEMENTS. A. H. Bass and M. A. Marchaterre. Section of Neurobiology & Behavior, Cornell University, Ithaca, N.Y. 14853.

One system controlling the generation of acoustic communication signals is the sonic motor system of marine teleost fishes. In some species, the effector organ consists of striated muscles that form the lateral walls of the swimbladder. The contraction rate of the "drum" muscles, which is under the control of a central sonic motor nucleus, determines the spectral features of the acoustic signals. In the midshipman, Porichthys notatus, there is a behavioral sex difference in that only males are known to produce sounds during the breeding season. We have now discovered a dramatic sex difference in the gross and fine structure of the swimbladder drum muscles of adult specimens. There is a highly significant sex difference ($p<0.0001$, $T=7.61$, $DF=18.5$) in the mean value of the ratio of swimbladder weight to body weight (sb/bw=0.030 for males, 0.018 for females). The bladder of males is heart-shaped with two large bands of muscle along its lateral margins; the female bladder is more conical-shaped with two small dorsolateral bands of muscle. The muscle of males also has a deep red coloration while that of females has a pale yellowish-white tint. At an ultrastructural level, there is a sex difference in individual myofibrils of sonic muscle: the width of Z bands in males are 10-15 fold that found in females, or the body wall muscle of males and females, or the swimbladder drum muscles of other sonic teleosts such as toadfish, Opsanus and sea robins, Prionotus. The sarcoplasmic reticulum of the sonic muscle is also hypertrophied in male midshipmen in comparison to females.

Given the extreme sex difference in sound production and the peripheral sonic swimbladder and its intrinsic muscles, we want to know the central structure-function correlates associated with these differences. Both males and females have a sonic motor nucleus. At an ultrastructural level there are several classes of terminal boutons in both males and females: axosomatic gap junctions associated presynaptically with pleomorphic vesicles, axosomatic chemical synapses associated with round or pleomorphic vesicles; axodendritic chemical synapses associated presynaptically with round vesicles. So far, axodendritic synapses with pleomorphic vesicles have been found only in males. While a limiting factor in sound production may indeed lie with the sonic muscles, the central neurophysiological correlates of the behavioral and structural sex differences await definition.

114.9 ELECTROLOCATION IN THE PRESENCE OF JAMMING SIGNALS: BEHAVIOR AND ELECTRORECEPTOR PHYSIOLOGY. J. Bastian. Dept. of Zoology, Univ. of Oklahoma, Norman, OK 73019. The electrolocation behavior of Apteronotus leptorhynchus was studied in the presence of various interfering or 'jamming' electrical signals. Electroreceptor afferent responses to the same moving electrolocation targets (metal cylinders) were also studied in the presence of the same jamming signals, allowing comparisons to be made of the effects of jamming on the behavior and on the receptors' responses. Broad-band noise, high frequency sinusoidal signals maintained at a given frequency difference (DF) from the fish's electric organ discharge frequency, and low frequency (5 or 50 Hz) sinusoidal signals were used to jam the electrosensory system. The latency of the fish's responses and the minimum distance maintained between the moving targets and the fish were used to estimate electrolocation performance.

Both noise and DF jamming had strong deleterious effects on electrolocation performance, and threshold amplitudes for DF jamming were about three-fold lower than thresholds for noise jamming. The rates of change of jamming effectiveness as a function of increasing jamming intensity were, however, not different for noise and DF. Response latency increased by 78 and 84 ms per 10 dB increase in the rms amplitude of noise and DF signals respectively, and minimum fish-target distance decreased by 0.21 and 0.24 cm per 10 dB increase in noise and DF respectively. Neither the 5 nor the 50 Hz stimuli, which are expected to primarily stimulate the ampullary receptor system, were effective in causing significant electrolocation response deterioration when presented alone. If, however, the 5 Hz stimulus was presented simultaneously with either the noise or DF stimulus, then the low frequency jamming augmented the response deterioration. This suggests that the ampullary system might provide supplementary information utilized by the fish when normal cues received over the tuberous system are interfered with.

Receptor afferent responses to the same electrolocation targets were more severely disrupted by the jamming signals, and both the threshold and the rate of increase of receptor response decrement as a function of increased jamming signal amplitude were significantly greater for DF jamming as compared to noise. Estimates of electroreceptor threshold distance decreased by 0.53 and 0.8 cm per 10 dB increase in noise and DF jamming respectively. 5 Hz jamming signals had no effect on tuberous receptor afferent responses, but this form of jamming did severely disrupt the responses of ampullary afferents to the galvanic potentials produced by the metal targets.

These results suggest that CNS mechanisms exist which improve the signal to noise ratio of relevant signals, and that these mechanisms are better able to reject disturbances created by DF jamming as compared to those resulting from noise. Supported by NIH grant NS12337.

114.10 SUPPRESSION OF SELF-GENERATED ELECTROSENSORY INTERFERENCE VIA A COMMISSURAL MEDULLARY PATHWAY IN THE LITTLE SKATE J.G. New and D.Bodznick, Dept. of Biology, Wesleyan University, Middletown, CT 06457.

Common mode electrosensory interference generated by respiratory activity in skates and rays may pose a significant neuroethological problem when the animal attempts to locate and orient to weak environmental electric fields. Previous studies demonstrate that while activity of electrosensory afferents in the anterior lateral line nerve (ALLN) is strongly modulated during ventilatory movements, ascending efferent neurons (AENs) within the dorsal octavolateralis nucleus (DON) are only weakly affected by ventilation (Montgomery, 1984; New & Bodznick, 1986). Direct evidence for active suppression of ventilatory electrosensory interference in the skate DON has been previously reported (New & Bodznick, 1986). The current study provides evidence that in skates this suppression is achieved by a commissural common-mode rejection mechanism and not by a ventilatory efference copy mechanism.

Extracellular recordings of ALLN fibers and AENs were made in little skates, Raja erinacea, that were decerebrate and either completely paralyzed by curare or spinalized to permit normal ventilation. AENs were identified by antidromic responses to lateral mesencephalic nucleus stimulation. In curarized animals AEN activity and responsiveness were examined for evidence of modulation by a ventilatory efference copy signal. The ventilatory motor burst in the hyomandibular nerve served to indicate the timing of fictive ventilation. However, in 18 AENs no modulation of ongoing activity phase related to the ventilatory burst was observed. Furthermore, AEN responses to weak electric fields were the same regardless of which point in the respiratory cycle stimuli were presented. Thus an efference copy mechanism is not supported.

In spinalized animals, transection of the contralateral ALLN caused a mean 93% increase in AEN modulation during ventilation. Furthermore, the responses of AENs to weak electric fields were diminished by a mean of 50% when the transected contralateral ALLN was driven via a train of stimulus pulses. These experiments argue that the commissural pathway mediates the suppression of common-mode electrosensory interference. The involvement of the commissural pathway in interference suppression may prove a useful comparative feature in investigations of medullary processes. Supported by a Sigma Xi Grant-in-aid to JGN and an NIH grant to DB.

114.11 A VERTEBRATE COMMUNICATORY BEHAVIOR ELICITED IN VITRO: CHIRPING IN THE WEAKLY ELECTRIC FISH, APTERONOTUS. J. Dye. Dept. of Neurosciences & Neurobiology Unit, Scripps Institution of Oceanography, UCSD, La Jolla, CA 92093.

Apteronotus is a weakly electric gymnotiform fish possessing a 'wave-type' electric organ discharge (EOD). The EOD is maintained continuously at a remarkably stable frequency. In addition to subserving electrolocation, the electrosensory system is a medium of intraspecific communication. Several modulations in the EOD frequency that are performed by these fish have been characterized at the behavioral and physiological levels. Chief among these is the jamming avoidance response (JAR), a slow, smooth shift in frequency away from that of a nearby conspecific to prevent impairment of electrolocation. These animals also have a repertoire of communications involving modulation of EOD frequency. The most salient of these is the chirp, a large, rapid acceleration used as a signal during aggression and courtship. Chirping, like the JAR, can be elicited in an animal during acute electrophysiological recording.

The EOD is commanded by a nucleus on the ventral aspect of the medulla, the pacemaker nucleus. It is composed of pacemaker cells, which are interneuronal and possess underlying pacemaker potentials, and relay cells, which project axons down the spinal cord to trigger each EOD cycle. We have previously recorded from both types of neurons in vivo and characterized distinct responses in histologically identified loci during naturally evoked chirps (Dye & Heiligenberg, 1987, J Comp Physiol, in press).

This presentation reports the reproduction of this behavior in an in vitro pacemaker preparation. The pacemaker nucleus fires at its characteristic frequency after removal from the brain and placement in a slice chamber. By retaining in the brain slice a large extent of tissue rostral to the nucleus, one which includes the sole afferent pathway to the pacemaker from the prepacemaker nucleus, characteristic chirps can be elicited with bipolar stimulation of this tract. These chirps, while briefer and somewhat stronger than those occurring in the animal, display the same distinctions between cell types and loci as those described in experiments in vivo. Moreover, a phase-dependence of the efficacy of afferent stimulation has been found, identical to that which has been seen in response to single prepacemaker cell spikes in vivo. The suggestion of chemical transmission from prepacemaker afferents, based thus far on anatomical studies, is further supported by the demonstration of frequency-dependent facilitation, blockage by manganese, and transient changes in input impedance during the chirp acceleration. Finally, brief trains of stimuli cause longer-lasting accelerations as well, which may be caused by excitation of those fibers responsible for the JAR.

114.12 CENTRAL INTEGRATION OF MECHANORECEPTIVE LATERAL LINE INFORMATION IN THE THORNBACK GUITARFISH, PLATYRHINOIDIS TRISERIATA (ELASMOBRANCHII). H. Bleckmann*, O. Weiss* and T.H. Bullock. Neurobiology Unit, Scripps Inst. of Oceanography & Dept. of Neurosciences, Sch. of Medicine, Univ. of California, San Diego, La Jolla, CA 92093.

The mechanoreceptive lateral line of P. triseriata is represented at all levels of the neuraxis, from medulla to telencephalon (Bleckmann, Bullock & Jørgensen, J. Comp. Physiol., in press). In the present study we have investigated in the same species the physiological properties of mechanoreceptive lateral line areas, from medulla to telencephalon, using averaged evoked potentials (AEPs), few unit and single unit responses as windows to brain functions. Recordings were analyzed with respect to frequency sensitivity, dynamic response properties, response latency, receptive field (RF) organization, and interaction with light flash, electric field and vibration. All lateral line areas encountered were sensitive to water movement. Best frequencies (BF) in terms of displacement vary between 75 and 250 Hz with threshold values as low as 0.02 um peak-to-peak, calculated at the skin, in the most sensitive units. For the frequencies 25, 50, and 100 Hz, the dynamic range of each lateral line area was tested and found to vary from 30 to at least 65 dB. Response latencies increase with increasing stimulus rise time and decreasing stimulus frequency below BF. Responses recorded in the medullary medial octavolateralis nucleus are phasic-tonic, i.e. the responses are strongest at stimulus onset but last for the whole stimulus duration in the form of a frequency following response (FFR) similar to that known for acoustic stimuli. The lateral line FFR persists after bilateral section of n. VIII. In contrast, unit responses recorded in the midbrain and the diencephalon are in most cases phasic. Responses recorded in the medulla are phase coupled to the stimulus; those recorded in the midbrain or forebrain are usually not. Units tested in several lateral line areas showed small well defined RFs. RFs are mostly contralateral to the recording side and usually in the anterior third of the fish. No obvious interaction of modalities was seen except in posterior central thalamic and anterior midbrain nuclei. AEPs in the telencephalic hot spot show positive peaks at 65, 200, and 360 ms with optimal stimuli and require stimulus intervals of 20 s or more.

Supported by grants to T.H.B. from NSF and NIH, to O.W. from Education Abroad Program of U.C.S.D. and Univ. of Göttingen and to H.B. from DFG.

114.13 ISOLATION - DEPENDENT ACTIVATION OF FOUR FOREBRAIN AREAS IN THE ZEBRA FINCH.
H.-J. Bischof* and K. Herrmann* (SPON: European Neuroscience Association). University of Bielefeld, Dept. of Ethology, POB 8640, D-4800 Bielefeld 1, F.R.G.

In a previous study (Bischof, H.-J. and Herrmann,K., Beh.Brain Res.,21:215,1986) we demonstrated that four forebrain areas of zebra finch males are activated in situations which arouse the animal, for example when chasing the birds around the cage, or when exposing them to a female. These areas, the Hyperstriatum accessorium (HA), a part of the medial Neostriatum (Nint), the lateral Neostriatum (Nlat), and a portion of the caudal Archi-Neostriatum (A+Ncaud) show an enhanced 14C-2-Deoxglucose (2-DG) uptake according to the experimental situation. On the basis of these experiments, we examined whether the activation of these areas is correlated with motor activity and is influenced by different isolation times prior to the 2-DG experiment, where courtship of the male birds was elicited by exposing them to a female zebra finch. For this purpose, we isolated male zebra finches for 1 day, 1 week, or 8 weeks, respectively, before we injected the 2-DG and exposed the birds to a female. During the experiment, besides other activities the number of song motifs performed by the bird and the frequency of changing the perches was recorded. Our experiments demonstrate that there is a negative correlation between motor activity and 2-DG uptake, and a positive correlation between isolation time and 2-DG uptake. We suggest that long isolation blocks courtship behavior by some unknown mechanism, and that the "internal drive" of the animal, which possibly corresponds with the activity of the four forebrain areas, is enhanced by isolation and by the fact that the birds do not perform the consummatory behavior, which would lead to a reduction of the "internal drive level". Our results also demonstrate that the 2-DG method can show up small differences in the internal state of an animal which cannot be easily detected by behavioral measurements.

114.14 PERIORAL STIMULATION FROM PUPS: ROLE IN NORWAY RAT MATERNAL RETRIEVAL, LICKING, CROUCHING AND AGGRESSION. J. M. Stern and J. M. Kolunie. Depts. of Psychology and Biological Sciences, Rutgers University, New Brunswick, NJ 08903.

The rat's snout is an obvious choice for reception of motivating and guiding cues from pups. Major deficits in pup retrieval were found following acute mystacial pad anaptia with lidocaine anesthesia (Kenyon et al., Physiol. Beh., 27:313, 1981) or infraorbital denervation (Kenyon, et al., Behav. Neurosci., 97:255, 1983). We now report the results of 3 studies in which primiparous postpartum (PP) rats were injected with mystacial pad lidocaine (LIDO) or saline (SAL) 30 min prior to testing.

Retrieval: On Days 2, 3, and 4 PP, retrieval of 5 pups in 5 min in the home cage increased from 5/8 to 8/8 in the SAL group, whereas 1/8 LIDO dam retrieved, on Day 4 only. In contrast, after a Day 2 practice session in the retrieval apparatus (light and dark compartments), 11/11 SAL and 8/10 LIDO dams retrieved on Day 3 PP, but the latency and duration were 3 and 2 times longer for LIDO dams. With no prior practice, 8/8 SAL vs. 1/8 LIDO dams retrieved in the test apparatus.

Licking (L), Handling (H), and Crouching (CR): After the home cage retrieval tests, onset of CR was 3-4 times longer for LIDO than SAL dams. LIDO dams also were greatly impaired in CR onset following a 6 hr mother-litter separation, even when retrieval was not required because pups were placed in the nest. The impairment was associated with markedly decreased L & H and was greater at 2 days than at 2 weeks PP, because older pups initiate nursing away from the nest. At 60 min post-reunion, pup weight gain was markedly reduced in the LIDO condition.

Materral Aggression (MA): Whereas all SAL dams attacked the strange male intruder (35-55 days old) at least once, MA was almost completely eliminated in LIDO dams. This effect was not altered by prior MA experience. Less MA was seen in the retrieval apparatus, but the group difference remained.

Comments & Conclusions: (1) In all these tests, initial sniffing (of pups, of male intruder) was not impaired, and duration often increased as dams failed to proceed in the usual sequence of behaviors. (2) Self-grooming was often increased, indicating that mouth opening and tongue protrusion are not impaired. (3) Whether or not retrieval occurs during acute perioral anesthesia is highly dependent upon an interaction of experiential and testing conditions, whereas MA seems to be disrupted more completely. (4) CR onset appears to require the dam's proximity to pups long enough for their initiation of suckling to take place.

115.1 PHENTOLAMINE SUPPRESSION OF IN VITRO POTASSIUM INDUCED LHRH RELEASE FROM THE BOVINE INFUNDIBULUM. G.A. Dissen*, P.G. Harms*, D.D. Zalesky* and N.H. McArthur. Departments of Animal Science and Veterinary Anatomy, Texas A&M University, College Station, TX 77843.

The influence of phentolamine on infundibular LHRH release in response to a 60 mM Potassium (K) challenge in eight 2-year-old steers was examined. The steers were exsanguinated and decapitated under deep xylazine anesthesia. The infundibulum was split into right and left halves and then dissected from the hypothalamus at the tuberoinfundibular sulcus. The tissues were weighed and placed in 0.5 ml perifusion chambers. The tissue was perifused with Krebs-Ringer Bicarbonate media saturated with 95% O_2 and 5% CO_2 (with 5.5 mM glucose and 0.06 g/l bacitracin) at 100 µl/min. The perifusate was fractionated at 10 min intervals for 360 min. Each fraction was assayed for LHRH and expressed as pg/ml·mg of tissue weight. The left or right infundibular halves were randomly assigned to either media with phentolamine (0.5 mM) from 0 to 180 min or to control perifusion media (no phentolamine). Tissues were perifused for 120 min to establish basal LHRH levels. Tissues were exposed to 60 mM K in the perifusion media (60 mM KCl in equimolar substitution for NaCl) for 30 min at 120 min and 240 min. Area under the curve (AUC) was calculated using the trapezoidal rule. Response to 60 mM K perifusion media was calculated as the AUC above baseline. All comparisons were paired and tested with the Student's paired t test. All comparisons presented were different ($P<.05$). Response to the K challenge was less in the phentolamine treated halves, 9.4 ± 2.2 compared to control 59.0 ± 9.3 (AUC arbitrary units ± SE). There was a partial return of responsiveness by 240 min, 21.9 ± 5.5 for phentolamine treated and 44.3 ± 8.0 for control. While the responsiveness of phentolamine treated halves was less than controls at the second challenge (240 min), the phentolamine treated second K challenge was greater than the first (120 min) phentolamine treated K challenge (21.9 ± 5.5, and 9.4 ± 2.2, respectively). However, in control tissues the response to the first K challenge was greater than the second K challenge (59.0 ± 9.3 and 44.3 ± 8.0, respectively). In addition to changes in responsiveness, the baseline in phentolamine treated tissues was greater (21.4 ± 7.3 vs 6.8 ± 1.9) than control tissues, thus contributing to the decreased responsiveness. Phentolamine increased the basal in vitro release of LHRH while it reduced the response of infundibular tissues to K.

115.2 MEASUREMENT OF BASAL AND STIMULATED MONOAMINE RELEASE IN FEMALE RAT HYPOTHALAMUS USING IN VIVO DIALYSIS AND HIGH PERFORMANCE LIQUID CHROMATOGRAPHY. I. Vathy* and A.M. Etgen. Depts. of Psychiatry and Neuroscience, Albert Einstein College of Med., Bronx, NY 10461.

The development of intracranial microdialysis methods has provided a valuable tool to study the release of endogenous neurotransmitters in living animals. In vivo microdialysis combined with high performance liquid chromatography (HPLC) and electrochemical detection (ECD) were used in the present experiments to measure extracellular monoamine concentrations in the ventromedial hypothalamus (VMH) of female rats. Urethane-anesthetized animals were implanted stereotaxically with a loop-type dialysis probe (Ungerstedt et al., 1982, Neurosci. Lett., Suppl. 10. 493). The probe was perfused at a flow rate of 2ul/min. with an artifical cerebrospinal fluid (CSF) composed of 147.2 mM NaCl, 2.0 mM $CaCl_2$, 2.76 mM KCl, 0.62 mM K_2HPO_4 with 0.113 mM ascorbic acid (to prevent oxidation of monoamines). In vitro calibration of the dialysis probe demonstrated a 5-10% recovery of monoamines. The collected dialysate (25 min. samples) was injected directly into a HPLC outfitted with ECD to evaluate the concentration of extracellular monoamines.

Under basal conditions detectable levels of norepinephrine (NE) 3,4-dihydroxyphenyl acetic acid (DOPAC) and 5-hydroxyindole acetic acid (5-HIAA) were found. Extracellular levels of all three monoamines remained stable for several hours. To monitor depolarization-induced monoamine release, the dialysis probe was switched for 5 min. to an artificial CSF containing elevated potassium levels. The potassium stimulus increased extracellular NE levels, decreased 5-HIAA and had no effect on levels of DOPAC. Since the VMH is a major site for ovarian steroid regulation of female reproductive physiology, in vivo dialysis combined with HPLC-ECD provides a direct method to evaluate the role of monoamine neurotransmitter systems in the hormonal regulation of neuroendocrine function.

115.3 **PRAZOSIN BLOCKS α_1 ADRENERGIC STIMULATION OF LHRH RELEASE FROM SUPERFUSED RAT HYPOTHALAMUS.** J.F. Gitzen, and V.D. Ramirez, Neural and Behavioral Biology Program and Dept. of Physiology and Biophysics, University of Illinois, Urbana, IL. 61801.

The in vitro pulsatile administration of the α_1 adrenergic agonist Methoxamine (MTX) stimulates the release of LHRH from superfused female rat medial basal hypothalami (MBH) (Endo. Soc. Abstracts, 1985, #945).

The present experiments examined the specificity of this presumed α_1 effect. The specific α_1 antagonist Prazosin was used. Five treatment groups were run: 1) Pulsatile MTX. 2) Pulsatile MTX + continuous Prazosin. 3) Continuous Prazosin only. 4) Continuous MTX only. 5) Untreated controls. Doses were 10^{-5}M MTX and 10^{-4}M Prazosin. OVX unprimed rat MBH were used.

MBH were first superfused with Krebs-Ringer Phosphate medium for one hour to establish baseline LHRH release. In groups 1&2, MTX was infused 3 times, 20 min each, one hour apart. In groups 2&3, the medium contained Prazosin during the baseline and all subsequent periods to blockade α_1 receptors. Effluents were collected at 10 min intervals and assayed for LHRH by RIA.

As previously shown, 10^{-5}M MTX (N=8) significantly stimulated LHRH release in each of the hours following the three MTX treatments, increasing from 11.6±4.1 pg/baseline hour to 17.6±2.6, 18.9±3.2, and 21.1±3.2 pg/hour during the three MTX treatment hours, respectively. In contrast, 10^{-4}M Prazosin (N=7) completely blocked the stimulatory effect of MTX: LHRH release fell from 11.7±3.2 pg/baseline hour to 10.5±3.0, 4.4±1.9, and 2.6±0.8 pg/treatment hour. Hypothalami treated only with Prazosin (N=7) showed a similar pattern, dropping from 13.1±2.3 pg/baseline hour to 11.3±2.8, 7.5±1.9, and 4.8±1.1 pg/treatment hour. Untreated controls were similar. Interestingly, constant MTX (N=8) did not stimulate LHRH release, with LHRH release of 9.33±2.8 pg during the baseline hour and 11.6±3.6, 9.6±3.9, and 7.1±2.7 during subsequent hours.

Prazosin's ability to completely block Methoxamine's stimulation of LHRH release demonstrates the α_1 specificity of this MTX effect. Also, in contrast to pulsatile MTX treatment, but like exogenous constantly applied norepinephrine's effects on rat LH levels (Gallo, 1982) and progesterone's effect on in vitro and in vivo LHRH release (Kim & Ramirez, 1982; 1984), administration of continuous MTX does not stimulate LHRH release. This implies that the adrenergic mechanisms involved in the release of LHRH in vitro are analogous to those in vivo.

115.4 INTERMITTENT INFUSION OF PREGNANOLONE INTO THE HYPOTHALAMUS OF CONSCIOUS UNRESTRAINED FEMALE RABBITS STIMULATES IN VIVO LHRH RELEASE. W.W. Lin* and V.D. Ramirez,(SPON: C.L. Prosser) Department of Physiology and Biophysics, University of Illinois, Urbana, IL 61801.

Previously, we reported that intermittent infusion of progesterone (P_4) into the hypothalamus of conscious unrestrained female rabbits stimulates in vivo LHRH release. New Zealand female rabbits were implanted with push-pull cannulae (PPC) aimed at the tuberal region of the hypothalamus and perfused with modified KRP at 10-14 µl/min. In six animals perfused with KRP, pH 7.4, for 200 min followed by six pulses of P_4 (10-min on, 30-min off, 10 ng/ml) delivered through the PPC during a 240 min period, the mean basal level of LHRH increased from 1.12±0.16 pg/10 min during the control period to 1.97±0.24 pg/10 min during the period of P_4 infusion. In order to determine whether progesterone is acting through a metabolite, pulses of pregnanolone were applied, at various doses, directly into the hypothalamus of female rabbits. Two of these animals were also perfused with 20- α-OH-progesterone and/or cholesterol.

Five female rabbits were used in nine perfusion experiments. In these experiments, animals were initially perfused with modified KRP for a control period of 100-150 min followed by six pulses of pregnanolone (n=4 at .001 ng/ml, n=1 at .01 ng/ml, n=1 at .1 ng/ml), cholesterol (n=2 at 10 ng/ml), or 20-α-progesterone (n=1 at .001 ng/ml) 10-min on, 30-min off. In two rabbits treated with pregnanolone at .1 ng/ml and .01 ng/ml, there was a decrease in mean LHRH levels during pregnanolone infusion. The rabbit treated with .01 ng/ml was also perfused with pregnanolone (.001ng/ml), 20- α-OH-progesterone (.001 ng/ml), and cholesterol (10 ng/ml) in three subsequent experiments. Only the experiment with .001 ng/ml pregnanolone showed an increase in mean LHRH release. A third rabbit was treated with pulses of cholesterol (10ng/ml) and pregnanolone (.001ng/ml) in two different experiments. Only the treatment with pregnanolone showed a marked increase in mean LHRH release levels. Two more animals, also treated with pregnanolone (.001ng/ml) responded with an increase in LHRH levels.

In the four animals treated with pregnanolone (.001ng/ml), there was a significant increase in mean LHRH release (.92±.31 to 1.80±.99 pg/10min $p<.035$) and amplitude of LHRH pulses (.86±.52 to 2.32±1.30 pg, $p<.035$) using the Wilcoxon's Match Paired test. Overall, these results clearly demonstrate that pregnanolone, at very low doses, stimulates the LHRH pulse generator, suggesting that this 3 ß-5 ß metabolite of progesterone may play a role in the control of LHRH release in rabbits.

115.5 THE ROLE OF PROTEIN KINASE C IN PROGESTERONE-INDUCED LHRH RELEASE IN VITRO. F.C. Ke and V.D. Ramirez. Department of Physiology and Biophysics, University of Illinois, Urbana, IL 61801.

It has been reported that phorbol ester as well as other protein kinase C activators enhance in vitro LHRH release from incubated median eminence tissue derived from the hypothalamus of male or female rats.

This study was designed to clarify the role of protein kinase C in the LHRH releasing action of pulsatile progesterone (P_4) from hypothalamic fragments superfused in vitro. To this effect, preoptic-mediobasal hypothalamic units from ovariectomized (OVX) as well as ovariectomized estrogen primed (OVX + E_2) 30-day-old rats were used to test the effect of phorbol ester on in vitro LHRH release.

4 α-Phorbol- 12,13, dibutyrate (PDBU) markedly stimulated LHRH release from either OVX or OVX + E_2 rat hypothalami. The mean LHRH release from the hypothalamic units during the two hours period after the initiation of PDBU treatment (10^{-6}M) increased 5.4 and 4.0 folds over basal level (N=5) in OVX and OVX + E_2 groups, respectively. This result contrast with the P_4-stimulatory effect on in vitro LHRH release which is estrogen-dependent. To identify more precisely the role of protein kinase C in the P_4-stimulatory effect on LHRH release, a protein kinase C inhibitor was used. Sphingosine (a physiological inhibitor of proten kinase C) at 10^{-5} M but not at 10^{-6} blocked the 10^{-6} M PDBU-stimulating effect on in vitro LHRH release. P_4-(10 mins on, 20 mins off, 10 ng/ml pulses, N=5) stimulatory effect on in vitro LHRH release was also inhibited by sphingosine at 10^{-6} M.

These results demonstrated that protein kinase C is involved in the in vitro P_4-stimulatory effect on LHRH release from superfused hypothalamic units. Future work will test the hypothesis of the involvement of protein kinase C in the postulated P_4 activating sequence of the LHRH neural apparatus (P_4-NE-LHRH) that ultimately lead to LHRH release in vitro.

115.6 ELECTROPHYSIOLOGICAL ACTIONS OF HISTAMINE ON ARCUATE NUCLEUS NEURONS IN VITRO. K.L. Jorgenson, L.-M. Kow and D.W. Pfaff. The Rockefeller University, New York, NY 10021.

Histamine (HA) has been localized in cell bodies, fibers and terminals of the medial basal hypothalamus (MBH), an area of importance in the neuroendocrine regulation of the pituitary gland. Receptors for HA are also found in the MBH. Furthermore, HA alters luteinizing hormone and prolactin secretion in female rats. Thus, in the present study we investigated the electrophysiological effect of HA at the level of extracellular single-unit activity of the arcuate nucleus in an in vitro slice preparation of the MBH.

Coronal slices (400 uM thick) of hypothalamus containing the arcuate nucleus were prepared from female rats and kept in artificial cerebrospinal fluid (ACSF) gassed with 95% O_2 and 5% CO_2. Extracellular single-unit activity was recorded with a ACSF-filled micropipette from slices submerged in a perfusion chamber containing ACSF continuously flowing at 2ml/minute and warmed to 36°C. Histamine, and other agents, were injected directly into the chamber. Changes in activity were assessed from continuous polygraph records of a firing rate histogram.

From a total of 96 arcuate neurons, HA caused a dramatic increase in firing rate in 66 neurons. No effect was seen in the remaining cells. The excitatory response was typically a sharp increase of 3-fold or more from basal firing rate within a minute followed by a gradual return to baseline. The response was repeatable in a single neuron. Histamine was routinely administered in 50ul of a 0.5 mM solution which was effectively diluted to 12.5 uM in the chamber. Dose-response testing revealed a linear decline in maximal firing rate with decreasing concentrations of HA and a loss of excitation around 1.0 uM HA. Neurons excited by HA varied in their basal firing patterns and responsiveness to other transmitters. Use of ACSF with high [Mg++] and low [Ca++] verified that HA was acting directly on recorded neurons rather than through synaptic inputs.

Tests with HA receptor antagonists showed that the excitation was mediated through H_1 receptors. The H_1 blockers pyrilamine and chlorpheniramine inhibited excitation in all 34 units tested. Recovery from inhibition could be seen after an hour or more, and the antagonists did not interfere with excitatory responses to other transmitters such as serotonin, norepinephrine and acetylcholine. Cimetidine, an H_2 blocker, had no effect.

These results confirm the reports of abundant H_1 receptors in the MBH and suggest that the H_1-mediated effects of HA on luteinizing hormone secretion (Miyake et al., Neuroendocrinology 45:191, 1987) could take place at the arcuate nucleus.

115.7 ESTROUS CYCLE-CORRELATED ALTERATIONS IN SINGLE UNIT ACTIVITY RECORDED FROM MULTIPLE EXTRA HYPOTHALAMIC NEURONS DURING LOCOMOTION. Sheryl S. Smith and John K. Chapin, Dept. of Physiology, Hahnemann Univ., Philadelphia, PA 19102-1192.

Ongoing studies have shown that, in the urethane-anesthetized, ovariectomized rat, both systemic and local administration of estrogen augment, while progesterone attenuates, excitatory responses of cerebellar Purkinje cells to iontophoretically applied glutamate. Using a behavioral paradigm, we have also shown that estrogen (s.c.) increases cerebellar discharge during treadmill locomotion to a greater extent than it alters activity during stationary periods. In contrast, progesterone decreases discharge during locomotion. Both sets of results are compatible with the hypothesis that estrogen enhances and progesterone diminishes evoked neuronal excitation, whether elicited pharmacologically or behaviorally.

In the present study, a more physiological approach was undertaken in order to determine changes in locomotor-correlated discharge relative to spontaneous across the days of the estrous cycle. Towards this end, adult female rats were implanted with 7 stainless steel microwires (.001" dia) lowered 1-4 mm into the cerebellum 1.5 mm lateral from midline. Inserted into Canon pins and a connector, which was cemented onto the skull, the wires transmitted neuronal activity from 5-7 individual units at one time. An additional wire from the connector grounded the plug to 5 skull screws. Neuronal discharge could then be monitored from the same neurons over a period of weeks. Implanted animals were trained to locomote on a computer-controlled treadmill device (alternately on 5s, off 5s) for a period of 1-3 hs daily. Preliminary data suggest that evoked discharge correlated with treadmill locomotion is increased on proestrus, when estrogen levels are elevated, relative to diestrus 1. This phenomenon also exhibited light-dark cycle variations, as peak levels of evoked discharge were seen on the night of behavioral estrus. Furthermore, these changes in discharge rate during treadmill locomotion were of significantly larger magnitude than corresponding cyclic alterations in discharge during stationary periods. These results are consistent with earlier reports suggesting that sex steroids may possess modulatory properties in the extrahypothalamic CNS. 115.8 GENOTYPE AND REPRODUCTIVE FUNCTIONS OF INBRED FEMALE MICE: EFFECT OF H-2 ALLELES. S.P. Lerner*, C.P. Anderson* and C.E. Finch (SPON: L. Weiner). Dept. of Neurobiology/Gerontology, University of Southern California, Los Angeles, CA 90089-0191.

The main histocompatibility complex (MHC; H-2 system in mice) is considered to be the "master genetic control" or regulatory system for immune function. It is possible to study links between alter- ations in physiologic functioning and specific genetic variants at the H-2 locus by utilizing highly-inbred strains of mice, bred to be genetically-identical except for the chromosomal region which carries the H-2 system. Thus far, H-2 variants are associated with differences in lifespan (Smith and Walford, Nature 270:727, 1977), fertility and other physiologic characteristics. The effect of the H-2 system on reproductive cycles, and the interaction of polymorphisms at this locus with other physiologic affecters of the reproductive system have yet to be examined. The purpose of this study was to determine the effect of H-2 variants female reproductive cycles and fecundity.

Beginning by 4.5 mo of age, estrous cycles of virgin mice of three congenic strains (C57BL/B10Sn, "B10"; B10.Br/Sg, "B10.Br"; and B10.RIII) were monitored for 3 mo. For each mouse, estrous cycles were categorized by length: 4, 5, 6, or 7-14 d. The effect of strain on estrous cycles was determined using a multivariate analysis of variance. For comparison we included C57BL/6J (B6) mice, whose cycling characteristics have been well documented (Nelson et al., Biol. Reprod. 27:327, 1982). Additionally, the number of litters produced, birthdate of last litter, and number of pups/litter were recorded for 18 age-matched pairs of mice (3-8 wks of age) of three strains (B10, B10.Br, and B10.RIII).

Estrous cyclicity differed with strain ($P<.0001$). B6 and B10.Br mice had predominantly 4-d cycles, whereas B10.RIII and B10 mice had more 5-d cycles than the other strains. F_1 hybrids from the reciprocal B10XB10.Br cross displayed a clear dominance of 5-d cycles, which indicates an autosomal allele on chromosome 17 in or near the H-2 complex. Moreover, F_1 hybrids from the reciprocal B6XB10 cross also display a dominance of 5-day cycles, which indicates a non-H-2 autosomal allele. The number of litters/pair, maternal age at last litter and total number of pups/pair differed with strain. In each case, B10.Br and B10.RIII had similar values and both had greater values than B10 mice. In conclusion, the present data that H-2 alleles influence female reproductive cycles and function. These data also raise the possibility that stable differences in menstrual cycle length of humans (Treloar et al., J. Fertil. 12:77, 1967) may also have a genotypic basis. (Supported by grant AG-004419)

115.9 A FAST, RELIABLE METHOD FOR REPEATED BLOOD SAMPLING FOR HORMONAL ASSAY IN RATS. L. O'Farrell, F. C. Martin, D. Novin and J.C. Liebeskind. Brain Research Institute and Dept. of Psychology, UCLA, Los Angeles, CA 90024-1563

Chronic blood sampling is useful for hormonal and pharmacokinetic studies. Blood cannot be sampled past 2 weeks using most cannulation methods, however, and chronic stress as (reflected by changes in plasma hormones) often occurs. We therefore modified the jugular cannulation technique of F. J. Smith and L. A. Campfield (Am J Phys. 251, R70, 1986) to improve blood sampling reliability, decrease time required for surgery and reduce stress. Cannulae were made from 3 pieces of tubing: 2.3 cm of PE-100 tubing pulled over a flame at one end to an O.D. of .65 mm; 9.5 cm of .3 mm I.D. by .64 mm O.D. Dow Corning Silastic cut on a bevel at one end; and 1.5 cm of .76 mm I.D. by 1.65 mm O.D. Silastic. Four mm of the small end of the PE tubing was inserted into the lumen of the non-beveled end of the smaller diameter Silastic. After securing this junction with a piece of suture, the larger diameter Silastic was slid over the smaller and pushed over the junction. Under aseptic conditions, the beveled end of the smaller diameter Silastic was inserted 32 mm into a small incision in the right jugular vein made 5 mm from where the vein enters the chest muscle. The cannula was tied to the surrounding tissue with a suture secured to the cannula with Silastic Elastomer. The other end of the cannula was threaded s.c. to an incision between the scapulae. The cannula was tied to the underlying muscle using a suture secured to the larger diameter Silastic, and the skin was closed with a purse string suture. Cannulae were flushed daily with 50 U/ml heparinized saline mixed with 25 mg/ml cephalosporin. Twenty-one of 24 cannulae implanted in this way remained patent for 1.5 months. Four features of this method were shown to be critical to long-term sampling: the placement of the cannula tip at the junction of the superior vena cava and the atrium (which the method described insures for rats 250-400 g); the small size of the tubing in the vein; the aseptic surgical conditions; and the use of antibiotics. Lights-off plasma corticosterone and prolactin levels were 174 ng/ml and 23 ng/ml 1.5 weeks postoperatively, indicating this technique is minimally stressful and suitable for measurement of stress-related hormones. (Supported by the David Murdock Foundation for Advanced Brain Studies and NIH grant NS07628).

115.10 NEUROCHEMICAL MECHANISMS OF REPRODUCTION IN THE JAPANESE QUAIL : I. THE PREOPTIC AREA. J. Balthazart (1)*, G.F. Ball (2), M. Gahr (3)* and B.S. McEwen (2) (SPON : ENA). University of Liège, Belgium (1), The Rockefeller University, New York, NY 10021 (2) and University of Kaiserslautern, F.R.G. (3).

The activational effects of testosterone (T) on copulation are sexually differentiated in quail : T activates copulation in males but not in females. We previously identified several neurochemical correlates of this behavioral dimorphism. The inducibility of the preoptic aromatase by T is significantly higher in males than in females (Brain Res. 1986, 370, p285) and the concentration of norepinephrine in the preoptic area (POA) is higher in females than in males (Poultry Sci. 1986, 65, p1413).

To determine more precisely the neuroanatomical localizations of these sexually differentiated aspects of brain biochemistry, we have used immunocytochemistry and quantitative autoradiography to map estrogen receptors on one hand and adrenergic and muscarinic receptors on the other hand. Immunocytochemical maping using the antibody H222SPgamma raised against E2 receptors from mammary tumors demonstrated the presence of E2 receptors in the POA and especially in the medial preoptic nucleus (POM). Presence of E2 receptors in POM is especially significant as this nucleus is sexually differentiated (Volume larger in males than females; Neurosci. Ltrs. 1986, 64, p129), its volume and coloration by Nissl stains are testosterone-sensitive (decrease by castration and increase following T treatment; Brain Res. 1987 in press) and in addition, POM contains most of the preoptic aromatase as demonstrated by the Palkovits punch technique combined with in vitro radioenzymoassays (Brain Res. 1987, in press).

Quantitative autoradiography demonstrated the presence of specific and saturable binding for alpha-2-adrenergic and for muscarinic ligands (respectively tritiated para-amino-clonidine, PAC and n-methyl-scopolamine, NMS). PAC binding was very high in all POA, the highest concentrations of receptors being measured in the POM. Interestingly, PAC binding permitted to outline the area of the POM. This adrenergic receptor type is thus a specific marker for the sexually differentiated nucleus. By contrast, NMS binding was extremely low throughout the POA demonstrating the nearly total absence of muscarinic transmission in this area.

The coexistence in the sexually differentiated POM of E2 and alpha-2-adrenergic receptors suggests that this nucleus is the site of neurochemical interactions which are probably playing a key role in the control of copulation.

115.11 NEUROENDOCRINE MECHANISMS OF REPRODUCTION IN THE JAPANESE QUAIL II: HYPOTHALAMIC AND EXTRA-HYPOTHALAMIC AREAS. M. Gahr*, G.F. Ball, J. Balthazart*, and B.S. McEwen. (SPON: P. Marler) University of Kaiserslautern, Kaiserlautern, FRG. The Rockefeller Univ., N.Y, N.Y. 10021, and University of Liege, Liege, Belgium.

The neuroendocrine control of reproduction involves the interaction of steroids and a variety of neurochemical substances in discrete regions of the brain. In the Japanese Quail, the sexually dimorphic pre-optic medial nucleus (POM) has been the focus of recent investigations of the central action of steroids underlying reproductive behavior. In order to better specify other potentially significant sites of steroid-neurotransmitter interactions involved in the control of reproductive processes we have mapped using immunohistochemistry, the distribution of 17β-estradiol (E_2) receptors and using quantitative autoradiography the distribution of $alpha_1$, and $alpha_2$ adrenergic receptors, and muscarinic cholinergic receptors.

Subjects were male and female Japanese Quail. For autoradiography, frozen brain sections were taken on a cryostat and freeze-dried. $Alpha_1$ adrenergic receptors were labeled with (^3H) prazosin (PRA), $alpha_2$ adrenergic receptors were labeled with (^3H) p-aminoclonidine, and muscarinic cholinergic receptors were labeled with (^3H) N-methyl scopolamine. Autoradiograms were analyzed with an image analysis system that converted optical densities to fmoles/mg protein using a standard curve derived from co-exposed plastic standards. E_2 receptors were visualized using the PAP immunohistochemistry technique. A monoclonal antibody (H-222SPγ) raised against E_2 receptors was employed.

E_2 receptors were seen in the lateral septum (LS), the n. intercollicularis (ICo), and in sub-regions of both the hypothalamus and the archistriatum. Heavy PAC binding was often apparent in regions that contained E_2 receptors. This was particularly striking in certain areas that may play a role in reproduction such as the LS, and the tubero-infundibulum area of the hypothalamus and an area important in vocal behavior, ICo. The distribution of PRA binding was quite different from PAC binding in that the heaviest regions were the dorsolateral cortex (CDL), and portions of the thalamus. NMS binding was highest in the Lobus parolfactorius and area archistriatalis. Other areas showing specific NMS binding include steroid sensitive areas such as the ventro-medial nucleus of the hypothalamus (VMN) and the ICo as well as several non-steroid sensitive areas. The co-occurrence of apparent alpha-adrenergic binding, muscarinic cholinergic binding, and E_2 receptors in a variety of discrete areas implicated in reproduction suggests that steroid interactions with these neurotransmitters may play an important role in the regulation of reproductive processes, including behavior.

115.12 INCREASE OF CIRCULATING LEVELS OF GLUCOSE AFTER THE ELECTROLYTIC LESION OF THE ARCUATE HYPOTHALAMIC NUCLEUS. I. Zarco de Coronado, M.C. Yepez Chamorro. Dpto de Fisiología. Fac. de Medicina. Universidad Nacional Autónoma de México.

It is well known that the arcuate nucleus of the hypothalamus (ARH) shows specific chemical characteristics, and previous results obtained in our laboratory suggest a role for this nucleus in the regulation of the blood glucose. To further define this participation we examined the effects of electrolytic lesions of the ARH on the circulating levels of glucose.

Anesthetized male Wistar rats (250gr. body weight) 16 hrs. food deprived were stereotaxically implanted, bilaterally, in ARH with a bipolar concentric electrode. A 2 miliAmp. direct current was applied during 30 sec. in experimental animals. In control rats, no current was applied. Serum glucose was determined before and after lesioning or placing of the electrode.

Subsequent histological analysis revealed that the lesions were confined almost exclusively in the ARH nuclei. Circulating glucose was increases about 130 % after the lesions.

The results obtained suggest that the ARH nucleus participates in the regulation of the glucose. This effect could be mediated by central or peripheral neural connections or by endocrine mechanisms.

115.13 FURTHER EVIDENCE FOR EXCITATORY AMINO ACID NEUROTRANSMISSION IN THE SUPRAOPTIC NUCLEUS OF THE RAT HYPOTHALAMUS. V. K. Gribkoff and F. E. Dudek. Dept. of Physiology, Tulane Univ. Sch. of Med., 1430 Tulane Avenue, New Orleans, LA 7011.

The development of specific antagonists for the excitatory amino acids has produced a wealth of evidence demonstrating the widespread mediation of synaptic events in the CNS by this class of substances. In the magnocellular neuroendocrine system of the hypothalamus, which includes the oxytocinergic and vasopressinergic neurons of the supraoptic nucleus (SON), the degree of involvement of these compounds in synaptic excitation may be extensive, based on previous studies in our laboratory. In the present experiments, we have further characterized the actions of an excitatory amino acid antagonist, kynurenic acid (KYN), on synaptic transmission in the SON of rat hypothalamic slices.

Stimulation of a region dorsolateral to the SON produces excitation, postsynaptic potentials (p.s.p.'s), and increases in the frequency of "spontaneous" p.s.p.'s. Bath application of KYN produced a rapid, concentration-dependent, and reversible antagonism of both evoked and spontaneous p.s.p.'s in every cell in which it was tested. Direct comparisons were made between the effect of KYN in this system and at the Schaffer-collateral synapse in the hippocampus, which is thought to use an excitatory amino acid as a transmitter. In both systems, the time course of effect was similar, with onset at 3-5 min and maximal effect at 10-20 min. The degree of suppression at millimolar concentrations was also similar. In the SON, concentrations of KYN as low as 200 µM produced partial antagonism, while 1-3 mM produced dramatic suppression.

The cells were often hyperpolarized to near -80 mV during the experiments to prevent spike discharge. This membrane potential is below the reversal potential for GABA. Therefore bicuculline methiodide, a specific GABA antagonist, was applied to some cells to determine if these p.s.p.'s contain a GABA-ergic component. Bicuculline (30-100 µM) was minimally effective, antagonizing a portion of the p.s.p. in some cells. Likewise, d-tubocurarine chloride, a nicotinic cholinergic antagonist, had very little effect on these potentials at concentrations between 30 µM and 1 mM. KYN antagonized the bicuculline- and curare-resistant p.s.p.'s.

These results are consistent with the hypothesis that an excitatory amino acid mediates most fast excitatory synaptic events in SON neurons via the pathways and local circuits activated by local stimulation near the SON.

115.14 ^{3}H-QUINUCLIDINYL BENZILATE BINDING IN THE BRAIN AND CAUDAL NEUROSECRETORY COMPLEX OF THE RAINBOW TROUT. D. Onstott and V. S. Seybold. Dept. of Cell Biology and Neuroanatomy, Univ. of Minnesota, Minneapolis, MN 55455.

The caudal neurosecretory complex (CNC) of fishes provides a valuable, simple model for the study of vertebrate neurosecretion. As part of a series of investigations designed ultimately to determine the relationship between neurotransmitter binding and neurosecretory activity, we have undertaken experiments to examine the relationship between putative neurotransmitter binding sites and urotensin II (UII)-producing neurosecretory neurons in the CNC of the rainbow trout. Histochemical, electron microscopic, and in vitro urotensin release studies have suggested that acetylcholine plays a role in regulation of CNC activity and that its effect is mediated through muscarinic receptors. Therefore, the binding characteristics of tritiated quinuclidinyl benzilate (^{3}H-QNB), a muscarinic cholinergic antagonist, were determined in trout brain, and then utilized in combined autoradiographic-immunohistochemical experiments in the caudal spinal cord.

Optimum binding conditions for ^{3}H-QNB were determined using slide-mounted, 20 µm cryostat sections cut from unfixed, chopped trout whole brains, removed from animals immediately following stunning and decapitation. Sections were exposed to various rinse and incubation times and ligand concentrations. Nonspecific binding was determined by incubation of adjacent sections in ^{3}H-QNB plus 1 µM unlabeled atropine sulfate. Following incubation and wash, sections were wiped from slides into vials for assessment of binding by liquid scintillation counting. Scatchard analysis using nonlinear regression (McPherson version of LIGAND, Computer Prog. Biomed. 17:107,1983) indicated a K_d of 0.4 nM and a B_{max} of 4.4 nmol/g protein (r=0.97). Under optimum conditions, specific binding of 95% was obtained.

For autoradiography, the caudal spinal cord and urophysis were removed, embedded in gum tragacanth, and frozen. Ten µm cryostat sections were incubated according to conditions determined in the biochemical studies, dried and opposed to emulsion-coated coverslips according to the method of Young and Kuhar (Eur. J. Pharmacol. 59:317,1979). Urotensin II immunoreactivity was detected in adjacent sections using the peroxidase-antiperoxidase technique. Analysis of autoradiograms indicates the presence of specific ^{3}H-QNB binding sites in spinal cord areas dorsal to those containing UII-immunoreactive neurons. Image processing methods are currently being used to quantify binding sites and to determine their relationship to UII-immunoreactive structures.

115.15 ULTRASTRUCTURE OF SEROTONIN AFFERENTS TO THE CAUDAL NEUROSECRETORY COMPLEX S.L. Cohen and R.M. Kriebel Dept. of Anatomy and Neurobiology, Univ. of Vermont Medical College, Burlington, VT 05405

The caudal neurosecretory complex (CNc) of fishes synthesizes and releases urotensins I and II. Biogenic amines have been associated with the regulation of the metabolism of these neuroendocrine cells. Serotonin (5HT) is one biogenic amine which has been identified in the CNc. A descending reticular projection and neurons intrinsic to the CNc are sources of serotonin inputs to this nucleus. This study examines the organization of these 5HT inputs at the ultrastructural level. Fish were anesthetized with MS-222, and perfused with 4% paraformaldehyde/0.1% glutaraldehyde in 0.06M phosphate buffer, pH 7.2. The unlabelled antibody method of peroxidase anti-peroxidase immunostaining was performed using anti-serotonin antisera (Immunonuclear). Serotonin processes in the CNc are of two types. Fibers with small (0.5-0.8um) varicosities travel in the central and dorsolateral aspects of the rostral CNc. This area contains the larger neuroendocrine cells and their processes, upon which many synaptic contacts are made from descending inputs. The density of these 5HT fibers is considerably reduced in the caudal portion of the CNc nucleus, which is characterized by tight clusters of smaller neuroendocrine cells that receive fewer synaptic contacts. Ultrastructural examination of these fibers reveals 1) varicosities filled with labelled vesicles (40-70nm). These varicosities were not found to make contact with neuroendocrine structures, and may be paracrine in nature. 2) 5HT terminals making contact onto clear vesicle filled terminals which in turn form synapses on neuroendocrine processes. Presynaptic modulation of this currently undetermined input is indicated for these 5HT afferents. 3) 5HT terminals on small (5-8um) cells that contain 70nm dense-core vesicles. These putative catecholamine cells are likely to be modulated by 5HT afferents.

The second type of fibers arise from intrinsic 5HT neurons. The cells and their initial segments are ensheathed by glial processes. Perikarya, axons, varicosities and terminals all contain 120-150nm vesicles. The axons course towards the ventrolateral edges of the spinal cord, and branch into fibers with many large (2-3um) varicosities. Some fibers terminate on the edges of the spinal cord in club-like extensions which increase in number and density as one proceeds caudally. These structures often lose their glial ensheathment to contact the basal lamina underlying the submeningeal space. Other fibers continue into the urophysis, which is the neurohemal contact site for the CNc. Varicosities in the urophysis are often situated near fenestrated capillaries. Secretion of 5HT into the CSF and blood is therefore possible. Intrinsic 5HT neurons may also modulate CNc function by paracrine secretion. PHS:RO119880

115.16 NOREPINEPHRINE AND SEROTONIN IN THE CAUDAL NEUROSECRETORY COMPLEX: A NEUROCHEMICAL AND IMMUNOHISTOCHEMICAL STUDY. T.W. McKeon, S.L. Cohen, E.E. Black, R.M. Kriebel and R.L. Parsons. Department of Anatomy and Neurobiology, University of Vermont, Burlington, Vermont 05405.

Intrinsic and supraspinal monoaminergic inputs have been identified previously in our studies on the poecilid caudal neurosecretory complex (CNc). The serotonin content and distribution in the CNc have been shown immunohistochemically (Cohen, S.L., Soc. Neurosci. Abst. 12:1487, 1986). The present study was done to determine biochemically the specific catecholamine(s) in the CNc and to show the relative contribution of indolamine and catecholamine to the CNc innervation.

Deafferentation of supraspinal monoaminergic projections was done by transecting the spinal cord at the level of the 5-6th preterminal vertebrae. Fish were killed 10 days after surgery; spinal cords were removed and processed along with control spinal cords for either HPLC or immunohistochemistry. HPLC analysis of monoamines was done on pooled samples (3-12) of the spinal cord from the terminal four vertebral segments. Dopamine and epinephrine generally were below the sensitivity limits of the HPLC methods. In one instance, a low level of dopamine, probably representing a precursor pool for norepinephrine (NE), was observed when 18 spinal cords were pooled. In control CNc, NE (35.4 $\pm$ 9.8 pg/µg protein) and serotonin (5-HT) (36.6 $\pm$ 6.9 pg/µg) protein) were detected. Following deafferentation, the content of the NE and 5-HT were significantly decreased. NE levels were generally below detectable limits. Serotonin was present in deafferented CNc (14.5 $\pm$ 7.5 pg/µg protein), with levels approximating 50% of control fish. For immunohistochemistry, terminal segments of the spinal cord were fixed with 4% paraformaldehyde. Thirty µm frozen sections were cut horizontally and stained using indirect immunofluorescent techniques with antisera for either serotonin (5-HT), tyrosine hydroxylase (TH), or dopamine β-hydroxylase (DBH). Patterns of innervation in the control spinal cords were consistent with previous reports using immunofluorescence and PAP methods. Similar patterns were observed using antisera to both TH and DBH. After deafferentation, the number of 5-HT labelled fibers was reduced, and numerous 5-HT labelled neurons were still observed. Occasional NE cell bodies and very fine fibers remained after spinal cord transection. The NE neurons were smaller and less numerous and their processes less extensive when compared to 5-HT labelled neurons.

This study confirmed biochemically the presence of serotonin and showed that NE is the catecholamine most prevalent in this neurosecretory nucleus. Both NE and 5-HT are associated with descending supraspinal projections, while 5-HT neurons predominate as the intrinsic monoaminergic innervation.

115.17 MOLLUSCAN BRAIN HORMONE STIMULATES REPRODUCTIVE ORGAN GROWTH *IN VITRO*. P.G. Sokolove and G.R. Albert* (SPON: T.A. Viancour) Dept. of Biolog. Sciences, Univ. of Maryland Baltimore Co. (UMBC), Catonsville, MD 21228

Reproductive tract development in the hermaphrodite slug, *Limax maximus*, is environmentally regulated. Long day lightcycles (LD16:8) stimulate growth and maturation of the gonad and of male and female accessory sex organs (ASO). Previous work has indicated that long days trigger the release from cerebral ganglia of a neurohormone which acts indirectly (via the gonad) to stimulate ASO development. Recent results suggest, however, that long-day cerebral ganglia (CG) also produce a substance that can directly stimulate growth of at least one ASO -- the so-called sperm-oviduct or "common duct" (CD). CG from long-day-stimulated female-phase slugs were homogenized in culture medium and added initially, and again after 3 days, to culture wells containing immature common ducts. After 6 days, ^{3}H-thymidine (1.0 Ci/ml) was added along with CG homogenate, and ducts were incubated for an additional 3 days. CDs incubated with CG homogenate incorporated from 8- to over 20-fold more label than CDs cultured alone. Additional experiments showed that considerably less incorporation occurred when CDs were incubated with homogenates of either sub-esophogeal ganglia or CG from short-day slugs. The stimulatory factor in long-day CG homogenate was found to be protease sensitive and did not pass through a 50 kdalton cut-off ultrafilter. About 75% of activity was retained after heating the homogenate to 95°C for 30 min. It appears based on these results that the CG of slugs exposed to long days produce a polypeptide factor which stimulates ASO cell proliferation *in vitro*. This factor probably plays an important role in normal, long-day-induced reproductive maturation, but its exact function and coordination with gonadally secreted sex hormone are presently not known.

115.18 ELECTROPHYSIOLOGICAL AND MORPHOLOGICAL EVIDENCES OF AN UTERUS PROJECTION TO NUCLEUS OF THE TRACT. M. Ortega-Villalobos*, G. Ninomiya-Alarcón*, C. de los Santos-Toledo* and R. Guevara-Aguilar. Dept. of Physiology, Fac. of Medicine. U.N.A.M. Apdo. Postal 70250, 04510 México, D.F.

The nucleus of the solitary tract (NTS) is a visceropective cell group located in the dorsal medulla. The NTS receives primary afferent terminations from the vagus nerve, which convey visceral information. Several studies confer to the vagus nerve, a role in reproductive functions. It is well known that the vagus nerve innervates the ovary. The aim of this work was to search for a possible pathway from uterus to NTS. The results were obtained from 11 Wistar female rats with a 188-307 g weight. The rats were anesthetized with chloral hydrate (400 mg/Kg). The firing rates of the NTS neurons were recorded, using a micropipette 3 um diameter tip, during cervix distention (0.4-0.6 ml. volume) infused by means of a pediatric urinary latex catheter. Only those animals that showed estrous vaginal smear, were recorded. Ten cells located in the dorsal part of the NTS were sensitive to cervix distention, all of them showed a stop of their firing rate with a latency of 39.63 sec after the begining of the distention and only in one case, it was observed an increase of firing rate during the distention. In five additional rats, horseradish peroxidase (Sigma type VI) was dissolved in isotonic saline solution; using a microsyringe fitted with a 26-30 gauge needle, 20 ul of a 40% horseradish peroxidase solution was injected along the cervix, the body of the uterus and the ducts of Falopio. After a survival time of 24-48 hs, the rats were reanesthetized with chloral hydrate and perfused intracardially with glutaraldehyde and paraformaldehyde fixative, the whole brain was removed and sectioned. The 50 um thick sections were processed with the TMB method and counterstained with thionin. Labelled neurons were identified in the NTS utilizing bright field microscopy.

These results, in terms of neurophysiological and neuroanatomical data, demonstrate a direct input to NTS from the uterus.

MONOAMINES AND BEHAVIOR III

116.1 FRACTIONATION OF THE SUBCOMPONENTS AND TRANSMITTER CONTROLS OF CONTACT-RIGHTING IN LABYRINTHECTOMIZED LATERAL HYPOTHALAMIC-DAMAGED RATS. S.M. Pellis, T.K. Morrissey, V.C. Pellis and P. Teitelbaum. Dept. of Psychology, Univ. of Florida, Gainesville, FL 32611.

Contact righting, that is, turning to prone from a recumbent lying position on the ground, is abolished from 2-4 days after large electrolytic lesions of the lateral hypothalamus. With recovery contact righting reappears, but does so in a distinct manner. At first the body is righted by backleg movements, in the absence of any active axial rotation. Later, a transitional form appears, in which tactile contact of the legs triggers axial rotation of the pelvis. Eventually, cephalic dominance is re-established, in which righting switches from back to front, so that righting begins in the shoulders and then proceeds to the pelvis. Such righting is achieved by pure axial rotation of the body, in which the limbs are carried by the torso. In shoulder girdle-led axial rotation, the head and neck do not turn, but are merely carried passively along by the body. Labyrinthectomy, when combined with the lateral hypothalamic (LH) damage, slows this recovery (now taking as long as three weeks), and reveals several intermediate stages of contact-righting more clearly.

The absence of axial rotation in the early stages of recovery from combined LH damage and labyrinthectomy is similar to the 'axial apraxia' seen in some Parkinsonian patients (Lakke, J.P.W.F. J. Neurol. Sci., 69: 37, 1985). In such Parkinsonian patients, axial rotation is not reinstated by L-dopa therapy, and thus has not been thought to involve the dopaminergic system. In the LH-damaged labyrinthectomized rat systemically injected 10 mg/kg quipazine maleate (a post-synaptic serotonergic agonist) reinstates shoulder girdle-led axial rotation. In contrast, systemically injected 2 mg/kg apomorphine hydrochloride (a post-synaptic catecholaminergic agonist) reinstates a different form of axial rotation, which involves tactile-triggered head and neck rotation which then recruits shoulder girdle and pelvis rotation cephalocaudally. In recovered animals systemically injected 25 or 50 mg/kg of pilocarpine hydrochloride (a post-synaptic cholinergic agonist) abolishes cephalic dominance and axial rotation reinstating backleg pushing of the body to prone. Thus, in the rat, several separate subcomponent reflexes, previously undescribed, are under separate transmitter controls, and act in an allied fashion to produce a composite reflex act of righting. These subcomponents, when acting in various degrees of isolation, may be a useful animal model of the abnormalities seen in Parkinsonian righting. Finally, the above results show that LH-damage produces major deficits in the proprioceptive/tactile controls over righting which are compensated for early in recovery by the vestibular system. One of these controls involves the rostro-caudal integration of righting.

116.2 ISOLATION-REARING IMPAIRS THE ACQUISITION OF SCHEDULE-INDUCED POLYDIPSIA. G.H. Jones*, T.D. Hernandez and T.W. Robbins* (SPON: S. Pellow) University of Cambridge, Department of Experimental Psychology, Cambridge, U.K. CB2 3EB

Isolation-reared rats develop an enduring spontaneous locomotor hyperactivity, are slower to habituate and are more aggressive than animals raised in social groups. Isolates also show enhanced oral behaviours in response to tail-pinch stimulation, are more responsive to stimulant drugs such as amphetamine and are less susceptible to CNS depressants. It has been proposed that isolation-reared animals exhibit higher levels of arousal than those reared in groups. In this experiment, the acquisition of schedule-induced polydipsia (SIP) was measured in rats reared in isolation and group-reared controls. The development of excessive drinking in response to an intermittent schedule of food presentation has been suggested to be a coping response which acts to reduce heightened arousal produced by the schedule (Brett, L.P. and Levine, S., *J. Comp. & Physiol. Psych.*, 93: 946-956, 1979).

Female Lister-hooded rats were weaned at 20 days and housed either individually or in groups of 4-5 per cage. At 14 weeks both groups of animals were food-deprived to 85% of their free-feeding weight and given 14 daily 30 minute exposures to a fixed-time food presentation schedule. Two 45 mg pellets were delivered every 60 seconds of the test and water consumption and activity were recorded. Rearing in isolation significantly impaired the acquisition of polydipsia. In contrast, mature animals housed in isolation for the same length of time did not differ from their control group. In confirmation of earlier studies, the isolation-reared rats weighed more and were hyperactive, not only in photocell cages, but also during SIP testing.

Plasma corticosterone (CCS) levels, a neuroendocrine index of stress, were determined following acquisition of schedule-induced polydipsia. The inverse relationship between CCS and drinking found in group-reared rats was not present in the isolates. Presynaptic dopaminergic function was also assessed, in vivo, using intracerebral dialysis in separate groups of isolates and socially-reared animals. Preliminary results indicate that there are enhanced extracellular dopamine levels in the striatum of isolation-reared rats after amphetamine treatment, when compared to group-reared controls. These results are discussed in terms of the hypothesis that isolation-rearing acts as a chronic stressor and enhances central dopaminergic activity.

116.3 EVIDENCE OF A FUNCTIONAL ROLE FOR EXCITATORY AMINO ACIDS IN THE MEDIAN RAPHE NUCLEUS OF THE RAT. D. Wirtshafter & R. Trifunovich*, Dept. Psychology, Univ. of Illinois at Chicago, Chicago, IL 60680.

Several recent anatomical studies have provided evidence for the existence of excitatory amino acid containing afferents to the median raphe nucleus (MR). We have reported that microinjections of nanogram quantities of the glutamate agonist kainic acid into the MR result in a marked reduction of spontaneous and ritalin-induced locomotor activity (Wirtshafter & McWilliams, 1987). In the current experiments we sought to further examine the role of excitatory amino acids in the MR by studying the behavioral and biochemical effects of injections of several excitatory amino acid antagonists into the MR or adjacent structures.

Intra-MR injections of the broad spectrum amino acid antagonist kynurenic acid (0, 2.5 or 5ug in 0.5 ul) produced a marked, dose-dependent increase in photocell cage locomotion in habituated rats. The effect was immediate in onset and its maximum amplitude was similar to that observed after intra-MR injections of muscimol. Similar dose-dependent hyperactivity was seen after intra-MR injections of the specific NMDA antagonist 2-amino-5-phosphonovaleric acid (2-APV, 0,1 or 2ug).

In order to determine whether the locomotor responses seen after injections into the MR could have been mediated by diffusion of these compounds to adjacent structures, we next compared the locomotor responses seen following injections of kynurenic acid, 2-APV or gamma-glutamylglycine into the MR, the dorsal raphe nucleus or the ventral tegmental area. For all of those drugs, the locomotor responses seen after injections in the MR were much larger than those seen after injections into either of the other two sites.

Finally, additional animals received intra-MR injections of 2-APV or its vehicle and were sacrificed 30 min. later to allow for regional examination of serotonin and dopamine metabolism by HPLC. Preliminary results indicate that animals who showed a pronounced locomotor response to the 2-APV injections displayed reduced levels of 5-HIAA in the hippocampus and increased levels of DOPAC and HVA in the nucleus accumbens.

The results of these studies suggest that a tonic excitation of MR cells is exerted via a stimulation of excitatory amino acid receptors within the nucleus. Blockade of these receptors results in an increase in locomotor activity and a decrease in hippocampal serotonin metabolism. Both of these effects are similar to those observed after intra-MR injections of the GABA agonist muscimol.

116.4 NEONATAL FOREBRAIN NOREPINEPHRINE (NE) DEPLETION REDUCES THE INFLUENCE OF THE REARING ENVIRONMENT ON LEARNING AND SOCIAL BEHAVIOUR. M.J. Saari, J. Armstrong*, J. Nobrega, J. Chambers* and D. Coscina. Dept. of Psychol., Nipissing Univ. Coll., North Bay, Ontario, P1B 8L7 and Dept. of Biopsychol., Clarke Institute of Psychiatry, Toronto, Ontario, Canada. M5T 1R8.

We have previously shown, that rat pups injected with 6-hydroxydopamine (6-OHDA) are less sensitive to environmental rearing conditions as measured by maze running latencies and in the Colony Intruder test. These results support our suggestion that NE plays a role in environmentally induced behavioural and neural plasticity. Although Mohammed, Jonsson & Archer (Brain Research, 398, 1986) have successfully replicated our findings Whishaw, Sutherland & Kolb (Beh. & Neural Biol., 46, 1986) have not. The present experiments further support our hypothesis that neonatal NE depletion attenuates the consequences of enriched and isolated rearing. We also provide some new data on cerebral glucose utilization following neonatal NE depletion and manipulation of the rearing environment.

Newborn male Wistar rats were injected subcutaneously, either with 6-OHDA (50 mg/kg) or vehicle (VEH, 1.0 mg/ml ascorbic acid in saline) within the first 12 and the first 24 hours after birth (assay results will be available at the poster). At 25 days the subjects were weaned and reared for 30 days either in isolation (IC), or enrichment (EC). Rats in IC were housed singly in standard, wiremesh, hanging cages (20x24x18 cm). EC housing consisted of social housing (6 per group) and daily, 30 min exposures to an open field containing regularly changed objects such as tunnels, platforms and balls.

At 60 days of age, in separate experiments, the rats were tested in the place navigation task and in two tests of competition/dominance. The tests were videotaped and scored by blind methods. The results of both experiments support the suggestion that the effects of rearing environment are reduced in NE depleted rats. Glucose utilization in several brain areas was found to vary primarily as a function of environmental rearing conditions.

116.5 TWO DISTINCT ROLES FOR THE MEDIALIS DORSALIS NUCLEUS OF THE THALAMUS ON FOCALIZED ATTENTION IN CONSCIOUS CAT. JJ. Bouyer, M.F. Montaron*, A. Rougeul* and P. Buser*.Institut des Neurosciences, CNRS and Université Pierre & Marie Curie, Paris 75005)

In cats, immobile focalized attentive behavior towards a target is accompanied by the development of beta (14 Hz) electrocortical (ECoG) rhythms in the pericruciate motor cortex (areas 4 and 6a). Both the behavior and the accompanying ECoG pattern are under the control of a dopaminergic mechanism originating in the ventral tegmental area (VTA, Montaron et al., Behav. Brain Res., 6 : 129, 1982) and are impaired after lesion of this structure. On the other hand, bilateral lesions of n.accumbens (Bouyer et al., Exp. Neurol., 92 : 698, 1986) were followed by the opposite syndrome, i.e.perseveration of attentive fixation and reinforcement of accompanying beta. Finally, retrograde HRP has shown that the cortical beta focus in the motor cortex receives some projections from the thalamic nucleus medialis dorsalis (MD). With this background we have now performed restricted kainic MD lesions and controlled the post-lesional beta and behavior. The results show that anteromedial MD lesions were followed by a clearcut deficit of the attentive immobility and accompanying beta (" VTA like" deficit), while posterolateral lesions induced the opposite syndrome(" ACC like"). From what we know of the connections between VTA, ACC, prefrontal cortex (PF) and MD, we suggest that two different parts of MD integrate two distinct, opposite controls from the VTA over attentive behavior and beta, the "meso-frontal" branch through PF, and the "meso-limbic" branch, via ACC.

116.6 DOES NICOTINE INCREASE LOCOMOTOR ACTIVITY BY STIMULATING MESOLIMBIC DOPAMINE ? P.B.S. Clarke, A. Jakubovic and H.C. Fibiger. Kinsmen Lab. for Neurological Research, Univ. of British Columbia, Vancouver, BC V6T 2A1.

Certain stimulant drugs appear to increase locomotion by increasing DA neurotransmission within the mesolimbic system. Given systemically to rats, (-)-nicotine stimulates locomotor activity (Clarke and Kumar 1983, Br J Pharmac 80:587-594). Nicotine receptors are associated with cell bodies and terminals of ascending dopaminergic (DA) pathways (Clarke and Pert 1985, Brain Res 348:355-358), and direct injection of a nicotinic agonist into the ventral tegmental area increases locomotion, apparently by a dopaminergic mechanism (Pert and Chieuh 1986, Soc Neurosci Abstr 12:250.4).

Rats received daily home cage injections of (-)-nicotine 0.4 mg/kg sc for two weeks, in order to enhance the drug's stimulant action (Clarke and Kumar 1983). A locomotor stimulant action was then verified by testing each subject with saline and with (-)-nicotine 0.4 mg/kg sc in photocell cages. Some days later, rats were injected with saline or nicotine, confined to photocell cages, and killed after 30 minutes. Major DA terminal regions (medial prefrontal cortex - mPFCX, olfactory tubercle - OT, nucleus accumbens - NACC, caudate-putamen - CP) were dissected on ice prior to HPLC/EC assay of catechols. DA utilisation was assessed by HVA/DA and DOPAC/DA ratios, or, in rats treated with the DOPA decarboxylase inhibitor NSD-1015, by DOPA/DA ratios.

The following effects were significant ($p<0.05$-0.005). Expt 1: (-)-Nicotine (0.2 - 0.4 mg/kg sc) increased locomotor activity and increased OT HVA/DA. Expt 2: (-)-Nicotine (0.1 - 0.4 mg/kg sc) stimulated locomotor activity in a dose-related way, and increased DOPA/DA ratios in a dose-related way in both OT and NACC, but not in CP. Expt 3: (-)-Nicotine (0.4 mg/kg sc) increased locomotor activity and elevated DOPA/DA ratios in OT and NACC, but again not in CP; in all these respects, the same dose of (+)-nicotine was ineffective.

These results suggest that systemic administration of nicotine at doses which increase locomotor activity may do so by selectively stimulating the mesolimbic DA system.

Supported by the Medical Research Council of Canada.

116.7 PHYSIOLOGY OF ABUSE POTENTIAL SUBSTANCES IN CENTRAL NEURONAL CIRCUITS: COCAINE EFFECTS ON SYNAPTIC TRANSMISSION OF AFFERENT SIGNALS TO RAT SOMATOSENSORY CORTICAL NEURONS. C.A. Jimenez-Rivera, E. Garcia* and B.D. Waterhouse. Dept. of Physiology and Biophysics, Hahnemann University, Philadelphia, PA 19102.

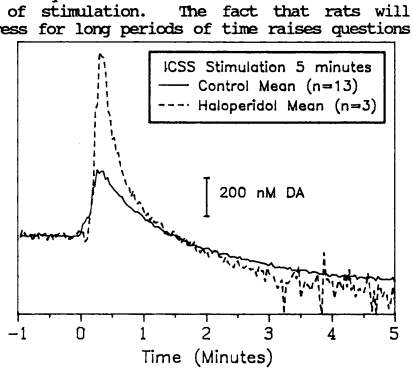
The psychostimulant effects of cocaine include increases in locomotion and enhanced sensitivity to tactile, visual and auditory stimuli. Biochemical studies suggests that such effects result from the ability of cocaine to elevate central synaptic levels of endogenous monoamines. The goal of the present study was to use electrophysiological assays developed in previous investigations of central monoamine function characterize the actions of cocaine on synaptic transmission of afferent signals through a primary sensory circuit in mammalian brain. Specifically, the responses of rat somatosensory cortical neurons to stimulation of thalamocortical afferent pathways were examined before and after parenteral (i.p.) administration of cocaine HCl. Extracellular unit activity from anesthetized rats was recorded using either glass or tungsten microelectrodes. Cortical afferents were activated via a bipolar stimulating electrode positioned in the VPL thalamus. Unit responses consisted of short latency excitation followed by a period of suppressed discharge or pure stimulus bound inhibition. Poststimulus time histograms of cell activity were collected every 3.5 min. for 15 min. before (control) and at least 40 min. after cocaine injection at 0.5, 1 or 2 mg/kg. Drug effects were quantitatively evaluated by comparing discharge rates during periods of stimulus bound and spontaneous activity in control and drug response histograms. In 6 of 11 (55%) neurons tested, cocaine suppressed spontaneous activity more than evoked discharges such that excitatory responses were enhanced relative to background firing. In one additional case, the magnitude and duration of a stimulus bound inhibitory response were augmented following cocaine injection. Facilitating effects of cocaine on evoked responses as well as suppression of background firing were observed within 3 min of drug administration, reached a peak around 7 min post-injection and began to return to pre-drug levels at 20-30 min post-injection. Enhancement of evoked responses was more consistently observed at lower doses (i.e. 0.5 mg/kg). Overall, these results indicate that cocaine can alter cerebrocortical neuronal responsiveness to synaptic inputs in a manner similar to that observed for norepinephrine. Thus, a physiological consequence of cocaine's biochemical action at central synapses and possibly a source of its stimulant properties may be the induction of noradrenergic-like modulatory actions in local brain circuits. (Supported by AFOSR-85-0155 and NS18081 to B.D.W.)

116.8 EFFECTS OF LY53857, A SELECTIVE 5-HT_2 RECEPTOR ANTAGONIST, ON COPULATORY BEHAVIOR OF MALE RATS. M. M. FOREMAN, R. L. LOVE*, J. L. HALL*, G. P. MARZONI* AND W. L. GARBRECHT*. The Lilly Research Laboratories, Eli Lilly and Company, Lilly Corporate Center, Indianapolis, IN, 46285.

Experimental manipulations that decrease serotonergic activity such as lesioning serotonergic pathways, inhibition of 5-HT synthesis with para-chlorophenylalanine or blockade of 5-HT receptor activity with antagonists such as methysergide, metergoline or mesorgydine, have been found to increase copulatory behavior in male rats. The conclusions that 5-HT has an inhibitory effect on sexual behavior are further supported by the observations of reduced sexual performance following administration of the 5-HTP, 5-HT reuptake inhibitors or the 5-HT receptor agonist, 5-MeO-DMT. However, reductions in sexual performance of male rats have also been observed following administration of 5-HT receptor antagonists, pirenperone and ketanserin (Mendelson and Gorzalka, Pharmacol. Bioch. & Behav. 22:565-571, 1985). These antagonists have a higher affinity for the 5-HT_2 receptor than the 5-HT_1 receptor, but also have high to moderate affinities for H_1-histaminergic, alpha$_1$-adrenergic and D_2-dopaminergic receptors (Janssen, T.I.P.S. 4:198-206, 1983). LY53857, a potent 5-HT_2 receptor antagonist that lacks prominent effects at other monoaminergic receptors (Cohen et al., J.P.E.T. 227:327-332, 1983; Drug Dev. Res. 5:313-321, 1985), was used in the present studies to evaluate the effects of selective 5-HT_2 receptor antagonism on male rat sexual behavior. The sexual behavior of each male, Sprague-Dawley rat was evaluated at two week intervals using a sexually receptive, female rat. Only rats with stable sexual performance in successive tests with vehicle administration were selected for these studies. These rats were given subcutaneous injections of either 0.01, 0.10 or 1.0 mg/kg 30 minutes prior to testing. No alterations in copulatory performance were observed at the 0.01 mg/kg. However, the administration of 0.1 or 1.0 mg/kg resulted in significant reductions in ejaculatory latency of 32.8 $\pm$ 8.8 and 40.6 $\pm$ 5.1 % compared to control responses, respectively. These latter doses also induced statistically significant increases in copulatory rate of 46.7 $\pm$ 18.1 and 110.7 $\pm$ 17.9 % compared to control responses. These data are supportive of the view that selective 5-HT_2 receptor blockade enhances copulatory performance of male rats. The previous findings of reduced sexual performance of male rats treated with pirenperone and ketanserin may be related to the alpha$_1$ antagonist activity of these compounds and not the 5-HT_2 antagonist properties. This conclusion is supported by the observations of suppressed sexual function in rats treated with the alpha$_1$ antagonist, prazosin (Clark et al, Neuroendocrinology 41:36-43, 1985).

116.9 **EFFECT OF STIMULATION CURRENT ON DOPAMINE RELEASE MEASURED BY IN VIVO VOLTAMMETRY: RELEVANCE TO INTRACRANIAL SELF STIMULATION.** **J. B. Justice, Jr., M. Ikeda*, L. C. Nicolaysen*, and D. B. Neill*. Departments of Chemistry and Psychology, Emory University, Atlanta, GA 30322.**

Electrically stimulated dopamine (DA) release is monitored voltammetrically in the rat striatum under varying stimulation conditions. At 200, 75 and 50 μA (80, 30 and 20 μA rms) stimulation, the maximum concentration of released DA was 29, 3.7 and 0.46 μM, respectively (100 Hz, 2 ms biphasic square waves). Computer modelling of the DA nerve terminal suggests that as lower stimulation currents are applied at constant frequency, fewer DA neurons are stimulated, rather than the same population being weakly stimulated uniformly. The data and model also indicate that the stimulated terminals become depleted of releasable DA during the stimulation of the MFB. From microdialysis studies, baseline extracellular DA is about 20 nM in the striatum of anesthetized rats. When typical intracranial self-stimulation (ICSS) conditions are applied for 5 minutes in anesthetized rats (bipolar electrode, 100 μA, 100 Hz, 0.5 ms biphasic square wave pulses in 150 ms trains at 2 Hz, overall 3 μA rms), DA reaches a maximum concentration of 342 nM (n=13) at 20 seconds, and then decreases within 1 minute to close to baseline values. After 0.05 mg/kg haloperidol, 5 minutes of ICSS stimulation produces a maximum DA concentration of 947 nM (n=3) at 20 seconds. Evidently the most intense release occurs within the first minute of stimulation. The fact that rats will continue to bar press for long periods of time raises questions about the role of DA in ICSS. The results also suggest that less than 10% of the DA nerve terminals in the striatum are stimulated during ICSS.



116.10 DOPAMINERGIC SUBSTRATES FOR CUES PRODUCED BY ELECTRICAL STIMULATION OF THE VENTRAL TEGMENTAL AREA. J.P. Druhan, H.C. Fibiger and A.G. Phillips. Dept. Psychol.; Div. Neurol. Sci., Univ. of British Columbia, Vancouver, B.C., Canada, V6T 1W5.

Previous studies have reported that the cue properties of amphetamine are mediated by mesocortical dopamine (DA) neurons originating in the ventral tegmental area (VTA). The present experiments investigated whether cues produced by electrical stimulation of the VTA might involve similar substrates. In the first experiment, rats were trained to discriminate between high and low intensities of VTA electrical brain stimulation (EBS). The discrimination task required that animals respond on one lever for food after being cued by prolonged, intermittent stimulation at a high intensity, or on an alternate lever after being cued by low intensity EBS. Rats that acquired this task were subsequently tested for generalization to 4 intermediate intensities after ip injections of amphetamine (0.5 & 1.0 mg/kg), haloperidol (0.1 & 0.125 mg/kg) and saline. Relative to saline tests, amphetamine caused the rats to respond to low-intensity cues as though they were higher, suggesting an enhancement of the EBS cues. In contrast, haloperidol resulted in the rats responding to high-intensity EBS cues as though they were of lower intensity, suggesting an attenuation of the perceived intensities of the EBS. The observed enhancement of the EBS cues by an indirect DA agonist (amphetamine) and their attenuation by a DA receptor antagonist (haloperidol) suggests a DA substrate for the VTA EBS cues measured in this experiment.

The second experiment assessed whether generalization could occur between amphetamine and VTA EBS cues. Eight rats were trained to discriminate 1.0 mg/kg amphetamine (ip) from saline, and then tested for generalization to VTA EBS. Each rat was given 6 generalization tests with VTA EBS presented intermittently at either 15 or 20 uA, and at a frequency of 1/10 s, 1/5 s or 1/2.5 s. Examination of the data for individual subjects revealed that three of the rats cosistently responded on the drug lever when VTA EBS was substituted for amphetamine, whereas the other five rats always responded on the saline lever. These results indicate that VTA EBS can mimick the amphetamine cue under certain conditions, but the generalization does not occur in all rats.

116.11 UNIQUE EFFECTS OF ATYPICAL NEUROLEPTICS ON AMPHETAMINE-INDUCED BEHAVIORS. JoAnn Tschanz* and George V. Rebec (SPON: G.P. Frommer). Dept. Psychol., Indiana Univ., Bloomington, IN 47405

Although both atypical and classical neuroleptics are used in the treatment of schizophrenia, these drugs do not exert comparable effects. Certain atypicals, for example, are more effective in treating negative-symptom schizophrenics, and these drugs, unlike the classicals, fail to produce extrapyramidal side effects. These drugs also differ in animal tests. The classical neuroleptics elicit catalepsy in rats, whereas the atypicals are devoid of this effect, even at relatively high doses. There also is general agreement that although both types of drugs block the forward locomotion produced by amphetamine and other dopamine agonists, the classicals also block focused stereotyped behaviors. To the extent that different neuronal systems mediate the locomotion and focused stereotypy produced by dopamine agonists, these systems appear to respond differentially to atypical and classical neuroleptics. In fact, this interpretation has led to the proposal that a blockade of the mesolimbic dopamine system, which appears to mediate the blockade of amphetamine-induced locomotion, plays an important role in the antipsychotic efficacy of the neuroleptics, whereas blockade of the nigro-striatal dopamine pathway blocks drug-induced stereotypies and leads to extrapyramidal side effects. Recent evidence, however, indicates that the atypicals also attenuate at least some components of focused stereotypy and may even enhance others (Robertson, A. & MacDonald, C., Pharmacol. Biochem. Behav. 21:97, 1984). It is conceivable, therefore, that a simple blockade of the behavioral effects of amphetamine is not an adequate model for studying the antipsychotic efficacy of neuroleptic drugs. In order to study this issue further, we tested several different neuroleptics in rats that received either low (1.0 mg/kg) or high (5.0 mg/kg) doses of amphetamine, and we monitored individual items of the amphetamine behavioral response.

Consistent with previous reports, pretreatment with the classical neuroleptic, haloperidol (0.1 or 0.25 mg/kg), significantly reduced all components of the behavioral response to low as well as high doses of amphetamine. The atypicals, however, were more variable in their effects. Although both clozapine (1.0 or 5.0 mg/kg) and thioridazine (1.0 or 5.0 mg/kg) blocked either sniffing or head bobbing produced by a low dose of amphetamine, clozapine was more effective than thioridazine in blocking the oral behaviors produced by a high dose of amphetamine. Moreover, the high dose of clozapine blocked amphetamine-induced rearing, but a comparable dose of thioridazine enhanced this response. Thus, as a class, the atypical neuroleptics appear to block only some components of the amphetamine behavioral response, but when considered individually each drug appears to exert a unique dose-dependent effect.

116.12 ANTAGONISM OF TRIADIMEFON-INDUCED HYPERACTIVITY BY RESERPINE IN RATS. K. M. Crofton*, V. M. Boncek*, R. C. MacPhail, and L. W. Reiter, Neurotoxicology Division, U.S. EPA, RTP, NC 27711 and Northrop Services, Inc, Environmental Sciences, RTP, NC 27709

Triadimefon (TDF) is a substituted triazole fungicide that has been shown to produce hyperactivity in both mice and rats (Crofton et al., Toxicologist 7:254,1987). TDF-induced hyperactivity was characterized by alterations in temporal and spatial patterns of activity, similar to effects seen following administration of compounds with catecholaminergic activity (e.g., amphetamine). To determine whether the TDF-induced hyperactivity is due to an interaction of this fungicide with CNS catecholaminergic systems, we evaluated the effects of combined treatment of TDF with either d,l-α-methyl-p-tyrosine methyl ester HCl (AMT) or reserpine (RSP). Adult male Long-Evans hooded rats, approximately 70 days of age were used. Dosage-effect functions were determined for AMT (0-200 mg/kg in 1.0 ml/kg saline administered ip 3 hr prior to testing), and RSP (0-4.0 mg/kg in 2.0 ml/kg deionized water administered ip 18 hr prior to testing). Motor activity was measured as photocell interruptions for one hr in figure-eight mazes (Reiter et al., Environ. Hlth. Perspect. 12:119,1975). A non-effective dosage was selected for each compound (AMT = 100 mg/kg, RSP = 0.62 mg/kg). The interaction between TDF and AMT was determined with the following groups: 1) vehicle control; 2) 200 mg/kg TDF (po in 2.0 ml/kg corn oil 1 hr prior to testing); 3) 100 mg/kg AMT; and 4) both AMT and TDF (n=7-8/group). Similar groups were used to test for an interaction between TDF and RSP, with 0.62 mg/kg RSP substituted for the AMT (n=13-16/group). In the first experiment AMT did not block the increased motor activity produced by TDF (i.e., both TDF alone and AMT in combination with TDF produced significant increases in motor activity. Since AMT does not antagonize the effect of TDF, these data suggest that increased motor activity produced by TDF is not mediated through newly synthesized catecholamines. In contrast, pretreatment with RSP blocked the TDF-induced hyperactivity, suggesting that TDF-induced hyperactivity may be due to an interaction with CNS catecholamines stored in reserpine-sensitive pools. However, since RSP also depletes other CNS aminergic transmitters, an interaction with other amines cannot be ruled out.

116.13 THE TEMPERATURE OF THE REARING ENVIRONMENT DETERMINES SENSITIVITY TO STRESS POTENTIATION OF MORPHINE ANALGESIA AND BRAIN TRYPTOPHAN METABOLISM. [3]J.E. Jans*, [1]F.V.Abbott, [2]K.B.J. Franklin and [3]B.C. Woodside. [1]Dept. Psychiatry and Sch. Nursing, [2]Dept. Psychology, McGill University; [3]Dept. Psychology, Concordia University, Montreal, Canada.

Early environmental manipulations e.g handling (Levine 1957) permanently alter the rat's responsivity to stress. We now report that rats reared at room temperature show increased biochemical and behavioral responses to restraint stress compared to rats reared in a nest box warmed to 30-33°, the temperature of natural rodent nest chambers (Daly, 1973).

Restraint is known to potentiate morphine analgesia, an effect that is associated with a rise in brain tryptophan and brain 5HT synthesis (Kelly & Franklin, 1984). We examined the effect of rearing conditions on these phenomena. The subjects were adult male Sprague Dawley rats that had been handled and reared with their dams, in either warm (30-33°C) or cool (20-22°C) nest boxes. They were tested for their responsivity to thermal stimulation (55° water) applied to their tails. Rats were tested before and every 10 min after injection of 4 mg/kg morphine sulphate s.c. One hour after the injection all rats were killed and brainstem and spinal cord samples were assayed for tryptophan, 5HT and 5HIAA by HPLC. Half the rats in each group (n=6) were tested while restrained in wire mesh tubes, the others were gently hand held during each test. All rats had been habituated to the test environment and handling.

Baseline tail flick latencies were similar for all groups. Restraint stress significantly increased morphine analgesia in rats reared in a cool environment ($p<.01$) but had no effect in rats reared in warm conditions. In cool reared animals restraint also increased tryptophan levels in spinal cord ($p<.01$) and brain stem ($p=.05$) but warm reared rats did not show this effect. Curiously restraint increased spinal cord 5HIAA in cool reared rats and depressed 5HIAA in warm reared rats ($p<.05$). There were no differences between the groups in brainstem or spinal cord 5HT.

These results show that the environmental conditions under which rat pups are reared may profoundly influence their susceptibility to stress potentiation of opioid analgesia and the changes in brain trypophan uptake and metabolism associated with it. This effect is not attributable to an early handling effect as both groups received similar amounts of "handling" in infancy.

116.14 MONOAMINE AND METABOLITE CONTENT IN THE RAT BRAIN DURING THE ESTROUS CYCLE, PREGNANCY, AND POSTPARTUM. W. Woodmansee*, P. Desan, S. Ryan, T. Smock and S. Maier (SPON: H. Alpern). Dept. of Psychology, Univ. of Colorado, Boulder, CO 80309.

A wide variety of physiological and behavioral changes in the female rat have been associated with the estrous cycle, pregnancy, and postpartum and their accompanying hormonal fluctuations. The most notable changes demonstrated include changes in mating behavior, pain sensitivity, and overall activity of the animal. Previous research has focused on the investigation of monoamine metabolism in the hypothalamus. The present study examined norepinephrine (NE), dopamine (DA), serotonin (5HT) and their primary metabolites (DOPEG, MHPG, DOPAC, and 5HIAA) in the anterior cortex, hippocampus, and cerebellum during the estrous cycle, late pregnancy, and postpartum

Subjects were Sprague Dawley rats individually housed and maintained on a 12:12 light/dark cycle with lights on at 0700. Samples were obtained for each of the four days of the estrous cycle, the 19th day of pregnancy, and the 6th postpartum day. Maintenance of the estrous cycle was assessed by daily vaginal smears and pregnancy was determined by the first sperm-positive day following the introduction of males. The animals were rapidly decapitated between 1400 and 1600 hr and brain samples were dissected and frozen. All samples were sonicated in pH 5.0 0.1M acetate buffer containing the internal standard DHBA and centrifuged. High performance liquid chromatography coupled with electrochemical detection was used to examine the monoamine and metabolite content of the tissue samples. Measurements of all compounds, except NE metabolites DOPEG and MHPG, were obtained with oxidative electrochemical detection. DOPEG and MHPG were assayed by a serial oxidative-reductive detection system as described elsewhere at this meeting (Desan, Gerhardt, Woodmansee, and Smock, 1987).

Results of this study indicated that NE and its metabolites, DOPEG and MHPG, do not vary during the estrous cycle in any of the three brain regions examined. However, serotonergic systems do appear to change during the estrous cycle. Serotonin's principal metabolite, 5HIAA, was significantly higher in proestrus and estrus than on metestrus and diestrus in the anterior cortex and cerebellum ($n=8$, $p<0.05$). Additionally, both noradrenergic and serotonergic systems vary as a function of pregnancy. 5HIAA levels in all brain regions were lower in late pregnancy than in early postpartum, a difference significant in the hippocampus and cerebellum ($n=5$, $p<0.01$). Similarly, NE levels in all brain regions were elevated in early postpartum as compared to late pregnancy, a difference significant in cortex and cerebellum ($n=6$, $p < 0.01$).

Thus, differences in serotonergic function may be related to changes in behavior during the estrous cycle and fluctuation in both serotonergic and noradrenergic function may be related to behavioral changes during pregnancy and postpartum. 116.15 EFFECTS OF ANOXIA ON SINGLE-UNIT ACTIVITY OF BRAIN STEM NEURONS IN FREELY MOVING CATS. W.J. Litto, C.A. Fornal and B.L. Jacobs. Prog. Neurosci., Dept. Psychol., Princeton Univ., Princeton, NJ 08544.

Our laboratory has been engaged in a systematic analysis of the activity of brain stem monoaminergic neurons in behaving cats in response to various physiological and environmental challenges. A major aim of this research has been to define the role of these neurons in CNS mechanisms underlying the stress response. The present study examined the response of monoaminergic and non-monoaminergic neurons to acute histotoxic anoxia in freely moving cats. Extracellular single-unit activity was recorded in the region of the dorsal raphe nucleus (DRN) and locus coeruleus using movable nichrome wire electrodes. Serotonergic (5-HT) neurons were identified on the basis of previously described criteria (see Fornal et al., this meeting). Sodium cyanide (NaCN; 0.05-0.5 mg/kg) was administered remotely, via an indwelling jugular catheter, to produce an acute anoxic condition. Cortical EEG, nuchal EMG, EOG, ECG, respiratory rate (RR) and behavior were monitored continuously for 60-90 min following NaCN injection. In addition, serial blood samples were obtained before and after NaCN administration for the determination of blood glucose. High doses of NaCN (0.4 and 0.5 mg/kg) reliably produced a decrease in EEG amplitude within 10 sec and periods of isoelectric EEG during the first 3 min following injection. These effects were accompanied by polypnea, bradycardia and hyperglycemia, indicative of global anoxia and subsequent chemoreceptor activation. The effects of NaCN on RR and blood glucose lasted for 30-60 min following injection. The transient decrease in heart rate observed immediately after NaCN administration was followed by prolonged tachycardia which then paralleled the RR response. In addition, cats displayed mild seizure activity, salivation, loss of postural support and vocalization, and often, emesis, urination, and defecation during the first 10 min following NaCN injection. None of the above behavioral, autonomic or EEG responses were observed following lower doses of NaCN (0.05-0.25 mg/kg). Preliminary data indicate that the activity of DRN-5-HT neurons is markedly suppressed during the initial interval following high (but not low) doses of NaCN. Since the activity of non-monoaminergic brain stem neurons was either unaffected or increased following high doses of NaCN, this suggests that DRN-5-HT neurons may respond preferentially to anoxia. These experiments are presently being extended to include noradrenergic neurons in the locus coeruleus. Supported by NIMH grant MH23433 and NRSA MH09529 to W.J.L.

116.16 ALPHA-1 ADRENOCEPTORS AND JUVENILE PLAY IN THE RAT. S.M. Siviy, D.M. Atrens* and L.J. Holmes*. Dept. of Psychology, University of Sydney, Sydney, NSW 2006, Australia.

Rough-and-tumble play is common among the juveniles of most mammals. It has only been recently, however, that any experimental analysis has focused on delimiting those neurochemical systems which may mediate this behavior (see Panksepp et al., Neurosci Biobehav Rev 1984, 8:465-492). To further this aim, we evaluated the extent to which alpha-1 adrenoceptors may be involved in the elaboration of play among juvenile rats. Prazosin (PRZ), a selective alpha-1 antagonist, was injected (IP) 20 minutes before a 5 minute opportunity to play. Rats (25-45 days old) were housed individually to amplify the amount of play during the observation periods. At 0.1 and 1.0 mg/kg, PRZ reduced the frequency of pinning, an indicator variable of play, by 26% and 51%, respectively. Dorsal contacts, an index of play motivation, were affected only by the highest dose (1.0 mg/kg), being reduced by 29%. When 1 hour was allowed between injection and test, PRZ (0.5 mg/kg) still reduced pinning by 24%, but had no substantial effect on dorsal contacts. We next evaluated the effect of PRZ with lower baseline levels of play, to allow room for any putative increase in play. The rats were given a 1 hour opportunity to play, injected, and then observed 20 minutes later for 5 minutes. While baseline levels of play during the 5 minute observation period were substantially reduced by the prior opportunity to play, PRZ had no effect on frequency of either pins or dorsal contacts. In preliminary work, we also evaluated the effects of ST587, a selective alpha-1 agonist, on play. While the highest dose of ST587 used (1.0 mg/kg) reduced pinning and dorsal contacts by 19% and 14%, respectively, this dose also resulted in a net 24 hour weight loss when compared to rats treated with vehicle, casting doubt on the extent to which any play reduction could be considered behaviorally specific. Lower doses of ST587 (0.125 - 0.5 mg/kg) had no consistent effect on either pins or dorsal contacts.

Taken together, these data show that acute selective blockade of alpha-1 adrenoceptors results in a state which is not fully compatible with rough-and-tumble play in the rat. The extent to which the observed effects on play following PRZ are behaviorally specific and do not reflect a non-specific behavioral impairment is still unclear. However, given that play motivation was less affected than pinning, there does appear to be some degree of specificity associated with PRZ's action on play. The inability of ST587 to produce effects symmetrical to those of PRZ, on the other hand, would argue against behavioral specificity. Work designed to clarify these issues further is currently in progress.

116.17 PERIPHERAL ADRENERGIC STIMULATION ATTENUATES PERFORMANCE DEFICITS IN RATS WITH HIPPOCAMPAL LESIONS. J. P. Ryan, D. L. Nock*, and R. L. Isaacson. Center for Neurobehavioral Sciences and Department of Psychology, State University of New York at Binghamton, Binghamton, NY 13901.

Long-Evans hooded rats with bilateral hippocampal lesions, neocortical lesions or sham operations were trained in the Morris water maze. The time required to escape from the maze by climbing onto the stationary hidden platform was measured. For each trial, the place in the maze from which an animal started was determined quasi-randomly within and between training days. Six trials were given each day. After the first three trials, the animal was placed into its home cage for one min before starting the final three trials.

In half the animals, adrenergic supersensitivity was induced with bretylium (5mg/kg, i.p.) administered beginning 24 hr after surgery for 13 consecutive days. On the first 7 days, injections were given with no other handling, testing or training. On postoperative days 8 to 13, injections were given following initial pretraining and actual training (days 9-13). On these days, the animals that had received bretylium also received Norepinephrine (NE) (4μg/kg, i.p.) 30 min prior to maze pretraining and 30 min prior to training. Following this, the animals were neither trained nor tested for 12 days. Then the bretylium alone treatment was resumed for 7 days. After this, animals were again trained in the Morris maze with bretylium and NE as given earlier. When tested at 27 days postoperatively, rats with hippocampal lesions treated with bretylium and NE reached the platform more quickly than the untreated animals with similar lesions. By training day five, these animals were indistinguishable from untreated animals. A similar trend was found at the earlier test period but the lesioned animals behavior was inconsistent from trial to trial. As is known, there is a markedly enhanced adrenergic response to NE after 7 consecutive days of bretylium. However, the mechanism effecting drug-induced attenuation of the hippocampal lesion performance in the water maze is uncertain. The near normal escape time to the platform seen in bretylium and NE animals treated 27 days postoperative may reflect an interaction of the prior training and drug treatment or it may be due to the different neurological conditions found at this later time. These findings suggest that peripheral adrenergic stimulation attenuates performance in rats with hippocampal lesions.

116.18 ENVIRONMENT DEPENDENT SENSITIZATION TO AMPHETAMINE-INDUCED CIRCLING BEHAVIOR IN UNLESIONED FEMALE RATS. K.L. DREW and S.D. GLICK. Dept. of Pharmacology and Toxicology, Albany Medical College, Albany, NY 12208

When paired repeatedly with amphetamine, stimuli such as the test apparatus have been shown to acquire conditioned stimulus properties; i.e., the test apparatus acquires the ability to produce amphetamine-like responses (e.g., Drew and Glick, 1986). Stereotypy, locomotion and circling behavior induced by amphetamine have been shown to increase over the course of repeated drug administration; the role of conditioning in the sensitization to behavioral responses induced by amphetamine has been debated (cf. Robinson, 1986). Here we report environment dependent sensitization to amphetamine-induced circling behavior in intact (unlesioned) female rats. No sensitization independent of the environment was observed regardless of the procedure used or the time interval between amphetamine injections.

All rats received two ip injections of 1.25 mg/kg d-amphetamine sulfate. One half of the rats experienced the effects of the first injection in the home cage and the effects of the second injection in the test apparatus. The other half experienced the effects of both injections in the test apparatus. Rats were further divided into subgroups such that for some the time interval between injections was 7 days and for others it was 24 hrs; for some rats the amphetamine was injected after a 15 min habituation period in the test apparatus and circling behavior was recorded for 60 min while for other rats the drug was injected 30 min prior to placement in the test apparatus and circling behavior was recorded for 30 min.

Regardless of the procedure used or the time interval between amphetamine injections, only those groups of rats that experienced the effects of the first amphetamine injection in the test apparatus displayed significant sensitization following the second amphetamine injection.

While other studies have shown (Browne and Segal, 1977; Robinson, 1984) and still others have suggested (Robinson et al., 1982) that conditioning is not necessary for behavioral sensitization, the present study as well as Tilson and Rech (1973) show that mechanisms independent of the environment are not necessary to produce behavioral sensitization to amphetamine. Both forms of sensitization may contribute to amphetamine-induced psychosis and both provide examples of neural plasticity. (Supported by NIDA grant DA 03817)

117.1 MONOCLONAL ANTI-CONJUGATED ACETYLCHOLINE ANTIBODY AS A RELIABLE MEANS TO STUDY THE TRIGGERING MECHANISMS OF MYASTHENIA GRAVIS. M.L. Souan, J.L. Chagnaud, A. Arné and M. Geffard. Lab. of Neuroimmunology, IBCN/CNRS - 33077 Bordeaux- France.

In addition to anti-acetylcholine receptor antibodies (ACh-R), we have found in the sera from patients suffering of myasthenia gravis (MG) other antibodies consisting of: (i) the antibodies directed against an epitope taking into account the structure of conjugated ACh called anti-conjugated ACh antibodies and (ii) the antibodies directed against the idiotypes of the above-mentioned ones and called anti-anti-conjugated ACh antibodies (Souan et al., 1986,1987; Souan and Geffard 1986). For a better evaluation and characterization of the human anti-anti-conjugated ACh antibodies, we have used a monoclonal anti-conjugated antibody raised from mouse. We have selected the AKR strain as the best responder to immunization with conjugated ACh. Spleen cells from one of this mouse were fused with cells of X63 mouse myeloma cells using polyethylene glycol 1000 as fusing agent. Using an ELISA method, specific antibodies present in cell medium from confluent cultures were tested. Selected hybridomas giving the best antibody affinity and specificity were then cloned twice. In order to determine monoclonal antibody affinity and specificity, competition experiments were performed by RIA. Using the lactoperoxydase method, monoclonal anti-conjugated ACh antibody was iodinated and then, G-25 chromatographed. From displacement curves we domonstrated that the most immunoreactive compound was thotin-glutaryl-protein (IC 50 = 5×10^{-10} M) The other related compounds were less recognized . Such a tool enabled us to confirm our previous results both in the experimental and clinical fields: (i) the administration of this monoclonal anti-conjugated ACh antibody to rabbits allows the raising of anti-idiotypic antibodies whose characterization, performed by RIA, shows that at the level of the antigen-combining site of the anti-conjugated ACh antibody, a popula tion competes with the conjugated ACh. Therefore these anti-idiotypic antibodies represent the internal image of ACh, and can bind to the ACh-R. After six injections, the immunized animals present signes of muscular weakness. The SFEMG recordings confirmed the symptoms suggestive of experimental autoimmune myasthenia gravis; (ii) we are able to evaluate the human anti-anti-conjugated ACh antibodies. The results obtained confirm that their titer in myasthe nic sera was higher than that in control sera. And what is more, when examining the sera from myasthenic patients we found a correlation between the anti-conjugated ACh antibody and the anti-anti-conjugated ACh antibody titers.These data confirm: on one hand the role of conjugated ACh, on the other hand that of the idiotypic/anti-idiotypic network in the triggering mechanisms of the MG autoimmune processes.

117.2 ALPHA-TOCOPHEROL PARTIALLY REVERSES THE IMINODIPROPRIONITRILE (IDPN)-INDUCED DYSKINETIC SYNDROME. J.B. Lohr, J.L. Cadet, T. Bryant*, R.J. Wyatt, W.J. Freed. Neuropsychiatry Branch, NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

Iminodiproprionitrile (IDPN) is a neurotoxin that causes a permanent motor disorder in rats and mice, consisting of excitement, dystonic or choreoathetoid neck movements, and circling behavior. The pathophysiological mechanism is unknown, but neuroaxonal changes following IDPN have been reported to resemble those seen in vitamin E-deficiency (Miyakawa et al., Acta Neuropath, 20:67, 1972). Moreover, since it is possible that the mechanism of IDPN-induced damage involves free radical production, and α-tocopherol (vitamin E) is a powerful free radical scavenger, we decided to test the hypothesis that treatment with α-tocopherol would decrease the movement disorder seen after IDPN administration.

Male Sprague-Dawley rats (500-600 g) were used in the experiments. Animals were injected daily with IDPN (100 mg/kg i.p.) until dyskinesia developed (14 days), following which they were tested using a modified version of a dyskinesia scale (Diamond, B.I. et al., Adv Neurol, 35:221, 1982). Animals were then assigned randomly to either daily injections of α-tocopherol (2 g/kg i.p., n=16) or of an equivalent volume of sesame oil placebo (n=18) for 7 days. After α-tocopherol, the animals were again evaluated on the dyskinesia scale.

Before treatment with α-tocopherol, there were no differences between the two groups. Following treatment, the α-tocopherol-treated rats demonstrated a significant reduction in vertical neck movements (10.0 ± 3.8 movements/min vs 5.9 ± 1.8 movements/min, t=3.9, $p<0.001$). In addition, there was a significant difference between the treated and untreated groups in the number of rats which demonstrated circling behavior (3/15 vs 10/16, $\chi^2=7.54$, $p<0.01$). There were no differences in hyperactivity.

These results suggest that α-tocopherol can partially reverse the movement disorder produced by the neurotoxin IDPN, and imply that IDPN may cause damage either through a free radical-based mechanism or through interference with the actions of tocopherols.

117.3 EFFECT OF MPTP AND ITS METABOLITES ON CATECHOLAMINES IN MOUSE BRAIN SLICES. J. A. Wilson, T. J. Doyle*, & Y. S. Lau. Depts. of Physiology and Pharmacology, Creighton Univ. Sch. of Med., Omaha, NE 68178.

MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) is able to cause a Parkinson's disease like condition in man and several species of mammals. In idiopathic parkinsonism, symptoms begin to appear after a large percentage of the dopamine containing neurons in the substantia nigra have died. The death of these neurons causes a decrease in the amounts of dopamine available in the target nuclei, the caudate and putamen. Dopamine is thought to modulate corticostriate synaptic transmission; therefore alterations in the available pool of dopamine can be expected to alter synaptic transmission. Brain slices have been used to study synaptic transmission in a variety of brain regions. In the mouse, synaptic transmission between the cortical efferents and the neurons of the neo-striatum has been studied, and MPTP has been found to cause a non-reversible decrease in the amplitude of the synaptically evoked component of an extracellularly recorded field potential (Wilson et al. 1986, Brain Res. 368 357). The effect of MPTP on synaptic transmission in the mouse brain slice was blocked by using the same classes of agents which blocked the long term changes in vivo in mice as well as other species. In the slice one of the metabolites of MPTP, MPP^+, causes only a temporary and reversible decrease in the synaptic potential. This finding contradicts the hypothesis that MPP^+ may be the active toxin. To better understand the differences in the actions of these agents and that of $MPDP^+$, the other candidate for the active toxin, we have treated brain slices with MPTP, $MPDP^+$, and MPP^+ and assayed the tissue for catecholamines using HPLC.

Five hundred micron thick slices containing the neostriatum, substantia nigra, and nearby structures were made exactly as they had been made for physiological studies. They were incubated in an artificial CSF for an hour before drugs were tested. Each drug was then applied for 20 minutes and the tissue was washed. The tissue was fixed in 0.2N perchloric acid solution, sonicated, filtered, and analyzed. An overall decrease in the levels of catecholamines was seen in all the slices incubated in ACSF. MPTP and $MPDP^+$ caused decreases in levels of catecholamines which were different from those caused by MPP^+. Thus neurochemical changes are associated with the electrophysiological changes seen in the mouse brain slice preparation.

117.4 **DOPAMINE TOXICITY TO PC-12 CELLS, PROTECTION BY SUPEROXIDE DISMUTASE AND CATALASE.** G.M. Alexander, J.R. Grothusen*, J. Joseph*, RL Knobler, and RJ Schwartzman. Department of Neurology, Jefferson Medical College, 1025 Walnut Street - Room 511, Philadelphia, PA 19107

PC-12 cells (rat pheochromocytoma) have been used to screen for compounds that are toxic to catecholaminergic cells. It has been shown by Denton and Howard, (Biochem. Biophys. Res. Commun. 119, 1984) that methylphenyltetrahydropyridine (MPTP) depletes the dopamine content of PC-12 cells and kills them in millimolar concentrations, and by Snyder and D'Amato (Neurology, 36, 1986) that methylphenylpyridine (MPP^+), the oxidation product of MPTP, is 20-50-times more toxic to PC-12 cells than MPTP. In this study, we found dopamine to be as potent as MPP^+ in killing PC-12 cells. This dopamine toxicity is due to the process or products of dopamine autooxidation; since dopamine that is allowed to autooxidize prior to addition to cells is as toxic as dopamine. It is known that oxidation of dopamine results in superoxides, hydrogen peroxide and aminochrome, a precursor of dopamine neuromelanin. We were able to show that addition of the two enzymes superoxide dismustase and catalase to the media completely protects PC-12 cells from lethal concentrations of dopamine. This study supports the hypothesis that dopamine autoxidation plays a key role in the fate of neurons in the pars compacta of the substantia nigra.

117.6 PERIPHERAL NERVE REPAIR: RELATIONSHIP BETWEEN FUNCTIONAL RECOVERY AND THE IDENTITIES OF REGENERATED MOTONEURONS. J.E. Swett, R.P. Wikholm*, Y. Torigoe, R.H.I. Blanks. Dept. of Anatomy and Neurobiology and Dept. of Surgery, Div. of Otolaryngol.-Head & Neck Surgery, U.C.I., Irvine, CA 92717.

There are often serious problems with conventional repairs of severed peripheral nerves, including poor functional recovery, and/or painful neuroma formation. The amount of recovery depends on factors such as the type of injury (crush, tear, cut), the number of neurons that survived axotomy, the type of nerve repair used and the skill with which it is effected. We describe here an anatomical model for evaluating the consequences of nerve injury and the quality of nerve repair techniques in conjunction with measurement of behavioral recovery. The left sciatic nerve was crushed or cut at mid-thigh levels under deep anesthesia in 57 rats. Crush injuries were allowed to recover without intervention while the cut nerves were reconnected either by epineurial sutures or by a new freeze-trim technique (de Medinaceli et al., Exp. Neurol. 81:488, 1983). Behavioral recovery was measured from weekly records of the animals' walking tracks to obtain the sciatic functional index (SFI) (*ibid.* 77:634, 1982). When behavioral recovery reached a plateau, the common peroneal nerves on both sides were labeled with HRP in the popliteal fossa to obtain accurate numbers of regenerated motoneurons according to the methods of Swett et al. (Exp. Neurol. 93:227, 1986). Their identities were also determined from their topographic locations in the ventral horn. Crush injuries recovered to normal. Freeze-trim repairs were 300-400% better, functionally, than epineurial repairs. Functional recovery did not relate well to the total number of motoneurons that regenerated axons into the peroneal nerve distal to the site of injury. The correlation coefficient was minimal ($r = -0.04$). Conversely, when the amount of functional recovery was compared with the proportion of the regenerated population that was composed of original peroneal motoneurons, the correlation coefficient was very high ($r = 0.88$), producing a regression line intercepting the abscissa at a value of 50% correct proportion for 0% functional recovery. This lower intercept implies that more than half of the regenerating motoneurons contributing axons to a given tributary branch must be correct (original) occupants if there is to be any recovery at all. The other intercept is at 100% functional recovery when the regenerated population is composed entirely, or nearly so, of original peroneal motoneurons, the condition prevailing in crush injuries.

In summary, recovery of motor performance, following surgical nerve repair, was independent of the number of regenerating motoneurons, *per se*. It was best correlated with conditions that favored a return of greater proportions of motoneuronal axons into their original tributary branches. The technique used for surgical repair can have a profound effect on improving the probability that regenerating axons will return to their proper branches. This combined quantitative anatomical and behavioral model is effective for evaluating nerve repair techniques. (Supported by grants NS-17630 and NS-23707 from NIH)

117PO MISDIAGNOSIS OF SPINAL CORD INJURY IN HUMANS. J. Walker. 881 Alma Real Dr., Pacific Palisades, CA 90272,

A complete lesion of the spinal cord is defined by the absence of voluntary motor control, sensation, or proprioception below the lesion. Much of our knowledge of complete injury stems from the pioneering work of Riddoch (Riddoch, G. Brain, 40: 264, 1917) who studied spinal cord injuries caused by transection by machine gun fire. The term "transection" survives in the lexicon of rehabilitation settings to this day, although the overwhelming majority of cases with spinal cord injury are now due to motor vehicle accidents and sports injuries. I now report that the term "complete" spinal cord injury is greatly overused.

There is controversy about when the diagnosis of complete injury should be made. Some claim that the diagnosis should be given 24 to 48 hours after the injury. Other authorities prescribe serial neurological testing for up to two years after the injury (Guttmann, L.S., Spinal Cord Injuries, Blackwell, Great Britain, 1976).

In this study, 99 subjects with chronic traumatic spinal cord injury received a full day evaluation one to 16 years after the trauma. The evaluation consisted of a somatosensory evoked potential, video-taped examination of the motor system, and complete physical and neurological examination. Our diagnosis was then compared to the initial one obtained from medical records. Sixty of the 99 subjects were originally labelled as "complete". The error rate for "complete paraplegia" was 57 out of 60, or 95%.

There are 500,000 people with chronic SCI with an additional 10-15,000 occurrences each year. Even a diagnostic error of 50% would lead to a misdiagnosis of hundreds of thousands of patients. This misdiagnosis gives the patient false pessimism and hopelessness about the possibility of functional improvement and often discourages even minimal participation in pulmonary (Walker, J. and Cooney, M.M., New Eng J Med, 316: 486, 1987) and cardiovascular programs (Cowell, L.L., et al, Med Sci Sports Exercise 18: 501, 1986) which could benefit the patient.

118.1 AUTORADIOGRAPHIC LOCALIZATION OF SUBSTANCE P BINDING SITES IN THE GUINEA-PIG VAS DEFERENS. E. Burcher* and C.J. Mussap* (SPON: B.G. Livett). Biological & Health Sciences, Deakin University, Vic. 3217, Australia.

In this work, we have investigated the presence of binding sites for radiolabeled substance P (SP) in the guinea-pig vas deferens, using in vitro labeling and autoradiography. Slide mounted frozen sections were preincubated in 50 mM Tris HCl (pH 7.4) with 0.02% BSA, then incubated for 2 hours in the same solution with the addition of peptidase inhibitors, 3 mM $MnCl_2$ and 0.1 nM of [^{125}I]-Bolton-Hunter labeled SP (BHSP), prepared and purified as described previously (Burcher et al., *JPET* 326, 819, 1986). Slides were then rinsed in icecold Tris and deionized water, dried, fixed, defatted and coated with Kodak NTB-3 emulsion, exposed for up to 14 days before being developed, stained with pyronin Y and viewed using light and dark field microscopy. Nonspecific binding was defined using 1 μM unlabeled SP. Dense numbers of binding sites were seen in sections labeled with BHSP. Specific binding sites were found over all three smooth muscle layers of the vas deferens, especially the innermost longitudinal layer, with no specific binding seen over the mucosa.

In the guinea-pig vas deferens, SP enhances the twitch response to transmural stimulation, and also has a direct contractile effect on the smooth muscle (von Euler and Hedqvist, *Acta Physiol. Scand.* 90, 651, 1974). SP-like immunofluorescence is found in smooth muscle, adventitia and epithelia of the guinea-pig vas deferens, (Alm et al., *Neurosci.* 3, 419, 1978). The present data showing binding sites for BHSP on smooth muscle of the guinea-pig vas deferens are in accordance with previous findings suggesting a role for SP in this tissue.

118.2 ISOLATION, PURIFICATION AND IDENTIFICATION OF SUBSTANCE P MEMBRANE RECEPTORS. M. L. SWENBERG*.(SPON: D. M. Chuang). Hypertension and Endocrine Branch, NHLBI, NIH. Bethesda, MD 20892.

Considerable progress has been achieved in the last few years in localization of substance P (SP) receptors (Rc) and their binding properties. However there are no reports of isolation and purification of the SP receptors (SPRc). Therefore we searched various tissues enriched with SPRc as source for these sstudies.

Fresh frozen tissue sections (20 μ) of brain, olfactory bulb, intestine, stomach and uterus from decapitated Sprague Dawley rats were mounted on slides and dried under vaccum at 4°C overnight. SP receptors were localized with ^{125}I-SP labeled with Bolton-Hunter reagent(BHSP). Isolated membranes of olfactory bulb and intestinal mucosa were extracted with 1% Chapso(3[(3-cholamidopropyl) dimethylammonio]-2-hydroxy-1-propanesulfonate) and the extracts were centrifuged and supernatant was purified with G-25 column to remove surfactant, then with wheat germ lechtin affinity column and eluted with N-acetylglucosamine. Further purification and chemical identification were carried out by isoelectric focusing electrophoresis on either sucrose gradient or acrylamide gel.

The antiserum was obtained by immunizing New Zealand white rabbits with purified olfactory receptor protein and tested on guinea pig ileum for its biological activity. The receptor proteins were tested for the binding effect of BHSP to the Anti-SP antibodies and the receptor in localization on tissue sections.

SP receptors were found most densely distributed in olfactory bulb and in all the lining tissues of hollow organs studied. Anti-SP-receptor antibodies at extremely low concentration (100,000X) exhibited stimulatory effect on SP induced contractility on guinea pig ileum. At higher concentration the antiserum alone also induced contraction on the guinea pig ileum.

Receptors isolated from olfactory bulb and intestine are different in their chemical composition. There were at least 2 components in each receptor but with different isoelectric points (IP) 6.2±0.2 and 5.4±0.2 for the brain and 5.4±0.2 and 4.5±0.2 for the intestine. Brain receptors enhanced BHSP binding with anti-SP but the intestinal receptors showed very high inhibition at the same protein concentration. Since the bound and free BHSP were separated by dextran coated charcoal that bound the free, the inhibition shown by the intestinal receptor might be due to the inability of charcoal to distinguish between the BHSP-Rc(intestine) and BHSP.

The results shown above in addition to the specific binding of BHSP to receptor affinity gel(1 ml of Affi-Gel-10 coupled with SPRc of 100 ng/ml) strongly suggest that the proteins obtained in this study are indeed SP receptors.

There are different chemical properties between the receptors isolated from olfactory bulb and intestine.

118.3 A GTP-INSENSITIVE COMPONENT OF HIGH AFFINITY SUBSTANCE-P BINDING TO RECEPTORS FROM RAT SALIVARY GLAND. J.A. Luber-Narod, N.D. Boyd,* B. Oblas,* and S.E. Leeman. Dept. of Physiology, Univ. of Mass. Med. Ctr., Worcester, MA 01655

A component of ^{125}I-Bolton Hunter conjugated substance P (^{125}I-BHSP) binding to membrane-bound and 0.5% digitonin solubilized receptors from rat submaxillary gland is dependent on coupling to a GTP-binding protein. We report here that there is an additional GTP-insensitive component. 10-20% of the total equilibrium ^{125}I-BHSP binding to submaxillary gland membrane-bound receptors is uneffected by incubation with a maximal concentration of GppNHp (100 μM). 20-40% of the binding of ^{125}I-BHSP (assayed via filtration after precipitation with protamine sulfate and polyethylene glycol) remains bound to prelabeled digitonin-solubilized receptors after 30 min in the presence of GppNHp (100 μM). Using Scatchard analysis, the affinity of the residual ^{125}I-BHSP membrane-bound sites is similar to the affinity before GppNHp treatment. Kinetic analysis of ^{125}I-BHSP dissociation from membrane-bound and digitonin-solubilized receptors also indicates a GppNHp-insensitive component. Rates assessed at 4°C in the presence of 100 μM GppNHp are biphasic with an initial rapid phase ($T_{1/2}$ = 4 min) and a second slow phase ($T_{1/2}$ = 120 min). This second phase is similar to the rate seen in the absence of GppNHp indicating that a fraction of the sites are not effected by GppNHp. Alkaline (pH 11.5, 30 min) pretreatment of submaxillary gland membranes, a method known to inactivate guanine nucleotide binding proteins, partially inhibits ^{125}I-BHSP binding leaving a residual, insensitive component constituting 10% of total ^{125}I-BHSP binding. Likewise pretreatment of the membranes for 1/2 hr. with varying concentrations (0.01-10mM) of the sulfhydryl reagent N-ethylmaleimide prior to incubation with ^{125}I-BHSP decreases the total equilibrium binding with a maximal effect at 0.1mM leaving a residual insensitive component of ~20% which is not inhibited even at much higher concentrations.

We conclude that while a guanine nucleotide-binding protein is necessary for high affinity ^{125}I-BHSP binding to the majority of receptors in the rat submaxillary gland, 10-20% of the ^{125}I-BHSP binding sites are not coupled to such a protein and may have a different mode of action.

118.4 RECONSTITUTION OF HIGH AFFINITY SUBSTANCE P-BINDING BY PURIFIED GUANINE NUCLEOTIDE REGULATORY PROTEINS. N.D. Boyd,* J.A. Luber-Narod, B. Oblas* and S.E. Leeman. Dept. of Physiology, Univ. of Mass. Med. Ctr., Worcester, MA 01655

The binding of substance P (SP) to receptors in both neuronal and non-neuronal tissues is subject to regulation by guanine nucleotides suggesting the possibility of a functional interaction between SP receptors and guanine nucleotide-binding regulatory proteins (G-proteins). To provide more direct evidence for the role of a G-protein in the high affinity binding of SP to its receptor, a receptor-enriched membrane preparation from rat submaxillary gland membranes was pretreated with buffer at pH = 11.5, conditions that have been shown to inactivate both G_s and G_i and to decrease high affinity agonist binding to receptors that are regulated by these proteins. Scatchard analysis of the binding of ^{125}I-Bolton Hunter conjugated SP (^{125}I-BHSP) to alkaline treated membranes indicated a decrease in the B_{max} of about 90%. To confirm that this loss of high affinity binding was due to an effect of alkaline treatment on a G-protein rather than on the SP receptor, alkaline treated membranes were reconstituted with a purified preparation of G-proteins (G_i/G_o) from bovine brain. Reconstitution was achieved either by PEG-induced fusion with G-protein containing phospholipid vesicles or, more simply, by incubation of the treated membranes with the 0.3% cholate solubilized G-protein preparation and gradual 20-fold dilution of the detergent. Under both conditions, increasing the amount of G_i/G_o resulted in a concentration dependent restoration of high affinity ^{125}I-BHSP binding. A maximal effect (about 80% recovery of the GTP-sensitive high affinity binding, Kd = 1nM) was achieved at a 150-200 fold molar excess of G-proteins over SP receptors. These results indicate that a G-protein is the target of alkaline treatment and that reconstitution with G_i and/or G_o can restore the high affinity agonist binding. The relative ease and sensitivity of this reconstitution assay indicates that it can be used in the identification and isolation from rat salivary gland of specific G-proteins capable of functionally coupling to SP receptors.

118.5 **OPPOSITE EVOLUTION OF SUBSTANCE P AND ELEDOISIN BINDING SITES IN THE VERTEBRATE BRAIN: APPARENT ABSENCE OF THE NK3 RECEPTOR SUBTYPE IN THE HUMAN BRAIN.** M.M. Dietl* and J.M. Palacios (SPON. W. Sieghart). Preclinical Research, SANDOZ LTD., Basle, Switzerland, CH-4002.

Quantitative receptor autoradiography was used to examine the characteristics and distribution of tachykinin receptor subtypes in vertebrate brains. [^{125}I]Bolton-Hunter substance P (BHSP) was used to label the SP-P (NK1) subtype, [^{125}I]Bolton-Hunter substance K (BHSK) for the SP-K (NK2) and [^{125}I]Bolton-Hunter eledoisin (BHEle) for the SP-E (NK3) receptor subtypes. BHSP binding sites were present in low densities in the brains of lower vertebrates such as fish, frog and snake. An increase in BHSP binding was observed in pigeons and all mammalian species investigated, including man. In contrast, BHEle binding sites were rich in fish, frog, snake, pigeon and rat brains, but decreased in some mammals (mice, guinea-pig, cat) and were apparently absent in monkey and human brains. BHSK labeled sites with a distribution similar to that detected by BHEle. In species presenting both tachykinin receptors, the regional distribution of these two subtypes was different. Some species differences in the distribution of BHSP binding sites or BHEle binding sites were also observed. SP-E (NK3) receptors were enriched in the accessory olfactory bulb, the intermediate layers of the neocortex, portions of the hippocampus, hypothalamic supra-optic and paraventricular nuclei, central portions of the interpeduncular nucleus, substantia nigra, solitary tract and substantia gelatinosa of the spinal cord. SP-P (NK1) receptors were enriched in the olfactory bulb (plexiform layers), corpus striatum, hippocampus, septum, certain thalamic nuclei, superior colliculus and substantia gelatinosa of the spinal cord, the neocortex being moderately labeled and the substantia nigra showing no significant densities. We conclude that in the vertebrate brain an opposite evolutionary trend is observed for two of the subtypes of the tachykinin receptors. SP-P (NK1) receptors appear to be preserved during evolution and increase in density and regional distribution in higher vertebrates. The contrary occurs with the SP-E (NK3) receptors, which are more abundant in the lower vertebrates and apparently are absent from the human brain. These results suggest that the predominant tachykinin peptide in the human brain is probably SP.

118.6 CHARACTERIZATION OF SUBSTANCE P RECEPTOR ON CULTURED RAT ASTROCYTES. C.W. Shults,o+ P. Johnston,*o+ and J. Bressler++: oVA Med. Ctr. V-127, San Diego, CA 92161, +Dept. Neurosciences, Univ. of Calif., San Diego, La Jolla, CA, ++Lab. Neurobiology, NINCDS, Bethesda, MD.

In astrocytes cultured from the cortices of neonatal rat pups the stimulation of cAMP production by norepinephrine has been shown to be modified by substance P (Rougon, G. et al., Nature 305:715-717, 1983). We have characterized the substance P (SP) receptor in cultured rat astrocytes. Primary cultures of glial cells were prepared from the cortices of 1-2 day-old rat pups. After the cells had become confluent, purified cultures of astrocytes were prepared by shaking the cultures on an orbital shaker at 250 rpm overnight and then subculturing the astrocytes, which remain adherent to the flask (McCarthy K.D. and de Vellis, J., J. Cell Biology, 85:890-902, 1980). Subcultured astrocytes were plated at 100,000 cells/cm^2 and binding studies were performed 2-3 weeks later. Our radioligand was SP labelled with ^{125}I by the Bolton Hunter method (^{125}I-BH-SP). Pharmacological characterization of the ^{125}I-BH-SP binding site by use of competition studies with related tachykinins and fragments of SP demonstrated a pattern similar to that previously demonstrated in the rat brain using in vitro homogenate and section binding techniques and in cultured mouse neurons. The IC_{50}'s were:

SP	$7.2\pm2.5 \times 10^{-10}$M
physalaemin	$6.2\pm0.8 \times 10^{-9}$M
neurokinin A	$4.0\pm0.9 \times 10^{-8}$M
neurokinin B	$7.0\pm2.2 \times 10^{-8}$M
SP 2-11	$3.2\pm0.8 \times 10^{-9}$M
SP 4-11	$3.0\pm2.1 \times 10^{-8}$M
SP 6-11	$7.2\pm4.0 \times 10^{-7}$M
SP-COOH	$>1 \times 10^{-6}$M

The pharmacologic studies indicate that the receptor has relatively low affinity for neurokinin A and B, tachykinins also found in the rat brain which share a common carboxyl terminus with SP. Also, sequential elimination of the amino terminus amino acids causes a progressive reduction in affinity. Finally, the amide group on the carboxyl terminus appears to be crucial for binding as demonstrated by the weak displacement of SP-COOH. Saturation studies and Scatchard analysis indicated that SP bound to the receptor with high affinity K_D-$8.9\pm1.9 \times 10^{-10}$M, B_{max} - 11.8 ± 5.7 fentomoles/2 cm^2 well. The Hill coefficient was 0.94 ± 0.06.

These studies provide characterization of the SP receptor studied previously by Rougon and extend the work of Torrens and his coworkers (Torrens, Y. et al., Proc. Nat. Acad. Sci., U.S.A., 83:9216-9220, 1986) which characterized a SP receptor in cultured mouse astrocytes.

118.7 DEVELOPMENTAL CHANGES OF SUBSTANCE P RECEPTORS IN THE RAT BRAIN. C.G. Charlton and C.J. Helke, Meharry Medical College, Nashville, TN and USUHS, Bethesda, MD.

Studies of the physiology and the distribution of receptors and immunoreactivity for substance P (SP) show a role of SP in neuronal functions. These functions show ontogenic changes, which if mediated by SP, suggest that the peptide and its receptors may also undergo postnatal changes. Interestingly, ontogenic changes of SP-like cell bodies and SP receptors have been reported. However, receptor changes in specific brain nuclei, that may be related to the actions of SP, were not studied. In this study membrane homogenate binding and light microscopic autoradiography of binding of ^{125}I-Bolton-Hunter SP were used to characterize SP receptors and study their ontogeny in specific brain nuclei in rats.

The binding was saturable and reversible, with an IC50 of 0.1 nM. Two classes of receptors with Kds of 0.07 and 5.9 nM and Bmax of 23 and 130 fmol/mg protein, respectively, were identified in whole rat brain. The autoradiograms showed that binding in the motor (MC) and somatosensory (SSC) frontoparietial cortex of 1 and 3 day old pups was of low density and poorly laminated, but increased in density and lamination as the rats aged. The reverse occurred in the primary olfactory cortex (POC), where the density of binding was higher in the 1 and 3 day old pups than in older rats. SP binding in the caudate-putamen, septum and nucleus accumbens varies inversely to age. SP receptors in the hindbrain of young pups were diffusely distributed and of higher density than in older rats, in which the receptors became more defined and distinct in the nucleus ambiguus, nucleus of the solitary tract, hypoglossal nucleus and the dorsal motor nucleus of vagus. Membrane homogenate studies showed that the ratio for the concentration (CPM/mg protein) of specific binding was 9: 2.5:2:1 for rats 11, 38, 90, and 260 days, and the ratio for the total bound/brain was 2.5:2.1:2:1. These data suggest that the inverse relationship of the mean density of SP receptors to age was not due entirely to increases in brain mass.

The high density of SP receptors in the POC in rat pups may be correlated with the early maturation of olfactory processes. Conversely, the low density of receptors in the MC and SSC may be correlated with the undeveloped motor and somatosensory processes in young rats. Similarly, the ontogenic changes of receptors in the hindbrain nuclei may be related to developmental changes in the functions that these nuclei subserve.

118.8 BIOSYNTHESIS AND GLYCOSYLATION OF THE LYMPHOCYTE SUBSTANCE P RECEPTOR. M.L. Organist*, J.P. McGillis, D.G. Payan* (SPON: Z. Hall). Dept. of Medicine and Howard Hughes Medical Institute, University of California, San Francisco, San Francisco,CA 94143

Cellular membrane receptors for the neuropeptide Substance P (SP) have been identified in the CNS, on human peripheral blood T lymphocytes, and in the cultured lymphoblast cell line, IM-9. In addition to its neurotransmitter properties, SP exhibits immuno- stimulatory activities which include the enhancement of T cell proliferation. Results from the present studies suggest that the lymphocyte SP receptor is translated as a precursor protein that is glycosylated.

IM-9 lymphoblasts were incubated for 14 hrs in the presence of ^{35}S-met with or without 3 ug/ml of tunicamycin. Cells were lysed and the SP receptor proteins were immunoprecipitated with a monoclonal antibody directed against the receptor, αSPR. SDS-PAGE analysis of untreated cellular lysates revealed specifically precipitated proteins of 38 kD and 33 kD. In tunicamycin treated cells, whose SP binding was not effected, the major immunoprecipitated protein had an apparent mw of 29 kD. Further glycosylation studies were done on the immunoprecipitated 38 kD receptor protein which had been separated on SDS-gels. To characterize the types of N linked sugars present, the 38 kD protein was digested with the enzymes N-glycanase, endoglycosidase F, and neuraminidase which cleave all N linked sugars, high mannose and complex carbo- hydrates and sialic acid residues, respectively. N-glycanase and Endo F both cleave the 38 kD receptor to a protein of 30 kD and neuraminidase causes a shift of 2 kD to give a protein of 36 kD. These studies indicate that the mature SP receptor is a glycoprotein of 38 kD with complex N-linked carbohydrates present.

Post translational processing of the receptor was studied by pulse chase analysis with ^{35}S-met. SDS-PAGE analysis of immunoprecipitates of cells pulsed with ^{35}S-met and chased with an excess of cold met for time periods of 30 min to 18 hrs identified 3 proteins of molecular weights 38 kD, 36 kD and 33 kD. Pulse chase analysis of IM-9 receptor proteins on cells downregulated by preincubation with SP suggested that expression of the receptor is regulated in part by the ligand. Preincubation of IM-9 cells with 1 uM SP for an 18 hr period decreases the number of active SP receptors by 60%, which correlates well with the decrease in receptor biosynthesis seen in pulse chase analysis. Studies are being done to determine if this decrease is due to increased receptor degradation, decreased receptor synthesis and/or receptor mediated endocytosis. In summary, the SP receptor on lymphoblasts appears to be a 29 kD protein which is glycosylated with complex N-linked sugars to form a mature receptor protein of MW 38,000.

118.9 TACHYKININ NK-2 RECEPTORS IN HAMSTER URINARY BLADDER POSSESS A SIMILAR SENSITIVITY TO CATIONS AND GUANINE NUCLEOTIDES BUT A DIFFERENT PHARMACOLOGICAL BINDING PROFILE COMPARED TO NK-1 RECEPTORS IN RAT SALIVARY GLAND. S.H. Buck, M.M. Racke* and J.L. Krstenansky*. Merrell Dow Res. Institute, Cincinnati, OH 45215

Physiological investigations and ligand binding studies have led to the hypothesis that there are three mammalian tachykinin peptide receptors: NK-1 with preferential affinity for substance P (SP), NK-2 with preferential affinity for neurokinin A (NKA), and NK-3 with preferential affinity for neurokinin B (NKB). In the periphery, some tissues seem to contain NK-1 and NK-2 receptors (e.g., rat bladder), some seem to contain only NK-1 (e.g., rat salivary gland), and some seem to contain primarily NK-2 (e.g., hamster bladder). We have used the latter two tissues in standard filtration binding assays to compare the biochemical and pharmacological profiles of NK-1 and NK-2 binding sites. In hamster bladder membranes, ^{125}iodohistidyl^{1}-NKA (INKA) binding was linear with tissue concentration, 80-90% specific, and was saturated at 10-15 nM. Scatchard analysis revealed a K_D of 4 nM and B_{max} of 10 fmole/mg tissue. Specific binding was enhanced by $Mn^{++} > Mg^{++} > Ca^{++}$ with an optimal effect at 2 mM Mn^{++}. The Mn^{++} effect was attributable to a reduced K_D (1 nM) and an increased B_{max} (15 fmole/mg tissue). Mn^{++} reduced the INKA association rate and markedly increased the dissociation $T_{1/2}$. Monovalent cations inhibited binding only at concentrations well above 100 mM. GppNHp inhibited up to 60% of INKA binding with an IC_{50} of 30 nM in the presence of Mn^{++} and 3 µM in the absence of Mn^{++}. AppNHp was inactive up to 10 µM. INKA binding was antagonized by preincubation of bladder membranes with phenoxybenzamine (PBZ) concentrations as low as 30 µM whereas salivary binding of ^{125}I-Bolton-Hunter-SP (BHSP) was only slightly inhibited by 300 µM PBZ. In competition of bladder INKA binding, NKA (K_I = 1 nM) was the most potent followed by KAS>ELE>NKB>SP>PHYLLO>PHY>UPE. NKA(3-10) (K_I = 1 nM) was as potent as NKA whereas NKA(5-10) (K_I = 200 nM) was much less potent and NKA(1-5) and NKA (1-7) were inactive up to 10 µM. Phosphatidylinositol (PI) turnover was stimulated by NKA (EC_{50} = 10 nM) and other tachykinins in a similar rank order in bladder tissue. In competition of salivary BHSP binding, SP (K_I = 0.2 nM) was the most potent followed by PHYLLO>PHY>NKA>UPE>ELE>KAS>NKB. SP(2-11) (K_I = 0.3 nM) was as potent as SP whereas SP(3-11) and smaller fragments were substantially less potent. SP N-terminal fragments were inactive up to 10 µM. NKA(3-10) and NKA(5-10) were weak competitors (K_I = 100 nM) of BHSP binding. The dogfish, NKA-like cyclic tachykinin scyliorhinin II (SCY II) and SCY II(7-18) had poor affinity for NK-2 sites (K_I = 1000 nM each) whereas SCY II (K_I = 200 nM) had higher and SCY II(7-18) (K_I = 5000 nM) had lower affinity for NK-1 sites. Thus, NK-1 and NK-2 receptors possess pharmacologically distinct agonist affinity profiles but similar biochemical characteristics and linkage to the inositol phosphate second messenger system.

NEUROENDOCRINE CONTROLS: PITUITARY III

119.1 ONTOGENY OF PROOPIOMELANOCORTIN-DERIVED PEPTIDE HORMONE SECRETION IN THE RAT PITUITARY GLAND. D.I. Lugo and J.E. Pintar. Dept. of Anatomy and Cell Biology, Columbia Univesity P&S, New York, NY 10032.

Proopiomelanocortin (POMC)-producing cells are present in both the adult anterior lobe (corticotrophs, 5-10%) and intermediate lobe (melanotrophs 100%). Both cell types are derived from a single embryonic rudiment (Rathke's pouch) and synthesize the same precursor but differ in their adult pattern of precursor processing and regulation of hormone secretion. Anterior lobe (AL) secretion is primarily regulated by CRH(+) and glucocorticoids(-), while intermediate lobe secretion is regulated negatively by dopamine. No study thus far has assessed directly the secretory capabilities of POMC producing cells prior to birth. Here we have utilized the reverse hemoloytic plaque assay to study the ontogeny of basal and regulated secretion by POMC producing cells during rat pituitary development. Basal secretion of B-endorphin from trypan blue excluding cells was first observed at embryonic day 13.5 (e13.5), the first age when POMC-related peptides were first detected immunocytochemically, and decreased with developmental age. CRH (10^{-9}M)-stimulated secretion was not detectable until e15.5. Beginning at e17, the anterior and neurointermediate lobes were assayed separately. CRH (10^{-9}M) increased both the amount of peptide secreted by individual corticotrophs and the number of detectable secreting corticotrophs in the AL. The slides were subsequently processed for B-endorphin immunocytochemistry. It was observed that even upon addition of CRH (10^{-7}M) approximately 23% of the anterior lobe-derived cells that were immunostained did not secrete detectable levels of B-EP related peptides.

Inhibition by glucocorticoids (dexamethasome 10^{-6}M; 1 hr pretreatment) of CRH (10^{-7}M)-stimulated secretion was observed in corticotrophs at the earliest stages thus far examined (e17.5). The plaque size following glucocorticoid inhibition was similar to that from non-CRH stimulated cells. CRH (10^{-7}M) stimulation of IL melanotroph secretion was first observed at e19 and continued postnatally. Dopamine (10^{-6}M) inhibition of melanotroph secretion was observed at the earliest stages examined (e17.5).

These results demonstrate that the POMC cells of the rat pituitary gland are capable of hormone secretion as early as peptides are first detected immunocytochemically (Lugo and Pintar, in submission). Moreover these cells respond in-vitro to physiological regulators in an adult-like manner many days prior to birth. The latter results demonstrate that these cells possess functional regulatory receptor systems prior to maturation of the hypothalamic-hypophyseal portal system.

119.2 GONADAL STEROID TREATMENT DOES NOT CHANGE BRAIN POSTTRANSLATIONAL PROCESSING OF β-ENDORPHIN L.A. Berglund*, W.R. Millington, C. Manzini*, G.P. Mueller, J.W. Simpkins, Department of Pharmacodynamics, University of Florida, Gainesville, FL 32610 and Department of Physiology, USUHS, Bethesda, MD 20814

Our previous studies demonstrated reduced sensitivity to morphine in female rats treated with ovarian steroids. Morphine responses appeared to be inversely related to the magnitude of the steroid-induced LH surge, suggesting that the mechanisms which mediate morphine effects are rendered insensitive during the LH surge. The present study was undertaken to determine if a steroid-induced change in the posttranslational processing of β-endorphin (β END) may account for the observed desensitization to morphine. We examined the effects of ovarian steroid treatments on posttranslational processing of β END in the preoptic area (POA), medial basal hypothalamus (MBH), brainstem (BS) and neurointermediate lobe of the pituitary (NIL). Ovariectomized rats received no steroids; 7.5 ug estradiol benzoate at 1000 h 2 days before the experiment; or EB treatment at 1000 h and 5 mg progesterone 48 h later. At 1600-1700 h rats were decapitated and tissues were removed and frozen on dry ice until extraction by boiling in 1N acetic acid for 20 min and sonication. β END peptides were separated by ion-exchange chromatography using a SP-Sephadex C-25 column and eluted with 50% acetic acid solution containing a NaCl gradient (0.05 to 0.55M). Fractions (1 ml) were lyophilized and reconstituted in assay buffer, and β END was measured by RIA. Each treatment group (n = 10) was run twice with sample pools from 5 rats each. NIL samples demonstrated the highest degree of posttranslational β END processing with 93% of the β END activity eluting as N-acetyl- β END (1-26, 1-27, or 1-31) and 3% eluting as β END 1-31. MBH and POA areas contained β END activity eluting as β Lipotropin, β END 1-31, β END 1-27 and β END 1-26 in equal amounts and less than 1% eluting as N-acetylated peptides. BS tissues exhibited β END 1-31 as the primary product, with smaller quantities eluting as β END 1-26 and β END 1-27. Less than 2% eluted as N-acetylated peptides. None of the brain regions examined in this experiment demonstrated any differences in total β END or posttranslational processing patterns due to steroid treatment. These data indicate that the decreased responsiveness to morphine associated with the steroid-induced LH surge cannot be explained by total β END content changes or by β END biological activity changes due to differential posttranslational processing products. Supported by AG 02021 and USAMRDC 86PP6813.

119.3 ACUTE STRESS AND CHRONIC STRESS RELEASE DIFFERENT FORMS OF B-END-IR FROM ANTERIOR LOBE. E.A. Young and H. Akil (Spon: J.F. Greden). Mental Health Research Institute, University of Michigan, Ann Arbor, Michigan, 48109.

We have previously reported that anterior lobe releases 2-fold more B-endorphin than B-LPH with acute stress in vivo or with oCRF stimulation of short-term anterior lobe suspension in vitro. This occurs despite the presence of B-LPH as the predominant form of B-endorphin-IR in anterior pituitary. The continued release of B-endorphin over B-LPH is also observed in short-term anterior lobe suspension from control and acutely stressed rats, despite the depletion of ACTH and B-endorphin content to 80% of control. This suggests an extremely rapid replenishment of the B-endorphin stores with acute stress. This is confirmed by pulse chase biosynthetic studies of POMC biosynthesis and processing by Shiomi, Kelsey and Akil in anterior lobe following acute stress.

Chronic footshock stress induces the anterior lobe leading to a doubling of the content of ACTH, B-END and B-LPH. It does not appear to induce changes in the ratio of B-LPH to B-END in the anterior lobe between control and chronically stressed animals. Although the anterior pituitary of chronically stressed rat stores normal ratios of B-LPH:BE (2:1), when the animals are restressed, B-LPH is the predominant form of B-endorphin-IR released with a ratio of B-END to B-LPH of 0.8:1. In short-term anterior lobe suspensions, we see this same change in oCRF stimulated release from predominantly B-END (2:1 ratio) to equimolar release of B-END to B-LPH (1.1:1). Again, this same stress paradigm has been demonstrated to decrease the rate of processing of POMC precursor to B-LPH and B-endorphin (Shiomi, Kelsey and Akil). Since this change in processing may be related to chronic CRF drive, we examined plasma from 7 day and 14 day adrenalectomized rats and see the same predominance of B-LPH over B-endorphin. This suggests that during times of high demand, the last step in the processing of B-endorphin is unable to keep pace with biosynthesis of POMC.

119.4 β-ENDORPHIN LEVELS IN TERM AND PREMATURE NEONATES FOLLOWING PERINATAL STRESS AND/OR ASPHYXIA

M.P. Leuschen, Robert M. Nelson, Jr.,* L.D. Eggert,* D.L. Bolam,* L.D. Willett*
Division of Neonatology
University of Nebraska Medical Center
Omaha, NE 68105

Plasma β-endorphin levels were evaluated in neonates in the well baby nursery (n=26) and NICU (n=121) at University Hospital, Omaha, NE within 24 hours of birth. In twenty seven NICU infants additional samples were taken at 2 week intervals during NICU hospitalization. CSF samples also were evaluated in some infants. Data were evaluated with regard to general demographics (i.e. gestational age, birthweight, Apgar scores, and whether inborn or outborn); maternal history and mode of delivery; and the infants status at the time of sampling (general diagnosis codes, respiratory status and subjective evaluation of stress level). Mean plasma β-endorphin level for normal term newborns was 35.6 ± 12.4 pg/ml (4 infants were delivered by repeat C-section; all others were vaginal deliveries). Term NICU infants (n-28) had plasma β-endorphin levels that had a biphasic distribution. While one group fell within the normal range for term well babies, the second group had elevated levels. Forty-three percent of term NICU infants had levels at least two standard deviations above the mean for normal newborns. Premature NICU infants grouped by demographic factors had significantly elevated plasma β-endorphin levels. For example, 35% of infants 25-32 weeks gestation (n=26) and 53% of infants 33-39 weeks gestation had β-endorphin levels significantly higher (95% confidence level) than normal term infants. Stress (transport, major cardiovascular defects, mild/moderate birth asphyxia and/or meconium aspiration) were correlated with a significant elevation in plasma β-endorphin. In addition, infants under long-term treatment for apnea and similar problems in respiratory control continued to exhibit elevated β-endorphin levels beyond the perinatal period. Plasma β-endorphin levels can be one means for evaluating neonatal well being particularly with regard to an infant's ability to mount a neuroendocrine stress response.

119.5 ACTH, PROLACTIN, CORTICOSTERONE AND PITUITARY CYCLIC AMP RESPONSES TO REPEATED 15 MIN ACUTE STRESS EXPOSURES SEPARATED BY 45 MIN RECOVERY PERIODS. G. J. Kant, T.E. Eggleston*, G.C. Driver*, C.C. Kenion*, E. H. Mougey* AND J.L. Meyerhoff. Dept of Medical Neurosciences, Walter Reed Army Institute of Research, Washington DC 20307-5100.

The stress-induced release of ACTH from the pituitary gland is regulated primarily via release of the hypothalamic peptide CRF. In vitro studies have shown that the release of ACTH by CRF is mediated via a cyclic AMP mechanism. We have reported that acute stress increases levels of pituitary cyclic AMP in vivo and that CRF is the most likely mediator of this in vivo response. Injection of exogenous CRF increases plasma levels of ACTH; however, plasma ACTH responses to repeated injections of exogenous CRF have been reported to be attenuated in animals receiving a second CRF injection within 2 hrs of the first. The present experiment was conducted to determine whether the responses of ACTH and pituitary cyclic AMP would attenuate upon repeated exposure to endogenous CRF generated via acute stressor exposure. Stress responses of plasma prolactin (a pituitary hormone not regulated via CRF) and corticosterone (an adrenal hormone regulated by ACTH) were also determined.

Control rats were sacrificed by decapitation immediately upon removal from their home cage. Stressed rats were exposed to one, two or three sessions of 15 min of forced running in a drum revolving at 6 rpm. Between sessions, rats were returned to their home cages for 45 min. Animals were either sacrificed immediately upon removal from their final stress session or after a 45 min recovery period. Trunk blood was collected with heparin and aprotinin (a protease inhibitor) and plasma subsequently frozen for later RIA of ACTH, corticosterone and prolactin. Pituitaries were rapidly weighed and heated in 90°C buffer to prevent post-mortem changes in cyclic AMP. Following sonication and centrifugation, supernatants were frozen until later RIA for cyclic AMP.

Acute stress quadrupled levels of plasma ACTH. In animals subjected to repeated stress exposures, the increase in plasma ACTH was similar following each stress exposure. Levels of ACTH returned to control levels after the 45 min recovery period. Pituitary cyclic AMP and other measured hormonal responses were similar to that seen for ACTH, i.e. similar responses to each stress period with return to control or near control levels between stress sessions. These results demonstrate that pituitary hormonal responses to brief stress exposures of moderate intensity do not attenuate upon repeated exposures, suggesting that the amount of CRF released by this stress is not sufficient in magnitude or duration to directly desensitize pituitary CRF receptors to a subsequent CRF stimulus 45 min later or to elevate corticosterone levels sufficiently to decrease CRF release via negative feedback.

119.6 CRF STIMULATION OF CYCLIC AMP ACCUMULATION, CYCLIC AMP DEPENDENT PROTEIN KINASE ACTIVITY AND ACTH RELEASE IN ANTERIOR PITUITARY CELLS PREPARED FROM CONTROL VERSUS STRESSED RATS. G.S. Dhillon*, C. Wormley*, C.P. D'Angelo* and G.J. Kant. (SPON= R.M Wylie) Dept of Medical Neurosciences, Walter Reed Army Institute of Research, Washington DC 20307-5100.

Corticotropin releasing factor (CRF) is a 41-amino acid peptide that is thought to be the primary physiological regulator of pituitary ACTH release. It has been suggested that the action of CRF upon ACTH release is mediated by the stimulation of pituitary adenylate cyclase and subsequent activation of cyclic AMP dependent protein kinase (A-kinase). It has been recently reported that pituitary CRF receptors are down regulated after adrenalectomy or after 48 hours of immobilization stress. After adrenalectomy pituitary adenylate cyclase is less responsive to CRF stimulation. The present experiments were conducted to compare the effects of CRF on pituitary cyclic AMP response and ACTH release in control versus chronically stressed rats. The chronic stresser in the present study was 72 hours of food restriction.

Male Sprague Dawley rats (150-175g) were limited to one hour of feeding every day for three days. Water was freely available. Control animals had free access to food and water. The rats were then decapitated and anterior pituitary cells were prepared by collagenous dispersion of freshly dissected pituitaries. For A-kinase activity and cAMP determinations, 500ul aliquots containing 0.5×10^6 and 0.25×10^6 cells respectively were first preincubated for 40 minutes and then further incubated in the presence or absence of CRF for 10 minutes at 37° C. Cells were then either lysed and supernatants assayed for A-kinase activity or heat deactivated and assayed for cAMP by RIA. The standard A-kinase assay contained 20mM MOPS pH 7.0, 16mM magnesium acetate, 0.1mM ATP, 0.4 mg/ml histone H1, 4mM dithiothreitol and ^{32}P ATP (1uCi/assay tube). Corrections were made for non-cAMP dependent protein kinases. For ACTH determinations cells were preincubated for 120 minutes and then further incubated in aliquots of 500ul containing 0.2×10^6 cells in the presence or absence of CRF for 60 minutes. Supernatants were assayed for ACTH content by RIA using an ImmunoNuclear kit.

In anterior pituitary cells from control animals, CRF stimulated cyclic AMP accumulation, A-kinase activity and ACTH release in a dose dependent manner. Five micromolar CRF increased levels of pituitary cyclic AMP over 4 fold, while A-kinase activity was stimulated three fold and ACTH release was increased two fold. In stressed animals, CRF-stimulated A-kinase activity was similar to that of control animals while cyclic AMP response was slightly less than in controls. CRF-stimulated ACTH release appeared to be significantly diminished in stressed animals in one of two experiments. Further experiments are required to definitively determine the changes in ACTH response to CRF in stressed versus control rats.

119.7 ACUTE ETHANOL ADMINISTRATION ENHANCES ANTERIOR AND INTERMEDIATE LOBE PROOPIOMELANOCORTIN-DERIVED PEPTIDE SECRETION AND PLASMA CATECHOLAMINE LEVELS. A.B. Thiagarajan,* I.N. Mefford,* S. Daggett* and R.L. Eskay*. (SPON: S. Katz) Section of Neurochemistry, Laboratory of Clinical Studies, National Institute on Alcohol Abuse and Alcoholism, Blg 10 Rm3C218, Bethesda, MD 20892.

In order to explore certain of the apparent contradictions between the acute and chronic effects of ethanol on the hypothalamic-pituitary-adrenal axis (HPAA), adult male (8-10 animals per treatment group) rats (275-300gm) received a single infusion of ethanol via a chronic indwelling intragastric catheter followed by the determination of plasma ACTH, alpha-MSH, corticosterone (CS) and catecholamines (epinephrine (EPI), norepinephrine (NOREPI), and dopamine (DA)). Blood ethanol concentrations determined at 30,60,90 and 150 min post-ethanol infusion were similiar at all sample times and ranged from 240-280 mg%. In order to obtain stress-free plasma catecholamine levels, an indwelling jugular cannula was inserted 24 hrs prior to ethanol infusion and catecholamine levels were obtained by high performance liquid chromatography. Basal EPI, NOREPI and DA levels were 105 ± 18.7 (MEAN ± S.E.), 220 ± 22.4 and 254 ± 21.6 pg/ml plasma, respectively. Following ethanol infusion, plasma EPI levels increased 6 fold at 30 min and returned to basal levels by 90 min. NOREPI levels increased approximately 2 fold by 30 min post-ethanol infusion and remained elevated for up to 2 hrs, whereas, DA levels remained unchanged. In contrast to the jugular cannula studies for obtaining catecholamine levels, rats were handled twice-a-day for 5-7 days and sacrificed by decapitation for the peptide and steroid studies. Plasma ACTH, alpha-MSH and CS levels were determined by radioimmunoassay following appropriate extraction methods. Basal plasma ACTH and CS levels exhibited a diurnal rhythm and ethanol-induced increases in ACTH and CS release, as determined 1 hr post ethanol infusion, were maximal when basal ACTH and CS were at their nadir. The maximal observed increases in ACTH and CS levels were 10- and 4-fold, respectively. Although the primary regulation of intermediate-lobe-derived alpha-MSH is quite different from ACTH release, alpha-MSH levels were also elevated by acute ethanol administration. The probable mechanistic differences of our observed changes in the HPAA following acute exposure to ethanol, as compared to our previously observed ethanol-induced changes in the HPAA following chronic-ethanol exposure, will be discussed.

119.8 RELATIONSHIP BETWEEN THE DST AND THE 5-HTP-INDUCED CORTISOL RESPONSE IN PSYCHIATRIC PATIENTS. M.T. Lowy and H.Y. Meltzer, Department of Psychiatry, Case Western Reserve University, Cleveland, OH 44106.

Failure to suppress serum cortisol following a low dose of dexamethasone (i.e. DEX suppression test; DST) and an enhanced cortisol response to the serotonin precursor, 5-hydroxytryptophan (5-HTP; 200 mg) are two abnormalities of the hypothalamic-pituitary-adrenal (HPA) axis which have been reported in psychiatric patients. The present study was designed to evaluate the relationship between these two tests of HPA function in 26 drug-free psychiatric patients (16 depressed and 10 patients with other psychiatric diagnoses). Based on a standard DST (1 mg; 5.0 ug/dl cutoff) there were 13 suppressors(S) and 13 nonsuppressors (NS). A median split procedure was used to divide patients into those with a high cortisol response to 5-HTP (5-HTP-HC; N=13) and those with a low cortisol response (5-HTP-LC; N=13).

S and NS did not differ in their cortisol response to 5-HTP (1926 vs. 2392 µg/dl x min). There were more NS in the 5-HTP-HC group (8/13) than in the 5-HTP-LC group (5/13). There was a trend for the subjects in the 5-HTP-HC group to have elevated cortisol levels at 8 a.m. (19.9 vs. 16.5 µg/dl; p=0.1) and 4 p.m. (12.9 vs. 6.8 µg/dl; p=0.06) prior to DEX administration. The 4 p.m. post-DEX cortisol (8.9 vs. 2.6 µg/dl; $p < 0.01$) and the highest post-DEX cortisol levels (10.0 vs. 4.5 µg/dl; p=0.06) levels were greater in the 5-HTP-HC group compared to the 5-HTP-LC group. The differences in post-DEX cortisol levels between the 2 groups were not due to alterations in DEX bioavailability as there were no significant differences in DEX levels between the 2 groups at either 8 a.m. (165 vs. 205 ng/dl) or 4 p.m. (29.3 vs. 41.3 ng/dl). Regression analysis indicated there were significant positive correlations between the 5-HTP cortisol response and the 4 p.m. post-DEX cortisol level ($r= 0.72$; $p < 0.001$) as well as the highest post-DEX cortisol level ($r=0.59$; $p < 0.01$).

These results suggest that a common neurochemical abnormality, possibly a decrease in brain serotonin resulting in supersensitive serotonin receptors, may contribute to both of these HPA abnormalities present in psychiatric patients.

119.9 PLASMA CORTICOSTERONE RESPONSES TO ELECTRICAL STIMULATION OF THE MEDIAL FRONTAL CORTEX. J. Dunn and D. Miller*. Dept. of Anat., Sch. Med., Oral Roberts Univ., Tulsa, OK 74171.

Recent studies conducted in this laboratory have been directed towards identifying central neural sites involved in regulating plasma corticosterone (Cpd B) levels. To date differential changes in plasma Cpd B have been observed subsequent to electrical stimulation of several forebrain areas, i.e., amygdala, bed nucleus of the stria terminalis, hippocampus and septum. Absent from our studies, however, has been an assessment of a cortical influence on adrenocortical regulatory mechanisms. The latter, in light of recent identification of a visceral cortical region prompted the present study.

To pursue the possibility that the frontal cortex is involved in adrenocortical function, blood samples obtained prior to and following electrical stimulation of the medial prefrontal cortex of female rats were assessed for corticosterone (Cpd B) concentration.

Rats, anesthetized with urethane ($1.3g \cdot Kg^{-1}$), were tracheotomized, instrumented and positioned in a stereotaxic apparatus. ECG, heart rate, mean arterial pressure, respiration and hippocampal EEG were monitored and timed blood samples (0.2ml) were obtained from a catheterized tail artery. Blood samples were taken at 0.5 min. prior to and at 5, 10, 15 and 30 min. after initiation of stimulation (monophasic square waves, 100µA, 50HZ, 0.5 msec, 1 sec on/1 sec off for 30 min.). For purposes of plotting Cpd B responses to stimulation a change in plasma Cpd B was considered different from no change when the average of the 5, 10, 15 and 30 min. samples deviated by more than 10% from the pre-stimulus level. However, statistics were derived from Cpd B responses grouped according to stimulation site.

Whereas no change in Cpd B levels were observed following sham stimulation ($p>0.05$) or stimulation of the lateral or dorsal aspects of the frontal cortex ($p>0.05$), stimulation of the the pre-limbic area (PL) of the medial prefrontal cortex ($p<0.05$) produced significant changes in plasma Cpd B levels. Stimulation of other medial frontal cortical areas were not effective in inducing changes in adrenocortical activity. The overall change in plasma Cpd B following PL stimulation was 17%, the largest increase (22%) occurred at 30 min.

These data are consistent with our previous observations and offer additional support for the concept of a medial visceral cortex.

119.10 SOMATOSTATIN REGULATES THE BRAIN-PITUITARY-ADRENAL AXIS: IN VIVO EVIDENCE. J.M. Radke and S.R. Vincent. Div. of Neurological Sci., Dept. of Psychiatry, Univ. of British Columbia, Vancouver, B.C., V6T 1W5, Canada.

Clinically, low CSF levels of somatostatin have been found to correlate with escape from dexamethasone-induced supression of the brain-pituitary-adrenal axis. There is also evidence that somatostatin can inhibit the evoked release of ACTH from anterior pituitary cells in vitro. In the present study the role of somatostatin in the supression of corticosterone secretion by dexamethasone was examined.

Male Sprague Dawley rats were group housed and handled for 1 week prior to receiving a standard dexamethasone supression test. Animals were injected at 9:00 a.m. with dexamethasone (10 µg/kg) subcutaneously and 5 hr later, at 1:00 p.m. blood samples were taken for the determination of plasma levels of corticosterone by radioimmunoassay. Immediately following the test, animals were killed and brain tissue was dissected and assayed for levels of somatostatin immunoreactivity.

Dexamethasone reduced plasma corticosterone from control values (174 ± 36 ng/ml) to undetectable levels (< 25 ng/ml). This dose of dexamethasone did not affect the levels of somatostatin in the hippocampus or hypothalamus. Subcutaneous injection of cysteamine (100 mg/kg) 5 min prior to dexamethasone, prevented the supression of plasma corticosterone. Levels of corticosterone 5 hr after injections of cysteamine alone did not differ significantly from control values. Cysteamine pretreatment was associated with a reduction in the levels of somatostatin immunoreactivity in the hypothalamus.

To block somatostatin receptors in the anterior pituitary and other peripheral sites, rats were given systemic injections of a somatostatin antagonist (cyclo [7-aminoheptanoyl-Phe-D-Trp-Lys-Thr(Bzl)]. Subcutaneous injections of this drug at 1.0 and 0.01 mg/kg had no effect on basal corticosterone levels and did not prevent the dexamethasone-induced supression of corticosterone levels. Pretreatment with this antagonist also had no effect on hypothalamic somatostatin levels.

These results suggest that a depletion of central somatostatin by cysteamine can prevent dexamethasone-induced supression of corticosterone secretion. Somatostatin neurons may therefore be involved in the feedback regulation of the brain-pituitary-adrenal axis by glucocorticoids.

Supported by the Medical Research Council of Canada.

119.11 ROLE OF CORTICOTROPIN RELEASING FACTOR (CRF) AND EPINEPHRINE ON PULSATILE ACTH SECRETION. F. J. López* and A. Negro-Vilar (SPON: M. Ching). LRDT, NIEHS, NIH, Research Triangle Park, NC 27709.

The importance of pulsatile hormone secretion for the modulation of target organ responsiveness is now clearly established. Regulation of pulsatile hormone secretion offers, perhaps, the best example of the complex neuroendocrine modulatory mechanisms that interplay to produce a coordinated pattern of episodic hormone secretion. The regulation of ACTH secretion is multifactorial, involving several secretagogues. Most of the experiments directed to analyze the physiological role of these factors involve situations of stimulated ACTH secretion. Until recently, no studies have been performed to provide a comprehensive characterization of the pulsatile pattern of ACTH release and of the factors that modulate that pattern. In the present study, we carried out experiments directed to analyze the role of a peptide, CRF, and of an amine, epinephrine, in pulsatile ACTH secretion. Intact Sprague-Dawley male rats were used. In one experiment, the animals were treated with 3 doses of α-helical-CRF (CRF antagonist). The first dose was given 5 min before the initiation of sampling (250 µg/rat) and the others (125 µg/rat), at 30 and 60 min after the bleeding started (10:00-11:00 am). Animals treated with the same volume of vehicle (PBS-BSA 1%) were used as controls. In another experiment, SKF 64139 (100 mg/kg BW i.p.), a PNMT inhibitor that crosses the brain blood barrier, was administered 12-13 h before sampling. Animals treated with saline were used as controls. In all cases, blood samples (0.15 ml) were taken through an indwelling atrial cannula during a 90 min period. A blood sample was taken every 3 min, and a replacement was given with a blood cell mixture obtained 15-20 h before from donor animals. Plasma aliquots (25 µl) were assayed for ACTH using a RIA protocol as previously reported (Nicholson et al., Clin. Chem. 30:259-265, 1984). The pulsatile ACTH pattern was analyzed using the "Cluster" analysis. α-Helical-CRF administration was not able to abolish the ACTH pulsatile pattern. We found no significant differences in the qualitative parameters of pulsatile ACTH secretion (pulse frequency, pulse duration and pulse interval). On the contrary, the treatment was able to decrease mean ACTH secretion, as well as the peak and trough values, without affecting pulse amplitude. On the other hand, blockade of epinephrine synthesis with SKF 64139 did not change any of the qualitative parameters. Nevertheless, peak values, trough values and the peak amplitude were significantly decreased. The data suggest that CRF and epinephrine affect the quantitative aspects of each ACTH pulse but not the frequency and other qualitative characteristics of the pulse. CRF, in addition, has a profound effect on maintaining mean ACTH levels probably by controlling the "gain" of the system.

119.12 INVOLVEMENT OF ALPHA-ADRENERGIC SYSTEM IN THE EFFECT OF MORPHINE ON HYPOTHALAMO-PITUITARY-ADRENOCORTICAL ACTIVITY. S.Suemaru*, M.F.Dallman*, D.N.Darlington, C.Cascio* and J.Shinsako* (SPON: M. Steele). Dept. of Physiology, University of California, San Francisco, CA 94143.

We examined the involvement of the α -adrenergic system in the effect of acutely administered morphine on the hypothalamo-pituitary-adrenocortical (HPA) activity in unstressed or stressed rats. The test substances were administered intraperitoneally (ip) or intravenously (iv) in non-cannulated or chronically cannulated (femoral artery and vein cannulas), conscious rats. In the ip experiment, prazosin (1 mg/kgBW) or vehicle was injected 45 min before morphine (2 mg/100 gBW) or saline injection. Some rats were exposed to ether vapor for 45 sec starting 15 min after the 2nd injection. The rats were decapitated 30 min after the 2nd injection and the plasma ACTH and corticosterone (B) were assayed. In the iv experiment, prazosin (0.5 mg/kgBW), yohimbine (0.5 mg/kg BW) or vehicle was injected 50 min before morphine (1 mg/100 gBW) or saline injection and 100 ul blood was taken through the cannula for plasma B assay before and 10, 20, 30, 45, 60 and 75 min after the 1st injection. Mean arterial blood pressure (MABP) and heart rate (HR) were measured throughout.

In unstressed rats, morphine markedly stimulated ACTH and B secretion. Prazosin increased plasma B levels and inhibited morphine-induced B secretion. Yohimbine also increased plasma B levels but potentiated morphine-induced B secretion additively. On the other hand, in ether-stressed rats, morphine inhibited stress-induced ACTH and B secretion and prazosin also inhibited stress-induced B secretion. Pretreatment with prazosin did not alter the inhibitory effect of morphine on stress-induced ACTH and B secretion. Prazosin caused a BP fall and tachycardia while yohimbine caused a BP rise and tachycardia. However, neither prazosin nor yohimbine affected morphine-induced enhancement of the vagal baroreflex, a pronounced bradycardia and short-lasting BP fall.

Taken together with the established concept that morphine acts in the HPA axis primarily at the level of the hypothalamus, these observations suggest that morphine acutely stimulates the secretion of corticotropin-releasing factor (CRF) or other ACTH secretagogues in the hypothalamus through a noradrenergic pathway via stimulation of α_1-adrenoceptors rather than α_2-adrenoceptors in unstressed rats and that, on the other hand, morphine may inhibit CRF secretion by attenuating the noradrenergic (α_1-adrenoceptor) activity in stressed rats. The stimulatory effect of morphine on the HPA system might be ascribed partly to the morphine-induced cardiovascular changes.

119.13 Adrenalectomy-Induced Changes in Hypophysial Portal Blood Concentrations of Corticotropin-Releasing Factor (CRF) in the Rat. J.I. Koenig, Neurology Service, Mass. General Hospital, Harvard Medical School, Boston, MA. 02114.

Several recent reports have indicated that metabolic and hemodynamic stressors change the secretion of corticotropin (ACTH) from the rat pituitary by altering the secretion of CRF and/or vasopressin (AVP) into the hypophysial portal circulation. Adrenalectomy (ADX) also is a potent stimulus for ACTH secretion. This effect is due to the removal of the negative feedback influence of the adrenal corticosteroids from the pituitary and the hypothalamus. Immunohistochemical studies have indicated that the paraventricular nucleus CRF-containing neurons produce more CRF but also begin to synthesize AVP after ADX. In fact, elevated concentrations of AVP and CRF have been reported in the median eminence after ADX. The concentration of AVP in the hypophysial portal blood of the rat also is elevated 6 days after the removal of the adrenal glands. Furthermore, the release of CRF from perifused median eminence fragments of ADX rats doubles, whereas the secretion of AVP from the same fragments increases 900%. These studies suggest that CRF may play a permissive role in controlling ACTH secretion after ADX. Therefore, the present study was undertaken to determine the effect of surgical removal of the adrenal glands on rat portal plasma concentrations of CRF. Male Sprague-Dawley rats (200-300 gm) were used in all studies. Bilateral ADX was performed under pentobarbital anesthesia. Hypophysial portal blood samples were obtained from urethane-anesthetized animals using the procedure outlined by Porter and Smith (Endocrinology 81:1182). Blood was collected in chilled plastic tubes containing aprotinin and EDTA. Plasma concentrations of CRF were determined by RIA using an antiserum purchased from IgG Corporation (Nashville, TN). Hypophysial portal plasma concentrations of CRF in urethane-anesthetized sham ADX animals were 680+170 pg/ml. One hour after ADX CRF concentrations in the portal plasma were unchanged. However, one day after ADX portal plasma concentrations of CRF were significantly lower (275+64 pg/ml). Portal plasma concentrations of CRF one or two weeks after ADX were no different than concentrations in control animals. These data suggest that after ADX, enhanced secretion of CRF may not be the primary driving force for the elevation of plasma ACTH concentration. However, CRF may play a permissive role in the activation of ACTH secretion after removal of the negative feedback influence of the adrenal steroids. This work was supported by NIH grant DK-39251.

119.14 EFFECT OF ALTERATIONS IN THE ACTIVITY OF TUBEROHYPOPHYSIAL DOPAMINERGIC NEURONS ON THE SECRETION OF ALPHA-MELANOCYTE STIMULATING HORMONE. S.E. Lindley*, J.W. Gunnet, K.J. Lookingland and K.E. Moore. Dept. Pharmacol./Toxicol., Michigan State Univ., East Lansing, MI 48824.

Alpha-melanocyte stimulating hormone (αMSH) is secreted into the blood by melanocytes located in the intermediate lobe (IL) of the pituitary. This lobe is innervated by tuberohypophysial dopaminergic (THDA) neurons, whose perikarya are located in the medial basal hypothalamus (rostral arcuate nucleus). The objective of the present study was to examine the effects of stimulation of the rostral arcuate nucleus on the activity of the THDA neurons and on the secretion of αMSH from the IL.

The activity of the THDA neurons was estimated by measuring the concentrations of the DA metabolite dihydroxyphenylacetic acid (DOPAC) in the IL using HPLC coupled to an electrochemical detector. αMSH was measured in serum by radioimmunoassay.

Male Long-Evans rats were anesthetized with gamma-butyrolactone (GBL, 1000 mg/kg; i.p.), a drug which reduces dopaminergic neuronal activity. In the present study, GBL decreased the concentration of DOPAC in the IL and increased the concentration of serum αMSH. Bilateral electrical stimulation of the rostral arcuate nucleus in GBL-anesthetized animals increased the concentrations of DOPAC in the IL and decreased serum αMSH concentrations. Increases in the concentration of DOPAC in the IL and decreases in serum αMSH were related to the intensity and duration of stimulation of the THDA neurons. In complementary studies it was found that the administration of GBL decreased and electrical stimulation of the arcuate nucleus increased the activity of tuberoinfundibular dopaminergic neurons which project from the arcuate nucleus to the median eminence; this was evidenced by alterations in the concentrations of DOPAC in the median eminence and in circulating levels of prolactin. Administration of a DA antagonist (haloperidol, 1 mg/kg, i.p.) 30 min prior to starting electrical stimulation of the arcuate nucleus prevented the stimulation-induced decline in serum levels of αMSH and prolactin. These results indicate that stimulation-induced increases or GBL-induced decreases of THDA neuronal activity are reflected in changes in the metabolism of DA in the IL and in the secretion of αMSH. (Supported by NIH grant NS15911.)

119.15 EFFECTS OF ACUTE RESTRAINT STRESS ON THE ACTIVITIES OF TUBEROINFUNDIBULAR AND TUBEROHYPOPHYSIAL DOPAMINERGIC NEURONS AND ON THE SECRETION OF PROLACTIN AND ALPHA-MELANOCYTE STIMULATING HORMONE IN MALE AND FEMALE RATS. K.J. Lookingland, J.W. Gunnet and K.E. Moore. Dept. of Pharmacol./Toxicol., Michigan State Univ., E.Lansing, MI 48824.

Dopamine (DA) neurons comprising the tuberoinfundibular (TI) and tuberohypophysial (TH) DA systems have cell bodies located in the arcuate nucleus and axons that project to the median eminence (ME), and the intermediate (IL) and neural lobes (NL) of the posterior pituitary gland, respectively. Acute restraint stress increases prolactin (PRL) concentrations in the serum and this is associated in the female rat with a decrease in the activity of TIDA neurons (Demarest et al., 1985, Neuroendocrinol. 41: 437; Neuroendocrinol 41: 504). By contrast, little is known regarding the effects of stress on the secretion of hormones from the posterior pituitary and the activity of THDA neurons. In the present study the effects of acute restraint stress on plasma alpha-melanocyte stimulating hormone (αMSH) concentrations and the activity of THDA neurons were compared in male and diestrous female rats. The activity of THDA neurons was estimated by determining the rate of DA synthesis [accumulation of dihydroxyphenylalanine (DOPA) after the administration of a decarboxylase inhibitor] and DA metabolism [dihydroxyphenylacetic acid (DOPAC) concentrations] in the IL and NL of the posterior pituitary gland. By way of comparison, the effects of acute restraint stress on plasma PRL concentrations and the activity of TIDA neurons were also examined. TIDA neuronal activity was estimated by determining the rate of DA synthesis and DA metabolism in the median eminence (ME).

Ten, 20 and 30 min following placement of unanesthetized animals in restraining tubes (restraint stress) there was a marked increase in plasma PRL concentrations in both male and female rats. In female rats this increase in PRL secretion was accompanied by a decrease in DOPA accumulation and DOPAC concentrations in the ME. In contrast, restraint stress had no effect on ME DOPA or DOPAC concentrations in male rats. These results are consistent with previous reports of a sex difference in the response of TIDA neurons to restraint stress and indicate that the stress-induced increase in PRL secretion in female rats may be due, at least in part, to a decrease in activity of TIDA neurons.

Restraint stress produced a marked increase in αMSH concentrations in the plasma of both male and female rats, and in both sexes this was accompanied by a decrease in DOPA accumulation and DOPAC concentrations in the IL. By contrast, restraint stress failed to alter DOPA or DOPAC concentrations in the NL of male or female rats. Taken together these results indicate that restraint stress decreases the activity of THDA neurons terminating in the IL and that this effect may be responsible for the stress-induced increase in αMSH concentrations in the plasma. Furthermore, since restraint stress caused similar effects in male and female rats, there is no sex difference in the response of IL THDA neurons to this manipulation. (Supported by USPHS Grants NS09174 and NS15911.)

119.16 **Dopaminergic Projections to the Median Eminence.** M.D. Fitzsimmons, S.J. Wiegand, and G.E. Hoffman. Dept. of Neurobiology and Anatomy, University of Rochester Medical Center, Rochester New York 14642.

Certain neurons regulate the function of the anterior pituitary by releasing trophic factors into the portal circulation at the median eminence, located on the ventral surface of the diencephalon. Use of retrograde tracers has allowed neuroanatomists to determine which cells project to the median eminence and therefore have the capacity to regulate directly anterior pituitary function. Dopamine is found in high concentrations in the median eminence and is thought to be the main physiological regulator of prolactin through a mechanism of tonic inhibition. By combining retrograde tract tracing and fluorescence immunocytochemistry, we have identified the population of dopamine neurons which projects to the median eminence.

Previous studies of afferents to the median eminence have included systemic injection of horseradish peroxidase (Broadwell and Brightman J Comp Neuro 166: 257-84, 1976). This technique takes advantage of the fact that the median eminence is a circumventricular organ (*i.e.*, has no blood-brain barrier). Hence, retrograde tracers in the blood can be taken up from the circulation by neurons whose projections end in the median eminence. We have taken a similar approach by injecting an autofluorescent retrograde tracer, fluorogold, systemically.

The fluorogold was introduced with a syringe into the jugular vein (0.5-5.0 mg/kg, 0.05-0.5% in saline). To date, the best results have been obtained with 5.0 mg/kg with a survival of 1to 5 days. The animals were perfused using a cannula inserted into the aorta with 0.9% saline followed by Zamboni's fixative. After the brains were removed, they were post-fixed, sunk in sucrose, and cut on a sliding microtome at 25 μm. The sections were incubated in 4% NGS and then rabbit-anti-TH (1:2000, Eugene Tech), diluted in 1% BSA and 0.4% Triton-X, overnight. After washing, the tissue was transfered to a solution containing biotinylated goat anti-rabbit (1:600-1:800) and then a solution of rhodamine coupled to avidin (10 μg/ml) for 1-3 hr. After thorough rinsing, the sections were mounted onto slides, cleared in alcohols and xylenes, and coverslipped with DPX mounting medium.

The distribution of fluorogold found in these animals closely approximates the distribution reported with systemic injection of HRP. Like HRP, fluorogold has a high affinity for endothelial cells, providing detailed information about neural vasculature. Components of the nervous system which have direct contact with the periphery, such as circumventricular organs and cranial nerve nuclei, also show fluorogold labeling. Included among the forebrain structures labeled with systemic fluorogold injections are neurons projecting to the posterior pituitary, subfornical organ, organum vasculosum of the lamina terminalis, and the median eminence.

Scattered TH-positive fluorogold cells were found as far rostral as the level of the anterior pole of the PVN, in the periventricular area. From the level of the rostral pole of the median eminence to the most posterior extent of the A12 group, all of the TH-positive cells were double labeled with fluorogold. None of the cells in the A13 (zona incerta) was double labeled. Thus, it appears that some TH-positive neurons in the more caudal A14 group and all of the TH-positive neurons in the arcuate A12 group project to the median eminence.

119.17 IMMUNOREACTIVE TYROSINE HYDROXYLASE (TH) AND SEROTONIN (5-HT) IN THE RAT NEUROINTERMEDIATE LOBE: A COMPARISON OF FIBER STAINING PATTERNS. L. C. Saland, J. A. Wallace, A. Samora* and L. Gutierrez* Dept. of Anatomy, Univ. of New Mexico School of Medicine, Albuquerque, NM. 87131.

Several investigations have demonstrated the presence of serotonin (5-HT)-immunoreactive nerve fibers in the pituitary neurointermediate lobe. We have previously suggested that the 5-HT fiber immunostaining in the intermediate lobe may in part be the result of uptake of 5-HT (Saland et al, '85, Soc. Neurosci. Abst. 11: 360, and MS submitted), perhaps from the adjacent neural lobe. This suggestion was based upon our findings that 5-HT immunostaining in the intermediate, but not the neural lobe, was eliminated after the administration of either 6-hydroxydopamine or fluoxetine. Therefore, the possibility exists that 5-HT and catecholamines co-localize in the intermediate lobe innervation. Here, we compare the staining patterns for 5-HT and tyrosine hydroxylase (TH) in the rat neurointermediate lobe. Adult male Sprague-Dawley rats were ether anesthetized and perfused intracardially with ice-cold phosphate buffered saline (PBS) followed by 4% paraformaldehyde in 0.1M phosphate buffer. Pituitary glands were processed for paraffin embedding and sectioned at 6-8 μm. Sections were incubated with primary antisera to 5-HT or to TH (Eugene Tech International, Inc.), and visualized with the avidin-biotin-peroxidase technique. As shown in earlier studies, 5-HT staining in the pars intermedia was variable, with some sections having numerous fine varicose fibers surrounding and within tissue lobules, and others with very few fibers. In comparison, the neural lobe consistently contained large numbers of relatively coarse 5-HT-stained fibers, frequently along border areas. TH-immunostained fibers, in contrast, were observed in all areas of the intermedia and neural lobes, at edges and within central tissue locations. The staining patterns for 5-HT and TH differed sufficiently to suggest the existence of multiple fiber populations. In particular, TH staining in the neural lobe suggests that catecholamine synthesis takes place in fibers throughout the tissue, while fibers containing 5-HT appear more restricted to border areas. Studies to directly examine the potential co-existence of TH and 5-HT immunoreactivity in a subpopulation of neurointermediate lobe fibers are in progress. Supported by NIH NS-21256 and RR-08139 (LCS) and NSF-BNS-82-08433 (JAW).

119.18 INCUBATION OF RAT NEUROINTERMEDIATE LOBES WITH CORTICOTROPIN-RELEASING HORMONE (CRF) AND NEUROTRANSMITTERS: EFFECTS ON PEPTIDE IMMUNOREACTIVITY AND INTRACELLULAR STRUCTURE. L. Gutierrez*, A. Samora*, and L. C. Saland. (SPON: S. Rogers). Dept. of Anatomy, Univ. of New Mexico Sch. Medicine, Albuquerque, NM 87131.

Pro-opiomelanocortin peptide (POMC) secretion from the pituitary intermediate lobe is thought to be modulated by specific inhibitory and stimulating molecules, including dopamine (DA) and serotonin (5-HT), respectively. Corticotropin-releasing hormone (CRF) has been recently shown to induce release of POMC peptides from the intermedia, in addition to its effects on cells of the anterior pituitary. Direct interactions of hypothalamic peptide and neurotransmitters on pituitary tissue are likely to have important influences on regulation of POMC secretion. Here, we demonstrate alterations in POMC-immunostaining after in vitro incubation of neurointermediate lobes (NILS) with DA, 5-HT, CRF, or a combination of CRF and DA. Adult male Sprague-Dawley rats were ether anesthetized, rapidly decapitated, and the NILS separated from anterior lobes. Tissues (2 NILS/ well) were incubated in 6-well plates in Gibco medium containing glutamine, glucose, 0.1 mM bacitracin, 0.1mM ascorbic acid, and 10 μM pargyline. DA or 5-HT were added at concentrations of 10-6M, while CRF was added at 10-10M. Plates were incubated in a Dubnoff metabolic shaking incubator at 37 degrees C. with continuous 95% O2-5% CO2 gassing. After 90-120 minutes, tissue was fixed for light microscopic immunocytochemistry or for transmission electron microscopy. Immunoreactive sites for primary antibodies to beta-endorphin or alpha-melanocyte-stimulating hormone were visualized on paraffin sections using the avidin-biotin-peroxidase technique. Serotonin (5-HT) and CRF induced a diminution in immunoreactive POMC peptides in the pars intermedia as compared to controls, while DA-treated tissue was intensely stained. Combined CRF-DA treatment produced a "mixed" response, with some tissue lobules devoid of stain and others retaining intense immunoreactivity for peptides. TEM of cells treated with 5-HT or CRF contained secretory granules, with many oriented towards the plasmalemma, while those treated with CRF-DA varied, from granule-filled to partially depleted. The effects of CRF-DA combined on cellular peptide content may depend upon relative sensitivity of individual endocrine cells to stimulation or inhibition. Supported by NIH NS-21256, BRSG S-07-RR-05583-22 and RR-08139.

119.19 CIRCADIAN RHYTHMS OF ACTH AND GROWTH HORMONE AFTER INSULIN HYPOGLYCEMIA. J.F. Lopez*, R. G. Kathol, R.S. Jaeckle and W.H. Meller*. Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109 and Dept. of Psychiatry and Internal Medicine, University of Iowa, Iowa City, IA 52242.

Insulin hypoglycemia is a known stimulant of pituitary ACTH and growth hormone (GH) secretion in experimental animals and humans. It is also known that both ACTH and GH show a circadian rhythm in normal humans. In this study we investigated the diurnal variation of ACTH and GH responses to insulin induced hypoglycemia in normal humans by administering insulin at three different times of the day: morning, afternoon and evening. To control for possible effects of repeated testing, we also performed the afternoon test three times.

Six healthy males (average age 31.6 ± 4 yrs) were given 0.1 units/kg IV of regular insulin, each on five separate occasions (three times at 16:00 hrs, once at 23:00 hrs and once at 8:00 hrs). Plasma ACTH and GH levels were assayed at 0,15,30,45,60,90 and 120 min after insulin administration. There was an interval of at least one week between each of the insulin infusions.

ACTH levels prior to insulin tended to be nonsignificantly higher at 8:00 hrs (30.7 ± 19.0 pg/ml) than at any other of the times (9.3 ± 8.3 pg/ml at 23:00 hrs; 10.6 ± 4.4, 10.8 ± 4.1 and 10.2 ± 3.2 pg/ml for each of the 16:00 hrs test). However, a repeated measure ANOVA as well as Kruskall-Wallis non-parametric testing failed to show any difference in peak ACTH levels ($F = .996$, $p > .25$), maximal ACTH increment ($F = .524$, $p > .25$) or at any other time points between the different times tested. Similarly, no differences were found in pre-insulin ($F = .546$, $p > .25$), peak ($F = 1.012$, $p > .25$) and maximal increment ($F = 1.003$, $p > .25$) GH levels between any of the insulin tests.

Our results suggest that the GH and ACTH response to insulin hypoglycemia is a stable response, not altered by repeated testing, and that similar results can be obtained with this stimuli regardless of the time of the day that it is performed.

119.20 THE EFFECT OF CHRONIC INTRACEREBROVENTRICULAR (ICV) INSULIN INFUSION ON FEEDING BEHAVIOR AND DIURNAL CORTICOSTERONE IN DIABETIC RATS. W. P. Meehan* and L. J. Leedom* (SPON: D. Lindsley). Dept. of Med., Sect. of Diabetes, Univ. So. Cal., Los Angeles, CA 90033.

Although hyperphagia is a cardinal symptom of diabetes, its etiology in diabetes is poorly understood. Chronic ICV insulin infusion inhibits feeding behavior in normal rats. Pancreatic insulin may be a satiety factor which, when missing in diabetes, results in hyperphagia. Another poorly understood concomitant of uncontrolled diabetes is elevated plasma corticosterone. It seems odd that a hormone which functions to increase glucose is elevated in diabetes under conditions of already profound hyperglycemia. It is our hypothesis that pancreatic insulin deficiency causes increased corticosterone by a central mechanism. To test this hypothesis, we chronically infused insulin into the ventricular system of diabetic rats. 40 male Sprague-Dawley rats had cannulae stereotaxically placed in the lateral ventricle. Rats were then made diabetic by IP injection (65 mg/kg) streptozotocin. 8 control rats received vehicle. 5 days post injection animals were bled at 08:00 and 17:00 hr for glucose and corticosterone determination, and implanted with 7 day osmotic minipumps. The following doses of insulin were given ICV and peripherally: 0, 0.5, 1.0 and 2.5 U/day. Food intake was measured daily. On day 7 (post pump) animals were bled at 08:00 and 17:00 for glucose and corticosterone.

During the 7 days of pump activity, nondiabetic rats consumed 23±4 sd g/day vs 36±6 g/day for vehicle treated diabetic rats ($p<0.001$). No insulin dose, central or peripheral, had a significant effect on feeding behavior in diabetic rats. Diabetes resulted in elevated AM (trough) corticosterone (diabetics: 31±13 vs 14±8, $p<0.01$). Peak corticosterone was not changed. Vehicle had no effect on corticosterone in diabetic rats. ICV insulin (0.5 U/day) normalized AM corticosterone in half the treated animals (to 9.0±5.6). Peripheral infusion of 0.5 U/day had no effect on plasma corticosterone. ICV infusion of 1.0 and 2.5 U/day normalized AM plasma corticosterone in all rats. Peripheral infusion of 1.0 and 2.5 U/day also lowered plasma corticosterone. No insulin treatment had a significant effect on plasma glucose.

In summary, ICV insulin infusion normalized trough plasma corticosterone but no effect on feeding or plasma glucose in diabetic rats.

120.1 SUPRACHIASMATIC KNIFE CUTS DISRUPT CIRCADIAN WHEELRUNNING IN HAMSTERS. R.F. Johnson, R.Y. Moore and L.P. Morin . Depts. Psychiatry and Neurology, Health Science Center, SUNY at Stony Brook, NY 11794.

The functional significance of suprachiasmatic nuclei (SCN) efferents in the control of circadian rhythms is not clear. The present study examined the effect of coronal cuts rostral or caudal to the SCN in hamsters.

Hamsters were entrained to LD 14:10. Cuts were made with a 1.5 mm L-knife lowered to the chiasm on both sides of midline. Another group received sham surgery (SHAM, N = 7). Wheelrunning was monitored for about a month in LD and then the cycle was switched to constant dark (DD) in the middle of the light phase.

Histology indicated three cut groups: Cuts rostral to the SCN with no SCN damage (ROST, N = 5) and cuts impinging on the Rostral SCN (ROST-SCN, N = 4) or on the caudal SCN (CAUD-SCN, N = 10).

Both the ROST-SCN and CAUD-SCN groups tended to show a loss of rhythmicity for about a week after surgery. The rhythmicity recovered and entrained in 1- 2 wks in most cases. Even when the LD rhythmicity recovered these animals showed a much higher tendency to run during the light phase than normal. Upon exposure to DD most of these hamsters showed dispersion of activity with many eventually losing clear circadian rhythmicity (3 of 4 ROST-SCN and 6 of 10 CAUD-SCN). In addition to the loss of rhythmicity these groups showed sharp persistent reductions in activity after surgery and several showed dramatic phase advances of several hours when switched to DD (not seen in SHAM or ROST Groups). The SHAM and ROST groups showed little effect on their entrainment, although the ROST group showed a slight dispersion of activity and reduced activity levels. All hamsters in the ROST and SHAM groups had clear freeruns proceeding from close to the previous phase of entrainment.

The effect of the CAUD-SCN and ROST cuts are consistent with previous work indicating the importance of caudo-lateral but not dorso-caudal or rostral (Brown, M. and Nunez, A., Brain Res. Bull., 16:705, 1986; Nunez, A. and Stephan, F., Behav. Biol., 20:224, 1977) efferents controlling circadian rhythmicity. The abolition of the circadian rhythmicity in the ROST-SCN may be due to destruction of a small portion of the rostral SCN, although very large portions of the SCN usually must be damaged to lose circadian rhythmicity (Rusak, B., J. Comp. Physiol., 118:145, 1977). The presence of rhythmicity under LD cycles in animals that gradually lose rhythmicity in DD suggests alternate photic pathways directly affecting wheelrunning activity or a driving effect of LD cycles on the SCN which increases the effectiveness of possible residual efferents controlling wheelrunning.

Supported by NIH NS 22168 to LPM.

120.2 LESIONS OF THE SUPRACHIASMATIC NUCLEI AND SURROUNDING BASAL HYPOTHALAMUS ABOLISH THE CIRCADIAN RHYTHMS OF ACTIVITY, DRINKING, AND BODY TEMPERATURE IN FEMALE RATS. E. Melanie W. Kittrell, University of Pittsburgh, Western Psychiatric Institute and Clinic, 3811 O'Hara St., Pittsburgh, PA 15213

While the suprachiasmatic nuclei (SCN) have been established as the primary neural substrate for the generation of rhythmicity, their role in the support of the circadian temperature rhythm (CTR) of body temperature is less clear. Studies concerning this particular function have been equally divided in supporting or refuting the claim that the SCN are responsible for the maintenance of the temperature rhythm.

In this study, we measured the CTR, activity, and drinking rhythms of 24 female hooded rats for 6 weeks under a 12/12 LD cycle. We then made bilateral electrolytic lesions of the SCN region in 20 of the rats and sham lesions in the remaining four. The survivors lived under 12/12 LD for 6 weeks and then under DD for an additional 6 weeks. The brains were then removed and alternate sections were reacted for cytochrome oxidase activity and stained with cresyl violet.

Results showed that all animals receiving complete SCN lesions (N=10) failed to recover rhythms in drinking, activity, and body temperature for the entire post-lesion period regardless of whether they were in entrained or free-running conditions. Three rats with some sparing of the SCN showed some return of rhythmicity in all three variables. All rats sustained varying degrees of damage to the optic chiasm and surrounding basal hypothalamus. Histological details will be presented in detail along with analyses of rhythmicity.

The fact that other areas of the basal hypothalamus were damaged in addition to the SCN means we cannot conclude definitely that the SCN are the sole support of the CTR. However, we found that the animals with the lowest amplitude ultradian fluctuations in their post-lesion measurements (the "flattest" looking results) had lesions that were primarily confined to the SCN and lateral SCN region. Animals with some SCN sparing but damage elsewhere in the hypothalamus did not lose their rhythms (as might be expected if the clock for temperature were located nearby the SCN) although some of their characteristics were altered.

These results suggest that the SCN are critically involved in the support of the CTR.

120.3 HAMSTER PHOTOPERIODISM AND THE PARAVENTRICULAR NUCLEUS: EFFECTS OF CORONAL, PARASAGITTAL OR ROOF CUTS. L.P. Morin, R.F. Johnson and R.Y. Moore. Depts. Psychiatry and Neurology, Health Science Center, SUNY, Stony Brook, NY 11794.

Lesions of the paraventricular nucleus (PVN) of the hamster hypothalamus block short photoperiod-induced gonadal regression (Lehman et al., Brain Res. 308:25, 1984; Pickard and Turek, Neurosci. Let. 43:67, 1983; Hastings et al., Neuroendocrinology 40:316, 1985). Horizontal knife cuts dorsal or ventral to the PVN or in the ventral preoptic area may also block the photoperiodic response (Nunez et al., Brain Res. Bull. 15:149, 1985; Eskes and Rusak, Neurosci. Let. 61:261, 1985; Inouye and Turek, Brain Res. 370:102, 1986). These studies have suggested that the PVN mediates photoperiodic information from the suprachiasmatic nuclei which is ultimately conveyed to the pineal gland. Two routes of PVN efferent fibers to the spinal cord have been identified which may be involved in the photoperiodic response (Luiten et al., Brain Res. 329:374, 1985; Swanson and Kuypers, J. Comp. Neurol. 194:555, 1980). The present experiments were designed to evaluate the importance of these two pathways to short photoperiod induced testicular regression.

Expt. 1 - Cuts were made with a retractable wire knife extended 1.5 mm except for the roof cuts which were made with a 1.5 mm L-shaped knife. Cuts were placed parasagittally on each side of the brain 0.7 mm lateral, in the coronal plane rostral or caudal to the PVN or horizontally above the PVN. After surgery, animals were kept in LD 14:10 for 10 wks then transferred to LD 8:16 for 19 wks. Testes and body weight were measured at weeks 0, 10, 20 and 29.

Expt. 2 - Roof cuts (ROOF) were made with a 2 mm L-shaped knife. Rostral (ROST) and caudal (CAUD) coronal plane cuts, near parasagittal (NPS) cuts made bi-laterally 0.6 mm and far parasagittal (FPS) cuts made 1.2 mm bi-laterally were made with a 3 mm L-knife. Rostral (ROST) and caudal (CAUD) coronal plane cuts were also made with the 3 mm L-knife. All groups were transferred to LD 8:16 after surgery as was a surgical control group. Another control group remained in LD 14:10.

In Expt. 1, there were small effects of surgery on body weight in LD 14:10 which disappeared in LD 8:16. None of the cuts blocked gonadal regression in short days. In Expt. 2, there was large variability in body weight associated with ROOF, ROST, NPS and FPS cuts. About 50% of these animals had elevated weights. Testis regression was blocked by most ROOF and FPS cuts. NPS cuts also blocked regression in a few animals while ROST cuts appeared to delay regression.

Information for photoperiodism may be transmitted from the SCN to the pineal by a dorso-laterally moving sub-PVN pathway (Watts et al., J. Comp. Neurol. 258:204, 1987), not usually reached by the NPS cuts, but usually destroyed by the FPS and wide ROOF cuts. Supported by NINCDS grant NS22168.

120.4 THE RETINOHYPOTHALAMIC TRACT (RHT) IN HAMSTER: NORMAL ORGANIZATION AND RESPONSE TO INJURY. L. Smale* R.F. Johnson, L.P. Morin and R.Y. Moore. (SPON: I. Feinberg) Depts. Psychiatry and Neurology, Health Science Center, SUNY, Stony Brook, NY 11794.

The suprachiasmatic nuclei (SCN) are important constituents of the circadian system in mammals. The RHT provides a direct pathway for photic information to reach the hypothalamus and, particularly, the SCN. Prior work (Pickard, G.E. and Silverman, A., J. Comp. Neurol., 196:155, 1983) indicates that the RHT in the hamster has a wider distribution than previously described for hamsters and other mammals. In this study, cholera toxin conjugated to HRP was used to re-examine the RHT in intact hamsters and hamsters with knife cuts designed to transect fibers of the RHT as they leave the optic chiasm. The cuts were made using an L-knife lowered to a position on the chiasm and rotating it to produce a linear cut between the chiasm and the SCN. RHT projections were analyzed by injection of cholera toxin-HRP (2 μl - 0.1%) into the vitreous and preparing sections for HRP histochemistry after a 24-hour survival period.

The RHT in normal animals first appears as scattered fibers in the rostral anterior hypothalamic area (AHA) above the optic chiasm. A moderate plexus is present in the rostral SCN with some fibers extending into adjacent AHA. In the caudal two-thirds of the SCN labeled fibers are present in a dense plexus in that portion of the nucleus containing vasoactive intestinal polypeptide-immunoreactive neurons and less dense in the area containing vasopressin-immunoreactive neurons. This projection to SCN extends significantly beyond the boundaries of the nucleus in several directions; laterally across the AHA into the perifornical region, dorsally in the periventricular zone to run along the ventral border of the paraventricular nucleus with a few fibers extending into it, and caudally into the retrochiasmatic area and in a periventricular zone, adjacent to the periventricular nucleus, to the level of the rostral ventromedial nucleus. In addition to these projections, there is an extensive innervation of the lateral hypothalamic area arising from fibers off the lateral chiasm and optic tracts with a few fibers extending into the supraoptic nucleus. Other fibers from the optic tracts run along the ventral surface into piriform cortex and the cortical amygdaloid nucleus.

In animals with cuts the RHT projection to SCN was markedly reduced, often with extensive anomalous growth of the RHT rostral to the cut in the AHA, medial preoptic area and extending into the septal nuclei. These observations indicate that the RHT has much more extensive projections than hitherto described and exhibits sigificant sprouting in response to injury with innervation of areas not normally receiving a projection. These findings should be important in the continuing functional analysis of the circadian system. Supported by NIH NS 22168 to LPM.

120.5 ENTRAINMENT OF ACTIVITY TO MULTIPLE FEEDING SCHEDULES IN RATS WITH SUPRACHIASMATIC LESIONS. F.K. Stephan. Dept. of Psychology, Florida State University, Tallahassee, FL 32306.

Wheel running activity of intact rats, as well as rats with suprachiasmatic (SCN) lesions, entrains to restricted food availability if the period of food access is between 23h and 31h and this effect is mediated by a circadian mechanism. Rats also are able to anticipate food access at 12h intervals, presumably by using a circadian clock.

Entrainment to multiple food availability per circadian cycle was further investigated in rats with SCN lesions. When two feeding times (1.5h each) were presented 8h apart, all rats (N=8) entrained to both schedules. Anticipatory activity (AA) to the second schedule was diminished when the interval was reduced to 5h. An 8h phase delay of one schedule resulted in delaying transients and a concomitant disappearance of AA to the unshifted schedule.

Seven rats were exposed to 3 feeding times (1h each) at 6h-6h-12h intervals, followed by 8h-8h-8h intervals. All rats entrained to two of the three schedules but no rat anticipated all 3 schedules simultaneously. However, AA occasionally shifted from one schedule to another so that entrainment was very unstable.

Five rats were maintained on 2 feeding times (1.5h each) 10h apart. The period of both schedules was 23:45h. The period of one schedule was then changed to 24:00h. Two rats entrained to both schedules for up to 40 days. The other rats entrained to the 24:00h schedule only. After the schedules intersected, 2 rats shifted from the 24:00h to the 23:45h schedule.

These results indicate that entrainment to food availability depends on phase angle differences and period differences of the feeding schedules and some of the observations suggest mediation by more than one pacemaker. Lack of AA (i.e., entrainment) was not related to food consumption in any of the conditions. It is unclear why activity failed to entrain to more than 2 feeding times per circadian cycle.

120.6 CONSTANT LIGHT SUPPRESSES VASOACTIVE INTESTINAL PEPTIDE (VIP)-LIKE IMMUNOREACTIVITY (LI) AND PEPTIDE HISTIDINE ISOLEUCINE (PHI)-LI, BUT NOT NEUROTENSIN (NT)-LI, WITHIN THE SUPRACHIASMATIC NUCLEUS (SCN). H.E. Albers, N. Minamitani*, E. Stopa* and C.F. Ferris. Lab. Neuroendocrinol. Behav., Depts. Biol. and Psych., Georgia State Univ., Atlanta, GA 30303; Dept. Endocrinol. & Pathology, Tufts Univ. Sch. Med., Boston, MA 02111 and Dept. Physiol., Univ. Mass. Med. Sch., Worcester, MA 01605.

Many neurotransmitter candidates have been localized within the SCN, however little is known about the involvement of these substances in the generation of circadian rhythms or the synchronization of circadian rhythms with the day-night cycle. Two substances of particular interest because of their co-localization within SCN neurons situated in a dense field of afferent terminals from the retina and lateral geniculate are VIP and PHI. The present studies examined whether the concentration of VIP, PHI and another peptide found within the SCN, NT, vary rhythmically within the SCN and whether their concentrations are altered by exposure to constant light(LL) or dark(DD). In experiment 1 adult male rats housed in LD 14:10 for at least three weeks were killed during the middle of the light(Day) or dark period(Night). Brains were removed and frozen on dry ice for subsequent removal of the SCN using a punch technique. SCN tissue was homogenized, extracted in 1 N acetic acid and boiled for 10 min prior to RIA using antisera generated to rat VIP, PHI and NT. The day-night concentrations of VIP-LI, PHI-LI and NT-LI were found to be similiar: Day: 6.91+0.87 pmol/mg protein (N=11), 6.69$\pm$1.0 (N=11) and 0.37$\pm$0.08 (N=7) and Night: 6.34$\pm$0.59 (N=9), 6.03$\pm$0.76 (N=9) and 0.28$\pm$0.07 (N=8), respectively. In a second experiment the effects of continuous lighting conditions on the concentration of each peptide was determined in rats exposed to LL or DD for 20 days. In rats exposed to LL VIP-LI and PHI-LI concentrations within the SCN were significantly ($P<0.01$) depressed when compared to the levels found in rats housed in DD or LD 14:10. In LL the VIP-LI concentrations of 2.16$\pm$0.37 pmol/mg protein (N=9) were 3-4 fold lower than seen in DD 8.18$\pm$1.65 or LD 14:10. Similiarly PHI-LI levels in LL (i.e. 3.12$\pm$0.39; N=9) were approximately 2 times lower than those seen in DD (i.e. 6.00$\pm$0.79; N=9) or LD 14:10. In contrast, NT-LI levels in LL (0.49$\pm$0.07; N=8) were not found to differ significantly from those observed in DD (0.54$\pm$0.14; N=10) or LD 14:10. In summary, no day-night differences were observed in the SCN concentrations of VIP-LI, PHI-LI or NT-LI, however VIP-LI and PHI-LI, but not NT-LI were significantly lower in rats housed in LL than in rats housed in either DD or LD 14:10. The selective effects of light on VIP-LI and PHI-LI levels within the SCN suggests that these peptide may be involved in the processing of photic information within the SCN. 120.7 DEVELOPMENT OF THE SUPRACHIASMATIC NUCLEI (SCN) IN FETAL HYPOTHALAMIC TRANSPLANTS TO THE THIRD VENTRICLE OF ADULT RATS WITH SCN LESIONS. Raul Aquilar-Roblero* and Robert Y. Moore. (SPON: C. Welt). Department of Neurology and Neurobiology, SUNY @ Stony Brook, Stony Brook, NY 11794.

It has been shown that fetal grafts from the anterior hypothalamus, but not the occipital cortex, are able to restore the circadian rhythm of drinking behavior in adult rats with SCN lesions. In the present study we attempt to identify the anatomical subtrate for these behavioral results. In particular we address whether the SCN develops in the grafted tissue and whether connections between the graft and the host are established.

Male Sprague-Dawley rats sustained electrolytic lesions of the SCN and received grafts from E-17 embryos into the 3rd ventricle either from the anterior hypothalamus or the occipital cortex. After one month, the animals received intraocular injection of cholera toxin conjugated to HRP, were allowed to survive for 48 hrs, and were then perfused and tissue processed for HRP histochemistry and immunohistochemistry for vasopressin (VP), vasoactive intestinal polypeptide (VIP) and neuropeptide Y (NPY).

Animals showed varying degrees of SCN destruction ranging from complete to partial, and unilateral lesions. Hypothalamic grafts routinely survived in the rostral aspect of the 3rd ventricle where they exhibited an SCN-like appearance with VP- and VIP-like immunoreactive neurons in adjacent parvocellular populations and extensive axonal plexuses with VP-, VIP- and NPY-like immunoreactivity. Projections to the host brain appear limited to tissue adjacent to the graft. All cortical grafts survived and showed neurons and fibers containing VIP, and NPY but not VP. HRP histochemistry showed retinal innervation of grafts, both hypothalamic and cortical. This was variable in extent but an anomalous retinal innervation of the medial anterior hypothalamus was present in all cases.

The present study shows that a structure with SCN-like appearance develops in grafts from the anterior hypothalamus, but not the cortex, of E-17 embryos. These findings provide an anatomical correlate which supports the suggestion that the SCN is responsible for the restoration of circadian rhythms by fetal implants in rats with SCN ablation. The anomalous retinal innervation of the hypothalamus and the grafts could explain the behavioral effects of both types of grafts on the drinking behavior seen under diurnal lighting conditions.

Supported by grant NS-16304.

120.8 THE AFFERENT AND EFFERENT ORGANIZATION OF THE CAT SUPRACHIASMATIC NUCLEUS. Dean M. Murakami* and Charles A. Fuller (Spon: Pamela A. Pappone). Department of Animal Physiology, University of California, Davis, CA 95616.

The suprachiasmatic nucleus (SCN) is critical for the control of circadian rhythms. In order to understand the neural organization of the circadian system, it is important to determine the afferent and efferent connections of the SCN. This study examined the neural interconnections of the cat SCN using horseradish peroxidase (HRP) as an anterograde and retrograde marker. A 30% HRP solution was electrophoretically injected into the SCN. Following a 3-day survival the animal was sacrificed, and brain prepared for histology. One series of coronal sections was reacted with tetramethyl benzidene, while the alternate series of sections was reacted with diamino benzidene. A second series of animals was injected with HRP into identified SCN efferent nuclei. The histological protocol was the same as above.

Injections of HRP into the SCN demonstrated that the region lateral to the SCN (LASCN), paraventricular nucleus, preoptic nuclei, ventromedial nucleus, septum, arcuate nucleus, retrochiasmatic region, anterior hypothalamus, diagonal band region and raphe nuclei send afferents to the SCN. The major nuclei that the SCN sends projections to include the: LASCN, paraventricular nucleus, preoptic nuclei, ventromedial nucleus, septum, arcuate nucleus, retrochiasmatic region and anterior hypothalamus.

The preoptic nucleus, anterior to the SCN, was injected with HRP. The SCN revealed labelled neurons in the dorsal and lateral portion of the nucleus. A few labelled SCN neurons were also found in the ventral portion of the SCN. The central region of the SCN appeared void of labelled neurons. The labelled neurons were primarily found in the SCN ipsilateral to the injection site, and concentrated from the middle to posterior SCN. The arcuate nucleus was also injected with HRP. Labelled SCN neurons were primarily located around the medial, dorsal and lateral borders of the SCN. The central and ventral regions of the SCN were essentially void of labelled neurons. The labelled neurons were found in highest concentrations from the anterior to middle sections of the SCN. In addition, the labelled neurons were nearly bilateral in distribution. Finally, the LASCN was injected with HRP. Labelled neurons were found primarily within the ventral SCN.

The afferent and efferent connections of the cat SCN were identified as being similar to those regions described by other investigators in other species. Further, this study identifies that the pattern of labelled SCN neurons following HRP injections was distinct for each of the nuclei examined. This suggests that the SCN neurons that project to different nuclei are organized into distinct but overlapping regions.

120.9 FREE-RUNNING CIRCADIAN PERFORMANCE RHYTHMS IN MONKEYS. W.N. Tapp and B.H. Natelson. Primate Neurobehavioral Unit, VA Medical Center and Department of Neurosciences, New Jersey Medical School, East Orange, NJ 07019.

We have developed a monkey performance model for examining the effects of time-of-day, circadian rhythms, and work-rest schedules on the efficiency of the performance of learned tasks. In this vigilance-discrimination model, rhesus monkeys must perform a two-component task to obtain food. The first component is a vigilance task, where the monkey must detect the onset of a trial and respond with a lever press within a time limit. Success on the vigilance task initiates a discrimination task where the monkey must press either a right or left lever, depending upon whether a red or green cue light comes on. Choices and response latencies are recorded on computer. The monkey's temperature and activity rhythms are recorded every 10 min around the clock. In previous work, we found strong time of day effects that differed in their peak time for the two tasks, and we found that a 6 hr phase advance produced a jet-lag-like syndrome that included significant performance deficits. However, the monkeys were working 8 hr sessions in entrained conditions in those studies. The current study was designed to examine the circadian characterstics of performance by determining whether (1) periodic performance variations are found in constant conditions, (2) the effects of free-run on overall performance, and (3) its effects on task-dependent performance patterns.

We studied the performance of three adult, male rhesus monkeys in constant light with trials presented around the clock on a variable interval schedule averaging one trial every 2.4 min. All 3 monkeys exhibited free runs as long as they were maintained in these conditions (up to 180 days). The monkeys exhibited free-running performance periods of 23.4 hr, 23.7 hr and 24.6 hr. Performance differed significantly from the levels seen in the 8 hr task in entrained conditions. Vigilance performance declined by an average of 30.7% $\pm$ 8.1 SEM ($p < 0.01$). The decline in vigilance may be due to the fact that monkeys were able to eat significantly more food in the continuous task than in the 8 hr task ($p < 0.01$). However, discrimination performance improved an average of 16.5% $\pm$ 1.2 SEM ($p < 0.01$) in free-running conditions. It seems unlikely that increased performance in constant conditions is due to decreased food motivation. Instead, the data suggest that changes in the internal phase relationships of rhythms during free-run may improve performance on more complex tasks.

120.10 THE PATTERNS OF RETINAL PROJECTION AND OXIDATIVE METABOLISM IN THE SUPRACHIASMATIC NUCLEUS OF PRIMATES AND THE TREE SHREW. Charles A. Fuller and Dean M. Murakami*. Department of Animal Physiology and California Primate Research Center, University of California, Davis, CA 95616.

Previously, we reported the pattern of metabolic activity using the cytochrome oxidase (CyOX) stain in the hypothalamus of rodents. In order to understand the generality of this neural organization, we examined the pattern of CyOX staining in the hypothalamus of the tree shrew, a New World (squirrel monkey) and an Old World primate (bonnet macaque). The pattern of retinohypothalamic (RHT) innervation was examined by placing a 30% horseradish peroxidase (HRP) solution into the vitreous chamber of one eye in the tree shrew (15 µl), squirrel monkey (50 µl), and bonnet macaque (75 µl). Following a 3-day survival, the animal was sacrificed and prepared for histology. Alternate coronal sections (40 µm) through the hypothalamus were reacted with the TMB protocol in order to reveal the anterogradely transported HRP. Alternate sections were stained for CyOX.

The pattern of retinal projection to the hypothalamus in squirrel monkeys and macaque is very similar. The SCN is the primary nucleus to receive retinal afferents in agreement with Moore [1975]. However, in this study the distribution of HRP granules suggest that retinal terminals are present from the anterior to posterior pole. The retinal terminals appear restricted to the ventral portion of the SCN in the anterior and middle portions. The posterior SCN exhibits a relatively even distribution across the nucleus. The retinal projection to the hypothalamus in tree shrews is in good agreement with Conrad and Stumpf [1975]. The retinal projection to the hypothalamus in tree shrews exhibits several anatomical differences compared to primates. Dense retinal terminals project to a region of the hypothalamus comparable to the location of the SCN in rodents and primates, but there is little concentration of neurons suggesting the presence of a nucleus. In addition, there is a dense retinal projection to the nucleus hypothalamic anterior (NHA) located dorsal to the SCN along the third ventricle. This suggests that the tree shrew receives retinal input to two specific hypothalamic nuclei (SCN and NHA).

Primates exhibit a pattern of CyOX activity similar to that demonstrated in rodents and cat. The SCN exhibits intense CyOX activity in the anterior two-thirds of the nucleus that is primarily confined to the ventral portion. The posterior SCN also exhibits intense CyOX activity, but is evenly distributed across the nucleus. This coincides with the distribution of retinal terminals. However, intense CyOX activity also extends laterally from the SCN along the hypothalamo-optic chiasm border (LASCN). It will be important to determine what relationship the LASCN may have in circadian function.

120.11 OPTIC ENUCLEATION ATTENUATES THE PHASE SHIFTING EFFECTS OF DIAZEPAM ON HAMSTER CIRCADIAN RHYTHMS. T.A. Houpt*, R.E. Mistlberger* and M.C. Moore-Ede. (SPON: Z. Boulos). Dept. Physiology & Biophysics, Harvard Medical School, Boston MA 02115.

Recently the benzodiazepines (BZDs), a class of GABA agonists, have been shown to cause both phase advances and delays in the circadian rhythms of hamsters. Phase response curves (PRCs) to triazolam (~25mg/kg) under constant light (LL) or constant darkness (DD) (Turek & Losee-Olsen, *Nature 321*:167-8, '86) and to diazepam (12.5 mg/kg) (Houpt *et al., Soc. Neurosci. Abs. 12*:1071, '86) under constant light have been obtained. A pharmacological agent that causes phase shifts might act either centrally on a circadian clock or peripherally on the pathways which mediate zeitgeber (e.g. light) input to the clock. Ralph & Menaker have reported that diazepam blocks light pulse-induced phase advances but not delays in hamsters kept in constant darkness, which suggests a modulation of photic input by BZDs (*Brain Res. 372*:405-8, '86). Also the PRCs to triazolam and diazepam are similar to a 2 hr dark pulse PRC (Boulos & Rusak, *J. Comp. Physiol. 146*:411-7, '82). We report here that removal of the retinal photoreceptors and cutting of the optic nerves by optic enucleation greatly attenuates or eliminates the phase shifting effects of diazepam. Male golden hamsters (90-100g) were enucleated under halothane and housed individually in cages equipped with running wheels and enclosed in light-tight ventilated chambers under LL (140 lux). After 2-3 wks recovery, 12.5mg/kg diazepam was given i.p. Animals received 2-3 injections at least 3 wks apart at one of the following circadian times: 0, 4,8,12,16,20h. While diazepam caused occasional phase shifts comparable in magnitude and direction to those in intact hamsters, the effects were not consistent and the average phase shifts were very small compared to the intact LL PRC. The attenuation of phase-shifting effects of diazepam in hamsters after enucleation strongly suggests that BZDs affect the circadian timing system by modulating photic input to the SCN. Future research producing a DD PRC to diazepam and in characterizing BZD receptors in the retina and SCN will further elucidate the site and mechanism of BZD action.

120.12 PHOTIC SENSITIVITY OF A MAMMALIAN CIRCADIAN PACEMAKER D. E. Nelson and J. S. Takahashi, Department of Neurobiology and Physiology, Northwestern University, Evanston, Illinois 60201

For mammals the environmental cycle of light and dark is the primary agent responsible for the entrainment of endogenous circadian rhythms to the solar day. The physical characteristics of light necessary for entrainment, however, are poorly understood. To characterize the photoreceptive system which mediates photic information to a circadian pacemaker in hamsters we have used the phase-shifting response of the oscillator to discrete light pulses as an assay. We have previously demonstrated that this system appears equally responsive to light stimuli of equal energy over a range of durations from 300 msec to 2700 sec. In addition the sensitivity of the circadian system to light (total response/total photons/cm^2) is similar for stimuli of 300 and 900 sec in duration (Nelson and Takahashi, Soc. Neurosci. Abst., 12:1068, 1986).

To test for sensitivity changes in this photoreceptive system for light pulses of shorter duration, we have measured the sensitivity of the circadian system to pulses 3 sec in duration. After 7 days in constant darkness 3-sec monochromatic stimuli of several irradiance levels (503 nm, HW=20 nm) were administered to hamsters at circadian time 19. The steady-state phase advance of the locomotor activity rhythm was measured. Preliminary results suggest that the sensitivity to stimuli of 3 sec is different from the sensitivity measured for pulses of longer duration. These changes in sensitivity may be due to a saturation of the ocular photoreceptor which mediates photic information to a pacemaker perhaps due to the higher irradiance of the shorter stimuli. To determine the sensitivity of the pacemaker phase-shifting mechanism following stimulation we have also examined the effects of prior stimulation upon the phase-shifting sensitivity. A 300-sec monochromatic stimulus was administered to hamsters at circadian time 19. Immediately following or 1 hr following this stimulus test-stimuli of various strengths were administered to determine the sensitivity of the circadian system to additional stimulation. Results demonstrate that the sensitivity of the circadian system to these stimuli is much less than for stimuli presented alone. The decreased sensitivity, however, is due primarily to response saturation which would be expected if the circadian system was integrating the two light pulses and responding to the total number of photons delivered in both light pulses.

These experiments suggest that the mammalian circadian pacemaker and the photoreceptive system which subserves it may be less sensitive to light stimuli of short duration but at the same time capable of integrating light inputs over extremely long periods of time.

120.13 PARAMETRIC ENTRAINMENT OF HAMSTER CIRCADIAN ACTIVITY RHYTHMS. G.E. Pickard. Dept. of Anatomy, West Virginia University, School of Medicine, Morgantown, WV 26506.

Circadian rhythms free-run in constant conditions and can be entrained by periodic environmental factors (zeitgebers). The light:dark (LD) cycle is the most powerful zeitgeber for mammals. Rodents entrain to a wide range of LD cycles, from 22:2 to 0.25:23.75. However, in all but a few cases, entrainment in mammals has been examined using square wave light cycles (non-parametric entrainment). To further explore the neural basis of photic entrainment, sine-wave light cycles (with no abrupt transitions in light intensity) were employed as zeitgebers to study parametric entrainment.

Male golden hamsters, housed individually in running-wheel cages, were maintained in light provided by electroluminescent panels (14cm x 30cm) positioned 28cm above the floor of each cage. Light intensity was varied by an electronic controller which produced a sine-wave light cycle with a period of 24 hr. The peak emission wavelength was approximately 510 nm and spectral shifts were not observed as panel voltage was varied.

In the initial experiment, 24 animals were maintained in a sine-wave light cycle for 65 days followed by 20 days of constant dark followed by 88 days in the same sine-wave light cycle. Between days 116-123, twelve animals received bilateral lesions aimed at the thalamic intergeniculate leaflet (IGL). The intensity of the light cycle varied from 10 lux to 0 lux with complete darkness lasting about 15 min. Using activity on-set as an index, all animals entrained to the sine-wave light cycle and many appeared to accomplish this by oscillating around a preferred phase; the mean phase angle of entrainment was 6.6 ±0.2 hr after peak intensity. The data also clearly indicated that many animals, if not all, were using the brief dark period as a daily cue. Under these conditions, ablation of the IGL had only minor effects on entrainment. Because the animals appeared to be entraining to the daily dark pulse, this light cycle did not represent a "pure" parametric signal.

In the second experiment, 24 animals were maintained in a low amplitude sine-wave light cycle (5-10 lux) which lacked a dark period. The effect of IGL ablation will be determined in these animals after they demonstrate parametric entrainment to the sine-wave light cycle. Supported by NIH grant NS-21165.

120.14 **THE EFFECTS OF ABERRANT LIGHTING ON THE CIRCADIAN RHYTHM OF LOCOMOTOR ACTIVITY IN THE SYRIAN HAMSTER.** J.S. Ferraro[1], F.M. Sulzman*[2] and H.N. Krum*[1]. [1]Dept. of Biol. Sci., SUNY-Binghamton, Binghamton, NY 13901; [2]Div. of Life Sci., NASA, Washington, DC 20546.

Male Syrian hamsters (*Mesocricetus auratus*) were placed in Wahmann activity wheels contained in individual light-tight sound attenuated chambers and exposed to one of eight lighting conditions for a duration of 10 weeks; constant light (LL, 45-75 lux), constant dark (DD, 0 lux), feedback lighting (LD_{FB}, a condition which illuminates the cage in response to locomotor activity), a feedback lighting neighbor control ($LD_{FB\ NC}$, the animal receives the same light pattern as a paired animal in LD_{FB}, but has no control over it), reverse feedback lighting (rLD_{FB}, a condition that darkens an illuminated cage in response to locomotor activity), a light-dark cycle of 14 hours of light followed by 10 hours of dark (LD14:10), a short LD cycle of 1 hour of light and 1 hour of dark (LD1:1) and a high frequency or ultrashort LD cycle of 1 minute of light followed by 1 minute of dark (LD1m:1m). The circadian rhythm of locomotor activity, of hamsters exposed to LD14:10, entrained to the 24 hour photoperiod. Free-running periods were similarly and significantly lengthened by exposure to LD_{FB} (24.72±0.03), LL (24.56±0.06), rLD_{FB} (24.56±0.04) and LD1m:1m (24.61±0.06). Hamsters exposed to LD1:1 (24.50±0.07), despite substantial masking, had a significantly shorter period than hamsters exposed to LD_{FB} ($P<0.05$), but a similar period to those exposed to LD1m:1m, rLD_{FB} and LL. The mean free-running periods observed in LL, LD_{FB}, rLD_{FB}, LD1m:1m and LD1:1 were found to be significantly longer ($P<0.01$) than the period of hamsters exposed to DD (24.16±0.04). Animals exposed to $LD_{FB\ NC}$ did not free-run and were therefore not included in the statistical comparisons. Most animals exposed to the $LD_{FB\ NC}$ condition displayed "relative coordination" (i.e. the locomotor activity rhythm responded differentially to the light cycle, depending on the phase of the light pulse, but did not entrain to the stimulus). One animal appeared to be unaffected by the imposed light cycle and free-ran, four animals displayed modest changes in phase in response to the LD cycle, four animals displayed robust changes and one animal entrained to the period of the LD_{FB} controller for several weeks before breaking off and regressing into a condition of relative coordination. These results suggest that an animal assumes a specifically defined free-running period in any lighting condition that evenly illuminates the subjective night. It does not appear to matter whether the lighting condition contains transitions, is endogenously or exogenously derived or whether the subjective day is illuminated or not. The only determinants appear to be the pattern of photosensitivity, defined by the phase-response curve and its delay to advance ratio (D:A), and that the the D and A portions are relatively evenly illuminated. Supported by NIH grant 1 R01 NS23128-01 (JSF).

120.15 ENTRAINMENT OF THE PACEMAKER FOR HAMSTER ACTIVITY RHYTHMS BY DAILY HOARDING OPPORTUNITY. B. Rusak, R.E. Mistlberger, B. Losier* and C.H. Jones*. Department of Psychology, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4J1.

When food is available for only a brief period each day, rats exhibit an activity component that anticipates the feeding time. This component is driven by a circadian oscillator that is different from the pacemaker (identified with the suprachiasmatic nuclei, SCN) that normally drives the activity rhythm. Hamsters cannot tolerate similar restriction schedules, so we tested whether another food-related event, a daily hoarding opportunity, might generate similar anticipation by the circadian system.

Eight hamsters were studied for 4-13 months while housed in constant dim illumination (0.5 lux). Each cage had an activity wheel and a door, normally locked, that opened onto a plexiglas tunnel (10 cm diameter, 93 cm long) leading into an empty box (47 x 47 cm). During hoarding availability, hamsters were allowed access to the tunnel and box for 30 min every 24 h, at which time 15 g of sunflower seeds were available in the box. Hamsters usually retrieved some or all of the seeds to their cages. If hamsters were not in their cages after 30 min, they were escorted there, and sufficient laboratory chow was left in the home cage to ensure that animals were not food deprived.

Five of eight hamsters showed entrainment of the activity rhythm to a 24-h period. The rhythms of two others were clearly affected by the hoarding opportunity, but they could not be said to be stably entrained. Entrainment usually followed many weeks of freeruns (or transients). Activity onset typically followed hoarding immediately or anticipated it by a few hours, although one animal entrained with the end of activity near the hoarding time. An individual might show different phase relations to the hoarding time during two different tests. When hoarding ended, freeruns were always initiated from the entrained phase of activity onset. These findings indicate that stimuli associated with the hoarding opportunity were able to entrain the light-entrainable pacemaker that drives hamster activity rhythms.

Large, but subtotal, SCN lesions were made in two entrained animals. One responded with a ~10-h advance shift in the entrained rhythm, a finding compatible with a shortened period in the underlying oscillator. The other hamster eventually developed a rhythm with a very short period that failed to re-entrain. These results are consistent with the known effects of partial SCN lesions on pacemaker period. They reinforce the conclusion that, in contrast to the effects of food restriction on rats, hoarding-associated stimuli entrain the SCN-based pacemaker for the hamster activity rhythm.

Supported by NSERC of Canada and Dalhousie RDFS.

120.16 EFFECTS OF NUTRIENT RESTRICTION SCHEDULES ON CIRCADIAN RHYTHMS IN THE RAT. R.E. Mistlberger*, T.A. Houpt* and M.C. Moore-Ede. Dept. Physiology & Biophysics, Harvard Medical School, Boston MA 02115.

Schedules of restricted food availability can entrain behavioral and metabolic circadian rhythms in the rat. The clearest manifestation of entrainment is the development of intense locomotor activity anticipating the daily meal by several hours. Anticipatory rhythms do not occur if the food availability cycle is outside the circadian range (24±3h), suggesting that the rhythms are generated by food entrainable circadian oscillators. Physiological substrates of these oscillators are unknown, but are separate from suprachiasmatic nuclei-based oscillators critical for photically entrained circadian rhythms. Stimuli associated with daily feeding which are necessary for entrainment are also unknown, but identifying these stimuli could provide clues to entrainment pathways and the rhythm generating substrate. Restricted daily access to water, salt or palatable but non-nutritive foods does not entrain anticipatory rhythms, suggesting that ingestion of nutrients is critical for entrainment to occur. This study asks whether restricted access to specific nutrients (protein) can entrain anticipatory activity rhythms in rats with *ad lib.* access to other nutrients.

Eleven individually housed female rats (225g) were maintained on a protein free diet for 10 days and then provided with an additional 5g protein meal (33% casein in a saccharine-vanilla solution) for 2h once each day 7h after lights-on (14h light/10h dark). After 28-40 days of daily protein meals, the rats were transferred to tilt floor cages and maintained on the feeding and lighting schedules for a further 7-14 days. Locomotor activity (floor tilts) was monitored continuously by computer. None of the rats showed evidence of meal anticipation, although all rats began consuming the meal immediately on presentation and usually ate all of the protein within 30 min. The protein meal was then increased to 10g daily for a further 25 days for 6 rats but again none of these rats showed meal anticipation.

The results indicate that the motivation to consume protein and the physiological responses to protein ingestion are insufficient to entrain the circadian timing system responsible for food anticipatory rhythms. Further studies are planned to assess whether restricted access to other nutrients can entrain anticipatory rhythms in otherwise free-feeding rats. Intestinal digestive enzyme rhythms will also be measured in nutrient restricted rats.

120.17 URINARY BASAL BODY TEMPERATURE IN ANOREXIA NERVOSA: A MEASUREMENT OF CLINICAL AND THEORETICAL UTILITY. J.M. Jonas*, J. Ehrenkranz*, M. Helmicki*, M.S. Gold. Eating Disorders Program and Research Facilities, Fair Oaks Hospital, Summit, NJ 07901.

Hypothermia is a frequently reported feature of anorexia nervosa (ANN), a life-threatening disorder of unknown etiology. The mechanism of temperature reduction is unknown, and may relate to poor nutrition and reduced caloric thermogenesis, set point displacement (Luck P, Wakeling A, Clin Science, 62:677, 1982), or perhaps dysregulation of the opiate system (Clark WG, Clark YL, Neurosci Biobehav Rev, 4:175, 1980). No longitudinal studies of the effect of weight gain on basal body temperature (BBT) have been reported. Oral temperatures are subject to manipulation, and other methods are too invasive and not acceptable (e.g. rectal probes) for long-term clinical or research use. We studied 3 individuals with ANN who were inpatients at the Fair Oaks Eating Disorders Program, over a period of 1-3 months, using a new method for obtaining BBT via first morning voided urine (Ehrenkranz JR, Endocrinology, 116:312, 1985). Urine samples were obtained upon arising daily, before eating and before the patient had left the bed. Temperature was measured using a disposable Franklin urinary thermometer. The results are summarized in the table below. In all 3 cases, there was a close correlation between urinary BBT and weight gain ($r=.75$ - $.84$; $p < .001$ in all 3 cases). In addition, in each case this relationship was lost as the patient reached 85-90% of ideal body weight. These data suggest that urinary measurement of BBT may be a useful measure of clinical improvement in ANN, perhaps superior to simple weight measurement, which is subject to patient manipulation. This method may also prove a reliable and acceptable technique for investigating circadian rhythms and temperature dysregulation in ANN and affective disorders.

Table 1

#	Height (inches)	Initial Weight (lbs)	Initial BBT (°F)	End of Study Weight	End of Study BBT	r	p
1	68	91	95	129	98.6	0.75	<.001
2	68.5	102	96.6	127	98.6	0.84	<.001
3	65	100	96.4	112	98.4	0.79	<.001

121.1 EVIDENCE FOR ENKEPHALINERGIC MECHANISMS MEDIATING AFFECTIVE DEFENSE BEHAVIOR ELICITED FROM CAT MIDBRAIN PERIAQUEDUCTAL GRAY. M.B. Shaikh, A.B. Shaikh* and A. Siegel. Dept. of Neuroscience, N.J. Medical School, Newark, New Jersey 07103.

The midbrain periaqueductal gray (PAG) has been implicated in the initiation and regulation of aggressive behavior in the cat. Enkephalin - containing cells and axon terminals are known to be present in abundant quantities within the PAG. Recent studies conducted in our laboratory have shown that microinjections of the opioid antagonist naloxone placed into the PAG effectively modulated affective defense behavior (AD) elicited from the hypothalamus (Pott, et al., 1987). In the present study, enkephalin analog [D-Ala^2]Met-enkephalinamide (DAME) was microinjected into the PAG to further determine how the opioid peptide system could regulate AD elicited from the PAG of the cat.

Utilizing a cannula-electrode, AD was elicited by electrical stimulation of the dorsal PAG. AD is characterized principally by hissing, growling and paw striking. The experimental paradigm involved the establishment of stable baseline thresholds for AD over a period of 4 days. Then, DAME (1 ug in 0.5 ul saline, pH=7.4) or vehicle control (saline) was injected through the cannula-electrode at the PAG site from which AD was elicited. Response thresholds were obtained 5, 30, 60, 120 and 180 min. post injection.

It was observed that injections of DAME significantly altered AD response thresholds. Threshold elevations were observed 10-20 min. post injection and, surprisingly, were sustained for 180 min. following drug administration at which time thresholds returned to baseline levels. Suppression of AD was reversed by the opioid antagonist naloxone (1 ug/0.5 ul saline) when injected directly into the same PAG site 30 min. following DAME administration. In contrast, injections of vehicle alone into the PAG had no effect upon attack thresholds.

These results indicate that the metenkephalinergic system is involved in the regulation of affective defense behavior elicited from the feline PAG.

121.2 NALOXONE INDUCED REVERSAL OF MIDBRAIN PERIAQUEDUCTAL GRAY MODULATION OF HYPOTHALAMICALLY ELICITED FELINE PREDATORY ATTACK. S. Weiner*, M. B. Shaikh, A.B. Shaikh* and A. Siegel. Depts. of Restorative Dentistry and Neuroscience, N.J. Dental and Medical Schools, Newark, New Jersey 07103.

It has recently been shown that electrical stimulation of the midbrain periaqueductal gray (PAG) can modulate quiet biting attack (QBA) and affective defense (AD) elicited from the lateral hypothalamus (LH) [Shaikh, et al., 1984]. Recently, our laboratory has demonstrated that endogenous opiates within the PAG can regulate AD [Pott, et al., 1987]. In the present study, we sought to determine the possible role of the PAG opioid peptide system in the modulation of QBA.

Initially, QBA, which involves the stalking and biting of the neck of an anesthetized rat, was elicited by electrical stimulation of LH. Cannula-electrodes were then implanted into PAG sites from which modulation of QBA could be identified by electrical stimulation. Here, a paradigm involving single stimulation of LH and dual stimulation of LH and PAG was employed to determine the presence and directionality of modulation. At this time, injections of 0.5 ul of naloxone (1 ug/0.5 ul of 0.9% saline, pH=7.4) were delivered through the cannula-electrodes into the modulatory sites.

Modulation of QBA was identified from 21 sites in the PAG. The attack response was inhibited at 16 sites and facilitated at five. While most modulatory sites tended to lie within the dorsal half of the PAG, sites which produced response facilitation were generally situated more rostrally than those which inhibited QBA. Following injections of naloxone, we observed a blockade of the facilitatory effect of PAG stimulation in four of the five cases examined. Concerning inhibitory sites, a blockade of modulation was noted in 10 of the 16 sites tested. In contrast, injections of vehicle alone (0.9% saline, 0.5 ul) did not alter the effects of modulation.

These data support the view that endogenous opiates are involved in the regulation of predatory aggression induced from the PAG. Further support for this notion was obtained in a separate experiment. Here, 0.5 ul of [D-Ala^2] Met^5 - Enkephalinamide (DAME) (1 ug/0.5 ul saline, pH=7.4) was injected into an inhibitory site within the PAG. This procedure reversed the naloxone effects generated upon the modulatory site.

121.3 FOREBRAIN ENKEPHALINERGIC CONTROL OF FELINE AGGRESSION. M. Brutus and A. Siegel. Dept. of Neuroscience, N.J. Medical School, Newark, New Jersey 07103.

The bed nucleus of the stria terminalis (BNST) is known to facilitate affective defense behavior (AD) in the cat. These results can be understood in light of its connections with such structures as the corticomedial amygdala and pyriform cortex which also facilitate AD. The BNST is also known to be rich in enkephalin-containing cells and fibers. Therefore, the major goal of this study was to examine the effects of opioid administration upon hypothalamically elicited AD following injections placed into the BNST and adjacent forebrain regions.

Moveable stimulating electrodes were stereotaxically placed into the medial hypothalamus from which AD could be elicited and into those BNST, nucleus accumbens and caudate nucleus sites from which significant modulation of this response could be obtained when hypothalamic stimulation was paired with stimulation of a forebrain site. Within-day stable baseline latencies and thresholds were first established which were followed by intracerebral injections (IC) of D-Ala^2-Met^5-Enkephalinamide (DAME) [1 ug/0.5ul saline] or vehicle alone (0.9% saline, pH=7.4) delivered over 2 min. Response threshold and latency determinations were made 5, 30, 60 and 90 min. post injections. During experimental drug testing, only single stimulation of the hypothalamus was applied.

We observed a facilitation of attack after DAME was injected into BNST sites from which significant facilitation of AD had previously been obtained. The drug induced facilitation of AD was sustained up to 60 min. post injection. Injections of vehicle control into the BNST had no effect upon the attack response. In contrast, inhibition of AD was generally observed following DAME administration into nucleus accumbens sites from which dual stimulation had previously facilitated the attack response, while similar injections placed into the caudate nucleus were largely ineffective. Consistent with the findings obtained when DAME was injected into the nucleus accumbens, injections of the opiate antagonist naloxone (0.5 ug/ul or 5.0 ug/ul) into the region of the n. accumbens resulted in a facilitation of AD.

The results indicate that the enkephalinergic systems within the BNST and nucleus accumbens may differentially regulate affective attack behavior. The mechanisms underlying the expression of these enkephalinergic effects are generally unknown but are currently under examination in our laboratory.

121.4 LESIONS OF THE NUCLEUS ACCUMBENS IN RATS REDUCE OPIATE REWARD, BUT NOT TOLERANCE. J. E. Kelsey, W. A. Carlezon, Jr.* and W. A. Falls*. Department of Psychology, Bates College, Lewiston, ME 04240.

Prior research has implicated the ventral tegmental area of the midbrain in the mediation of the rewarding effects of exogenous opiates such as morphine and heroin. One intent of this study was to determine if the nucleus accumbens (NACC) of the forebrain, which receives an extensive dopaminergic projection from the ventral tegmentum, is also involved in mediating the rewarding effects of morphine. Indicating that it is, lesions of the NACC were found to attenuate the rewarding effects of morphine as measured by a conditioned place preference test. A single i.p. injection of 10 mg/kg of morphine altered the place preference of rats with NACC lesions in a two chambered box less than it altered the place preference of the sham-operated control rats. The groups did not differ on initial place preference, and saline injections did not alter the place preference of either group.

Indicating that this effect did not reflect an inability of rats with NACC lesions to associate morphine with a distinct environment, a second experiment revealed that morphine produced as much conditioned tolerance to morphine in rats with NACC lesions as it did in control rats. Specifically, an i.p. injection of 5 mg/kg morphine in a distinct environment produced more tolerance, as measured by less analgesia, in rats that had previously received morphine injections paired with that environment than it did in animals that had previously received morphine injections unpaired with that environment. Moreover, the magnitude of the increased tolerance observed in the paired rats was identical for both rats with NACC lesions and control rats.

These findings that NACC lesions reduced the rewarding effects of morphine without altering morphine tolerance suggest that the neural systems mediating the initial rewarding effects of opiates are distinct from the neural systems mediating subsequent opiate tolerance and dependence. They further suggest that the NACC is only involved in the former process.

121.5 **PRO-LEU-GLY-NH2 INTERFERES WITH MORPHINE TOLERANCE AND ANALGESIA IN A MULTI-TRIAL TEST.** C. R. McLaughlin, A. H. Lichtman*, M. S. Fanselow* and C. P. Cramer. Department of Psychology, Dartmouth College, Hanover, NH 03755.

Previous reports suggest that a single dose of Pro-Leu-Gly-NH2 (melanotropin-release inhibiting factor, MIF) will inhibit tolerance in rats that are chronically implanted with morphine pellets for up to three days without interfering with acute morphine induced analgesia (Bhargava et al, 1980, 1979, 1976). Differences in morphine administration may result in two different types of tolerance (Baker & Tiffany, 1985; Paletta & Wagner, 1986): short-term tolerance, which is facilitated by closely spaced and chronic administration of morphine (Tiffany & Baker, 1981), or long-term tolerance, which occurs with lower doses and widely spaced administration of morphine and appears to be mediated by Pavlovian conditioning (Siegel, 1977).

We tested MIF in both short- and long-term paradigms. In the short-term test, adult male rats were given either MIF (4 mg/kg, ip) or water on Day 1 only. Two hours later, they were exposed to either morphine or saline three times per day for three days with progressively higher doses (20, 30, 40 mg/kg, ip). Testing, begun approximately eight hours after the final morphine exposure, consisted of administering morphine (10 mg/kg, ip) 30 minutes prior to a hotplate (52°C) test of analgesia. Latency to lick the hindpaw, to a maximum of 90 seconds, was measured in two consecutive trials.

In the long-term test, the animals received either MIF (4 mg/kg, ip) or water each day two hours prior to either morphine (10 mg/kg, ip) or saline within a salient peppermint context to facilitate conditioned tolerance. The animals were tested, as described above, within the peppermint context approximately 48 hours after the final exposure to morphine.

In both experiments, animals treated with MIF prior to morphine exposure showed a longer latency to pawlick in the first trial, suggesting that the peptide had interfered with tolerance. In the second trial, however, both MIF-treated groups exhibited much shorter latencies, a surprising result given that the saline group had no prior experience with morphine. The animals treated with water did not show such a dramatic decrease across trials. These findings suggest a complex interaction between MIF exposure and the expression of morphine-induced tolerance in a multi-trial test.

121.6 DEVELOPMENT OF BEHAVIORAL SUPERSENSITIVITY TO APOMORPHINE DURING CHRONIC TREATMENT WITH CYCLO(HIS-PRO). S.A. Spahn* and C.Prasad (SPON: J.B. Green). Section of Endocrinology, Department of Medicine, Louisiana State University Medical Center, New Orleans, LA 70112.

Cyclo(His-Pro) (CHP) is an endogenous cyclic dipeptide that not only exists in the basal ganglia of rodents, monkeys, and human, but also exhibits a variety of central nervous system-related biologic activities. Some of these biologic activities (e.g. dopamine (DA)-antagonist reversible hypothermia, potentiation of amphetamine-induced stereotypic behavior (SB), in vivo inhibition of tyrosine hydroxylation, in vitro inhibition of DA uptake) suggest CHP to act like a presynaptic DA-agonist. Treatments that chronically attenuate DA synaptic transmission (e.g. DA antagonists, inhibitors of tyrosine hydoxylase, etc.) result in an enhancement of effects associated with DA synaptic transmission. This has been generally interpreted as evidence for the development of postsynaptic receptor supersensitivity. Therefore, we propose that chronic treatment with CHP will result into a postsynaptic supersensitivity. Experiments presented here are designed to test this hypothesis.

Male Sprague-Dawley rats were divided into two groups of 10 animals/group. The first group was allowed to drink water, while the second group received a solution of cyclo(His-Pro) in water (average daily CHP intake = 0.76 ± 0.07 mg/kg). Both groups were injected with apomorphine (0.5 mg/kg, i.p.) and SB scored (Brain Res. 84:1935, 1975) every 10 min. (90 sec. observation epoch) for a total of 90 min. APO-induced SB was measured every week for 8 weeks. The data show that median SB score of CHP-treated rats was significantly different than water-treated animals (ANOVA: $F_{1,14} = 16.84$, $p < 0.005$,). For example, there was a significant augmentation in median SB of group treated for 8 weeks with CHP (water group: control, 0.30 ± 0.19; treated, 0.29 ± 0.15; $p > 0.05$ and CHP group: control, 0.25 ± 0.11; treated, 0.90 ± 0.22; $p < 0.05$). Although these data clearly show a postsynaptic dopaminergic supersensitivity, the mechanism underlying such changes can only be speculated. CHP could act at a dopaminergic site, considered to be the primary mechanism in controlling SB, or at some modulating site involving cholinergic, noradrenergic, or serotoninergic mechanism. Alternatively CHP treatment could simply attenuate APO metabolism.

121.7 MODIFICATION OF NALOXONE-PRECIPITATED WITHDRAWAL SIGNS BY CAPTOPRIL AND CAPSAICIN IN THE MORPHINE-DEPENDENT RAT. L.G. Sharpe, J.H. Jaffe*, M.M.S. Lo and L.J. Porrino. Addiction Research Center, National Institute on Drug Abuse, Baltimore, MD 21224

The neurokinins, especially substance P (SP), appear to be among several endogenous substances that are released during withdrawal from chronic morphine. In the present study, we examined the possible role of SP in the opioid withdrawal syndrome with drugs that alter SP tissue levels. Captopril increases tissue levels of SP through enzyme inhibition whereas capsaicin produces a long-lived SP depletion in several tissues innervated by type c sensory fibers. Captopril in doses of 0.1, 0.3, 1 and 3 mg/kg was injected s.c. 15 min before naloxone (0.5 mg/kg, s.c.) in rats implanted (s.c.) with a 75 mg morphine pellet for 3 days (N=8-12 in each dose group). Only the 0.3 mg/kg dose increased naloxone-precipitated withdrawal, an effect observed in three strains of rats. Captopril alone had no effect in the morphine-dependent rat. In another experiment either saline or captopril (0.3 mg/kg) was injected (s.c.) immediately before naloxone in morphine-dependent rats that were pretreated (4-10 days before the morphine pellet implant) with either capsaicin (125 mg/kg, s.c.) or the capsaicin vehicle (N=8 for each of 4 groups). Capsaicin treatment inhibited withdrawal signs of rhinorrhea, lacrimation and salivation. Captopril increased the occurrence of the three secretory responses in the vehicle treated but not in the capsaicin treated animals. Other withdrawal signs (grooming, penile licking, activity, stretching, teeth chattering, chewing, body weight loss) were not altered by either captopril or capsaicin treatment. It was concluded that substance P and related neurokinins may be involved in the expression of some signs of opioid withdrawal.

121.8 EFFECTS OF MIF ON ROTATIONAL ACTIVITY. S. Davy*, J.W. Boja, B.J. Pomerants*, and H.K. Kulmala. Dept. of Pharmacology, NEOUCOM, Rootstown, Ohio 44272

The tripeptide, MSH Release Inhibitory Factor (MIF) or l-prolyl-l-leucyl-glycineamide (PLG), significantly potentiates the central effects of l-dopa. It has also been shown to dramatically improve the symptoms of Parkinson's Disease when administered intravenously. The present study was initiated to determine if peripherally administered MIF affects central dopamine neurotransmission.

A total of sixteen rats were tested using a hemiparkinsonian rat model and rotational activity. These were divided into four groups of four animals each. All groups were tested initially for rotational activity in a computerized rotometer (details of the apparatus and methods reported in Kulmala et al., Br. Res. Bull., 1987) in response to amphetamine and apomorphine. Two groups received unilateral nigrostriatal lesions and the other two groups received sham lesions. One of the lesioned and one control group were given daily i.p. injections of MIF (25 mg/kg) for four days. Rotational activity in response to apomorphine (0.5 and 1.0 mg/kg) was examined in all animals on days 5, 10 and 15 of the experiment (day 1 was considered the first day of MIF administration). The MIF treated animals all demonstrated a significant enhancement of rotational activity ($p < 0.05$) to the 1.0 mg/kg dose of apomorphine as compared to activity measured prior to MIF. Sham lesioned animals treated with MIF reversed the direction of their rotational activity. These changes in activity were still evident on day 10, but disappeared by day 15. In separate studies with lesioned and unlesioned animals, MIF was found to depress or have no effect on amphetamine-induced rotation. Further studies are planned to determine if the actions of MIF to enhance apomorphine-induced rotation are mediated through DA1 and/or DA2 receptors.

121.9 THE ANTIOPIATE TYR-MIF-1 EXHIBITS GREATER EFFECTS AFTER MODERATE THAN HIGH STRESS. Z. Harry Galina & Abba J. Kastin. VA Medical Center and Tulane University School of Medicine. New Orleans, LA, 70146

We used the endogenous peptide Tyr-MIF-1 (Tyr-Pro-Leu-Gly-NH_2), a component of an endogenous antiopiate system, to test the concept that various environmental situations would alter the effectiveness of a peptide to antagonize stress-induced analgesia. Our observations demonstrate that Tyr-MIF-1, and by implication other putative antiopiates, functions better under conditions that induce less intense analgesia than under stronger analgesia.

Antinociception was measured in male CD-1 mice on a hot-plate (52.5°C). In each of the three studies, mice received a coded solution (10 ml/kg) of either diluent (0.9% NaCl, 0.01M acetic acid) or Tyr-MIF-1 (0.1 mg/kg) ip 20 min before exposure to stress.

Various levels of stress-analgesia were induced in mice by one of three methods which we or others have shown to be opiate mediated. We used 90 sec of 0, 0.25, 0.50, or 1.00 mA of constant current electric shock; forced swimming in warm-water (32°C) for 0, 3, 6, 12, 24, or 48 min; or 20 min of exposure to a novel environment. In the novelty experiment we manipulated the intensity of stress by using six different levels of temperature on the hot-plate varying from 47.5 to 60°C in increments of 2.5°C.

The results (ANOVA and Duncan's multiple range tests) indicated that shock effectively induced analgesia that was reduced by Tyr-MIF-1 at moderate but not high intensities of shock. Tyr-MIF-1 reduced the analgesia induced by warm-water swimming after moderate times of exposure. Novelty-induced analgesia was reduced by Tyr-MIF-1 measured at the lower temperatures but not at the higher ones.

These results indicate that the endogenous antiopiate system can discriminate levels of intensity of stress. One of the functions of the antiopiate system may be to curtail the suppression of pain, thus re-establishing antinociceptive homeostasis. Since the danger to the animal at any given moment may be related to the intensity of the stress-evoking situation, the balance of opiate and antiopiate action may be regulated by the intensity of stressor. This is supported by our findings that at least one system of endogenous antiopiates functions better at moderate than high levels of stress.

121.10 EFFECTS OF CYSTEAMINE-INDUCED MANIPULATIONS OF CENTRAL SOMATOSTATIN ON LOCOMOTION AND GENERAL ACTIVITY IN RATS. G.R. Sessions, C.L. Winstead*, K.H. Chantry* and G.F. Koob. U.S. Army Med Res & Dev Cmd, Ft. Detrick, MD 21701, U.S. Air Force Academy, Colorado Springs, CO 80840 and Scripps Clinic & Res Foundation, La Jolla, CA 92037.

The recently hypothesized role of somatostatin neurons in Alzheimer's Disease (Roberts, et al., Nature, 314:92, 1985) has greatly increased research interest in determining the functional role of this peptide in influencing behavior. Cysteamine HCl has been shown to produce initial release and temporary depletion of brain somatostatin (Bakhit, et al., Reg. Peptides, 6:169, 1983) without altering levels of other neuropeptides (Palkovits, et al., Bn. Res., 240:178, 1982) and has become a useful tool in exploring this problem. Cysteamine effects on activity have been very variable, with studies reporting increased activity (Bakit & Swerdlow, 1986), decreased activity (Vescie, et al., Pharm. Biochem. Beh., 21:833, 1984), or no effects at all (Sessions, et al., Neurosci. Abs., 11:1113, 1985). The current study was designed to investigate the effects of centrally administered cysteamine on locomotor and general activity in rats following acute administration, when somatostatin would presumedly be released in brain, and after chronic treatment, when somatostatin levels should be depleted. Locomotor activity was recorded continuously in automated chambers in three groups of rats (N = 5 ea.) for 150 min following 4 daily intracerebroventricular (ICV) infusions of buffered saline vehicle, 250 or 350 ug of cysteamine in volumns of 2 ul. Frequency and durations of individual behaviors were recorded during ten-min observational tests conducted 30 and 90 min following drug administration. Results showed that acute administration of cysteamine produced initial suppression of locomotor activity lasting approximately 5-15 min, followed by sustained increases 90 min following injections in behaviors characteristic of stereotypy: sniffing, rearing, or standing immobile, and concomitant decreases in resting behaviors, ie., lying down. The cysteamine-induced effects on activity were significantly attenuated following the fourth daily treatment of the drug, when no differences in locomotor activity or general activity levels of individual behaviors was observed. With the exception of first injection effects on rearing, no significant differences were observed between the effects of the two drug doses. The results suggest that the initial activation of stereotypical behaviors was produced by cysteamine-induced release of endogenous somatostatin in brain, and was attenuated following chronic treatments due to the depletion of neuronal stores of the peptide.

121.11 INTRA-MEDIAN RAPHE INFUSIONS OF TACHYKININS PRODUCE LOCOMOTOR HYPERACTIVITY. J.M. Paris and S.A. Lorens. Behavioral Pharmacology Laboratory (Bldg. 135), Stritch School of Medicine, Loyola Univ. of Chicago, Maywood, IL 60153

We have demonstrated previously that intra-median raphe (MR) infusions of the metabolically stable neurokinin analogue, [$pGlu^5$, $MePhe^8$, Sar^9] substance P(5-11), abbreviated DiMe-C7, produce dose-dependent increases in locomotor activity as measured in photocell chambers. This hyperactivity was found to be dependent upon intact intra-MR serotonin neurons, and is blocked by administration of the dopamine antagonist, haloperidol (200 µg/kg) (Behav. Brain Res., 1987). The present series of experiments were undertaken in order to determine the relative rank-order of potency of the various tachykinins for eliciting hyperactivity following intra-MR infusion. The non-mammalian tachykinins: eledoisin (ELE), kassinin (KAS), and physaelamin (PHY); and the mammalian neurokinins: substance P (SP), neurokinin A (NKA), and Senktide (a neurokinin B agonist) were tested.

In the first experiment, separate groups of rats, chronically implanted with intra-MR cannulae, were tested with vehicle and three doses of either ELE, KAS, or PHY. The doses used (0.03 nmoles/µl, 0.23 nmoles/µl, and 1.14 nmoles/µl) were equimolar with the approximate ED_{25}, ED_{50}, and ED_{100} doses, respectively, of DiMe-C7. The rank order of potency of the tachykinins for eliciting hyperactivity was: ELE = KAS = DiMe-C7 >> PHY.

In the second experiment, separate groups of rats, implanted with chronic intra-MR cannulae, were tested with the identical equimolar doses of either SP, NKA, or Senktide. The rank order of potency for eliciting hyperactivity was: Senktide > NKA = DiMe-C7 >> SP.

The results suggest that the hyperactivity produced by intra-midbrain raphe neurokinin injections is mediated by stimulation of NK-2 and NK-3 receptors located, most likely, on serotonin neurons which in turn regulate the activity or targets of ascending dopamine projections.

121.12 MODULATION OF CARDIAC ORIENTING REFLEXES BY MULTIPLE OPIOID SUBSYSTEMS. L.L. Hernández. Neuroscience Lab., Dorn Veterans' Hospital, Columbia, SC 29201.

Albino rabbits were tested for heart rate orienting reflexes (HR ORs) to novel tones following intravenous treatments with opioid peptide analogs and opiate antagonists. DADL (d-ala^2-d-leu^5-enkephalin; 10 µg/kg) or the antagonist naloxone-HCl (0.5 mg/kg) attenuated bradycardiac HR ORs to initial tone presentations compared to saline controls, but did not affect habituation during later tone presentations or retention of habituation 24 hours later. DALA (d-ala^2-met-enkephalinamide; 10 µg/kg) induced a much smaller decrease in initial HR OR magnitude but appeared to speed habituation, although it did not affect retention. The quaternary analog naloxone methobromide (0.5 or 5.0 mg/kg) failed to affect HR ORs, habituation or retention. Combined treatments with DALA plus naloxone-HCl or DADL plus naloxone-HCl did not affect HR ORs, i.e. the effects of naloxone and the peptides were antagonized by combined treatments. However, DADL plus naloxone did decrease HR OR magnitude during the retention test. These data suggest that multiple opioid subsystems in the central nervous system interact to modulate orienting and habituation. Specifically, preferential δ-opioid receptor stimulation by DADL, or preferential µ-opioid receptor blockade by this low dose of naloxone, attenuated HR ORs and therefore may influence attention and sensory processing of stimuli. Conversely, stimulation of both δ- and µ-opioid receptors by DALA had little effect on initial HR ORs but may have influenced later habituation. These data concur with other evidence indicating that opioid peptides modulate attention and sensory processing, and further suggest that an imbalance among multiple opioid receptor subsystems disrupts these perceptual functions.

The opioids also influenced baseline (pre-tone) HR following intravenous injection. DALA, DADL and naloxone-HCl generally increased HR, whereas naloxone methobromide and the combined treatments generally decreased HR. These data concur with other evidence suggesting that cardiovascular activity is influenced by complex interactions among central and peripheral opioid subsystems. However, these data also suggest that changes in tonic HR following intravenous opioid treatments cannot, by themselves, account for the observed changes in HR OR magnitude.

121.13 EFFECTS OF A NEW PEPTIDASE INHIBITOR ON MEMORY PROCESSES AND CENTRAL CHOLINERGIC METABOLISM IN MICE AND RATS. G. Wiemer*, P. Usinger*, F.J. Hock, H.J. Gerhards*, B.A. Schölkens*, R.H.A. Becker*, R. Henning* and H. Urbach*. Hoechst AG, 6230 Frankfurt/M. 80, FRG.

In the last years there are a large body of hints that several neuropeptides (e.g. enkephalines, substance P and somatostatin) are involved in memory and learning processes. For that reason, there is a suggestion that peptidase inhibitors are able to modulate cognitive functions by blocking the degradation of peptides.

A new heterocyclic peptidase inhibitor was found to be highly effective in inhibitory (passive) avoidance as well as eight-arm-radial maze. In the 2 tests an amnesia induced by scopolamine was antagonized by a pretreatment in mice and rats respectively on 3 consecutive days with the peptidase inhibitor (0.1 - 30 mg/kg p.o. and i.p. respectively). The resulting U-shaped dose-response-curves most likely reflect an interaction of two or more peptides influencing the acquisition and retention of information.

How these peptides interact with one another and other neurotransmitters is till now a matter of speculation. From our investigations it becomes obvious that acute or repeated administration of the peptidase inhibitor (0.03 - 3 mg/kg i.p.) induces a pronounced decrease of acetylcholine (ACh) in different brain areas of the rat. The fall in brain ACh-content is most likely due to an enhanced release of ACh. This interpretation is established by experiments carried out with the choline uptake inhibitor hemicholinium-3 (HC-3). Co-administration of HC-3 (20 µg i.c.v.) and the peptidase inhibitor (0.3 mg/kg i.p.) potentiates the decrease of ACh-content induced by HC-3. In parallel the peptidase inhibitor enhances in the same dose range the activity of the enzyme choline acetyltransferase. Probably this enzyme activation is the consequence of the augmented ACh-release. The dose-response-curves of the biochemical data are also U-shaped.

The results indicate, that the new peptidase inhibitor enhances cholinergic metabolism in rat brain which is accompanied with a nootropic effect.

121.14 CENTRAL ADMINISTRATION OF ALPHA-HELICAL CORTICOTROPIN-RELEASING FACTOR ATTENUATES THE ACQUISITION OF A CONDITIONED EMOTIONAL RESPONSE. B.J. Cole.* K.T. Britton and G.F. Koob. (SPON: C. Rivier). Div. Preclinical Neuroscience and Endocrinology. Scripps Clinic and Research Foundation. La Jolla. CA 92037. Dept. Psychiatry. San Diego Veterans Administration Medical Center. La Jolla. CA 92161.

Central administration of corticotropin-releasing factor (CRF) in the rat reliably induces behaviors normally exhibited during conditions of high stress. These findings have led to the hypothesis that this neuropeptide is important not only for the neuroendocrine, but also the behavioral response to stress. To examine the behavioral significance of endogenous CRF in fear motivated behavior, we used the specific, competitive antagonist of CRF, alpha-helical CRF (9-41). This CRF-antagonist has been shown to reverse the 'anxiogenic' effects of CRF in a conflict test, but does not have any effect itself in this behavioral paradigm (Brain Res.,369:303, 1986).

Food deprived rats were trained to respond on a RI-90 schedule for food reinforcement. After a stable level of responding had been attained, all the subjects were implanted with a guide cannula aimed at the lateral ventricle, and assigned to one of 4 experimental groups, equated for baseline response rates. After a post-operative recovery period, the effects of alpha-helical CRF on the acquisition of a conditioned emotional response were examined, by infusing the antagonist (0, 1, 5, 25ug / 5ul) into the lateral ventricle, 30 min before each test session. During these test sessions, 4 pairings of a light conditioned stimulus (CS) and a 0.5 sec, 2.1 mA (biphasic, direct, constant current) footshock were presented, while the animals were responding for food reinforcement.

The control animals showed a significant decrease in response rate during the presence of the CS in the 9 test sessions, demonstrating their acquisition of a conditioned emotional response. However, this response suppression was significantly attenuated by alpha-helical CRF, at all of the doses studied.

These results provide further evidence for the importance of CRF in the behavioral response to stress. However, further experiments are necessary to determine the nature of the behavioral impairment. One possibility is that alpha-helical CRF produces an 'anxiolytic-like' effect, qualitatively similar to benzodiazepines. Alternatively, endogenous CRF may be specifically involved in the acquisition of the conditioned fear.

121.15 FOOTSHOCK-ELICITED FREEZING IN THE RAT IS ENHANCED BY INTRACEREBROVENTRICULAR ADMINISTRATION OF CORTICOTROPIN-RELEASING HORMONE AND IS ATTENUATED BY ITS ANTAGONIST. J.E. Sherman,* C.M. Barksdale,* L.K. Takahashi,* and N.H. Kalin* (SPON: L. Hegstrand). Dept. of Psychiatry, Univ. of Wisconsin-Madison 53792, and William S. Middleton Veterans Hospital, Madison, WI 53705.

Freezing is a defensive behavior in rodents displayed in response to fear-eliciting stimuli including predators and aggressive conspecifics. In an initial study we found that footshock significantly ($p < .05$) increased freezing and plasma levels of ACTH in a manner directly related to shock intensity. To assess whether corticotropin-releasing hormone (CRH) plays an endogenous role in shock-elicited freezing, we administered synthetic CRH or its antagonist α-helical CRH[9-41] intracerebroventricularly to rats and observed their behavioral response to mild footshock. In Experiment 1, rats were given 0 (vehicle), 100, or 300 ng of CRH. Twenty-four minutes after drug administration the test rats received three brief footshocks (0.79 mA, 1.0 s each, 20 s apart); controls were not shocked. CRH significantly enhanced shock-elicited freezing in a dose-dependent fashion but had no effect on freezing in nonshocked controls. In Experiment 2, rats given vehicle or CRH (300 ng) displayed comparable response latencies on the hot-plate test of pain sensitivity, ruling out the possibility that altered sensitivity to pain could account for CRH's effect on freezing. In Experiment 3, rats were given 0, 5, or 25 µg of the CRH antagonist 24 min before footshock (1.0 mA, 1.0 s each, 20 s apart). The 25-µg dose significantly attenuated shock-elicited freezing but the 5-µg dose had no effect. Hot-plate tests of pain sensitivity showed that the CRH antagonist did not significantly modulate nociceptive processing. These findings suggest that in the rat, endogenous CRH systems play a role in shock-elicited freezing and do so via processes unrelated to nociception.

121.16 CORTICOTROPIN-RELEASING FACTOR (CRF) AND NOREPINEPHRINE INVOLVEMENT IN THE REGULATION OF EXPLORATORY BEHAVIOR. C.W. Berridge and A.J. Dunn.
Department of Neuroscience, University of Florida, Gainesville, FL 32610.

Corticotropin-releasing factor (CRF) within the brain has been postulated to participate in the regulation of both behavioral and physiological responding in stress. Using the multicompartment chamber (MCC) described by Arnsten & Segal (Life Sci. 25: 1035-1042, 1979) to study exploratory behavior in a novel environment, we have observed similar effects of restraint stress and ICV CRF on investigatory behavior in mice. Both restraint and ICV CRF (10-150 ng) decreased the mean time per contact with environmental stimuli in the absence of significant effects on locomotor activity as measured by rears or compartment entries. This effect of restraint was observed in hypophysectomized animals, indicating an action independent of the pituitary-adrenal axis. The CRF-antagonist, alpha-helical CRF_{9-41}, injected ICV 10 min prior to restraint reversed the effect of restraint in a dose-dependent manner with significant effects at 10, 20 and 50 µg. This effect of the antagonist was observed in the absence of consistent effects on locomotor activity. These results support the hypothesis that endogenous CRF participates in the regulation of behavioral responding in stress.

Both CRF and stress activate cerebral noradrenergic systems, and norepinephrine (NE) has been implicated in behavioral responding in stress. Therefore, we examined the effect of clonidine, an alpha-2 agonist, on the response of mice in the MCC. Clonidine increased the mean time per contact with the environmental stimuli in a dose-dependent fashion with significant effects observed at 25 and 50 µg/kg. This effect of clonidine was prevented by the alpha-2 antagonist, yohimbine (1 mg/kg). Our results suggest the possibility that one mechanism by which restraint and CRF act to decrease investigatory behavior in the MCC involves an activation of noradrenergic sytems.

Supported by National Institute of Mental Health (MH25486) and a fellowship from the Center for Neurobiological Sciences (NIMH Training Grant MH15737).

121.17 ENVIRONMENTALLY-DETERMINED BEHAVIORAL EFFECTS OF ICV ADMINISTERED CRF: DIFFERENTIAL INHIBITION BY CHLORISONDAMINE. D.R. Britton and E. Indyk*. Department of Pharmacology University of the Health Sciences / Chicago Medical School and Neurosciences Research, Abbott Laboratories, North Chicago, Ill. 60064

Rat/human corticotropin-releasing factor (CRF) (kindly provided by J. Rivier of the Salk Institute) was injected icv into rats prior to testing in either the home cage or a modified open field test (Britton and Britton, 1981). As previously reported, CRF produces an increase in grooming, a decrease in food consumption and an alteration in locomotor activity. The nature of the altered locomotion is dependent upon the environment in which the animal is tested. Twenty-four hr. fasted rats tested in a familiar environment with CRF (30 or 60 pmol, icv) show increased rearing and horizontal locomotion while in the modified open field test, both measures of locomotion are decreased.

In an attempt to address the question of the possible contribution of sympathetic activation to the observed behavioral effects, some animals were pretreated with the ganglionic blocking agent chlorisondamine which has previously been shown to prevent the sympathetic activation produced by centrally administered CRF (Fisher et al., 1982). In the home cage test, chlorisondamine reduced locomotor activation following 60 or 120 pmol CRF and also reduced the suppression of eating. However, in the open field test where the effect of CRF is to reduce locomotor activation, chlorisondamine failed to reverse the CRF effect.

These data demonstrate that the CRF-induced activation of locomotor activity in the home cage is either a) mediated by, or b) dependent upon, different processes than the locomotor suppressive effects of CRF observed in the open field test. The chlorisondamine-sensitive component of activation could be mediated in part by elevated catecholamine levels which could serve as stimuli to arousal. Alternatively, an intact autonomic system may be required to support the metabolic demands of heightened activity. Since the locomotor inhibition seen in the novel open field was unaltered by chlorisondamine it appears unlikely that sympathetic activation is critical to that effect of CRF. The data fail to support the hypothesis that the behavioral effects of CRF are directly mediated by activation of the sympathetic nervous system.

121.18 INTRA-ACCUMBENS INJECTIONS OF CCK-8 ATTENUATE THE LOCOMOTOR RESPONSE TO APOMORPHINE IN 6-OHDA LESIONED AND CHRONIC-NEUROLEPTIC TREATED RATS. F.Weiss, A. Ettenberg and G.F. Koob. Div. of Neuroscience and Endocrinology, Scripps Clinic and Res. Fnd. La Jolla, CA 92037, Dept. of Psychology, University of California, Santa Barbara, CA 93106

Substantial anatomical data show that CCK-8 coexists with dopamine (DA) in midbrain DA neurons innervating the basal forebrain. Several lines of evidence (including electrophysiological, biochemical and behavioral data) indicate that, in this coexistence system, DA and CCK may have functionally opposing roles. For example, in behavioral tests CCK-8 has been shown to antagonize the locomotor effects of psychostimulants. There is, however, some evidence to suggest that CCK is more effective at reversing the behavioral effects of indirectily, rather than directly acting DA agonists. In fact, the peptide has been reported to enhance DA-mediated behaviors following joint injection of DA and CCK-8 into the nucleus accumbens (N.Acc.) Thus, it remains unclear whether the DA antagonist-like action of CCK is pre-or postsynaptic in nature. We have, therefore, studied the postsynaptic effects of intra-N.Acc. administered CCK-8 on APO-stimulated hyperlocomotion using two rat behavioral preparations of DA receptor supersensitivity.

The locomotor response to SC injections of APO (0.15 mg/kg) was markedly enhanced following 12 days of cis-[z]-flupenthixol treatment (4 mg/kg; IP). Bilateral intra-N.Acc. injections of CCK-8 (2 μg) reliably reduced the supersensitive locomotor response to APO challenge and also attenuated APO-stimulated locomotor activity in chronic-vehicle treated rats. The magnitude of CCK-8 effects was comparable to those of intra-N.Acc. injected haloperidol (5 μg). A lower dose of CCK-8 (20 ng) was without effect in both supersensitive and intact rats.

Intra-N.Acc. injections of CCK-8 also antagonized APO-stimulated (0.1 mg/kg;SC) hyperlocomotion in rats with bilateral 6-OHDA (8 μg/side) lesions of the N.Acc. In contrast to its actions in chronic-neuroleptic treated rats, however, CCK-8 reversed APO effects in the animals with lesions in a dose-dependent manner, and at much lower concentrations (1-100ng).

This attenuation of APO-induced locomotor activity by intra-N.Acc. injected CCK-8 in both DA supersensitivity paradigms strongly suggests that the peptide has potent antagonist effects on mesolimbic DA transmission, and supports the view that DA and CCK are functionally opposed to each other at the postsynaptic level.

SUBCORTICAL VISUAL PATHWAYS II

122.1 FUNCTIONAL PROPERTIES OF THE RETINOTECTAL CONDUCTION GROUPS IN THE OPTIC TRACT AND BRACHIUM OF THE SUPERIOR COLLICULUS IN HOODED RAT. D. Impelman and D. A. Fox. College of Optometry, University of Houston, Houston, TX 77004.

The electrophysiological characteristics and photic responses of the three retinal ganglion cell (RGC) conduction groups recorded in the optic tract (OT) differ from their properties in the brachium of the superior colliculus (SC). Previous electrophysiological studies have shown that the fast conducting t1/Y-like (12.5 m/sec) and the middle conducting t2/X-like (6.0 m/sec) axons branch to innervate both the superior colliculus and the dLGN (Sefton, Vis.Res.8: 867, 1968). In addition, HRP retinotectal studies have demonstrated that the largest percentage axonal projection to SC (63%) is comprised of the slow conducting t3/W-like (3.5 m/sec) axons (Schober et al., 1977, Z. Mikrosk. Anat. Forsch. 92: 283, 1977). We are interested in the presynaptic transfer properties of retinotectal axons and therefore studied their functional characteristics in OT and SC brachium recordings of field potential responses to electrical and photic (flicker and spatial frequency) stimulation. Our orthodromic response amplitude measurements of t1, t2 and t3 correlate better with the SC HRP estimates of the RGC conduction group projections than with SC unit latency histograms. Conduction velocity slowing predicted by changes in fiber diameter was measured in optic chiasm responses to antidromic OT/SC stimulation. Onset conduction velocities for t2 and t3 are decreased 3-9% and 15-20%, respectively, while only t3 peak velocities are decreased. Waveform rise times, durations and chronaxie increases are inversely proportional to SC brachium conduction velocities. Orthodromic OT/SC amplitude intensity functions are linear and show a sensitivity decrease correlated with threshold excitability. Recovery of excitability in SC brachium axons is characterized by increased refractoriness and a subnormal period in t2 fibers which is probably mediated by an increased intracellular potassium concentration. The ionic sensitivity of the t3 conduction group to the 4-AP K+ channel blocker (5 mM) suggests that the t3/W-cell activity produces the depression period characteristic of SC recovery functions. The functional differences in the photic properites of OT and SC brachium axons show a decreased acuity correlated with their receptive field properties. Flicker and frequency following properties of the t1 conduction group are unattenuated in the SC brachium. The slowing of impulse transmission and the delayed recovery, which is selectively amplified in the t3 conduction group, may act to enhance the response stationarity characterisitic of the W-cell population. Supported by NIEHS Grant ES 03183 (DAF).

122.2 FURTHER OBSERVATIONS ON TOPOGRAPHY AND COMPARTMENTALIZATION OF THE CAT'S SUPERIOR COLLICULUS. R.-B. Illing* (SPON: European Neuroscience Assoc.), Unit for Morphol. Brain Res., HNO-Klinik, D-7800 Freiburg, Fed. Rep. Germany.

The pattern of the retinal innervation of the superior colliculus (SC) has been reexamined and correlated to the mosaic of terminal zones of those afferent systems represented by the distribution of acetylcholinesterase (AChE) activity in the intermediate tectal layers of the cat.

In the colliculi ipsilateral to the eyes injected with horseradish peroxidase, a tripartite organization of the visual field representation was apparent. The rostral quater is supplied only by a crossed pathway and thus remained largely unlabeled except for fibers on the level of stratum opticum, which bridge this region to reach their terminal areas further back. The middle part of the SC was sharply demarcated against the rostral zone by receiving a substantial uncrossed innervation. The terminals of this pathway form clusters which appeared in tangential sections as a rather regular mosaic of islands with an average spacing of about 500 μm. The caudal collicular quater was void of labeling, indicating a monocular innervation from the nasalmost contralateral retina. The SC contralateral to the injection was labeled throughout the caudorostral extent, but included "holes" of weaker labeling corresponding in depth and distribution to the clusters seen in the uncrossed path. Thus only the middle two collicular quaters harbor a binocular representation. Depth and extent of the total retinal innervation is closely matched by the area of high AChE-activity in the superficial layers.

AChE-activity in the intermediate layers of the SC has been reported to be distributed in a complex gridwork. While this grid is prominent at caudal levels, it is largely absent from rostral regions. Serial reconstructions of longitudinal and tangential sections revealed that this change in architecture corresponds to the retinotectal system as the non-compartmentalized rostral part lines up with the rostral quater of the superficial layers characterized by the lack of an uncrossed retinal input. The topographic landmarks supplied by the retinal innervation helped to project the AChE-rich gridwork, and thus the mosaic of afferents related to it, back into the visual field. The periodicity of this pattern agrees well with the receptive field sizes determined in the intermediate collicular layers.

It is concluded that the structural changes across the cat's SC correlate to its topographic organization. Those tectal parts representing ipsilateral stimuli lack a compartmentalization, while intricate mosaic arrays of functionally distinct domains apparently prevail in tectal zones that fit the classical concept of contralateral representation.

122.3 DISTRIBUTION, MORPHOLOGY AND SOURCES OF CHOLINERGIC AXON TERMINALS IN THE SUPERIOR COLLICULUS OF THE CAT. W.C. Hall, D. Fitzpatrick, D. Raczkowski and L.L. Klatt* Dept. Anatomy, Duke Univ. Med. School, Durham N.C. 27710

We examined the cholinergic innervation of the superior colliculus (SC) in the cat using a monoclonal antibody for choline acetyltransferase (ChAT) and tract tracing methods. ChAT immunoreactive fibers with small en passant swellings are found throughout the SC, but the highest concentrations are in the superficial and intermediate layers. In the superficial layers, the distribution is homogeneous, while in the intermediate layers ChAT immunoreactive terminals are distributed in a patchy pattern similar to the pattern of acetylcholinesterase staining in this layer (Graybiel, A.M. Nature 272, 1978). Electron microscopic analysis confirms the presence of cholinergic axon terminals within the SC and indicates that, in both the superficial and intermediate layers, the terminals form synaptic contacts on dendrites with small but distinct postsynaptic densities.

Potential sources of the ChAT immunoreactive fibers were identified by making injections of WGA-HRP into the SC and processing the sections for the demonstration of both retrograde transport and ChAT immunocytochemistry. Double labeled neurons are present in the parabigeminal nucleus (Pbg) and in a band of cells that stretches across the midbrain and pontine reticular formation and includes nucleus tegmenti pedunculopontis and the lateral dorsal tegmental nucleus. Since the Pbg projects to the superficial layers (Graybiel, A.M. Brain Res. 145, 1978), it is probably the major contributor of cholinergic terminals in these layers. Anterograde transport of WGA-HRP suggests that ChAT positive neurons in the reticular formation are the major contributors to the terminals in the intermediate layers. These two sources of cholinergic innervation may have distinct functions. The pathway from Pbg may be involved primarily with influencing the relay of visual information through the superficial layers. In contrast, the cholinergic pathway from the reticular formation has close associations with the substantia nigra and may play a role in the premotor functions of the intermediate grey layer.

A third potential source of ChAT innervation in the SC is a population of neurons scattered throughout the superficial grey and stratum opticum. However, it remains to be determined whether the axons of these ChAT positive neurons have local arborizations and thus contribute to the innervation within the SC, or whether they terminate in distant targets with few or no local terminations (supported by NSF grants # BNS-86-07060, BNS-84-11964 and BNS-85-19709).

122.4 Origins of visual input to the deep layers of the superior colliculus in rabbits. R. W. Sikes and C. R. Payette*. Dept. of Physical Therapy, Northeastern Univ., Boston, MA 02115.

The deep layers of the rabbit superior colliculus (SC) contain neurons which respond especially well to visual stimuli moving in a particular direction. The receptive fields of these units are large but topographically organized. While visual afferents from the retina and primary visual cortex terminate in the superficial layers of SC, no direct projection from the superficial to deep layers has been demonstrated. Thus, the pathways which provide visual information to the deep layer neurons are unknown.

An indirect trans-striatal projection from the visual cortex to SC via the substantia nigra, pars reticulata (SNr) has been proposed as a source of visual input to the deep layers. The projection from SNr to SC may be topographically organized. To test this suggestion directly, multiple injections of Fluoro-Gold and rhodamine-labeled latex microspheres (0.05 to 0.1 µl) were made into physiologically identified regions of the SC in Dutch rabbits. Spread into the superficial layers of the SC and the overlying cortex was controlled by injecting through permanently implanted guide cannulas. After survival times from 3 to 7 days, the rabbits were perfused with 10% phosphate buffered formalin. The brains were then removed and sectioned at 30 µm. The sections were viewed with fluorescent microscopy and the location of single or double labeled neurons was plotted.

Injections placed into SC regions which corresponded to each visual quadrant labeled neurons throughout the substantia nigra. Labeled neurons were observed in both pars reticulata and lateralis but not in pars compacta. Both large and medium sized cells were seen. Medium sized neurons were more frequently located ventromedially both above and within the fibers of the cerebral peduncles. In the latter case, the cells were frequently spindle shaped. Although the projection was primarily ipsilateral, a considerable number of labeled neurons were observed in the contralateral SNr.

Little evidence for a clear topographical organization of the SNr projection to SC was obtained. Rostrally and caudally placed injections labeled neurons at both rostral and caudal levels of the SNr. Multiple injections into distinct quadrants of the SC produced double-labeled neurons at most rostrocaudal levels. Although clusters of singly labeled neurons were observed, these clusters were intermixed and had little or no topographical relation with the injection sites. Thus, the SNr projection appears to be quite diffuse and would be expected to have global effects on SC neuronal activity. Other labeled regions which might bring topographically organized visual information to SC will be described.

122.5 LIGHT AND ELECTRON MICROSCOPIC OBSERVATIONS ON THE DEVELOPMENT OF THE CORTICOTECTAL PROJECTION IN CATS. K. LORD*, AND M. BEHAN. (SPON: L. STANFORD). Neurosciences Training Program, Univ. of Wisconsin, Madison, WI 53706.

A robust projection from primary visual cortex to the superficial layers of the superior colliculus (SC), as demonstrated following injections of tritiated leucine, is present at birth in the cat. It has been shown, however, that the adult physiological properties of collicular neurons in the superficial layers do not appear until several weeks after birth (Stein, 1973). It has been suggested that this immaturity in the physiological properties of collicular cells may reflect the developmental stage of corticotectal neurons, or the lack of well developed synaptic organization in the SC. A further possibility is that collicular neurons are still maturing postnatally.

Adult cats, and kittens aged 1 day, 1 week, and 2 weeks were used to examine the corticotectal projection, and the progression of neuronal development in the superficial layers of the SC. The corticotectal projection was studied at the light microscopic level using the anterograde tracer, Phaseolus vulgaris-leucoagglutinin (PHA-L), and at the electron microscopic level using wheat germ agglutinin conjugated with HRP (WGA-HRP). The rapid Golgi method was used to examine the morphology of cells in the superficial layers of the SC.

Following injections of PHA-L in area 17, preliminary results indicate that the morphological appearance of the corticotectal projection at 1 and 2 weeks of age is similar to that in adults. However, the distribution of axonal arborizations in the superficial layers of the kittens appears to differ from that in adults. In the young animals the density of labeled axons and terminals is higher in the stratum zonale and the upper part of stratum griseum superficiale (SGS) than in the adult where the density appears slightly higher in the lower part of SGS.

WGA-HRP labeled axon terminals are present at all ages examined. Corticotectal terminals make synaptic connections at 7 days of age, but it is not yet clear how extensive synapse formation is before this time.

Light microscopic observations of Golgi-impregnated neurons have revealed that while all the major types are present at birth, they are morphologically immature. Based on comparsions with adult tissue, many vertical field and horizontal cells are well developed at birth, while stellate and marginal type cells appear to be at an earlier stage of development at this time.

In summary, there are a number of morphological changes occuring after birth in the superficial layers of the SC. The exact nature of these changes requires further study. (Supported by NIH Grant EY04478)

122.6 AN ULTRASTRUCTURAL ANALYSIS OF THE CORTICOTECTAL PROJECTION FROM THE LATERAL SUPRASYLVIAN AREA TO SUPERIOR COLLICULUS IN THE CAT. M.J. Graper* and M. Behan. (SPON: A.J. Weber). School of Veterinary Medicine and Neurosciences Training Program, University of Wisconsin, Madison, WI 53706.

In the mammalian visual system, the lateral suprasylvian area (LS) of cerebral cortex represents an important source of visual input to the superior colliculus (SC). Segal and Beckstead (J. Comp. Neurol., 225:259-275, 1984) have shown that two distinct areas of LS cortex, the posteromedial (PMLS) and posterolateral (PLLS) areas, project to superficial and deep laminae of the SC respectively. While the superficial layers of the SC are a primary target of visual input from retina and visual cortex, the deep layers receive multimodal input from a variety of different cortical and subcortical regions. Efferent targets of superficial and deep collicular layers are also different.

We are interested in the differential input of LS cortex on neurons in the superficial and deep layers of the SC, and in particular, whether the synaptic morphology of PMLS and PLLS neurons is different.

Injections of tritiated amino acids were made into PMLS or PLLS. Following a 24 hour survival, animals were perfused with mixed aldehydes and alternate sections through the SC were prepared for light (LM) and electron microscopic (EM) autoradiography. LM autoradiograms were analyzed to determine those areas of highest radioactive label. Corresponding areas from adjacent sections prepared for EM were serially thin sectioned and processed for EM autoradiography.

LM autoradiograms show the expected differential projection pattern from PMLS and PLLS in the superficial and deep layers of SC. Preliminary EM autoradiographic data indicates that there may be a difference in the morphology and synaptology of terminals from PMLS and PLLS. PMLS terminals are larger, up to 3.5µm in diameter, with clusters of centrally located mitochondria. They contain loosely packed vesicles which are predominantly pleomorphic, and make asymmetrical contacts on large caliber dendrites and axon initial segments. PLLS terminals are smaller, ranging from 0.5 - 1.5µm, have clear axoplasm, and several scattered mitochondria. They contain predominantly pleomorphic vesicles and make symmetrical contacts with smaller caliber dendrites.

It may be necessary to look upon the projection from LS cortex to SC as two distinct pathways that exert quite different effects in superficial and deep layers.

Supported by NIH grant EY04478.

122.7 LOCAL PROJECTIONS OF NEURONS IN THE DEEP LAYERS OF THE CAT SUPERIOR COLLICULUS: A STUDY USING PHASEOLUS VULGARIS-LEUCOAGGLUTININ (PHA-L). M. Behan and P.P. Appell*. School of Veterinary Medicine and Neurosciences Training Program, University of Wisconsin, Madison, WI 53706.

The purpose of the present series of experiments was to examine the intrinsic projections of neurons in the deep layers of the superior colliculus in the cat.

Small, iontophoretic injections of the neuroanatomical tracer Phaseolus vulgaris-leucoagglutinin (PHA-L) were made in the superior colliculus in layers deep to the stratum opticum. After a six day survival, animals were perfused transcardially with mixed aldehyde fixatives. The tissue was sectioned at 80μm, reacted immunocytochemically for PHA-L, and alternate sections prepared for light and electron microscopy.

The injection sites usually measure less than a millimeter in diameter, and contain a maximum of 25 labeled cells in any section. Many neurons at the injection site can be classified easily. Almost all labeled neurons are small (10-15μm in diameter), and resemble the vertical, horizontal, and multipolar neurons described in previous Golgi studies of this area. Axonal arborizations and synaptic terminals are also clearly labeled with PHA-L. As previous investigators have determined that there is virtually no uptake of PHA-L by fibers of passage, it is probable that the arborizations described in this study originate from labeled cells at the injection site.

One of the most interesting findings is the extent of axonal projections in the superior colliculus. Following injections of PHA-L in the deep layers in the middle of the colliculus, labeled axons and terminals are found throughout the rostrocaudal and mediolateral extent, and in all superficial and deep laminae. A few axons and terminals are also found in the contralateral colliculus. Outside the borders of the superior colliculus, there are extensive axonal arborizations in the ipsilateral periaqueductal grey, and the mesencephalic reticular formation.

Are these axons derived from interneurons or are they the local collaterals of projection neurons? While it is not yet possible to answer this question with certainty, it is likely that both neuronal types are labeled. Regardless of their origin, these preliminary data suggest that very localized regions of the superior colliculus can influence extensive areas of the mesencephalon. We are now examining the ultrastructure of PHA-L labeled synaptic terminals and their postsynaptic targets.

Supported by NIH grant EY04478.

122.8 MORPHOLOGY AND PHYSICLOGICAL CHARACTERISTICS OF SUPERIOR COLLICULUS NEURONS IN THE HAMSTER THAT PROJECT FROM THE SUPERFICIAL TO THE DEEP LAYERS. P.R. Hess*, Z.K. Allen, M.M. Nikoletseas, R.D. Mooney and R.W. Rhoades. Dept. of Anatomy, University of Medicine and Dentistry of New Jersey-School of Osteopathic Medicine and Robert Wood Johnson Medical School, Piscataway, NJ 08854.

An issue of considerable importance with respect to the organization of the mammalian superior colliculus (SC) is the extent to which cells in the superficial laminae communicate with the deep layers. Conventional anatomical tracing methods have been unable to provide a definitive answer to this question so we have used intracellular recording and horseradish peroxidase (HRP) injection techniques to label SC cells and define their interlaminar axonal projections.

We have recovered 65 superficial layer SC cells whose axons were well enough filled with dense reaction product to determine whether or not they projected to the deep layers. Of these, 44.6% (N=29) gave off one or more axon collaterals that descended at least as far as the intermediate gray layer. Not all morphological cell types projected to the deep layers with equal frequency: 33.3% of the recovered marginal cells, 17.7% of the stellate cells, 76.9% of the narrow field vertical cells, 71.4% of the widefield vertical cells, 20% of the horizontal cells and 50% of the neurons that we could not classify according to this scheme had axonal projections to the deep laminae. Those neurons with deep going axon collaterals generally had their cell bodies in the lower stratum griseum superficiale (SGS) or stratum opticum (SO). Neurons whose axons were restricted to the superficial layers usually had their cell bodies in the upper portion of the SGS.

As might be expected on the basis of previous correlations between the physiological and morphological characteristics of superficial layer SC neurons in hamster (Mooney, R.D. et al., J. Neurosci., 5:2989, 1985), most of the cells that projected to the deep layers were non-directional, but movement sensitive.

These data thus indicate that only a portion of the sensory processing accomplished by the superficial SC laminae is conveyed to the deep layers and that the interlaminar pathway does not equally involve all cell types in the SGS and SO.

122.9 MORPHOLOGICAL AND PHYSIOLOGICAL CHARACTERISTICS OF THE SUPERIOR COLLICULUS CELLS THAT PROJECT TO THE LATERAL POSTERIOR NUCLEUS IN THE GOLDEN HAMSTER. M.M. Nikoletseas*, R.D. Mooney and R.W. Rhoades (SPON: R. Waziri). Dept. of Anatomy, University of Medicine and Dentistry of New Jersey-School of Osteopathic Medicine and Robert Wood Johnson Medical School, Piscataway, NJ 08854.

The projection from the superficial layers of the superior colliculus (SC) to the lateral posterior nucleus (LP) in rodent and the pulvinar nucleus, its homologue in cat and monkey, has been the focus of considerable attention for a number of years. Nevertheless, there is relatively little detailed information regarding the physiological and morphological properties of the SC neurons that give rise to this pathway. This is especially true in rodents, and in an effort to fill this gap in our information regarding extra-geniculostriate visual pathways, we have used intracellular recording and horseradish peroxidase (HRP) injection techniques to characterize, both physiologically and morphologically, tecto-LP cells in hamster.

We have recovered 17 SC cells that were antidromically activated at low current intensities from LP stimulating electrodes. These neurons were remarkably uniform in both their physiological and structural properties. The average antidromic latency to LP shocks was 3.2 ± 1.5 ms and, with one exception, all of the recovered neurons had their cell bodies in the lowermost stratum griseum superficiale or stratum opticum (SO). One tecto-LP cell had its soma in the upper stratum griseum intermediale, but its dendrites extended into the overlying SO. Thirteen (76.5% of the sample) of the recovered neurons were widefield vertical cells. Nearly all of these were movement sensitive, but not directionally selective. Two of these cells had heavily filled axons that could be traced to LP. The rest of the sample was comprised of three narrow field vertical cells and one large stellate neuron.

The structural and functional homogeneity of tecto-LP projection neurons in hamster stands in sharp contrast to the superficial layer cells that give rise to the projection from SC to the lateral geniculate nucleus (LGNd) in this species (see Mooney, R.D. et al., this meeting). A variety of structural and functional cell types contribute axons to the tectogeniculate pathway, but only one of the 18 SC-LGNd cells we have recovered so far was a widefield vertical cell.

Supported by EY 04170 and BNS 85 00142.

122.10 MORPHOLOGICAL AND PHYSIOLOGICAL PROPERTIES OF THE SUPERIOR COLLICULUS CELLS THAT PROJECT TO THE DORSAL LATERAL GENICULATE NUCLEUS IN THE HAMSTER. R.D. Mooney, M.M. Nikoletseas* and R.W. Rhoades. Dept. of Anatomy, University of Medicine and Dentistry of New Jersey-School of Osteopathic Medicine and Robert Wood Johnson Medical School, Piscataway, NJ 08854.

The superficial layers (the stratum griseum superficiale-SGS, and stratum opticum-SO) of the mammalian superior colliculus project to a number of thalamic targets. While retrograde tracing and electrophysiological methods have been employed to assess the physiological and morphological characteristics of subsets of tectothalamic projection neurons, only a very small number of experiments have examined both of these variables for individual SC cells. We have used intracellular recording and horseradish peroxidase (HRP) injection techniques to characterize the SC neurons which innervate the dorsal lateral geniculate nucleus (LGNd) in the hamster.

We have recovered 18 SC cells that were antidromically activated at low currents by stimulating electrodes positioned in LGNd. The average latency to LGNd stimulation was 2.11 ± 0.70 ms. All of the recovered neurons had their cell bodies in the SGS and all but three were located in the upper two-thirds of this layer. Not all of the morphological cell types in the superficial SC laminae contributed equally to the sample of recovered neurons: 38.9% were marginal cells, 33.3% were narrow field vertical cells, 16.7% had stellate morphology, 5.6% were widefield vertical cells and 5.6% were horizontal cells. Two thirds of the marginal cells were movement sensitive and/or directionally selective while one-half of the narrow field vertical cells responded nearly equally to stationary and moving stimuli and exhibited no preference for stimulus direction. This was also the case for the horizontal and widefield vertical cells that we recovered. One of the stellate cells had weak and variable visual responses and the other two were equally responsive to stationary, flashed and moving stimuli.

These data suggest that a variety of cell types in the superficial laminae of the hamster's SC contribute to the tectogeniculate projection, but that the dominant types in this pathway may be marginal and narrow field vertical neurons. Our data indicate further that several types of visual information are conveyed by this pathway and that it may not be appropriate to consider this tectal efferent projection as a single information channel.

122.11 PROPERTIES OF LATERAL GENICULATE CELLS WHICH ARE INFLUENCED BY THE SUPERIOR COLLICULUS

S. Molotchnikoff, A. Cerat* and P. Rouillon.
Département de Sciences biologiques, Université de Montréal, Montréal P.Q. Canada H3C-3J7.

The retinal output, in mammals, is carried to the cortex along two parallel channels. It passes either through the Superior Colliculus (SC), or through the Lateral Geniculate Nucleus (LGN). In broad terms, the geniculo-cortical path is involved in fine discrimination of discrete target, while the colliculo-cortical system is associated with ambient vision and eye movements. Furthermore, neurons of the visual dorsal layers of the SC send axons to the LGN. To test the relationship between these two paths, two light sources are presented in the visual field. The first one is a light source, remotely located (the conditioning stimulus), the second one is the central stimulus which is located in the Receptive Field (RF) of a geniculate cell. Thus, the influences of the conditioning stimulus upon responses to the test stimulus are studied at the geniculate level, prior to, during, and after collicular inactivation.

Experiments were carried out on rabbits which were anesthetized, paralyzed and prepared for single units recordings from the lateral geniculate nucleus.

Results may be summarized in the following way: 1) All geniculate cells (30%) which reacted to collicular inactivation had their RF close to the optic axis. 2) It appears that the conditioning stimulus facilitates geniculate responses if the RF is located eccentrically. 3) Cells that decreased their responses had their RF distributed throughout the visual field. From data obtained so far (N=75) it may be inferred that the colliculo-geniculate fibers influence mostly the central vision. This conclusion is further supported by our previous observation that cells with concentric RF, that is, those which transmit successive contrasts, are particularly sensitive to the inactivation of the superior colliculus.

122.12 **PROPERTIES OF TECTAL CELLS PROJECTING TO DIFFERENT REGIONS OF THE PULVINAR IN RABBITS.** C.Casanova*+ and S. Molotchnikoff. (SPON: R.D. Freeman) Dept de Sciences biologiques, Universite de Montreal, Montreal, P.Q., Canada, H3C 3J7.

Electrophysiological techniques were used to study the tecto-pulvinar pathway in rabbits, which had previously only been studied anatomically. The animals were anesthetized with urethane and prepared for single unit recordings. Stimulating electrodes were placed in the anterior or posterior part of the pulvinar nucleus and in the optic tract. Using glass micropipettes a total of 563 neurons were recorded throughout the superior colliculus (SC). Of these, thirty-two were identified as tecto-pulvinar cells on the basis of antidromic activation (constant latency, persistence of response to high frequency stimulation, positive collision test). The latencies of the antidromic spikes were distributed between 0.5 and 6.0 ms; mean= 2.76 ± 1.37 ms. Interestingly, there appeared to be a marked difference in the response properties of collicular cells which responded to stimulation of anterior and posterior pulvinar. When the anterior part of the pulvinar was stimulated, the majority (91%) of the tecto-pulvinar cells recorded were visual and usually located in the superficial layers of the SC. However, when the posterior region was stimulated, tecto-pulvinar units were rarely visual (22%) and they were found in the deep layers of the SC. It thus seems that there is a segregation of the SC projections such that the visual layers project to the anterior part of the pulvinar and the multimodal layers to the posterior region.

Additionally, trans-synaptic responses were recorded in the SC following stimulation of the pulvinar (latencies between 1.5 and 14 ms; mean= 4.8 ± 2.6 ms, N= 143). These trans-synaptic responses cannot be attributed to possible activation of the ganglion fibers located near the pulvinar because they were also recorded in rabbits with a degenerated contralateral optic tract (mean= 5.7 ± 3.3 ms; N=23). As noted with the antidromic responses, there was a difference between the properties of the collicular neurons activated trans-synaptically, depending on which region of the pulvinar was stimulated. More precisely, 70% of the tectal cells driven by stimulation of the anterior part of the pulvinar were visually responsive, while only 40% when the posterior part was stimulated. Thus it seems that the two pulvinar regions receiving a tectal input send back information to the SC (sensorimotor loop), probably along an indirect pathway involving cortical areas, although a more direct pathway cannot be ruled out.

122.13 A COMPARISON OF MAO AND ACHE STAINING PATTERNS IN THE MIDBRAIN WITH SPECIAL REFERENCE TO THE SUPERIOR COLLICULUS.

D.D. Dunning, J.G. McHaffie and B.E. Stein. Department of Physiology, Medical College of Virginia, Richmond, VA 23298.

The superior colliculus (SC) displays laminar specific patterns of acetylcholinesterase (AChE) staining which has, in part, given rise to ideas concerning compartmentalization of its afferents, efferents, and internal structure. The relationship between AChE and other biochemical markers, however, remains to be established. Thus, we sought to establish the spatial relationship between AChE and monoamine oxidase (MAO) staining in the hope of finding systematically related markers that would facilitate our understanding of functional compartmentalization in the SC.

Tissue was obtained from hooded rats, ferrets, belted rabbits, and mongrel cats. Fixation was by mixed-aldehyde perfusion. Serial sections were stained alternately for AChE by the copper ferricyanide method (Tsuji, S., Histochem. 42:99, 1974) and for MAO by the coupled peroxidase method (Kitahama, K., et al., Brain Res. 324:155, 1984). AChE staining in the SC was distributed homogeneously in the superficial gray layer with a slight dorsal to ventral density gradient. In the deeper layers, AChE staining was organized in a series of enzyme-positive patches distributed so as to form an interrupted band within the layer. In serial reconstruction these patches appear as elongated, partly cross-linked longitudinal bundles. Similar features were observed in all four species.

Overall, the distribution of MAO and AChE in the SC were quite similar with only a few noticeable differences. In the superficial gray layer, both MAO and AChE staining were distributed homogeneously although MAO had a ventral to dorsal density gradient. In the dorsal tier of the intermediate gray layer, patches of MAO and AChE were overlapping, but in the ventral tier they were not systematically related. In both intermediate and deep layers, AChE staining was primarily in the caudal SC, whereas MAO was found throughout the rostro-caudal extent of the SC. Furthermore, in deeper layers and periaqueductal gray, MAO staining exhibited a characteristic U-shaped band symmetrical about the midline where AChE staining was weak.

In the cholinergic afferents to the SC, we found a dichotomy of MAO-AChE staining. In these areas, AChE staining was very heavy and MAO staining was either weak (pedunculopontine tegmental nuc., lateral dorsal tegmental nuc.) or very weak (parabigeminal nuc.).

In light of the overall similarity of MAO and AChE staining in the SC, it is possible that spatially overlapping inputs utilize different transmitters. Whether or not these two independent systems can influence the same neuron remains to be determined.

122.14 **MULTISENSORY INTEGRATION IN SUPERIOR COLLICULUS NEURONS IS DETERMINED BY MODALITY-SPECIFIC RECEPTIVE FIELD PROPERTIES**

M. A. Meredith and B. E. Stein, Depts. Anat. and Physiol., Med. Col. Va., Va. Commonwealth Univ., Richmond. Va. 23298.

The receptive field properties of visual, somatosensory and auditory neurons in the superior colliculus of the cat have been well described and are essentially the same for unimodal and multimodal cells. However, multimodal cells are known to integrate inputs from different sensory modalities so that their responses to stimuli from one modality are markedly enhanced or depressed when a stimulus from another modality is also presented. Thus, their efferent messages represent a "synthesis" of multisensory inputs. At present, it is not known whether or not this synthesis disrupts the fundamental receptive field properties characteric of a specific modality of input (e.g., visual). The present experiments were initiated to examine this possibility by evaluating the receptive field properties of visual cells in the absence and then in the presence of an auditory stimulus.

Cats, chronically prepared for extracellular recording, were anesthetized with ketamine HCl, paralyzed and artificially respired with a mixture of N20 and 02. Neurons in the deep laminae of the superior colliculus were isolated, their receptive fields mapped and their modality-specific receptive field properties (e.g., direction selectivity) were determined using electronically controlled stimuli (visual: galvanometer driven mirror projected onto translucent hemisphere; auditory: broadband noise generator routed through a hoop-mounted speaker). Single-modality tests (visual only, auditory only) appropriate to evaluate a given response property were presented alone and in combination with a stimulus from another modality (visual and auditory together) in an interleaved fashion.

In most of the neurons examined, the auditory stimulus could enhance or depress visual responses, depending on "rules" previously described (see Meredith and Stein, J. Neurophysiol. 56:640, 1986). However, under the present experimental conditions, the receptive field properties of a neuron appeared to be immutable: directionally selective cells retained directional assymmetries; velocity selectivities and spatial sensitivities were also maintained during combined visual-auditory tests. Apparently, integration resulting from combined-modality stimulation enhances or depresses the activity of a cell but does not disrupt the fundamental receptive field properties that define how specific stimulus parameters will be encoded.

122.15 **BEHAVIORAL STUDIES OF MULTISENSORY INTEGRATION IN THE CAT** B.E. Stein, W.S. Huneycutt and M.A. Meredith, Depts Physiol & Anat. Med Coll Va/Va Commonwealth Univ, Richmond, Va. 23298.

Recent physiological experiments have demonstrated that visual, auditory and somatosensory inputs converge on, and are integrated by, individual neurons in the superior colliculus (SC). This convergence often results in activity which exceeds that produced by either of the stimuli presented alone. This 'response enhancement' is dependent on the spatial and temporal coincidence of the stimulus combination. In contrast, the same stimulus combination presented out of spatial and/or temporal synchrony can often depress neuronal activity. Since most multisensory SC cells have projections to premotor areas, their enhanced or depressed responses should be reflected in overt, SC-mediated, behaviors. The present experiments were designed to test this postulate directly.

The behavioral apparatus consisted of 7 LEDs (40 ms duration, range=0.0013-0.011 ft-candles) and 7 speakers (broad-band noise burst; 40 ms duration, range=27-34 dB SPL) arranged in 30° intervals (90° left to 90° right) on a 90cm diameter semicirular track. Two cats were trained to fixate directly at 0° and to approach each stimulus when presented alone, or when presented simultaneously at the same locus (regardless of the particular eccentricity). The animals received a food reward from trays mounted beneath each LED-speaker pair. Two other cats were trained in a similar fashion, but were taught to ignore the auditory stimulus and to respond only to the visual stimulus even when both stimuli were presented stimultaneously at different loci. Once these tests were completed both pairs of animals were trained and tested on the opposite task. Each animal had a total of 20 trials of each stimulus condition (visual, auditory, visual/auditory) at each position (n=7) and at each stimulus intensity (n=5) (total trials = 2100 to 2800/animal).

In all animals, and at all stimulus eccentricities, correct responses to combinations of low intensity spatially coincident stimuli far exceeded that evoked by either stimulus presented alone. This behavioral response enhancement was multiplicative and could exceed a five-fold increment over that produced by the most effective single-modality stimulus. In contrast, when the visual and auditory stimuli were presented at the same time but at different loci, responses to these combinations were reduced below that evoked by the visual stimulus alone. This occurred even though the animals were taught to ignore the auditory stimulus. These observations are consistent with physiological data from multisensory SC neurons and indicate that the same rules that govern multisensory integration at the level of the single neuron also govern attentive and orientation responses of the intact, behaving animal. Supported by NIH grant NS 22543.

122.16 SINGLE UNIT ACTIVITY IN THE DEEP LAYERS OF THE SUPERIOR COLLICULUS IN BEHAVING RATS. D. A. Weldon and P. J. Best. Department of Psychology, University of Virginia, Charlottesville, VA 22903.

Multiple unit recordings in rats (Malmo & Malmo, EEG & Clin. Neurophysiol., 42:501, 1977) and single unit recordings in hamsters (Rose, Exp. Neurol., 87:225, 1985) have demonstrated relationships between neural activity in the superior colliculus and head movements. In order to investigate this phenomenon further, we measured single unit activity in the deep layers of the superior colliculus as rats performed a visuomotor orientation task in which head movements were under experimental control.

Long-Evans hooded rats were trained in an apparatus containing four cue lights and adjacent spouts through which 20% sucrose reinforcement was provided. Orientations towards the spout located adjacent to an illuminated light were reinforced. After stable performance was obtained, each rat was anesthetized with sodium pentobarbital and received a cranial implant including a moveable microelectrode assembly consisting of ten 25 μm wires (modified after Kubie, Physiol. Behav., 32:115, 1984) and electrodes positioned for electrooculogram recording. When retested in the behavioral task, a miniature 12 v light was affixed to the head to permit accurate measurement of head position and movement. Electrophysiological and behavioral data were stored on videotape and later analyzed off-line. Each unit was tested for visual, auditory, somatosensory, and vestibular responsivity, as well as for a relationship with specific behavioral events.

The activity of some deep collicular units was related to movements of the head in specific directions. Other units were silent until the rats engaged in specific postures involving neck extension, when the neural activity attained average rates of 25 spikes/second with bursts of up to 120 spikes/second. In several cells in which neural activity occurred during rearing behavior, the neurons also fired 1) when the animal was held such that neck extension was required for the animal to walk from the experimenter's hand to a platform and 2) when the animal drank from the lower spouts in the testing apparatus in a way that involved neck extension. Several neurons were responsive to somatosensory stimuli applied to the snout and vibrissae when the freely moving animal actively approached the stimulation probe; some of these neurons were unresponsive when the probe was presented while the animal was held in the experimenter's hand. These results indicate a role of the rat superior colliculus in head movements during visuomotor orientation and in sensorimotor integration.

This research was supported by NIMH 1-F32-MH09513-01 and a faculty fellowship from Hamilton College.

122.17 RETINOTECTAL PROJECTIONS IN RAY-FINNED FISHES: PHYLOGENETIC AND TAXONOMIC IMPLICATIONS. C. S. von Bartheld* and D. L. Meyer* (SPON: G. Rager). Dept. of Neuroanatomy, University of Göttingen, 3400 Göttingen, Federal Republic of Germany.

Retinotectal projections were studied after intraocular injections of horseradish peroxidase or cobaltous lysine in 33 different actinopterygian species (ray-finned fishes). The distribution of retinorecipient layers in the contralateral optic tectum was analysed. In addition, the degree of differentiation of the stratum periventriculare, and the presence of ipsilateral retinotectal projections was examined.

Retinofugal fibers are labeled in the stratum opticum (SO), stratum fibrosum et griseum superficiale (SFGS), stratum griseum centrale (SGC), stratum album centrale (SAC) and stratum periventriculare (SPV). Some species lack the projection to SO, others lack the projection to SGC, and a third group of fishes lack both projections. Five different patterns of retinorecipient tectal strata are distinguished. These patterns correlate with the species' taxonomic position and naturally fall into 5 groups within the actinopterygians:

Type I	(Non-teleost-actinopterygians)	: SO - SFGS - SGC/ SAC/SPV.
Type II	(Osteoglossiformes)	: - SFGS - SAC/SPV.
Type III	("Prototeleostei")	: SO - SFGS - SGC - SAC/SPV.
Type IV	(Siluroidei)	: - SFGS - SGC - SAC/SPV.
Type V	(Neoteleostei)	: SO - SFGS - SAC/SPV.

For the group of teleosts with the type-III pattern, we suggest the term "Prototeleostei". The retinotectal projection patterns provide a useful indicator for phylogenetic relationships.

The degree of stratification in the SPV decreases from the less to the more advanced ray-finned fishes. Stratification in the SPV - hitherto not described in teleosts - is prominent in most osteoglossomorphan teleosts, similar to the nonteleost actinopterygians (e.g. Polypterus, Acipenser). Ipsilateral retinotectal projections are present in nearly all "lower" actinopterygian orders, but not in the more advanced teleosts (Neoteleostei).

Preliminary studies on the distribution of acetylcholinesterase in the optic tectum indicate that the lamination pattern differs in different groups of ray-finned fishes. Further species need to be examined to possibly demonstrate a correlation of retinotectal projection patterns and acetylcholinesterase distribution.

122.18 RELATIONSHIP BETWEEN ISTHMO-TECTAL AND RETINO-TECTAL FIBERS IN THE FROG RANA PIPIENS. E. Gruberg, M. Mote*, R. Waldeck* and M. Wallace* Biology Dept., Temple Univ., Philadelphia, PA 19122

The nucleus isthmi and the retina both project to the superficial layers of the frog tectum. Loss of n. isthmi leads to loss of tectally mediated visually-guided behavior. Isthmo-tectal and retino-tectal fibers appear to have an exclusive anatomical relationship. We explored the relationship in 3 ways: 1) we assessed whether other extrinsic inputs also terminate in the superficial tectum; 2) we investigated if there was any overlap of retino-tectal and isthmo-tectal pathways; 3) we determined whether other fiber systems cross in the supraoptic decussation with n. isthmi fibers.

1) We either applied bibulous paper soaked in a solution of 25% horseradish peroxidase (HRP) plus 2% lysolecithin to the surface of the tectum or injected 25% HRP solution into the tectum. After survival periods of 3 to 7 days we determined the distribution of retrogradely labelled cells. When HRP was restricted to the most superficial layer virtually all stained cells were found in the contralateral retina and contralateral n. isthmi. With deeper penetration of HRP, contralateral retina and both n. isthmi were stained. In the deepest penetration of HRP a significant number of cells were stained in other areas, particularly posterior thalamic areas, in addition to contralateral retina and both n. isthmi. We suggest that in the most superficial tectal layers the retina and n. isthmi are virtually the only extrinsic inputs.

2) We unilaterally injected n. isthmi with HRP (staining for orthogradely labelled fibers) and injected both retinas with tritiated-proline. We found an admixture of retinal and n. isthmi fibers after n. isthmi fibers decussate.

3) At the midline we cut the posterior half of the optic chiasm and the overlying supraoptic decussation and applied HRP to the cut. Only n. isthmi and retinal fibers were stained. Thus, no other fibers cross at the supraoptic decussation. In addition, animals with such cuts lost visually-guided threat avoidance behavior while visually-guided prey catching was unaffected.

We conclude that isthmo-tectal and retino-tectal fibers have an intimate and exclusive relationship. Supported by NIH grant EY04366.

122.19 SINGLE-UNIT ANALYSIS OF THE OPTIC PRETECTAL NUCLEUS, LENTIFORMIS MESENCEPHALI IN RANA PIPIENS. Katherine V. Fite, Carol Kwei-Levy and Lynn Bengston. University of Massachusetts, Amherst, MA.

The large-celled pretectal nucleus, lentiformis mesencephali, (nLM) receives a major projection from the retina and appears to be critically involved in horizontal optokinetic nystagmus (hOKN) in amphibians (Montgomery et al, 1982). Previously, several neurophysiological investigations have reported directional-specific unit responses in the pretectal region (Katte & Hoffman, 1980; Cochran et al, 1984) of ranid species, many with sensitivity to horizontally moving optokinetic patterns. Thus, we anticipated that nLM would contain a high proportion of such units, also with temporal-to-nasal sensitivity, since hOKN shows a strong asymmetry under monocular viewing conditions.

The present study was based upon a quantitative, computer-assisted single-unit analysis of visually responsive units from nLM under monocular conditions, with electrode recording sites recovered histologically for each unit (N=80). Eight directions of pattern movement at 3 stimulus velocities were presented to each unit (vertical, horizontal and oblique vectors; 6, 15 and 25 degrees/sec.). Surprisingly, only 26% of the total were found to be directionally sensitive, while 70% of the total were responsive to pattern movement, in general. Most units were spontaneously active and among the directionally sensitive units, no preference was observed for any direction of pattern movement. No systematic changes occurred in unit responses as a function of pattern velocity. Injection of picrotoxin into the contralateral eye 30 minutes prior to recording correlated with a 50% reduction in the number of directionally sensitive units and a larger proportion of movement-sensitive units than was observed in normal animals (86%). Thus, picrotoxin appears to reduce directional sensitivity.

These results are consistent with our previous 2-deoxyglucose studies (Fite et al, 1986) which showed an equivalent uptake of 2-DG during either temporal-to-nasal or nasal-to-temporal OKN stimulation. The lack of directionally selective units in nLM indicate that the directional nature of OKN reponses must originate elsewhere; alternatively, that other neural structures modulate the output of nLM such that the asymmetry of hOKN with monocular viewing involves more complex circuits than previously imagined. Results obtained from our 2-deoxyglucose studies strongly suggest that the accessory optic nucleus, nBOR, shows enhanced uptake of 2-DG only in the nasal-to-temporal direction of pattern movement. Since the primary efferent projection of nBOR is to nLM, we postulate that an inhibitory pathway from nBOR to nLM exists which may play a major role in the hOKN asymmetry. At present, studies are in progress to test this hypothesis.

AGING AND DEMENTIA: TRANSMITTERS

123.1 CORTICAL CHOLINERGIC RECEPTORS IN AGING RHESUS MONKEYS. M.V. Wagster†, L.C. Walker†, P.J. Whitehouse§, K.J. Kellar§§ and D.L. Price†. †Neuropathology Lab., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205; §Alzheimer Neuroscience Center, Univ. Hospitals of Cleveland, Cleveland, OH 44106; §§Dept. of Pharmacology, Georgetown Univ. Sch. of Med. & Dent., Washington, DC 20007.

In the cortex of the rhesus monkey, cholinergic and serotoninergic receptor binding declines significantly with age [Wagster et al., Soc. Neurosci. Abstr. 12:1469, 1986]. In this study, the effect of age on binding patterns of cortical cholinergic receptor subtypes was examined in rhesus monkeys (Macaca mulatta). Using in vitro receptor autoradiography (ARG), the distributions of cholinergic muscarinic receptors ([^{3}H] N-methyl scopolamine [NMS], [^{3}H] pirenzepine, and [^{3}H] oxotremorine) and nicotinic receptors ([^{3}H] acetylcholine) were mapped in the temporal cortices of 17 rhesus monkeys ranging in age from 2-22 years. The ligand, [^{3}H] NMS was selected to measure high- (M2) and low- (M1) affinity agonist cholinergic muscarinic receptor subtypes. The pattern of distribution in the temporal cortex revealed a greater concentration of M1 receptors in superficial cortical layers than in deep layers, although M2 receptors were concentrated in deep layers. M1, but not M2, receptor binding site concentrations were significantly decreased with age (ANOVA, $p = 0.0017$). In cortex, [^{3}H] pirenzepine ARG revealed a nonsignificant trend for M1 receptors to decrease with age. The pattern of distribution of [^{3}H] pirenzepine binding sites was identical to that of the low-affinity [^{3}H] NMS binding sites. The pattern of distribution of [^{3}H] oxotremorine binding for the M2 cholinergic receptor subtype in cortical layers was similar to that of high-affinity [^{3}H] NMS binding sites. M2 receptors were significantly decreased with age in the temporal cortex (ANOVA, $p < 0.0001$). The ligand, [^{3}H] acetylcholine (using atropine to block muscarinic receptors), was used to assess nicotinic receptors in the temporal region. Nicotinic receptor binding decreased significantly with age (ANOVA, $p = 0.0081$). In summary, M1 and M2 receptor binding occurred across all layers of temporal neocortex in macaques, but M1 receptor binding was highest in superficial cortical layers, and M2 receptor binding was highest in deeper cortical layers. The number of muscarinic and nicotinic receptor binding sites decreased with age in this cortical region. The age-related decline in binding site concentrations for both muscarinic receptor subtypes (M1 and M2) was uniform across cortical layers and cortical nicotinic receptor binding appeared to parallel this pattern.

Tissues obtained from the Regional Primate Research Center at the University of Washington, NIH grant RR 00166.

123.2 CHOLINERGIC RECEPTORS IN HIPPOCAMPUS OF AGED RHESUS MONKEYS. M.D. Applegate*†, M.V. Wagster†, L.C. Walker†, P.J. Whitehouse§, K.J. Kellar§§ and D.L. Price† (SPON: E.H.M. Koo†). †Neuropathology Lab., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205; §Alzheimer Neuroscience Ctr., Univ. Hospitals of Cleveland, Cleveland, OH 44106; §§Dept. of Pharmacology, Georgetown Univ. Sch. of Med. & Dent., Washington, DC 20007.

Using in vitro receptor autoradiography, distributions of nicotinic and muscarinic cholinergic receptors were mapped in several regions of hippocampus and in the tail of the caudate of 17 rhesus monkeys (Macaca mulatta) ranging in age from 2-22 years. The age range and number of monkeys in each of the four groups were: Group I, two years old (n = 3-5); Group II, 6-7 years old (n = 2-3); Group III, 13 years old (n = 2); and Group IV, 18-22 years old (n = 6-7). [^{3}H] Acetylcholine (with atropine to block muscarinic receptors) was used to label nicotinic receptors. [^{3}H] Pirenzepine (M1), [^{3}H] oxotremorine (M2), and [^{3}H] N-methyl scopolamine (M1 and M2) were used to label muscarinic receptor subtypes. In the hippocampus, nicotinic receptor binding was generally low; the presubiculum exhibited binding concentrations 250-600% higher than in adjacent hippocampal regions. The oldest monkeys (Group IV) showed a significant ($p < 0.01$) reduction (<60%) in nicotinic receptor binding concentrations in the presubiculum. Total muscarinic binding in the hippocampus was much higher than nicotinic binding, and a reciprocal pattern of regional M1 and M2 binding was evident. Both low and high affinity M1 binding concentrations were relatively low in the subiculum and CA3 regions of hippocampus, whereas M2 binding concentrations were high in those areas. One exception to this pattern was the mossy fiber field in the apical dendrites of CA3, which showed low levels of both M1 and M2 receptor binding. Unlike reductions that occur in muscarinic receptors in the temporal neocortex [Wagster et al., Soc. Neurosci. Abstr. 12:1469, 1986] and in the tail of the caudate (where 40% and 21% decreases in M2 and M1 receptor binding, concentrations, respectively, were found), no clear age-related changes in muscarinic receptors were observed in the hippocampus. This age-related decrease in nicotinic, but not in muscarinic, receptor binding in the hippocampus, in concert with reported decreases in muscarinic receptor binding in other brain regions, suggests a selective regional vulnerability of certain cell populations with aging.

Tissues were obtained from the Regional Primate Research Center at the University of Washington, supported by NIH grant RR 00166.

123.3 ^{3}H-PIRENZEPINE BINDING IN AGED RAT BRAIN: REGULATION OF MUSCARINIC (M1) RECEPTORS AFTER CHRONIC CHOLINERGIC DRUG ADMINISTRATION. Norman W. Pedigo, Jr. Depts. of Pharmacology and Anesthesiology, Univ. of Kentucky Medical Ctr., Lexington, KY 40536.

A senescent rat model of aging was used to assess the effects of chronic cholinergic drug treatment on muscarinic receptors in frontal cortex. Young, adult and senescent rats (3,9 and 27 months old, respectively) were treated for three weeks with either intracerebroventricular (ivt) saline (2 µl/hr), ivt methylatropine or ivt oxotremorine (3 µg/hr). Age-related and treatment-induced receptor changes were quantitated via selective binding of ^{3}H-pirenzepine (^{3}H-PZ) to the M1 receptor subtype.

M1 muscarinic receptors in rat frontal cortex show a significant decline with advanced age. The density of ^{3}H-pirenzepine binding sites (Bmax) determined in saturation studies was reduced by 25-40% in young versus senescent rats, while Kd increased in older animals. Bmax values for ^{3}H-PZ in 3,9 and 27 month old rats were 290 ± 18, 262 ± 25 and 174 ± 24 fmol/mg protein, respectively (mean ± SEM).

Young rats administered chronic ivt methylatropine exhibited a significant (40%) increase in ^{3}H-PZ binding compared to age-matched controls. In contrast, 3 month old animals treated with ivt oxotremorine showed a 30% loss of M1 receptors in frontal cortex. Similar up-regulation, but no down-regulation was noted in adult rats. However, ^{3}H-PZ binding was not altered in senescent rats treated chronically with either ivt methylatropine or oxotremorine.

Thus, there was a marked age-related impairment of muscarinic (M1) receptor plasticity in rat brain. These results support previous observations from studies using the nonselective ligand ^{3}H-QNB. Current research endeavors will attempt to correlate these receptor alterations to changes in phosphatidylinositol turnover. Such information could have important implications for the potential treatment of Alzheimer's disease patients and cholinergic drug therapy in the elderly.

Supported in part by the American Federation for Aging Research and an NIA grant (AG04991).

123.4 ENDOGENOUS ACETYLCHOLINE RELEASE FROM BRAIN HEMISPHERIC REGIONS OF YOUNG AND SENESCENT FREELY MOVING RATS DETERMINED BY MICRODIALYSIS TECHNIQUE. S. Consolo*, C.F. Wu*, G. Pepeu° and R. Bertorelli* (SPON : A. Giachetti). Istituto di Ricerche Farmacologiche"Mario Negri", Milan, Italy and °Department of Preclinical and Clinical Pharmacology, University of Florence, Italy.

The in vivo extracellular acetylcholine (ACh) release from striatum (ST), frontal cortex (FC) and dorsal hippocampus (DH) of young (2 months) and old (18 months) freely moving rats was measured by intracerebral microdialysis technique coupled with a sensitive and specific radioenzymatic method. The procedure used for implanting the fibers was essentially the same as already described by others. A thin dialysis tube (AN 69 membrane, DASCO) was inserted trasversally through both ST and FC of the same animal. In other rats, the fiber was inserted through both DH. The day after implantation the rat brain areas were perfused with a Ringer solution containing 10 µM physostigmine sulphate, at a constant rate of 2 µL/min. The perfusates were collected at 10 min (ST) and 20 min (FC, DH) intervals. The collected samples were lyophilized and the ACh was assayed by a radioenzymatic method (sensitivity 1 pmole). After 30 min of perfusion, the ACh output from the three hemispheric areas studied reached a steady state level. In the young rats, the net average output of ACh, when corrected for the recovery (49.5%) and expressed as fmoles/min was 1804 ± 134 from ST, 608 ± 61 from FC and 669 ± 64 from DH. In the old rats, the basal ACh release was 53%, 35% and 37% lower in ST, FC and DH, respectively. The effect of hemicholinium-3, a choline uptake blocker, was studied in the striatum, the area most affected by age. The marked time-dependent decrease caused by the drug (20 µg i.c.v.) in the ACh release was not statistically different in the two groups. Thus, the release mechanisms in vivo do not seem to be impaired by age and more likely the decline in ACh release from the striatum of old rats is accompanied by a reduction of ACh synthesis. (The rats, Wistar strain, were kindly supplied by I.S.F., Trezzano sul Naviglio, Milano).

123.5 Cholinergic neurotransmission in the aged rat: a behavioral, electrophysiological, and anatomical study. D.M. Armstrong, G. Buzsaki, K. Chen, R. Ruiz, R. Sheffield, and F.H. Gage. Department of Neurosciences, University of California, San Diego, LaJolla, CA 92093.

In the rat, cognitive impairments are often associated with deficiencies in cholinergic neurotransmission. In the present study we employed behavioral, electrophysiological, and anatomical techniques to investigate age-related alterations of basal forebrain cholinergic neurons. Throughout these studies young (8 months) and aged (24 months) female Fischer 344 rats were examined. Behavior: As a group aged rats show behavioral impairments compared to controls. However, some of the aged rats performed as well as young controls. Electrophysiology: Most aged rats show pathologic EEG patterns as reflected by frequent long-duration high voltage neocortical spindles present during immobility. Anatomy: Cholinergic neurons were identified by immunohistochemical techniques using antibodies against choline acetyltransferase (ChAT), the acetylcholine biosynthetic enzyme. The quantitative assessment of neuronal number and size was made on a computerized image analysis system. Thus far our studies of representative tissue sections of the medial septum (MS) and magnocellular preoptic/substantia innominata (MgPO/SI) indicate no significant decrease in cell number. Cholinergic neurons, however, are reduced in size (i.e., area) by 12% in the MS and 20% in the MgPO/SI compared to young controls. Moreover, the degree to which cholinergic neurons are shrunken appear to correlate with extent of cognitive impairment.

In the present investigation we also observed swollen ChAT-positive neurites in the neocortex of the aged rat. These neurites appear either singularly or bunched together forming a "plaque-like" structure. These latter structures appear similar to the dystrophic ChAT-positive neurites observed in autopsied tissue of patients with Alzheimer's disease. This research was supported by the J.D. French Foundation and NIH grants AG05344 and AG06088.

123.6 ALTERATIONS IN MUSCARINIC CONTROL OF STRIATAL DOPAMINE AUTORECEPTORS IN SENESCENCE: A DEFICIT IN MEMBRANE CALCIUM MOBILIZATION? J.A. Joseph, G.S. Roth*+, T.K. Dalton*, and W.A. Hunt*, The Armed Forces Radiobiology Research Institute, Bethesda, MD 20814, +Gerontology Research Center, NIA,Baltimore, MD 21224.

Numerous reports have indicated that the release of striatal dopamine (DA) is controlled by inhibitory DA autoreceptors (ATR) which are in turn regulated by inhibitory cholinergic heteroreceptors (HTR) located in close vicinity to the ATR. Muscarinic HTR (eg., via oxotremorine) activation enhances K+ induced release of DA from striatal slices from mature (M) but not senescent (S) rats. Since it has been shown that age-dependent declines in Ca++ mediated acetylcholine release can be restored by the ionophore A23187, it was of interest to determine if age-related decrements in calcium mobilization might contribute to the alterations in muscarinic control of the striatal DA ATR seen in senescence. Striatal tissue slices (300 mu) obtained from M (6 mo.) and S (24 mo.) Wistar rats were placed in chambers and superfused with a modified Krebs-Ringer medium containing (in mM) NaHCO3 21, glucose 3.4, NaH2PO4 1.3, EGTA 1, MgCl2 .93, NaCl 127, KCl 2.5 (Ph 7.4) ("Lo KCl buffer"). After a 30 min equilibration period, a 5 min baseline fraction was collected. The M & S tissue in four of the chambers was then perfused with "Hi KCl" (30 mM KCl, 1.26 mM CaCl2.2H20, NaCl 57 mM, in addition to the components described above) and 0 or 500 uM oxotremorine. In other parallel chambers A23187 (10 or 100 uM) was added to Hi KCl buffer which contained one of four Ca++ concentrations (in mM; 1.26, 6.2, 11.2, or 27.2) and no oxotremorine. Six 5 minute fractions were collected. DA release was determined using HPLC coupled to electrochemical detection. The results indicated that, as previously demonstrated, oxotremorine was not effective in enhancing DA release in striatal tissue from the senescent animals (193 + 8% peak DA enhancement young; 2 + 0.5% old). However, application of 10 uM A23187 to senescent striata evoked a 181 + 10% enhancement of K+ induced release of DA in the presence of 11.2 mM Ca++. In the presence of 100 um A23187, K+ induced release of DA was enhanced at all Ca++ concentrations in the senescent tissue. While age-related differences in enhancement of K+ induced release of DA still remained at both 10 and 100 uM A23187, they were reduced with the application of the higher A23187 concentration (eg., 10 uM A23187, 1.2 Ca++ DA peak enhancement = 153% + 6% young, 110 + 5% old; 100 uM A23187, 1.2 Ca++ = 175 + 12% young, 165% + 6.5%). (Note: Neither concentration of A23187 induced DA release with the Lo KCl.) These results suggest that a deficit in Ca++ mobilization may occur in senescence, and that this decrement may contribute to reduced control of striatal ATR's by muscarinic HTR's.

123.7 AUTORADIOGRAPHIC EVIDENCE FOR REDUCTION IN D1 DOPAMINE RECEPTOR BINDING IN AGED RHESUS MONKEY CORTEX. F. Filloux, *+ P.J. Whitehouse, ++ T.M. Dawson,+ M.V. Wagster, D.L. Price, L.C. Walker and J.K. Wamsley.+ Depts. of Psych., Pharmacol., Neurol., Univ. of Utah Sch. Med.,+ SLC, UT 84132; Neuropath. Lab., The Johns Hopkins Univ. Sch. Med., Baltimore, MD 21205-2182; and Alzheimer Neurosci. Center, Univ. Hosp. Cleveland,++ Cleveland, OH 44106.

Behavioral studies have demonstrated impaired cognitive functioning in aged non-human primates. The precise neurobiological correlates of this deterioration in cognitive ability are unclear; however, both animal and human studies have demonstrated age-related alterations in a variety of neurotransmitter systems. Surprisingly, a recent report (Rinne, Brain Res. 404:162, 1987) failed to demonstrate D1 receptor alterations in the brains of aged humans. In contrast, using [^{3}H]-SCH 23390 receptor autoradiography, this study demonstrates a highly significant reduction in D1 receptor binding in the temporal cortex of aged rhesus monkeys (M. mulatta).

Ten micron sections of hippocampus and adjacent temporal cortex were obtained from the brains of seventeen M. mulatta monkeys aged 2-22 years. Three age groups were sampled: two year-old animals; animals 6-15 years; animals 17-22 years of age. Tissue sections were incubated according to previously described methods (Dawson et al., J. Neurosci. 6:2352, 1986) in a Tris-HCl buffer containing NaCl, $CaCl_2$, $MgCl_2$, KCl and 1.0 nM [^{3}H]-SCH 23390. Labeled sections and brain paste standards were apposed to tritium-sensitive LKB Ultrofilm for two months. Quantitation of the resulting autoradiograms was performed by computerized microdensitometry.

[^{3}H]-SCH 23390 binding in hippocampal structures ranged from 0.43 fmoles/mg tissue (stratum oriens) to 4.16 fmoles/mg tissue (CA1, pyramidal layer), and did not show significant age-related changes. However, in all layers examined, cortical [^{3}H]-SCH 23390 binding was prominently reduced in the oldest compared to the youngest group. Specifically, binding was reduced from 7.93, 8.77 and 5.79 fmoles/mg tissue to 5.98, 6.56 and 4.73 fmoles/mg tissue in layers II-III, layer V and layer VI, respectively ($p<0.001$, $p<0.005$, $p<0.05$, respectively). Animals 6-15 years of age had intermediate levels of binding which approached those of the youngest animals, but which were not statistically different from receptor densities in either of the other two groups.

These results demonstrate that age-related changes in the mesocortical DA system do occur in the rhesus monkey. How this may relate to impaired cognitive functioning in non-human primates is currently unknown.

Tissues were obtained from the Regional Primate Research Center at the University of Washington, supported by NIH grant RR 00166.

123.8 AGE-RELATED AND REGIONAL DIFFERENCES IN BETA-2 ADRENERGIC RECEPTORS IN RAT CEREBELLUM: *IN VITRO* AUTORADIOGRAPHY WITH [^{125}I]CYP. E. Pearlman*, D. Lorton, R.M. Booze, H.H. Yeh and J. N. Davis. Departments of Medicine (Neurology) and Pharmacology, Duke University, Durham, NC, and Department of Neurobiology and Anatomy, University of Rochester School of Medicine, Rochester, NY. (Spon: Dorothy G. Flood).

Membrane binding studies of age-related changes in rat cerebellar beta-adrenergic receptor densities have reported increases, decreases and no changes in these receptors with age. To clarify these conflicting reports, we have used *in situ* receptor autoradiography to study age-related changes in cerebellar beta-2 adrenergic receptor densities. In addition, we compared the distribution of beta-2 receptors within several representative lobules of the rat cerebellum.

In situ receptor autoradiography was performed with [^{125}I]-cyanopindolol (CYP), a specific beta-adrenergic antagonist. The selective beta-1 adrenergic antagonist ICI-89,406 was used to localize the beta-2 adrenergic receptor subtype. Six- and 24-month old (N = 6 and 7, respectively) Long Evans hooded rats were sacrificed, the brains were quickly removed, blocked and frozen. Midsaggital cryosections of cerebella (16-um thickness) were slide-mounted for autoradiography and incubated with [^{125}I]CYP and either ICI 89,406 or 1 um dl-propranolol. The sections incubated with propranolol were used to estimate non-specific binding. Following incubation, the labeled sections were apposed to LKB ultrofilm for 30 h and the resulting autoradiographs examined using RAS 1000 Image Analyzer. Densitometric readings were made in cerebellar lobules II-III, VI and IX-X. Adjacent sections were processed histologically to aid in identifying [^{125}I]CYP-labeled lobules. A 2 (age) X 3 (lobule) X 2 (section) analysis of variances was employed to estimate the significance of the densitometric data.

We found significant overall effects related to age ($F_{1,10} = 12.5$, $p = 0.0054$), lobule ($F_{2,20} = 36.9$, $p = 0.0001$) and of an age X lobule interaction ($F_{2,2} = 5$, $p = 0.018$). The optical densities of beta-2 receptors in 24-month old cerebella were reduced by 30% when compared to those of 6-month old cerebella. Quantitative differences in beta-2 adrenergic receptor densities were evident among certain cerebellar lobules — beta-receptor density within lobule II-III was lower than that measured from lobule VI or loblules IX-X. On the other hand, no obvious differences in beta-2 receptor density were found in lobules VI and IX-X at any age examined.

These results suggest that there is an overall decline in beta-2 adrenergic receptors with age in the rat cerebellum. This change occurs with regional uniformity from lobule to lobule independent of any interlobular variations in beta-2 receptor densities.

Supported by the Veterans Administration and NIH grant AG00029.

123.9 THE SEROTONERGIC AND DOPAMINERGIC SYSTEM IN THE AGED RAT CNS AS STUDIED BY IMMUNOCYTOCHEMISTRY WITH ANTIBODIES TO SEROTONIN AND DOPAMINE. H.W.M. Steinbusch, M.G.P.A. Van Luvtelaar*, J.G.J.M. Bol* and #J.A.D.M. Tonnaer*. Dept. Pharmacology, Free University, Amsterdam and #Dept. CNS Pharmacology, Organon Int. BV., Oss, The Netherlands.

Normal aging has been characterized neurochemically among others by a decrease of the cholinergic/serotonergic transmission. It has been observed that transmitter systems such as dopamine is involved in Parkinsonism, and acetyl choline and serotonin in Alzheimer's disease. For this study we used young adult (3 months old) and aged (28 month and older) rats for serotonin- and dopamine-immunocytochemistry. The serotonergic system in the aged rat appeared to be particularly degenerated in all layers of the frontoparietal cortex, the caudate-putamen complex, the medial preoptic region and the intermediolateral cell column of the spinal cord. In these regions we did not only observe a decrease in innervation, but in addition a large number of swollen varicose fiber clusters. A large decrease of serotonergic fibers was demonstrated in the hippocampus. With regard to the dopaminergic system we found a small but overall decrease in the number of dopaminergic fibers, but did not observe the appearance of highly degenerated varicose fibers like seen for the serotonergic system. No differences between young and old were demonstrated in the area of the entorhinal cortex, the medial habenulae or the caudate-putamen complex. However, there was a striking loss of dopaminergic cell bodies both in the substantia nigra, pars compacta as well as in the ventral area tegmental. The dopaminergic cells in the zona incerta and the arcuate nucleus show a decrease in immunostaining, while the dopaminergic cells in the posterior hypothalamic periventricular region show an increase in immunoreactivity.These results indicate that aging results in a local and not an overall degeneration of the serotonergic and dopaminergic system. It is known that both serotonergic as well as dopaminergic cell bodies send their axons to a whole variety of different forebrain regions. Retrograde tracing studies have shown that these cell bodies can give collaterals to various brain regions. The local degeneration of the serotonergic system in some forebrain regions and the absence of this degeneration in the dopaminergic system indicates the appearance of an intraneurotoxic compound, possibly receptor specific, for the serotonergic system, having no effect on the dopaminergic system. The specific disappearance of subpopulations of dopaminergic neurons in the substantia nigra and the ventral tegmental area in conjunction with a decrease of the cellular dopamine-immunoreactivity in the other diencephalic dopaminergic nuclei points towards the same direction, i.e. intraneuronal neurotoxic compounds, which induce a retrograde axonal degeneration. Both anterograde and retrograde tracing studies will provide further evidence for this hypothesis.

123.10 AGE-RELATED CHANGES IN IN VITRO CORPUS STRIATUM DOPAMINERGIC FUNCTION: INFLUENCE OF INTERNEURONS. D. E. Dluzen*, N. J. Laping and V. D. Ramirez (SPON: G. Jackson). Department of Physiology & Biophysics, University of Illinois, Urbana, Illinois 61801.

In the present experiment we examined the basal and stimulated in vitro efflux of dopamine from the corpus striatum of male rats as a function of three developmental periods (2-4, 11-13 and 18-24 months of age). Effluent samples were collected at 10 minute intervals (~300 ul) for 15 intervals and immediately assayed for dopamine using HPLC-EC. After a basal collection period of 5 intervals the responsiveness of these tissue preparations was evaluated following infusions of either potassium (30mM) or amphetamine (10^{-5}M).

In none of these experiments were any significant age-related changes in basal dopamine efflux observed with levels remaining relatively stable and ranging between 3-7 pg/mg/min. In Experiment I the potassium stimulated dopamine efflux from corpus striatum of 18-24 month old animals was significantly reduced (Peak Response = 6.0+.63 pg/mg/min, N=8) compared to the other two age groups, who failed to differ from one another (2-4 month = 32.2+11.8, N=5 and 11-13 month = 30.4+9.1, N=4). To asses whether this marked decrease in responsiveness of the corpus striatum from 18-24 month old animals represented a specific alteration in dopaminergic function or a generalized, non-specific decrement to potassium stimulation, in Experiment II we examined the response of these preparations to amphetamine, a specific activator of dopaminergic terminals. Amphetamine stimulated dopamine efflux from the corpus striatum of 18-24 month old animals was actually increased (Peak Response = 26.6+2.9, N=4) compared to 2-4 (17.6+2.9, N=4) and 11-13 (17.1+2.3, N=4) month old animals. In Experiment III corpus striatum tissue fragments from 2-4 and 18-24 month old animals were superfused with medium containing 10^{-6}M tetrodotoxin (TTX) to block interneuronal influences and subsequently challenged with infusions of potassium. In contrast to the results from superfusions with normal (TTX-free) medium (Experiment I), in the presence of TTX both age groups responded similarly to the potassium infusion (Peak Response: 2-4 month = 19.7+6.9, N=4 versus 18-24 month = 15.5+5.4, N=6).

These results suggest that age-related decrements in in vitro potassium stimulated dopamine efflux as obtained in 18-24 month old male rats may not necessarily be a direct result of an alteration in dopaminergic function per se, but seem to be due to changes in control of dopaminergic function exerted by interneurons.

123.11 AGE-RELATED CHANGES IN PRIMATE NEUROCHEMISTRY. G.L. Wenk, L.Cork, R. Struble, D. Pierce, and D. Price. Departments of Psychology and Neuropathology, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Deterioration in sensory, motor and cognitive functions is frequently associated with old age. Because these functions depend on the integrity of cortical processes, their impairment with age may be due to structural or functional alterations that may be expressed by changes in neurochemistry. Recent studies in humans have revealed decrements in various biochemical measures that correlate with age. In the present studies, the concentrations of monoaminergic neurotransmitter levels and the density of their receptors were determined in the brains of rhesus monkeys ranging from 2 to 37 years of age. Major changes that occur with increasing age include: (1) a decrease in cortical levels of dopamine and its major metabolites, homovanillic acid and dihydroxyphenylacetic acid, that is correlated with the increased presence of senile plaques, and (2) a decrease in cortical levels of serotonin and serotonergic (type 2) receptors. Significant, age-related changes were not found in measures of the (1) acetylcholinergic system, including choline acetyltransferase activity, and nicotinic and muscarinic receptors, (2) norepinephrine and beta-adrenergic receptors, or (3) benzodiazepine receptors. These findings demonstrate the selective neurochemical changes that occur in various neurotransmitter systems of the primate neocortex during normal aging. Supported by NIH AG 05146.

123.12 AGE-RELATED CHANGES IN DENSITY AND UP-REGULATION OF TYPES I AND II HIPPOCAMPAL CORTICOSTERIOD RECEPTORS. J.C. Eldridge*, D.G. Fleenor*, D.S. Kerr*, L.W. Campbell*, and P.W. Landfield. (SPON: J.H. Robinson). Dept. of Physiol and Pharmacol, Bowman Gray School of Medicine, Winston-Salem, NC 27103.

The rat hippocampus contains a high density of receptors for corticosteroids (cf. review in McEwen et al, 1975; in: The Hippocampus, Plenum). Because of occupation by endogenous steriods, receptor analyses have used prior adrenalectomy (ADX). Prolonged ADX up-regulates corticoid binding in hippocampus (McEwen et al, 1974, Brain Res.), while diminished binding occurs with advancing age (Sapolsky et al, 1985, Brain Res.) or exposure to stress (Sapolsky et al, 1984, Endocrinology). Recent studies have indicated two distinct binding components in hippocampus: Type I receptors (CR) which exhibit high affinity and saturation during basal adrenal activity, and Type II sites (GR) which exhibit lower affinity and approach saturation only at elevated plasma corticoid levels (Reul and de Kloet, 1985, Endocrinology). However, the separate receptor types have not yet been studied extensively in response to prolonged ADX or aging.

Either single or paired hippocampi were dissected from Fischer 344 male rats for single point binding assays. Cytosols were prepared and incubated with 20 nM ^{3}H-Corticosterone (CORT). Type II binding capacity was assessed by co-incubation with 100-fold excess of non-radioactive RU-28362, a synthetic steroid that has specificity for Type II sites. Type I binding was calculated from the difference between total receptor capacity (using 500-fold excess dexamethasone) and binding displaced by RU-28362. Non-specific binding was also determined with non-radioactive CORT.

The quantity of Type I binding at 2 days post-ADX was significantly less in aged rats (23-26 mo-old) than young rats (4-6 mo-old). Type II receptor content did not differ with age at this point. Between 3 and 7 days post-ADX, a significant up-regulation of both receptor types occurred in young animals, although less consistently for Type I. In aged rats, Type II up-regulation was less than in young rats, while increases in Type I binding did not occur. Because of variability of Type I up-regulation, however, further work is needed on the latter point. In young animals, a further up-regulation of Type II, but not Type I, binding was exhibited after 11 days post-ADX.

These results indicate that neither decline of hippocampal CORT receptor binding in aging nor up-regulation after ADX is equivalent for the two receptor types. Type II binding exhibited more pronounced up-regulation, whereas Type I receptors appeared more affected by aging, at 2 days post-ADX and during prolonged ADX. (Supported by grants AG-04207 and DA-03637. We thank Roussel-Uclaf for assay materials).

123.13 UP-REGULATION OF OPIATE RECEPTORS IN MATURE AND AGED WISTAR RATS FOLLOWING CHRONIC NALOXONE. J. L. Neisewander, A. J. Nonneman, S. A. McDougall*, and M. T. Bardo. Department of Psychology, University of Kentucky, Lexington, KY 40506.

Previous research has shown a compensatory increase in 3H-naloxone binding sites, known as up-regulation, following chronic naloxone in adult rats. It is not known, however, whether aged rats are also capable of up-regulating opiate receptors. The present experiment therefore assessed whether there are age-dependent differences in up-regulation of 3H-naloxone binding sites in 19 mature (112-119 days) and 20 aged (27 months) male Wistar rats. Half of each age group was implanted subdermally with two slow-release pellets containing naloxone (10 mg free base in each). The other half received a sham surgery, for which an incision was made but no pellets were implanted. Ten days later the animals received a second surgery where the pellets were removed or another sham surgery was given. The day immediately following pellet removal or sham surgery, the rats were decapitated and the brains and spinal cords were removed. The brains were hemisected and the following areas were dissected from the left hemisphere: cerebellum, hindbrain, midbrain, diencephalon, hippocampus, striatum, olfactory tubercle/nucleus accumbens, and prefrontal cortex. These tissues were homogenized in 0.5 M tris buffer (pH 7.4) and incubated at 0° C for three hours with 1 nM 3H-naloxone in the presence or absence of 100 nM levallorphan tartrate. Each sample was washed over GF/B glass fiber filters and radioactivity was determined by liquid scintillation spectrometry.

There was a significant main effect of pellet treatment in all areas except cerebellum, indicating that chronic naloxone treatment produced up-regulation in these areas regardless of age. There was also a significant main effect of age in spinal cord, midbrain, striatum, and olfactory tubercle/nucleus accumbens, which showed that aged rats had fewer binding sites in these areas than mature rats. Interestingly, there was a significant age by pellet interaction in the hippocampus. A Newman-Kuels test showed that there was an enhanced up-regulation in hippocampus of aged naloxone-treated rats relative to mature naloxone-treated rats. There was no difference in binding sites between the sham groups in this region.

123.14 ACETYLCHOLINESTERASE IN CHOLINERGIC NEURONS INCREASES IN ALZHEIMER'S DISEASE. Younkin, L. H., Palmert, M. R., Usiak, M., and Younkin, S. G. Depts. of Pathology and Pharmacology, Case Western Reserve University, Cleveland, OH 44106.

In a previous study of 26 cases of Alzheimer's disease (AD) and 14 controls well matched for age and postmortem interval, we assayed acetylcholinesterase (AChE) and evaluated cholinergic neurons in the nucleus basalis of Meynert (nbM). In AD there was a significant 61% decrease in the number of cholinergic neurons, an insignificant 19% decrease in nbM AChE, and a significant 266% increase in nbM AChE per cholinergic neuron. To eliminate AChE contributed from the region surrounding the nbM, we reevaluated 13 AD and 11 control cases by taking punches (3 mm in diameter) from the center of the nbM in the frozen tissue blocks previously examined. In AD the mean AChE per cholinergic neuron measured in these central nbM punches increased over 2-fold. We have also employed a quantitative immunocytochemical approach to evaluate AChE in cholinergic somata. In these experiments, sets of AD and control sections well matched for age and postmortem interval were processed in parallel. Thaw mounted 12 um cryostat sections were fixed 5 min in 10% buffered formalin, rinsed in water, and exposed serially to 1% normal goat serum (NGS) in 0.1 M Tris pH 7.6, 0.15 M NaCl (TBS) for 5 min X3, 10% NGS/TBS for 10 min, a 1:500 dilution of anti-human AChE antibody in 1% NGS/TBS for 16 h, 1% NGS/TBS for 5 min x3, ^{125}I-labelled goat anti-rabbit IgG in 1% NGS/TBS for 1 h, and 5 copious TBS rinses. Each section was dipped in Kodak NTB-2 emulsion, exposed for 48 hours, developed, stained for AChE, and the grains over cholinergic somata counted. To assess non-specific binding of radiolabelled secondary antibody, grains were counted over cholinergic somata in sections processed identically except for the omission of primary antibody. The primary antibody employed was an affinity-purified rabbit polyclonal that we raised against affinity-purified human red blood AChE (provided by T. L. Rosenberry). In parallel with the assessment described above, a series of standard sections (prepared by mixing human cerebral cortical brain paste with known amounts of AChE) was examined to establish that, for AChE levels like those in the sections examined, the amount of radiolabelled antibody bound is proportional to the AChE present. Grain counts over cholinergic somata showed (a) acceptable neuron to neuron variability (SEMs for grains/soma fell to less than 5% of the mean when 20-40 neurons were assessed) and (b) a significant increase in the number of specific grains (primary and radiolabelled secondary antibody - secondary only) over cholinergic somata when 7 AD cases were compared with 6 controls. (Supported by AG-06656 and a grant from the American Federation for Aging Research)

123.15 VARIABILITY OF GANGLIOSIDE CONTENT IN NUCLEUS BASALIS OF ALZHEIMER PATIENTS. P.B. Crino, M.D. Ullman*, B.A. Vogt, L. Volicer and E.D. Bird. E.N. Rogers Mem. Vet. Hosp., GRECC, Bedford, MA 01730, and Depts. of Psychiatry, Anatomy and Pharmacology, Boston Univ. Med. Sch., Boston, MA 02118.

Dementia of the Alzheimer type (DAT) is characterized by neurofibrillary tangles, neuritic plaques, neuronal cell loss, and reactive gliosis in specific brain regions such as nucleus basalis, hippocampus, and some neocortical areas. Because gangliosides are components of neuronal and glial cell membranes and because they may have been detected in neurofibrillary tangles, changes in regional distribution of brain gangliosides in DAT would be expected. We have measured gangliosides from affected and unaffected brain regions of five neuropathologically and clinically diagnosed DAT patients and from three controls.

Gangliosides GM1, GD1a, GD1b, and GT1b were quantified by HPLC of their perbenzoylated derivatives. They were extracted by solvent partition and isolated on a reversed-phase sample preparation cartridge. The isolated gangliosides were perbenzoylated at 45°C for 24 hours in 5% benzoyl chloride in 25% toluene in pyridine. The derivatives were quantified by their UV absorption at 230 nm and expressed as nmoles ganglioside/mg protein.

We have found that in hippocampus and areas 28 and 24, there were no consistent differences in ganglioside content between control and DAT tissues with little variability between subjects. In contrast, there was a large variability (up to 25 times) in ganglioside content of nucleus basalis in the DAT brains, although mean ganglioside concentrations were not significantly different from controls. This finding was replicated by TLC analysis. Ganglioside concentration did not correlate with age at disease onset, age at death, sex, post-mortem interval, and hemisphere analyzed. All DAT brains had pronounced deposition of plaques and tangles in the region of the nucleus basalis. Amyloid angiopathy and temporal lobe atrophy were noted in two brains. Ganglioside variability in nucleus basalis may reflect neuropathological heterogeneity of DAT.

123.16 A "NATURAL" ANIMAL MODEL OF PARKINSONISM. V.M. Trulson and M.E. Trulson. Dept. Anat., Coll. Med., Texas A&M Univ., College Station, TX 77843.

Previous studies have proposed the use of various experimental animal models of Parkinsonism. These include chemical (6-hydroxydopamine, 6OHDA) or mechanical destruction of the nigrostriatal dopamine (DA) system and administration of the apparently specific DA neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). Destruction of the nigrostriatal DA system by these methods has been shown to produce abnormal motoric function. However, these behavioral changes do not mimic Parkinsonism in humans. We examined the aged mouse as a potential model for studying Parkinsonism. Four types of behavioral measures were taken in normal and aged mice, and those treated with either 6OHDA or MPTP. These tests included locomotor activity, roto-rod performance, ergometric activity and videotape records. In addition, both in vivo and in vitro electrophysiological recordings from DA-containing neurons in the substantia nigra were obtained from control mice, aged mice, 6OHDA and MPTP-treated mice. Locomotor activity measures revealed that 6OHDA treated mice showed no significant change from control animals (+6.4%) while both MPTP (-36.9%) and aged mice (-59.8%) showed a significant decrease from control values. Aged mice also moved significantly slower (-44.2%) than control animals, while 6OHDA and MPTP-treated mice showed no change. Aged mice fell off the roto-rod significantly more (+82.3%) than control, 6OHDA (+16.7%) or MPTP (+29.9%) treated mice. Ergometric activity was observed at regular intervals (mean = 7.2 sec) in aged mice. Video analysis revealed that this activity consisted of body tremors and head weaving. By comparison, little ergometric activity was observed in control, 6OHDA or MPTP-treated animals. When it did occur, video analysis revealed that it was associated with grooming. DA-containing neurons recorded in mice that had received MPTP or 6OHDA displayed the characteristic electrophysiological and pharmacological properties seen in control animals, with the exception that many fewer cells were encountered. However, aged mice showed altered electrophysiological (longer duration action potentials and slower discharge rates) and pharmacological (decreased responsiveness to DA agonists) properties. The reason for these differences among animal models of Parkinsonism may be due to the fact that, when a subpopulation of DA-containing neurons is destroyed by MPTP or 6OHDA in young animals, aside from the changes in the central DA system, the brain is still a "young brain." On the other hand, numerous neural changes have taken place in aged mice. These changes may be in terms of both afferent and efferent projections of the DA-containing neurons, as well as possible changes in membrane and receptor properties of individual cells due to the aging process.

123.17 **BENEFITS OF RAPID VS. DELAYED AUTOPSY IN HUMAN BRAIN CATECHOLAMINE AXONAL MORPHOLOGY.** C.R. Gutman*, R.M. Booze, and J.N. Davis. (SPON: G. Marsh) V.A. Medical Center and the Joseph and Kathleen Bryan Alzheimer's Disease Research Center, Departments of Medicine (Neurology) and Pharmacology, Duke University, Durham, NC 27705.

The aims of this study were: 1) to identify and classify tyrosine hydroxylase immuno-reactive (TH-IR) axons in normal aged human brain tissue, 2) to examine the regional distribution of six different types of TH-IR neurites and 3) to determine the role of post-mortem delay in axonal pathology.

Normal brain tissue was obtained via rapid autopsy (<1 hr) and routine autopsy (mean delay 5 hrs). Tissue blocks were collected from the superior frontal cortex (Brodmann area 9), hippocampal gyrus, and calcarine cortex (Brodmann area 17). The blocks were immersion-fixed in 4% paraformaldehyde (24 hours, 4°C) and stored in PBS. Adjacent Vibratome (50 um) sections were processed for H&E, Nissl, AChE, or TH-IR. A naive observer sampled 25 fibers from each TH-IR section and classified them into distinct fiber type categories based on their morphology (r^2 test-retest=.95, interobserver=.90).

Of the 650 fibers counted less than 1% were unclassifiable and 1-2% occurred in unusual clusters consisting of several fiber types. These rare fibers were not included in the analyses. All other fibers were easily classified into one of the six remaining classes. Of these six fiber types, autopsy delay significantly decreased the frequency of fine fibers with axonal varicosities (fiber type 2). The decreases were significant in the hippocampus and calcarine cortex with decreases of 27% and 26% respectively.

In summary, we have identified six distinctly different types of TH-IR fibers in human brain tissue. Our data demonstrates that even a relatively short post-mortem delay selectively alters distribution of fiber morphologies. These results suggest that post-mortem delays in fixation may compromise conclusions regarding axonal pathology.

123.18 **CATECHOLAMINE AXONAL MORPHOLOGY IN ALZHEIMER'S DISEASE: EXAMINATION OF THE SYMPATHETIC INGROWTH HYPOTHESIS.** R.M. Booze, C.R. Gutman*, and J.N. Davis. VA Medical Center and the Joseph and Kathleen Bryan Alzheimer's Disease Research Center, Depts. of Medicine (Neurology) and Pharmacology, Duke Univ. Durham, NC 27705.

We have hypothesized that the loss of cholinergic neurons in Alzheimer's disease results in the abnormal growth of peripheral sympathetic fibers (Booze and Davis, 1986). Sympathetic ingrowth occurs in experimental animal models in response to cholinergic denervation of the hippocampus. We have tested this hypothesis using rapid autopsy tissue obtained from normal and Alzheimer's disease patients and studying alterations in fiber morphology.

Tissue was obtained within one hour post-mortem from the superior frontal cortex (Brodmann area 9), the hippocampal gyrus, and the calcarine cortex (Brodmann area 17). The tissue blocks were immersion-fixed for 24 hours, Vibratome-sectioned, and processed for tyrosine hydroxylase immunocytochemistry (TH-IR). Sections were further processed for Thioflavin-S to neuropathologically confirm Alzheimer's disease. Additional adjacent sections were processed for Nissl, H & E, and AChE. All TH-IR sections were coded and 25 fibers from each section were surveyed and classified into one of six distinct fiber-type categories based on fiber morphology. A total of 925 TH-IR fibers were counted.

Statistical analyses of the categorical fiber count data found significant overall shifts in the relative proportions of fibers in Alzheimer's brain tissue. When analyzed by region, only the hipppocampus demonstrated significant changes in the fiber category profile. These changes were characterized by a decrease in long (up to 2 mm) TH-IR fibers and an increase in short, tortuous, axons with thick-caliber axons.

In summary, we have found shifts in fiber morphology in Alzheimer's disease that are quantitatively and qualitatively different from those occurring as a consequence of delays in tissue processing (Gutman, Booze, and Davis, this meeting). This specific shift in hippocampal catecholaminergic fiber morphology could represent sympathetic ingrowth in Alzheimer's disease. However, the lack of a specific marker for sympathetic fibers in human brain tissue precludes definite conclusions at this time.

123.19 CEREBROSPINAL FLUID QUINOLINIC ACID ALTERATIONS IN NORMAL AGING AND ALZHEIMER'S DISEASE. M.M. Mouradian*, M.P. Heyes*, S.P. Markey*, T.N. Chase (SPON: J.R. Walters), Experimental Therapeutics Branch, NINCDS, Lab of Neurophysiology and Lab of Clinical Science, NIMH, Bethesda, MD 20892.

Excitatory amino acid transmission has recently been implicated in the pathogenesis of Alzheimer's disease. Quinolinic acid, an endogenous tryptophan metabolite, has potent excitotoxic properties and a high affinity to the N-methyl-D-aspartate receptor. Quinolinic acid is found in the human central nervous system, and is not derived from the systemic circulation. In this study quinolinic acid levels were measured in the cerebrospinal fluid of 19 patients with Alzheimer's disease and 14 neurologically normal volunteers. Spinal fluid was collected between 8 and 9 am after overnight fast and complete bedrest, at sequential 1 ml aliquots and frozen immediately. Quinolinic acid was assayed by negative chemical ionization gas chromatography/mass spectrometry as the dihexafluoroisopropanol ester using [^{18}O]-quinolinic acid as internal standard. There was no significant gradient in quinolinic acid levels between the first (5.67 $\pm$ 0.50 ng/ml) and thirtieth (4.63 $\pm$ 0.95 ng/ml) aliquot in five individuals. Quinolinic acid values increased with normal aging as measured in 14 controls with an age range of 22 to 81 years ($r = .655$, $p < .02$). Patients with Alzheimer's disease (mean age 64 $\pm$ 1.5 years, range 53-80) had significantly lower quinolinic acid levels (3.73 $\pm$ .48 ng/ml) compared to 9 age matched (mean age 64 $\pm$ 3.2 years, range 54-81) healthy volunteers (5.90 $\pm$ 1.07 ng/ml), (37% lower, $p < .05$). There was no significant correlation between quinolinic acid levels and symptom duration, age of onset, WAIS-R, Mattis Dementia Rating Scale, or Memory Quotient.

Whether the observed alterations in quinolinic acid in lumbar spinal fluid reflect changes in its central metabolism or transport remain uncertain. Nevertheless, the present results could cast doubt on the suggestion that an accumulation of this excitotoxin in the central nervous system accounts for the neuronal degeneration in Alzheimer's disease.

123.20 CORRELATIONS BETWEEN SOMATOSTATIN-LIKE IMMUNOREACTIVITY AND QUANTITATIVE EEG IN ALZHEIMER PATIENTS. H. Soininen*, J. Partanen*, J. Jolkkonen*, V. Laulumaa* and P.J. Riekkinen. Department of Neurology and Clinical Neurophysiology, University of Kuopio, 70210 Kuopio, Finland.

The most consistent neurochemical abnormalities in Alzheimer's disease (AD) are deficits in cholinergic and somatostatinergic systems. Reduced levels of somatostatin-like immunoreactivity (SLI) in cerebral cortex and also in CSF have been reported in several studies. A recent study demonstrated correlation between CSF SLI and cognitive impairment and glucose utilization measured by PET. We were interested in neurochemical substrates of EEG and analysed correlations between CSF SLI and variables of quantitative EEG (QEEG) in 24 patients with probable AD of mild to moderate severity.

The beta percentage ($r = 0.53$, $p < 0.05$) and mean frequency in alpha and theta range ($r = 0.49$, $p < 0.05$) correlated significantly with CSF SLI. However, in mild patients there appeared several other significant correlations: CSF SLI correlated positively with beta ($r = 0.71$, $p < 0.05$) and alpha ($r = 0.67$, $p < 0.05$) power, negatively with theta power and positively with alpha/theta and alpha/delta ratios, as well as with mean and peak frequency parameters.

The amount of beta activity is reduced in AD, and this is one of the main findings in the beginning of the disease. Interestingly we observed a significant correlation between beta percentage power and CSF SLI. To our experience CSF SLI is reduced already in early stages of AD and the observed association between beta activity and CSF SLI further supports the hypothesis that the disturbance of somatostatinergic cortical neurons is an early phenomenon in AD.

123.21 NEUROPEPTIDES AND NEUROPATHOLOGICAL CHANGES IN THE AMYGDALA IN ALZHEIMER'S DISEASE. J. Unger*, T. McNeill, L. Lapham* and R. Hamill. Depts. Neurology, Pathology, Univ. Rochester School of Medicine and Dentistry, Rochester, NY 14642.

Alzheimer's disease (AD) is clinically marked by a progressive decline in intellectual acuity and memory as well as deficits in emotional, motivational and psychosocial behavior. Neuropathological studies have indicated the involvement of several neurotransmitter systems including acetylcholine and norepinephrine and in particular one neuropeptide, somatostatin. Since it is known that the amygdala, an important component of the limbic system, contains a large population of somatostatinergic neurons, partially co-localized with neuropeptide Y (NPY), we investigated the distribution and morphology of these neurons in AD. Further, we examined the distribution of classical neuropathological changes, neuritic plaques (NP) and neurofibrillary tangles (NFT) in subregions of the amygdaloid complex to determine if particular subnuclei of the amygdala may be more susceptible to the pathology of AD. Brain tissue was obtained within 11 hours postmortem from 10 patients with clinical signs of dementia and autopsy confirmed AD and seven normal controls of similar age. Serial sections were either stained with Bodian's silver method for NP or processed for SOM- and NPY-immunohistochemistry. Sizes of SOM- and NPY-IR perkikarya from 100 cells per case were morphologically analyzed using an IBM Bioquant IV computer system. The distribution curves, based on the number and size of SOM- and NPY-IR neurons in controls were identical, supporting the finding of a high rate of co-localization for both peptides. In AD, the curves showed an increase in the number of smaller neurons (<150 μm^2) for both SOM and NPY. However, the reduction of SOM immunoreactive cells was not as severe as reported for the cortex and is consistent with radioimmunological studies that showed only modest quantitative changes for SOM and NPY in the amygdala in AD. Subregional analysis revealed similar size reductions in all subnuclei. In contrast there was a characteristic pattern of NP distribution observed in 8 of the 10 AD cases. High density of NP was observed in the cortical, assessory basal, granular nuclei and transitory zone, moderate density in the medial and central nuclei and few NPs were seen in the basal and lateral nuclei. Double labeling with thioflavin showed some SOM- and NPY-IR fibers closely associated with NP but most of the IR fibers and neurons were found in areas between plaques. Supported by PHS Grant AG03644 and DFG, Un 59/1-2 (JU).

123.22 CHANGES IN CORTICOTROPIN-RELEASING FACTOR IMMUNOREACTIVE NEURONS IN THE PARAVENTRICULAR NUCLEUS OF ALZHEIMER'S DISEASED BRAINS. J.C. Pearson and L. Jennes. Dept. of Anatomy, Wright State Univ. Sch. of Med., Dayton, OH 45435.

Alzheimer's diseased (AD) and control brains have been examined for cytoarchitectural differences, distribution of corticotropin-releasing factor (CRF)-immunoreactive neurons, and the presence of amyloid protein (Congo Red stain) in the paraventricular nucleus (PVN) of the hypothalamus. Human PVN may be cytoarchitecturally subdivided into parvocellular and magnocellular parts similar to those described in the rat. In control brains, CRF-immunoreactive (CRF-IR) neurons are scattered throughout the anterior, dorsal, and lateral parvocellular subnuclei. In the periventricular subnucleus, CRF-IR is contained in fusiform somata and in strands of varicose fibers. In the medial parvocellular subnucleus, CRF-IR neurons are densely packed and show extreme heterogeneity in soma shape and immunoreactive staining intensity. The magnocellular subnuclei make up a relatively small part of the PVN in human hypothalamus. The large neurons within the posterior magnocellular subnucleus show no CRF-immunoreactivity. In Alzheimer's diseased brains, cresyl violet stained sections show a dramatic reduction in the number of neurons and an increase in the number of glial cells in the PVN when compared to control brains. AD brains also show a significant reduction (approximately 80%) in the number of CRF-IR neurons in the PVN when compared to control brains. The greatest reduction in CRF-IR neurons is found in the medial parvocellular subnucleus. The number of CRF-IR fibers is also reduced in the PVN of diseased brains. Many existing fibers consist of swollen and irregularly spaced varicosities with thin intervaricose segments and resemble axons undergoing degenerative reaction. In Congo Red stained sections, amyloid protein deposits are located throughout the PVN of AD brains but not controls. The present results suggest that CRF-IR neurons in the hypothalamic PVN are strongly affected in the Alzheimer's disease process and may undergo degeneration similar to that which has been described for cortical CRF-producing neurons.

123.23 RECEPTOR CHANGES IN HIPPOCAMPUS OF ALZHEIMER'S DISEASE. D.L. Debowey*, W.F. Maragos, Z. Hollingsworth*, J.T. Greenamyre, A.B. Young and J.B. Penney. (Spon: M.B. Bromberg) Dept. of Neurology, University of Michigan, Ann Arbor, MI 48104.

There is extensive cellular pathology in the hippocampal region of Alzheimer's disease (ALZ) brains with many neurofibrillary tangles (NFTs) in CA1, subiculum and entorhinal cortex. Receptor studies have varied in the degree of change found depending on the assay used and the brains examined. No studies have directly compared multiple receptors to cellular pathology in the same regions of ALZ brains. Therefore, we have measured receptors in stratum moleculare (SM) and stratum pyramidale (SP) of CA1, dentate gyrus (DG), subiculum (SUB), presubiculum (PRE) and layers 2 (EC2) and 4 (EC4) of entorhinal cortex in 9 ALZ, 9 age and post-mortem-delay matched control and 7 similarly matched demented, non-Alzheimer's cases using quantitative receptor autoradiography. Serial cryostat sections were assayed for NFTs with congo red stain, muscarinic receptors with 1 nM [3H]-QNB (QNB), benzodiazepine receptors with 25 nM [3H]flunitrazepam (FLU), dissociative anesthetic receptors with 20 nM [3H]TCP (TCP), NMDA receptors with 200 nM [3H]glutamate plus 2.5 μM cold quisqualate both in 50 mM Tris-acetate buffer (NMA) and in 50 mM Tris-HCl buffer with 2.5 mM $CaCl_2$ (NMC) and total glutamate receptors with [3H]glutamate in the Tris-HCl with calcium buffer (GLU). All assays were performed, autoradiograms generated and data analyzed by observers blind to the diagnoses. Statistical analyses were determined by one way ANOVA.

Binding for all ligands was highest in DG and CA1, high in PRE, SM, and EC2 with less binding in EC4 and SUB. In ALZ brains there were significant binding reductions of 20-30% for QNB in SP and SUB; of 20-30% for FLU in SM, SP, SUB, PRE and EC2; of 30% for TCP and NMA in SM and SP; of 45% for GLU in SP; and of 50-60% for NMC in SM, SP and SUB. There were good correlations between the NMDA receptor changes and NFTs. The non-Alzheimer's brains had QNB and FLU reductions in SUB, PRE, EC2, and EC4 with NMA reductions in EC2 and EC4.

The results suggest that all the receptors measured were abnormal in ALZ hippocampus, but that NMDA/TCP receptors were more affected than others. The greater NMDA receptor changes measured in the presence of chloride suggest that Cl^- may reveal a set of binding sites that are absent from ALZ brains.

Supported by the Arbogast foundation, the Fraternal Order of the Eagles, Roy Gettel, and USPHS grants NS15655 and AG06155.

123.24 AGE-RELATED IMPAIRMENTS IN CONTINUOUS NON-MATCHING TO SAMPLE MEMORY PERFORMANCE ARE LESS ROBUST THAN IMPAIRMENTS PRODUCED BY DISRUPTION OF CHOLINERGIC TRANSMISSION. M.J. Pontecorvo, M.F. White*, D.B. Clissold* and L.H. Conti*. (Spon: L.R. Steranka). Nova Pharmaceutical Corporation, Baltimore, Maryland 21224.

Young (4 months) and aged (24 months) rats were trained in two experiments to perform a two choice tone/light continuous non-matching to sample (CNM) working memory task. In both experiments the rats were reinforced for responding on one lever if the stimulus was the same as on the previous trial (match), and reinforced for responding on the second lever if the current stimulus differed from the previous (non-match). Thus, the rats were required to remember across the intertrial interval (retention interval) which stimulus was presented most recently.

In Experiment I, young and aged rats were trained to criterion at short (1, 2.5 sec) retention intervals, then tested for asymptotic performance with retention intervals of 2.5, 10 and 20 sec. Under these conditions no age-related differences were observed. Both young and aged rats acheived the initial learning criterion ($A' > 0.80$, with 1 sec retention intervals) in less than 30 days, and acheived a stable, accurate asymptote ($A' > 0.85$ at 20 sec). In contrast to this lack of an age-related impairment, disruption of cholinergic transmission in these young rats by administration of the muscarinic antagonist scopolamine produced a significant impairment that was particularly evident at long retention intervals. Similar effects have also been observed in our lab following lesion of cholinergic neurons in the nucleus basalis magnocellularis.

Experiment II examined performance of young and aged rats on a more difficult version of the task. Rats were trained as in Experiment I. The ratio of match to non-match trials was then reduced, increasing potential confusion from previous trials (proactive interference), and the retention intervals were changed to 2.5 and 40 sec. As in Experiment I, no age differences were observed in acquisition or performance at the 2.5 sec retention interval. However, when the 40 sec retention interval was introduced, aged rats were both more variable (between subjects) and less accurate than the young rats. Asymptotic levels of performance (in progress) will be reported.

In summary, age-related impairments in CNM memory performance were not observed under conditions that are sensitive to disruption of cholinergic transmission. However, age-related impairments were observed under more difficult experimental conditions. Thus, there are at least quantitative differences between the memory impairments produced by aging and cholinergic dysfunction in this task.

AGING AND DEMENTIA: FUNCTION I

124.1 ENVIRONMENTAL ENRICHMENT AND BEHAVIOR: A LIFESPAN APPROACH. T.L. Petit and E.J. Markus. Div. of Life Sciences, Univ. of Toronto, Scarborough, Ont. M1C 1A4, Canada.

Environmental input plays an important role in the development of mammalian neuronal systems. It is of interest to examine the degree of environmental plasticity past early development as well as the lasting effects of these environmentally induced changes at different ages.

We examined the short and long term effects of environmental enrichment on learning and long-term retention in young (1-4 month) and aged (24-30 month) male rats.

The animals were in one of three regimes:

1) Control: standard housing.
2) Previously enriched: an environmental enrichment period followed by three months of standard housing.
3) Recently enriched: three months of environmental enrichment.

The animals were tested on a series on symmetrical mazes (Davenport et al., Behav Res Meth Instru 2:112-118, 1970) prior to, and following the final three months of housing

Preliminary results show:

1. Young animals are more effected by environmental enrichment than aged.
2. Long-term retention is best preserved in previously enriched animals kept in standard housing.
3. In both young and aged rats previous environmental enrichment improved learning even three months after the enrichment period.
4. There is a decay in the effect of environmental enrichment: recently enriched rats performed better than previously enriched rats.

124.2 POST-NATAL HANDLING ATTENUATES AGE-RELATED CHANGES IN THE ADRENOCORTICAL STRESS RESPONSE AND SPATIAL MEMORY DEFICITS IN THE RAT. M.J. Meaney, D.H. Aitkens*, C. Berkel*, S. Bhatnagar*, A. Sarrieau* and R.M. Sapolsky. Douglas Hospital Research Centre, Dept. Psychiatry, McGill Univ., Montreal, Canada H4H 1R3 and Dept. of Biological Sciences, Stanford Univ., Stanford, CA 94305.

Age-related changes in the adrenocortical axis of the rat result in an increased exposure to adrenal glucocorticoids, both as a result of increased basal levels and of steroid hypersecretion following stress. These increased glucocorticoid levels have been implicated in the age-related degeneration that occurs in the hippocampus, a principle corticoid target region in the brain. Adult rats handled (H) daily for a brief period of time (15 min) for the first three weeks of life show more efficient adrenocortical negative-feedback (reduced corticoid secretion during and following stress) associated with increased glucocorticoid receptors in the hippocampus, a critical brain region for the corticoid-induced inhibition of CRF and ACTH release.

In the present experiments H and NH Long-Evans rats were examined at 6, 12, and 24 months of age. All animals exhibited an age-related hypersecretion of corticosterone (CORT) following the termination of immobilization stress (delayed suppression of ACTH secretion), although this effect was significantly greater in the NH animals. NH animals also showed an age-related increase in basal CORT levels, suggesting that cumulative CORT exposure with age was greater in the NH animals. Cell counting in the hippocampus showed pronounced neuron loss in the CA_1 and CA_3 cell fields in the 24-month old NH animals, with only slight loss in the 24-month old H animals. The performance of the aged 12 and 24-month old H animals in the Morris' Water Maze (a spatial memory task that is highly dependent on hippocampal function) was significantly superior to that of the same-aged NH animals, and not reliably different from the younger animals (either H or NH). These data reveal an age-related spatial memory impairment in the NH animals, but not the H animals.

Taken together, these data suggest that individual differences in age-related hippocampal cell loss and cognitive impairments are related to differences in the adrenocortical stress response. The underlying mechanism for this relationship appears to involve the neurotoxic effects of increased glucocorticoid exposure on hippocampal neurons.

124.3 EFFECTS OF CHRONIC PROGESTERONE AND ESTRADIOL ON CYCLICITY OF MICE:IMPLICATIONS FOR AGING. S. G. Kohama* P. C. May, C. E. Finch (SPON: W. O. McClure). Department of Biology, U.S.C., Los Angeles, CA. 90089-0191.

Increases in progesterone (P) due to pseudopregnancy or P administration, increases the incidence of short cycles (Flurkey et al., Biol Repro, 1987). Orally administered estradiol (oE2) on the other hand accelerates the loss of cyclicity (Kohama et al., NSci Abst. 395.2, 1986). We tested the effects of P+oE2 to see if the hormones had an antagonistic influence on the cyclicity of mice. Young (5 month) C57BL/6J mice were given the following steroids: E2 implants (yielding serum levels of 15-25 pg/ml, iE2), P (70 ng/ml), oral E2 (80 pg/ml, oE2), P+oE2 (same doses) and appropriate controls. During treatment, the E2 and oE2 groups displayed persistent vaginal cornification, while the P and P+oE2 groups had vaginal cytology typical of low E2 levels. After 6 weeks, treatment stopped and cyclicity was evaluated for 5 months.

Cyclicity after treatment was evaluated on a monthly basis examining % cyclicity (contingency table analysis, CATMOD), cycles/mo (general linear model, GLM), and cycle length analysis, the mean number of 4, 5, 6 or >6 day cycles/mo/treatment (multivariate analysis, MANOVA).

Analysis of % mice cycling (CATMOD) revealed effects of treatment ($p<0.001$) and time ($p<0.001$). The estradiol treated groups (iE2, oE2 and P+oE2) lost cyclicity with aging faster than the other groups. The cycles/mo, showed differences due to treatment ($p<0.01$), time ($p<0.001$) and the interaction of treatment and time ($p<0.01$). At mo 2 and 3, the P group had more cycles than controls and iE2, whereas oE2 and P+oE2 cycled less than controls.

Cycle lengths were compared by MANOVA. The 4 and 5 day cycle length categories showed effects due to treatment, time and an interaction. During mo 2 and 3, the P and P+oE2 groups had more 4 day cycles than the respective control and E2 groups. All other treatments during this period resulted in predominantly 5 day cycles, except for the E2 implants which reduced cyclicity. Thus, chronic P leads to the prolonged reinstatement of short cycles, reversing age-related cycle lengthening.

124.4 LORDOSIS RESPONSES IN AGING FEMALE RATS: EFFECTS OF PROLONGED ESTRADIOL TREATMENT. K. C. Chambers. Repro. Biol. & Behav., Oregon Regional Primate Research Center, Beaverton, OR 97006

Although most investigators have not found decreases in lordosis responses in aging female rats, Peng, Chuong and Peng (Neuroendocrinology 24:317-324, 1977) found that 41% of the old females given high doses of estradiol benzoate (EB) and progesterone (P) showed a decrease in lordosis responses to male mounts. In the following study, the lordosis responses of 20 young sexually naive and 20 aging retired breeder female Fischer 344 rats were examined. Since prolonged exposure to E has been shown to accelerate age-related changes in the reproductive system of female rodents (Finch et al., Endocrine Reviews 5:467-497, 1984), the effects of prolonged estradiol treatment on the lordosis responses of the young and aging females also was determined. Ovariectomies were performed when the younger females were 2 months old and the older females were 12-13 months old. Two weeks after surgery, all of the females were given a treatment of EB and P (10 µg/150 g of body weight of EB on 2 consecutive days and 0.5 mg/150 g of body weight of P 24 hours later). One week later sexual behavior testing was initiated. Females were given 1 test per week for 3 weeks while under EB and P treatment (tests 1-3). Tests lasted 20 minutes or until the males ejaculated. Both the younger and older females then were randomly divided in equal numbers into 2 groups: oil and EB. The EB-treated females received 10 µg/150 g of body weight of EB on 2 consecutive days per week for 18 weeks and the oil-treated females received an equal volume of oil per body weight on 2 consecutive days per week during the same period. The females were not tested behaviorally during this time. Three EB-treated older females died during the course of the treatment. On the 19th week, all of the females were given a treatment of EB and P. One week later sexual behavior testing was initiated. The females again were given 1 test per week for 3 weeks while under EB and P treatment (tests 4-6). The oil-treated older females had a significantly lower lordosis to mount ratio than the oil-treated younger females on test 1 but not tests 2 and 3. The lordosis to mount ratio of the oil-treated older females also was lower than the oil-treated younger females on test 4. Whereas the EB-treated older females had a significantly lower lordosis to mount ratio than the EB-treated younger females on test 1 they did not differ on test 4. Both groups of older females did not differ on test 1 but the EB-treated females had a higher lordosis to mount ratio on test 4. These data suggest that after an absence of E, older females require more exposure to E than younger females. Repeated exposure to E does not accelerate the decreases found in lordosis responses of older females.

124.5 BEHAVIORAL, PHYSIOLOGICAL, AND HISTOLOGICAL ASSESSMENT OF FETAL HYPOTHALAMIC TISSUE TRANSPLANTED TO DORSAL THIRD VENTRICLES OF AGED MICE. D. Ingram*, M. Talan, E. Bresnahan, J. Hengemihle*, S. Kobayashi*, H. Kametani*, and F. Gage. Gerontology Res. Ctr., NIA, NIH, Baltimore, MD 21224 and Dept. of Neuroscience, School of Medicine, UCSD, San Diego, CA 92093.

Decline in hypothalamic function is hypothesized as a mechanism of mammalian aging (Everitt, A., Exp. Gerontol., 8:265, 1973). Previous reports have demonstrated that fetal neural grafts can improve behavioral performance in aged rat hosts (Gage, F., et al., Science, 221:966, 1983). Relatively less research in neural tissue transplantation has been directed toward the aged mouse as a model. Therefore, we are investigating in inbred mice the feasibility of grafting fetal hypothalamic tissue from C57BL/6J donors to male hosts of the same genotype. Specifically, from 15-16 day old fetal brains, we dissected a basal diencephalonic area (< 1 sq mm) from the approximate anatomical location of the adult median eminence. Pieces of this tissue were transplanted via cannula into dorsal third ventricles of anesthetized aged (26-mo old) hosts using appropriate stereotaxic coordinates. Control groups include: young (6-mo) unoperated mice for age comparisons; aged sham-operated (cannulae lowered) and unoperated controls; and aged operated hosts that received fetal neocortical tissue or nonneural tissue (fat and muscle) taken from the fetal groin area. At 30 mo of age, all mice were subjected to an age-sensitive performance battery (Ingram, D., Exp. Aging Res., 9:225, 1983; Talan, M. & Engel, B., Exp. Gerontol., 19:79, 1984), including open-field activity, tight-rope test, rotorod test, water consumption, body temperature, oxygen consumption, cold tolerance, runwheel activity, and running speed test, and were then sacrificed. The hypothesis being tested was whether viable hypothalamic grafts would restore or prevent further age-related performance decline compared to controls. Although we have observed many examples of histologically viable grafts, i.e., well-developed neurons, minimal or no gliosis, interfaced to adult tissue, little evidence of functional effects have emerged from this on-going study. Preliminary analysis indicates that the most likely candidates for observing effects of this treatment were those tests reflecting more clearly defined hypothalamic involvement, e.g., body temperature and water consumption. Thus, this technique has proven feasible in mice for conducting further functional analysis of its effects on aging rate in behavioral and physiological performance. Grafting into younger (18 mo) mice may be a more productive approach to more efficiently prevent hypothalamic decline before senescent processes have had major impact. As such, we will be testing hypothalamic involvement in governing aging rate in a mammalian model.

124.6 OLD RATS ARE CAPABLE OF ADEQUATE PERFORMANCE ON SPATIAL AND AVOIDANCE TASKS. J. Rick *, N.W. Milgram and G.O. Ivy. (SPON: C. Bielajew). Life Sci. Div., Scarborough Campus, U. of Toronto, Scarborough, ONT, M1C 1A4.

In addition to numerous morphological and biochemical effects on the brain, aging results in a number of behavioral changes. For example, aged rats have been reported to show marked deficits in spatial learning ability. We decided to further investigate such deficits in order to provide a basis for a future study involving young rats subjected to a treatment which produces morphological and biochemical changes similar to those observed in aged animals.

Mature (6-8 mo.) and old (18-22 mo.) Sprague-Dawley rats were tested for acquisition and retention of a spatial and a passive avoidance (PA) task. Using a Morris water maze we were able to assess differences in both reference and procedural memory. The latter was studied by moving the goal platform between the three tests. Five trials per day with a 30-minute intertrial interval were used to minimize the development of hypothermia. Each test consisted of a maximum of 25 trials.

The aged rats required significantly more trials to reach criterion on each of three tests and showed significantly less retention 3 days after the first test. No differences were observed on the second retention test. That the slower learning was not due to age-related deficits in motor ability can be concluded from the fact that the rats were equally capable of reaching criterion. In the PA tests, few rats of either group (50% young, 12.5% old) learned not to cross, though the groups did not otherwise differ significantly. Latency to cross increased significantly over trials for both groups. Subjects later received a second, more intense shock which produced complete avoidance in both groups within two trials.

Although the differences were less than anticipated, the old rats exhibited greater variability. While only one old rat did not learn, others were indistinguishable from mature animals. We conclude that old and mature rats are equally capable of learning and retaining memories of these tasks over periods of days or weeks, though older rats may require more time or more salient stimuli.

124.7 GLUCOSE RELATIONSHIPS WITH MEMORY AND SLEEP IN OLD RATS. P.E. Gold, W.S. Stone, S.M. Martin*, R.J. Rudd* and N.C. Salustri*. Dept. Psychology, University of Virginia, Charlottesville, VA 22903.

Aging is accompanied by both memory and sleep deficits. Recently, we found significant correlations between the decline in paradoxical sleep parameters and the decline in memory performance in individual old rats. In previous studies we also found that age-related memory impairments could be reversed by epinephrine, which may enhance memory through its hyperglycemic actions, in rodents and by glucose itself in elderly humans. In the study using elderly humans, we also found that the response to a glucose tolerance test predicted the performance of individual subjects on a battery of memory tests; those individual subjects with poor glucose control had significantly poorer performance on the memory tests than did same-age subjects with good glucose control. The present experiment was designed to ask: (1) whether glucose would ameliorate the paradoxical sleep deficits (previously associated with memory impairment) in aged rodents and (2) whether the response to a glucose tolerance test would predict memory in aged rodents as it does in humans.

Twelve 2-year-old male Sprague-Dawley rats were trained on a one-trial inhibitory avoidance task and tested for retention 24 hrs later. EEG and EMG electrodes were then surgically implanted for cortical recordings. After recovery, 3 hr baseline sleep samples were obtained from each animal. On separate days, the rats were then injected with saline or glucose (100 and 500 mg/kg, counterbalanced) and sleep samples were again obtained. After these trials, a small incision was made in the rats' tails and blood glucose levels were obtained using a Glucometer. A single injection of glucose (500 mg/kg) was then administered, and blood glucose was monitored over the next 2 hours.

The results indicated that: (1) Glucose (500 mg/kg) significantly increased paradoxical sleep bout duration to levels approaching those of young rats. (2) Retention performance for inhibitory avoidance training was negatively correlated with change in blood glucose after the glucose injection (e.g., at 10 min, $r = -0.81$, $p < 0.01$); at 2 hrs, $r = -0.76$, $p < 0.05$).

These findings demonstrate that glucose administration to rats attenuates age-related sleep impairments which are closely associated with memory impairments. In addition, the results indicate that in rats, as in humans, glucose regulation is negatively correlated with memory performance in individual animals. Such results are consistent with the general view that glucose utilization may be an important contributor to age-related changes in sleep and memory. 124.8 **HABITUATION RETENTION: AGE DIFFERENCES IN YOUNG NZB/B1NJ MICE PARALLEL SENESCENCE-RELATED CHANGES IN C57BL/6NNIA MICE.** M.J. Forster, K.C. Retz, T.L. Johnson*, M.D. Popper*, and H. Lal. Department of Pharmacology, Texas College of Osteopathic Medicine, Fort Worth, TX 76107-2690.

Relatively young mice of several autoimmune-prone strains show senescence-like declines in learning/memory (Forster et al., Soc. Neurosci. Abstr., 11:722, 1985) and sensorimotor capacity (Forster et al., Soc. Neurosci. Abstr., 12:175, 1986). In the current experiments, we investigated the possibility that autoimmune mice show senescence-like changes in habituation retention. Separate age groups of non-autoimmune C57BL/6Nnia (1.5, 3, 6, 12, or 26 mo) and autoimmune NZB/B1NJ mice (1.5, 3, or 6 mo) were given 20-min sessions in computerized animal activity monitors (Omnitech Electronics) on each of 8 consecutive days. Habituation retention was considered to be the decrease in total daily activity as a function of the 8 daily sessions. Within-session habituation was addressed by sampling locomotor activity within 5-min periods during each session. Horizontal (total distance traveled) and vertical activity (rearing) within the 39.5 X 39.5 X 30.5 cm activity chamber were recorded. In addition, the floor of the apparatus was divided into 9 equal zones (approximately 13.2 X 13.2 cm) by the recording system, and the total time spent by the mice within the center zone and the 5 noncorner zones were measured independently. Horizontal (total distance) and vertical components of activity showed overall decline over the life spans of each strain. Those declines occurred between 6 and 26 months for C57BL/6Nnia mice, but between 1.5 and 6 months for the NZB/B1NJ mice. Age-related changes in habituation retention were most evident when the spatial components of activity were considered. The times spent in the center and noncorner zones showed a marked decrease as a function of test session in 1.5-, 3-, and 6-month-old C57BL/6Nnia mice, whereas the 26-month old C57BL/6Nnia mice showed a much slower rate of change in these measures over the 8 consecutive test sessions. Session-related decreases in horizontal and vertical components of locomotor activity showed a similar, but less marked change with age. NZB/B1NJ mice showed a senescence-like pattern of age differences in spatial components of activity between 1.5 and 6 months, but failed to exhibit session-related changes in horizontal activity components at any age tested. The NZB/B1NJ mice showed significant within-session and 1-h habituation retention at all ages. These findings indicate that for selected components of locomotor activity, age-related changes in habituation retention are accelerated in NZB/B1NJ mice. 124.9 AGE DIFFERENCES IN PURKINJE CELLS AND RATE OF CLASSICAL CONDITIONING IN YOUNG AND OLDER RABBITS. D. S. Woodruff-Pak and J. B. Sheffield* Departments of Psychology and Biology, Temple Univ., Phil., PA 19122

Significant progress has been made in the understanding of the neural circuitry involved in classical conditioning of the eyelid response in rabbits. This model system has important implications for learning and memory in aging because large age differences have been demonstrated in eyelid conditioning in rabbits and humans. In a hypothetical model of the neuronal system that could serve as the essential memory trace circuit for this response, it has been postulated that one of the sites of the memory trace is at Purkinje cells in cerebellar cortex. Purkinje cell loss with age has been demonstrated in rats, monkeys, and humans. The purpose of this study was to examine Purkinje cells in young (Y) and older (O) rabbits which had been behaviorally trained in the trace eyelid classical conditioning paradigm.

Twelve New Zealand white rabbits were used in the study: 6 Y of a mean age of 3 months; 6 O ranging in age from 27-50 months with a mean age of 40 months. They were trained in a paradigm in which an 85 dB, 1 KHz, 250 msec tone CS was presented and followed 750 msec after its onset by a 2.1 N/cm^2, 100 msec corneal airpuff US. The trace interval between the offset of the CS and the onset of the US was 500 msec. Y rabbits took an average of 471 trials to attain learning criterion, and O rabbits took 1169 trials. Animals were sacrificed with an overdose of Nembutal and perfused through the heart in saline followed by 10% formalin. Brains were maintained in formalin for 2 or more days and then embedded in an albumin-gelatin mixture. Every fourth 80 μm section through the cerebellum was mounted for reconstruction. Tissue was stained with cresyl violet. Six sections for each rabbit were used. Images were obtained from each section on the left and right HVI area and the vermis. Counts of Purkinje cells in a single row 0.5 mm wide were made on 18 photographs for each animal by two investigators who were blind to the age of the animal. Inter-rater reliability was .82, and an average of the two counts was used. Comparisons of the total number of Purkinje cells counted for each age group revealed a highly significant difference ($t=4.3$; $p < .001$) with older rabbits having fewer cells. Molecular cell counts in the same animals indicated no age differences suggesting that differential tissue shrinkage in Y and O brains was not affecting the age difference in Purkine cell number. The correlation between Purkinje cell number and age was $-.77$ ($p<.005$). The correlation between trials to criterion and Purkinje cell number was $-.79$ ($p < .005$). A partial correlation was computed partialling out the variance due to age, and the resulting relationship between Purkinje cell number and trials to criterion was $r = -.61$ ($p < .025$). These results suggest that differences in Purkinje cells in Y and O rabbits may be related to age differences in rate of classical conditioning.

124.10 SENILE PLAQUES AND BEHAVIOR IN AGED SQUIRREL MONKEYS. E. Schwam[1], L.C. Walker[2], B. Buckwald[1]*, F. Garcia[1]* and J. Sepinwall[1]. [1]Hoffmann-La Roche Inc., Nutley, NJ 07110 and [2]The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205-2182.

A relationship between senile plaque density and cognitive decline has been reported in patients with Alzheimer's Disease (Tomlinson et al., 1970) and needs to be explored more fully in nondemented aged individuals. A nonhuman primate model of this relationship would provide an important methodology for developing effective treatments.

The behavior of four 23-year-old squirrel monkeys (Saimiri sciureus) with varied drug and experimental histories was evaluated on three tasks: choice reaction time, spatial learning, and delayed matching-to-sample. Acquisition and maintenance behavior differed among the animals as reflected in an overall ranking of performance shortly before death.

Brain sections at levels of the rostral temporal lobe and prefrontal cortex revealed the presence of neuritic plaques (silver stain) consisting of abnormal, swollen neurites around an amyloid (thioflavin-T stain) core. In sections through the level of the anterior temporal lobe, plaques were most frequent in the inferior temporal cortex. Occasional plaques were seen near the cingulate sulcus and in parahippocampal cortex, insular cortex, hippocampal formation and amygdala. In sections through prefrontal cortex, most plaques were located in the orbitofrontal cortex, frontal opercular cortex, and occasionally in cingulate cortex. Compared to a 31-year-old rhesus monkey, plaques were smaller (20-55 μm vs. $\leq$ 100 μm) and less dense (4-5/mm^2 vs. 8/mm^2 in regions of greatest density) in the aged squirrel monkeys. Plaque distribution and composition were comparable in the two species. No plaques were found in a group of three, eight-year-old squirrel monkeys.

In this limited sample of aged squirrel monkeys, the largest number of plaques (mean = 18.5/section) was found in the monkey with the poorest overall performance on the behavioral tasks. The density of plaques in the other three aged monkeys ranged from 3.25 - 9 plaques/section and was not related to performance.

While these results suggest that plaque density must increase beyond a certain threshold to become a predictor of performance, it is also possible that performance on specific tasks is affected preferentially by pathological changes in certain brain areas. Studies utilizing larger numbers of animals are clearly required to resolve these issues. Nevertheless, the present finding of a possible relationship between neuritic plaques and behavioral deficits in the aged squirrel monkey supports the utility of this model as a research strategy to find treatments for cognitive impairments in aged humans.

124.11 **DEFICITS ON OLFACTORY IDENTIFICATION AND DISCRIMINATION TASKS IN THE EARLY STAGES OF ALZHEIMER'S DISEASE.** J.P. Kesslak, C.W. Cotman, H. Chui*[1], H. Fang*[1], S. Van den Noort and G. Lynch. Department of Psychobiology, University of California, Irvine, CA, 92717, [1]Department of Neurology, University of Southern California, Los Angeles, CA.

The pathology of Alzheimer's disease (AD) is characterized by early and severe loss of neurons in the entorhinal cortex and associated structures of the primary olfactory cortex. To determine the extent of olfactory dysfunction resulting from this neural loss, odor identification and discrimination tests were administered. The Smell Identification Test (SIT) required identification of common odors, was well standardized and had a high correlation with threshold detection tasks. The match-to-sample test required odor discrimination, using uncommon odors to minimize dependence on verbal ability. Subjects in the early stages of AD (n=18) were diagnosed according to NINCDS-ADRDA guidelines. Also tested were subjects with Parkinson's disease (PD, n=14), multiple sclerosis (MS, n=14) and age matched controls (n=18).

Scores for each olfactory test were normalized to account for the different levels of chance performance. On the SIT subjects with AD scored below normal (52% correct) but only two subjects were in the anosmic range. There was a severe deficit on the match-to-sample test for subjects with AD (19% correct). The subjects with PD were severely impaired on the SIT (25% correct), with 10 out of 14 scoring as anosmic. Only the 4 nonanosmic PD subjects were administered the match-to-sample test (27% correct) and they scored below controls. Control and MS groups performed at normal levels on the SIT (respectively, 84% and 83% correct) and significantly better on the match-to-sample test (respectively, 65% and 55% correct) than the AD and PD groups. The correlation coefficient between scores on the SIT and match-to-sample test was quite low (r^2= .27). Scores for AD subjects on the SIT and match-to-sample test had low correlation coefficients with scores on the mini mental status test (respectively, r^2=.001 and .160). The SIT and match-to-sample test were found to have no significant correlation with either age or sex.

The results of the SIT indicate that AD subjects, at least during the early stages, are able to discriminate and identify common odors although they have a quantitative deficit in this regard. The more dramatic impairment on the match-to-sample test may reflect a problem in short-term memory or difficulty in processing novel odors or both. The results encourage the idea that refined tests of olfactory function, in conjunction with other tests, may provide a simple means of detecting and monitoring select neurodegenerative diseases.

124.12 FAMILIAL ALZHEIMER'S DISEASE: NEUROPSYCHOLOGY AND NEUROIMAGING. Gary D. Miner, Linda A. Miner*, William S. Yamanashi*, and Seppo Saksanen*. Alzheimer Disease & Related Geriatric Disorders Laboratory, Oral Roberts University School of Medicine, Departments of Pharmacology & Radiology, Tulsa, Oklahoma; and Familial Alzheimer's Disease Research Foundation, Tulsa, Oklahoma.

Subjects from two Familial Alzheimer Disease (FAD) families have been studied with a battery of neuropsychological tests with a goal of finding early 'pre-disease' risk factors. Tests of first-order capabilities such as visual perception, reaction time, or motor ability, which might be closer to measuring central nervous system disability than abstract-conceptual abilities, were included in the test battery. Additionally MRI brain imaging has been done on some of these subjects. The first of the subjects tested has been diagnosed with FAD 2 years following the neuropsychological testing. Analysis of 6 of the neuropsychological tests (Lezak's Tinkertoy Test; Benton's Controlled Word Association, Judgment of Line Direction, Facial Recognition, & Visual Retention; and Shipley's Verbal Abstractions) indicate that the experimental subjects apparently fall into 2 groups, whereas the control subjects score within a single group. Additional measures of possible early subtle changes in behavior have been made: a 'tapping test', and the 'Torque test'. The variable torque occurred more frequently in the low-scoring at-risk group than in the not-at-risk group (46% compared to 10%). The relationship among neuropsychological, neuroradiological and other indexes are not well understood yet for Alzheimer's disease. The clinically diagnosed FAD subject and another subject showing cortical atrophy by MRI both appear in the at-risk group, providing evidence that there may be pre-morbid neuropsychological risk-factors for FAD. This study has really only begun. Some directions are emerging which may prove useful in building an algorithm to be tested (1) over time, as family members are diagnosed, and (2) as additional members are tested and (3) as new FAD families are located. Therefore, this report must be considered tentative in nature, but hopeful as a beginning.

124.13 MULTIPLE MORPHOLOGICAL AND BIOCHEMICAL MEASURES COMPLETELY DISTINGUISH PATIENTS WITH ALZHEIMER'S DISEASE. Rochester Alzheimer's Disease Project: R. W. Hamill, E. D. Caine, P. D. Coleman, T. A. Eskin, D. G. Flood, R. J. Joynt, L.W. Lapham*, T. H. McNeill, and C. L. Odoroff*. Depts. of Neurology, Psychiatry, Neurobiology and Anatomy, Neuropathology, and Biostatistics, Univ. of Rochester Sch. of Med. & Dent., Rochester, NY 14642.

In spite of the fact that there are statistically significant differences between cases with Alzheimer's disease (AD) and aged-matched controls for many morphological and biochemical measures considered separately, there are still AD cases in most studies that are within the normal range for the measure taken. It seems apparent that any measure showing any degree of overlap between AD and control is not a singular marker of AD. The general problem of overlapping values for AD cases and controls is particularly apparent when examining older cases. This issue assumes added importance for patients who meet the neuropathological criteria of AD but apparently lack clinical features.

This failure to find complete separation between AD cases and controls for any single morphological or biochemical measure led us to consider that multiple disease markers may provide a more convincing diagnosis of AD and may better correspond to the observed behavioral devastation. In testing this possibility, we have examined the middle frontal gyrus, an area which often shows overlap between AD and control cases for any single measure. There were 7 AD cases ranging in age from 59 to 97 years, and 7 controls ranging in age from 63 to 84 years. Measures taken for this analysis included those that are traditional: 1) counts of senile plaques and neurofibrillary tangles, 2) counts of neurons, and 3) choline acetyltransferase (CAT) activity, and those that are somewhat less traditional: 1) soma size of somatostatin-containing neurons and 2) dendritic extent.

Each of these measures alone resulted in some, but not complete, separation of AD and control subjects. However, a multivariate analysis (Biplot) utilizing these measures produced complete separation of all of the AD subjects from all of the controls. These data suggest that perhaps the best substrate for diagnosing dementia of AD is the summed effect of changes in a number of morphological and biochemical measures.

Supported by the National Institute on Aging, grant AG 03644.

124.14 NEUROPSYCHOLOGICAL IMPAIRMENT IN PATIENTS WITH EARLY- AND LATE-ONSET ALZHEIMER'S DISEASE. D. Salmon, W. Heindel*, D. McCullough*, N. Butters, and I. Grant. Depts. of Neurosciences and Psychiatry, Univ. of Cal., San Diego, La Jolla, CA 92093 and VA Medical Center, San Diego, CA 92161.

Recent investigations of the neuropsychological features of dementia of the Alzheimer type (DAT) have revealed different patterns of impairment in those patients who developed the disease before (early onset) or after (late onset) age 65. Specifically, early-onset DAT is reportedly characterized by greater language impairment than is late-onset DAT, while visuospatial deficits are reported to be more prevalent in late-onset than in early-onset DAT.

To further examine the relationship between age-at-onset and neuropsychological performance in DAT patients, we examined 27 early-onset (age-at-onset=59.6) and 41 late-onset (age-at-onset= 71.5) patients with a battery of tests which assessed language, visuospatial, memory and problem solving abilities. The patient groups did not differ in years of education, duration of symptoms, or overall level of dementia.

The performances of these well-matched early- and late-onset DAT patients were not significantly different on any component of the extensive neuropsychological test battery. In addition to equivalent deficits on tests of verbal and nonverbal memory and problem solving, the two DAT patient groups were impaired to the same degree in a number of language abilities including confrontation naming, fluency and vocabulary. Similarly, equally deficient performances were elicited from the early- and late-onset patients on tests of visuospatial functions including complex figure drawing and the WISC-R Block Design subtest. Similar results were obtained with separate analyses which included only those patients whose duration of illness was limited to 3 or 4 years, or only the very early-onset (mean age-at-onset=56.8) and late-onset (mean age-at-onset=78.1) DAT patients.

These results suggest that the patterns of neuropsychological deficits evidenced by early- and late-onset DAT patients do not differ when the duration of symptoms and overall level of dementia of the two groups are equated. Thus, in terms of neuropsychological functioning, presenile and senile DAT appear to represent a unitary disorder.

Supported by NIA grant AG-05131 and the Medical Research Service of the Veterans Administration.

125.1 DISCHARGE OF BASAL FOREBRAIN PROJECTION NEURONS DURING WAKING AND SLEEP. R. Szymusiak and D. McGinty. Dept. Psych., U.C.L.A., Los Angeles, CA and Neurophysiol. Res., V.A. Med. Ctr., Sepulveda, CA.

The basal forebrain (BF) is the origin of several ascending and descending projection systems. Little is known about the discharge correlates of identified BF projection neurons in behaving animals. We have described a population of unidentified BF neurons which exhibit elevated discharge rates during slow-wave sleep (SWS), and low rates during alert wakefulness (Brain Res. 370: 82-92, 1986). These sleep-active neurons (SANs) were recorded throughout the lateral preoptic area/substantia innominata (LPO/SI) and ventral globus pallidus (VGP). We report here attempts to antidromically activate SANs and other BF cell types by stimulation of ascending and descending efferent pathways.

Three adult cats were prepared for chronic sleep-waking and unit recordings. Microwires (32u diameter) were aimed at the LPO/SI and VGP. Bipolar stimulating electrodes were placed in the midbrain reticular formation (MRF) and corticopetal fiber tracks; the external capsule (EC), and anterior cingulate bundle (ACB).

Of 128 neurons studied, 31 were in the LPO/SI and 97 were in the VGP. Antidromic responses were recorded in 2 LPO/SI cells and in 57 VGP cells. Sleep waking discharge of driven cells was correlated with antidromic latency (ADL). Eleven cells had ADLs <5 ms, and had high discharge rates during waking with low rates in SWS. Cells with short ADLs were dorsally located. The remaining 48 cells had ADLs >5 ms. Long ADL neurons were characterized by low rates during waking (Table I); several were silent during periods of exploratory locomotion. These cells were not responsive to startle stimuli, or to the sight and ingestion of palatable food. Approximately 25% of long ADL cells had elevated rates during grooming, compared to other waking behaviors. All long ADL cells had peak discharge rates in SWS (Table I), but several had peak rates <1 spike/s. There was no anatomical segregation of cells identified as having ascending or descending projections.

These results demonstrate that, in one BF subregion, SANs are a source of both ascending and descending projections, and that they have more slowly conducting axons than adjacent projection neurons.

TABLE I SLEEP-WAKE DISCHARGE AND ANTIDROMIC LATENCIES

125.2 EVIDENCE FOR OLFACTORY INPUTS TO THE SEPTUM. C. Reyher*, University of Berlin, West Germany; J.H. McLean and M.T. Shipley, Dept. of Anatomy and Cell Biology, University of Cincinnati College of Medicine, Cincinnati, OH 45267 (Spon: R. Cardell)

A unique feature of the olfactory system is its remarkably direct and heavy innervation of telencephalic limbic structures. The main and accessory olfactory bulbs have dense and partially reciprocal connections with the hippocampal formation (entorhinal cortex, hippocampal rudiment) and the cortical amygdaloid nuclei. Direct hypothalamic inputs to the bulb are well established and the piriform cortex has reciprocal connections with the hypothalamus. Early neuroanatomists reported olfactory projections to the septal region in several vertebrate species but subsequent tract-tracing experiments failed to support this view. Here, we report that there is a dense, focal projection to the septal area from a restricted subfield of the anterior olfactory nucleus (AON).

Discrete, iontophoretic injections of WGA-HRP were made in architectonic subdivisions of AON. The injections resulted in anterograde and retrograde labelling of olfactory bulb and olfactory cortical connections previously described by others. With focal injections in the dorsomedial transition area (AONdm) and dorsal peduncular cortex (DPC) there was dense anterograde labelling in the medial half of the lateral septal nucleus. The labelling directly abutted but did not encroach upon the medial septal nucleus. This projection was confirmed by placing WGA-HRP injections in the septum. A discrete population of neurons was retrogradely labelled in AONdm and DPC. The apical dendrites of these neurons are directed towards the molecular layer of AON, a zone which receives a dense terminal projection from the main olfactory bulb.

Classical reports of axons from the olfactory bulb to the septum were based on descriptive methods, and the observations were largely confined to non-mammalian vertebrates. The present findings suggest that an olfacto-septal circuit may exist, but that the projection arises from third order neurons in AON rather than second order neurons (mitral and tufted cells) in the olfactory bulb.

Based on these results, we hypothesize that olfactory bulb mitral/tufted cells activate a discrete population of dorsomedial AON neurons; these AON neurons project to a specific zone in the septum and, thus, act on multiple limbic circuits.

The AON projection does not terminate in the medial septal nucleus, but an analysis of the terminal field in relation to sections stained for the cholinergic enzyme ChAT suggests that olfactory inputs may be able to modulate medial septal neurons. Medial septal neurons play a key pacemaker role in hippocampal theta rhythm. During investigatory sniffing behavior, hippocampal theta, olfactory bulb theta and sniffing are temporally correlated. The AON to septum projection could function to link olfactory bulb theta to hippocampal theta when the two structures become phase locked during olfactory learning (Macrides, *et al.*, 1982).

125.3 SUBNUCLEAR ORGANIZATION OF THE BED NUCLEUS OF THE STRIA TERMINALIS: A CYTOARCHITECTURAL, CONNECTIONAL AND IMMUNOCYTOCHEMICAL STUDY. M.M. Moga, T.S. Gray and C.B. Saper. Dept. Anatomy, Loyola Univ., Maywood, IL 60153; Dept. Pharm. Physiol. Sci. and Neurol., Univ. of Chicago, Chicago, IL 60637.

The bed nucleus of the stria terminalis (BST) is closely associated with the amygdala, its major source of afferent input, and, like the amygdala, has been implicated in neuroendocrine regulation and reproductive behaviors. Traditionally, the BST has been divided into medial and lateral subdivisions. Recently, investigators have noted additional subdivisions within the BST (i.e., DeOlmos et al., '85; McDonald, '83) but there has been no complete description of the BST subnuclei. In this study, we examine BST subnuclei for their Nissl cytoarchitecture, WGA-HRP labeled afferent and efferent connections, and neuropeptide immunocytochemistry.

Subnuclei of the BST can be grouped into lateral, medial and preoptic divisions. Lateral BST subnuclei are extensively connected with autonomic nuclei. For example, the posterior lateral (PL) subnucleus projects to the nucleus of the solitary tract (NTS), ventrolateral medulla (VLM) and parabrachial nucleus (PB). Dorsal lateral (DL) BST projects heavily to PB and contains numerous CRF- and NT-immunoreactive neurons. Ventral lateral (VL) BST receives heavy NTS input and contains a dense cluster of CRF-immunoreactive cells and fibers. Juxtacapsular (JXC) BST receives input from insular cortex.

Medial BST subnuclei can be characterized by their connections with medial portions of the amygdala and hypothalamus. For example, the anterior medial (AM) subnucleus receives heavy input from the medial amygdala. ENK-, SS- and CRF-immunoreactive neurons are scattered throughout AM. Posterior medial (PM) BST receives input from the posterior medial amygdala and projects to ventromedial hypothalamus. Substance P fibers are particularly dense within PM. Posterior intermediate (PI) BST is interconnected with the ventromedial hypothalamus.

Preoptic BST (PO) projects strongly to the brainstem. PO may be divided into medial and lateral portions. Many of the neurons in the lateral part of PO are immunoreactive to CRF and galanin.

The subnuclear organization of the BST may reflect a diversity of function, heretofore, unstudied.

125.4 PATTERNS OF ACTIVATION EVOKED BY STIMULATION OF THE RAT LIMBIC FOREBRAIN. K.M. Carnes and J.L. Price. Dept of Anat. & Neurobiol., Washington Univ. Sch. Med., St. Louis, MO 63110.

The 14C-2-deoxyglucose (2-DG) method has been used to define the patterns of activity which are produced by repetitive, train stimulation of the amygdala, piriform cortex and olfactory bulb in the awake, unrestrained rat. Low levels of stimulation, which did not produce generalized convulsive behavior, resulted in patterns of 2-DG uptake which reflect the majority of known primary projections from each of these structures. Thus, moderate stimulation of the basolateral amygdala activated the infralimbic, agranular insular and perirhinal cortical areas, the bed nucleus of the stria terminalis (BNST), the substantia innominata and other nuclei of the amygdala. More lightly activated areas included the nucleus accumbens, lateral septum, substantia nigra and entorhinal cortex. There was little or no evoked activity in the thalamus or hypothalamus. Equivalent stimulation of the piriform cortex activated other parts of the olfactory cortex, including the entorhinal cortex, the olfactory bulb and, to a lesser extent, the amygdalohippocampal area and the rostral hippocampus. Low level stimulation of the olfactory bulb produced substantial uptake of 2-DG only in the olfactory cortex and the nucleus of the horizontal diagonal band.

In contrast, intense stimulation of each of the three regions invariably activated the other two areas, together with a consistent constellation of other brain structures. Furthermore, regardless of the site of stimulation, similar convulsive behaviors were observed, including motionless stares, "wet-dog shakes", head jerks with chewing, salivation, and episodes of rearing with bilateral forelimb clonus and loss of posture. In addition to the areas activated by less intense stimulation, the structures most prominently labeled were the prelimbic area, the mediodorsal, midline, ventromedial (principal and basal divisions) and posterior nuclei of the thalamus, the anterior, lateral and ventromedial areas of the hypothalamus, the olfactory tubercle and nucleus accumbens, the medial and posteroventral parts of the caudate/putamen, the lateral habenular nucleus, the substantia nigra and ventral tegmental area, and the hippocampal formation. In many cases these structures were labeled bilaterally.

It is not yet clear which of these structures may be labeled directly from the stimulation and may therefore be considered causative for the convulsive behaviors, and which structures may be activated as a result of those behaviors. However, it is apparent that seizures produced by stimulation of different parts of the limbic forebrain are associated with a remarkably consistent pattern of both brain activity and behavior.

125.5 INVESTIGATION OF CONNECTIONS FROM THE DIAGONAL BAND OF BROCA TO THE SUPRAOPTIC NUCLEUS IN THE RAT. E. L. Weiss and R. W. Rieck, Dept. of Physical Therapy, Louisiana State University Medical Center and Dept. of Anatomy, Tulane Medical School, New Orleans, LA 70112.

The nucleus of the diagonal band of Broca (DBB) is one of several nuclei within the basal forebrain which contributes projections to neocortical and subcortical structures. Recent physiological evidence also indicates that the supraoptic nucleus (SON) of the hypothalamus receives a projection from the DBB. Thus, the DBB is a limbic structure that may play a fundamental role in the regulation of cardiovascular function. The present study utilizes several anterograde tracing techniques to determine if the nucleus of the DBB gives rise to a direct projection to SON. Neuroanatomical tracers which included either tritiated amino acids, wheat germ agglutinin conjugated horseradish peroxidase (WGA-HRP) or phaseolus vulgaris-leucoagglutinin (PHAL) were placed within the dorsomedial portion of the horizontal limb of the DBB. Following the deposition of the tracers, anterogradely transported label was located within both a dorsal and a ventral descending pathway. Terminal label associated with the dorsal descending pathway was apparent within thalamic nuclei, including the paratenial nucleus, the mediodorsal nucleus and the habenular nuclei. Label associated with the ventral pathway extended caudally into the medial forebrain bundle, the magnocellular preoptic area and the lateral hypothalamic area. Anterogradely transported label was located directly dorsal and lateral to SON. Thus, in autoradiographic cases, reduced silver grains were located immediately dorsolateral to SON, however, reduced silver grains were never apparent directly over SON. Corresponding results were obtained following the placement of WGA-HRP within the DBB. Thus, labeled fibers were located dorsolateral to the supraoptic nucleus but terminal label was not apparent within SON. Similarly, following restricted injections of PHAL within the horizontal limb, numerous PHAL immunoreactive fibers (PHAL-IR) were adjacent to SON. Although PHAL-IR fibers did approach the nuclear boundary of SON, PHAL-IR fibers were not found within the nucleus. These data indicate that although the DBB provides a descending projection which terminates within an area immediately dorsolateral to SON, perikarya within SON do not receive a direct projection from the DBB. It, however, is possible that perikarya within SON give rise to dendritic arborizations which extend outside the nuclear boundary into the DBB-terminal zone. Further investigation is indicated to determine if descending fibers from the DBB come into contact with dendritic processes of neurons which have cell bodies located within SON. Supported by LSUMC-SAHP Intramural Grant(ELW) and BRSG 533112 (RWR).

125.6 STUDIES ON THE ORGANIZATION OF THE EFFERENT CONNECTIONS OF THE DIAGONAL BAND IN THE RAT. T. R. Stratford and D. Wirtshafter, Dept. of Psychology, University of Illinois at Chicago, Box 4348, Chicago, Illinois 60680.

The nucleus of the diagonal band (DB) is located in the basal forebrain and perhaps is best known for containing large numbers of putatively cholinergic cells. The nucleus does, however, contain a central core consisting of cells which do not appear to contain either choline acetyltransferase (ChAT) or acetylcholinesterase (AChE). While the efferent connections of the DB have been extensively investigated, few studies have examined whether the cells of origin of these various projections might be differentially distributed within the nucleus. In the present study we injected several fluorescent retrograde tracers into structures receiving DB efferents and used the pharmacohistochemical detection of AChE to partially map the internal structure of the nucleus of the DB.

Injections of tracers into the median raphe nucleus (MR) resulted in heavy labeling of cells within the apparently non-cholinergic core of the DB as did injections confined to the interpeduncular nucleus (IPN). Double-labeling studies indicated that many of the cells projecting to the MR sent collaterals to the IPN. While disruption of the stria medullaris at the habenula did not apparently affect the transport of the tracers, lesions of the medial forebrain bundle (MFB) completely abolished the labeling of neurons in the ipsilateral DB. In contrast to injections confined to the midbrain, injections into the hippocampus resulted in the intense labeling of a band of cells within the DB, most of which were located ventral to the MR/IPN projecting cells. Most of these cells were relatively large and many appeared to contain AChE. A similar band of large cells was observed in the caudal DB dorsal to the MR/IPN projecting cells following injections into the retrosplenial cortex (RSpl). Multiple tracer injections demonstrated that very few, if any, of the large cells in either the dorsal or ventral laminae appeared to send collaterals to the MR.

In short, the nucleus of the diagonal band appears to have a laminated structure which is observable when stained for ChAT or AChE or when labeled by retrograde tracers. The most ventral lamina consists of large AChE containing cells, a large proportion of which project to the ipsilateral hippocampus. A central core of relatively small cells which do not stain intensely for AChE appears to project, in part, to the MR and/or IPN via the MFB. The dorsal lamina contains large AChE staining cells from which arise a possibly cholinergic projection to the ipsilateral RSpl.

125.7 NEURONS IN THE MEDIAL SEPTAL NUCLEUS INNERVATE CHOLINERGIC NEURONS IN THE DIAGONAL BAND, HISTAMINERGIC NEURONS IN THE MAMMILLARY BODY, AND SEROTONERGIC NEURONS IN THE NUCLEUS RAPHE DORSALIS. A DOUBLE-LABEL STUDY COMBINING PHA-L-TRACING AND ENZYME IMMUNOCYTOCHEMISTRY. F.G. Wouterlood*, H.W.M. Steinbusch and T. Watanabe (SPON: ENA). Depts. Anatomy (FGW) and Pharmacology (HWMS), Free Univ., Amsterdam, The Netherlands, and Dept. Pharmacology (TW), Tohuku University Med. School, Sendai, Japan.

By previous autoradiographic tracing, neural connections have been found between the medial septal nucleus (MSN) and telencephalic, diencephalic and mesencephalic nuclei (Swanson, L.W. and Cowan, W.M., J.Comp.Neurol.,186:621, 1979). We reinvestigated these connections with the Phaseolus vulgaris-leucoagglutinin (PHA-L)-tracing technique. In 6 female rats, PHA-L was injected in the MSN. A two-color, double-peroxidase immunocytochemical technique (Wouterlood,F.G.,Bol,J.G.J.M. and Steinbusch,H.W.M., J. Histochem. Cytochem.,35, 1987) was used to detect simultaneously the transported PHA-L and target neurons immunoreactive against one of the following substances: choline acetyltransferase (ChAT), histidine decarboxylase (HDC) or serotonin Alternating, frozen brain sections were incubated with one of the following combinations of primary antisera: goat anti-PHA-L mixed with rat anti-ChAT, goat anti-PHA-L mixed with rabbit anti-HDC and goat anti-PHA-L mixed with rabbit anti-serotonin. Secondary antisera (IgG) were also mixed (donkey anti-goat with rabbit anti-rat or swine anti-rabbit). Following incubation in goat-PAP, reaction was performed with Nickel-diaminobenzidine, staining the PHA-L-labeled fibers blue. Subsequently, the sections were incubated with rabbit-PAP and reacted with diaminobenzidine, staining the neurons containing the second antigen brown. PHA-L-labeled fibers originating in the MSN descend through the vertical (VDB) and horizontal (HDB) limbs of the diagonal band of Broca to the hypothalamus. In the VDB and HDB, they form varicosities, closely apposing ChAT-immunopositive neurons. Also ChAT-immunopositive neurons in the medial part of the nucleus accumbens and deep in the olfactory tubercle are innervated by PHA-L-labeled fibers. Descending fibers further course caudally either loosely organized, or contained in the medial forebrain bundle. Nearly all the HDC-immunoreactive neurons in the posterior hypothalamic region are apposed by varicosities on PHA-L--labeled fibers. Labeled fibers cross in the supramammillary decussation, course dorsally to the mesencephalic central grey, and reach the nucleus raphe dorsalis. Here, varicosities on the fibers appose serotonin-immunoreactive cell bodies and dendrites. Appositions between varicosities on PHA-L-labeled fibers and cell bodies immunoreactive against the second antigen suggest the existence of synaptic contacts.

125.8 BASAL FOREBRAIN PROJECTIONS TO THE HYPOTHALAMUS AND BRAINSTEM IN THE RHESUS MONKEY. K.K. HREIB and D.L. ROSENE. Boston Univ. Sch. of Med., Boston, MA 02118.

To investigate the projections of the basal forebrain (BF) to the hypothalamus (HYP) and brainstem, tritiated amino acid injections (TAA) were made in the BF of three rhesus monkeys and injections of fluorescent retrograde tracers (FRT) were made in the medial HYP, the mamillary complex (MC) and the ventral tegmental area (VTA)--substantia nigra (SN). One TAA injection involved the ventral part of the septal area (SA), the vertical limb of the diagonal band (VDB) and the bed nucleus of the stria terminalis (BNST) and produced dense label throughout the HYP except the ventromedial nucleus (VMH) and the medial mamillary nucleus (MMN). In the brainstem, heavy label occured over VTA, SN-pars compacta (SNc), nucleus centralis superior (CS), dorsal raphe (DRa), pontine and mesencephalic reticular formation (RF), the ventral part of central gray (CG), parabrachial nuclei (Pb), and the locus coeruleus. Another injection limited to the BNST produced labeling mainly in the medial preoptic area, the arcuate nucleus (Arc), tuberomamillary nucleus and the lateral hypothalamic area. In the brainstem, label was observed over SNc, CS, mesencephalic RF, ventral CG and Pb. Another injection located in the substantia innominata (SI) included the nucleus basalis. Anterograde label from this case was mainly observed in SNc, and Pb. Thus, all the TAA injections showed projections to the SNc and Pb. None labeled the MMN or VMH, only the SA-VDB labeled VTA and the SI does not project to the HYP. In the BF separate FRT injections placed in the MC and VTA-SN labeled neurons mainly in the ventral intermediate septal nucleus (VIS), some in the lateral SA and few in VDB and SI. An FRT injection in VMH and Arc labeled neurons only in VIS. Examination of the size and distribution of these retrogradely labeled neurons indicated that most are parvocellular neurons of the BF. Thus in contrast to the well-known projections of the cholinergic magnocellular neurons to cortex and our own description of projections to the medial dorsal thalamic nucleus and the amygdala, it appears that at least some of the hypothalamic and brainstem projections originate largely from the non-cholinergic parvocellular population.

(Supported by NIH grants NS 19416 and AG 04321)

125.9 POSSIBLE INTERDIGITATION OF BASAL FOREBRAIN AFFERENTS IN THE MEDIODORSAL THALAMIC NUCLEUS OF THE RAT. J.P. Ray* and J.L. Price, Dept. Anat. & Neurobiol., Washington Univ. Sch. Med., St. Louis, MO 63110.

The medial part of the mediodorsal nucleus of the thalamus (MDm, including both the medial and central segments in the rat) receives afferents from several different parts of the basal forebrain, especially the deep layers of the piriform and entorhinal cortices, the amygdaloid nuclei, the ventral pallidum (including the polymorph zone of the olfactory tubercle) and other parts of the substantia innominata. Previous investigations have indicated that fibers from each of these structures tend to be concentrated in different parts of MDm, although there is apparent overlap at the edges of each projection (e.g. Groenewegen et al., '86; Russchen et al., '87). In order to determine the organization of these afferents within MDm more precisely, a series of experiments is being done in which two anterograde tracers, ^{3}H-leucine and the lectin Phaseolus vulgaris leucoagglutinin (PHA-L) have been injected into different parts of the basal forebrain in the same animal. After appropriate survival, the brains were fixed and serially sectioned; alternative series of sections were prepared for autoradiography, PHA-L immunohistochemical staining, or both. The results suggest that while there is a variable degree of separation of fibers from different basal forebrain structures, there is substantial segregation into interdigitating patterns even when the fibers appear to occupy the same region within MD.

Paired injections into distinctly different structures such as the posterior piriform cortex and the polymorph zone of the olfactory tubercle tend to label two adjacent zones in MDm, which are well segregated. On the other hand, projections from different parts of the same structure tend to have interdigitating patterns of termination. For example, injections in the anterior and posterior parts of the polymorph zone label fibers in the central segment of MD. The fibers from the more anterior part are concentrated ventrally and those from the posterior part dorsally, but in the middle region where both projections are represented the autoradiographic and PHA-L labeled axons tend to be grouped into small clusters surrounded by the other label, indicating interdigitation rather than overlap. Similarly, fibers labeled from paired injections in the different parts of the posterior piriform cortex occupy approximately the same region of MDm, but tend to be clustered into small interdigitating patches.

Supported by NIH research grant NS09518. JPR is supported by GM08151.

125.10 BASAL FOREBRAIN CHOLINERGIC AND NON-CHOLINERGIC PROJECTIONS TO THE THALAMUS AND BRAINSTEM IN CATS AND MONKEYS. A. Parent, Y. Smith, D. Paré and M. Steriade. Lab. of Neurobiol. and Lab. of Neurophysiol., Fac. of Med., Laval Univ., Québec, Canada.

It is generally thought that the thalamus is regulated by various brainstem neuronal aggregates, some of which being cholinergic. In this study we combined the retrograde transport of WGA-HRP with choline acetyltransferase (ChAT) immunohistochemistry in search for other control systems, particularly those of the basal forebrain that could influence thalamic activity through direct inputs as well as through indirect connections with the brainstem. Thus, WGA-HRP was injected (1) into virtually all sensory, motor, and intralaminar nuclei, and into the rostral pole of reticular nucleus (RE) in 27 cats, (2) into the mediodorsal nucleus (MD) in one macaque monkey (Macaca sylvana) and (3) into the peribrachial area (PB) of the brainstem tegmentum in 4 cats. Furthermore, the fluorescent tracers fast blue and nuclear yellow were injected (1) into various thalamic nuclei and PB, and (2) into sensorimotor cortex and PB in 8 squirrel monkeys (Saimiri sciureus). The WGA-HRP experiments revealed that neurons in diagonal band nuclei and substantia innominata in cats project massively to the rostral pole of RE and to MD, less importantly to anteromedial nucleus (AM), and only slightly to ventromedial nucleus (VM). Approximately 7-15% of all retrogradely-labeled neurons disclosed after RE, MD and AM injections were also ChAT-positive while no double-labeled (HRP/ChAT) cells were found after VM injections. The basal forebrain projection to MD was also documented in the macaque monkey. Injections of WGA-HRP into PB in cats led to profuse retrograde cell labelling in nuclei of stria terminalis and anterior commissure and in substantia innominata but no double-labeled cells were found. Fluorescent tracer experiments revealed that a significant number of basal forebrain neurons send axon collaterals to both RE and PB, whereas no branching neurons were found after injections involving PB and other thalamic nuclei or PB and cerebral cortex. These results reveal that cholinergic and non-cholinergic neurons in the basal forebrain project to the thalamus as well as to the brainstem tegmentum. Since recent data showed that the brainstem in turn projects to the basal forebrain, it is possible that, in addition to their direct influence upon many thalamic nuclei, the brainstem neurons in PB modulate the excitability of RE, MD and AM indirectly through basal forebrain neurons.
(Supported by MRC grants MT-5781 and MT-3689).

125.11 RADIAL-ARM MAZE DEFICITS PRODUCED BY COLCHICINE ADMINISTERED INTO THE AREA OF THE NUCLEUS BASALIS ARE AMELIORATED BY CHOLINERGIC AGENTS. Ronnie L. McLamb*, S. Shaw*, Brian Rogers*, Peter Pediaditakis*, G.J. Harry, and Hugh A. Tilson, Lab. Behav. Neurol. Toxicol., NIEHS, Research Triangle Park, NC 27709.

One approach to the study of cognitive dysfunction in animal models has been to inject excitotoxicants such as kainic or ibotenic acid into the nucleus basalis, an area which gives rise to cholinergic neurons projecting diffusely to the neocortex. The following research determined the effects of injecting colchicine, a neurotoxicant that binds to tubulin and disrupts axonal transport, on acquisition and performance of a working memory task and responsiveness to pharmacological agents. Fischer-344 rats were given bilateral injections of colchicine (1.25 or 2.5 ug/site) into the area of the nucleus basalis. Three weeks later, the rats were food-deprived and trained in a radial arm maze task. Colchicine interfered with the rate of acquisition of the maze. Subsequent experiments found that systemic administration of cholinergic agents, including physostigmine, RS-86 and nicotine, decreased the number of errors made by colchicine-treated rats. Levels of acetylcholine transferase, NE, DA, DOPAC, 5-HT, and 5-HIAA were decreased in the frontal cortex. Such changes were not observed in the hippocampus or corpus striatum. Light microscopic assessment of tissue stained with cresyl violet and Luxolfast blue indicated limited tissue damage near the site of injection. Colchicine produced a dose-dependent increase in the size of the lateral ventricles. These data indicate that intracerebral administration of colchicine into the area of the nucleus basalis adversely affects acquisition and performance of a radial arm maze task. This animal model may be useful in the study of compensatory processes associated with neural degeneration and the development of rational approaches for the treatment of cognitive disabilities. (BR is supported by the Toxicology Curriculum, University of North Carolina, Chapel Hill, NC).

125.12 ENKEPHALIN UNILATERALLY MICROINJECTED INTO THE VENTRAL PALLIDUM/NUCLEUS BASALIS INDUCES CIRCLING. T.C.Napier and K.Marx*. Dept. of Pharmacology, Loyola Univ. of Chicago, Stritch Sch. of Med., Maywood, Il 60153.

The ventral pallidum (VP; including the substantia innominata) and nucleus basalis (nB) regions of the rat basal forebrain are homologous to the primate nucleus basalis of Meynert. These regions contain a high density of neuronal fibers which demonstrate enkephalin-like immunoreactivity. Since the VP/nB receives inputs from brain areas involved in motor function (e.g. the substanta nigra), and sends efferents to the mesencephalic locomotor region, we proposed that VP/nB opioid peptides may alter measures of locomotion. The present study was designed to test this hypothesis using a rotating animal model.

Male Sprague-Dawley rats were anesthetized with pentobarbital and bilaterally implanted with 26 gauge guide cannulaes. Two weeks after surgery, the rats (5-8/treatment group) were habituated to the rotation apparatus for at least 30 min. The rats then received a microinjection into the VP/nB of either saline (vehicle) or [D-ala^{2},D-leu^{5}]-enkephalin (ENK), at a rate of 0.1 ul/min for a total volume of 0.5 ul. Amphetamine (1 mg/kg i.p.) was administered immediately and the rats were replaced into the apparatus for determination of circling behaviors. The number of 360^{o} turns was quantified for 75 min after amphetamine administration.

Rats treated with intra-VP/nB saline plus amphetamine demonstrated classical amphetamine-induced locomotor increases and stereotypic behaviors. Unilateral microinjections of 0.1 nM ENK into the VP/nB did not alter these behaviors nor cause unilateral circling. ENK treatments ranging from 0.3 to 10 nM caused a significant, dose dependent increase in both the number of contralaterally rotating rats and the rate at which they circled. A maximum response for both parameters was obtained at a dose of 3.3 nM ENK where 80% of the rats tested circled contralaterally, with a mean rate of 9$\pm$1.4 rotations per min. These preliminary results support the following hypotheses: (1) the VP/nB is directly involved in motor function, and (2) opioid peptides in the VP/nB alter amphetamine-induced locomotion.

125.13 CAUDAL HYPOTHALAMIC PROJECTIONS TO THE ROSTRAL FOREBRAIN WITH SPECIAL REFERENCE TO AFFERENTS OF CHOLINERGIC NEURONS.
W.E. Cullinan and L. Zaborszky Neuroscience Program and Dept. of Otolaryngology, University of Virginia School of Medicine, Charlottesville, VA 22908

Recent autoradiographic evidence concerning the organization of corticopetal projections from the lateral hypothalamus (Saper, 1985) has suggested that these ascending fibers establish contact with several regions of the rostral forebrain, including areas with cholinergic projection cells. We examined this possibility using the anterograde tracer Phaseolus vulgaris leucoagglutinin (PHA-L), in which the detailed morphology of fibers and terminals may be distinguished at the light microscopic level.

Discrete iontophoretic PHA-L injections were sterotaxically delivered to the tuberal and caudal aspects of the lateral hypothalamus, the zona incerta, and fields of Forel, according to the method of Gerfen and Sawchenko (1984). Following survival periods of 7-10 days, brains were fixed via transcardial perfusion, sectioned at 40 um in the coronal plane, and processed for detection of the lectin by either the avidin-biotin peroxidase (ABC) or indirect fluorescence technique. PHA-L containing fibers and terminal varicosities were found within the medial and lateral septal nuclei, nucleus of the vertical limb of the diagonal band (VDB), dorsal aspect of the horizontal limb of the diagonal band nucleus (HDB), bed nucleus of the stria terminalis, sublenticular substantia inominata (SI), ventral pallidum, central amygdaloid nucleus, and the anterior hypothalamus.

To determine the extent to which PHA-L terminals contact cholinergic cells, sections were processed using different double labelling protocols for the simultaneous detection of cholinergic cells and PHA-L labeled terminals. These included the double fluorescence method (FITC/RITC), and the ABC technique utilizing the same (DAB-intensified/DAB; Gorcs et al., 1986), or separate (DAB/BDHC; Levey et al., 1986) markers. PHA-L stained fibers and terminals were found in close proximity to choline acetyltransferase labeled cell bodies and dendrites in the lateral aspect of the VDB, the dorsal portion of the HDB, the SI, and the lateral hypothalamic area. Subsequent electron microscopic investigation may confirm synaptic contact, and support the hypothesis that the direct corticopetal projections of the lateral hypothalamus are paralleled by a multisynaptic corticopetal system involving cholinergic neurons. Also, as the lateral hypothalamus is composed of a chemically heterogenous population of cells, studies are underway to reveal the neurotransmitter specificity of the projecting neurons.

Supported by USPHS Grant NS.23945,17743 and by a Grant from the American Health Association Foundation.

125.14 HIPPOCAMPAL INNERVATION OF CHOLINERGIC NEURONS IN THE VENTRAL STRIATUM (NUCLEUS ACCUMBENS) OF THE RAT. A DOUBLE-LABEL STUDY COMBINING PHA-L-TRACING AND IMMUNOHISTOCHEMISTRY OF CHOLINE ACETYLTRANSFERASE.
G.E.Meredith, F.G.Wouterlood and H.J.Groenewegen. Dept. Anatomy, Vrije University, Amsterdam, Netherlands.

A relatively small population of neurons exhibiting choline acetyltransferase (ChAT) immunoreactivity, and thus presumably cholinergic, is distributed over the entire striatum, including the nucleus accumbens (Acc). According to pharmacological studies, striatal cholinergic transmission is influenced by excitatory amino acids, which may imply that the cholinergic neurons receive input from corticostriatal fibers. However, there is as yet little anatomical evidence to substantiate this hypothesis. Presently, we report our light microscopical findings on the anatomical relationship between hippocampo-striatal fibers and ChAT-immunopositive neurons in Acc. We employed a double-labeling strategy, including marking of the hippocampal fibers by injecting the lectin Phaseolus vulgaris-leucoagglutinin (PHA-L) in different parts of the hippocampus, and staining sections through Acc for both PHA-L and ChAT.

PHA-L was injected microiontophoretically (5 #A, positive pulsed current, 20 min.) into the subiculum or the CA1 region of deeply anesthetized female rats. Following survival times of 5-14 days, the animals were reanesthetized and perfused (3% paraformaldehyde in phosphate buffer). Vibratome sections (40 #m) were processed according to a double-label protocol (see Wouterlood et al., J.Histochem.Cytochem., 35, 1987) using a goat antiserum against PHA-L and a rat monoclonal antibody against ChAT (provided by Dr.F.Eckenstein). Nickel-enhanced diaminobenzidine (Ni-DAB) was used to stain the PHA-L-labeled fibers (blue-black color), while DAB was used to stain ChAT-immunoreactive neurons brown. The distribution of ChAT-immunopositive neurons in Acc was studied with the aid of an Apple II computer equipped with a digitizing tablet. The present analysis indicates that the distribution of ChAT-immunoreactive neurons in Acc is inhomogeneous, but not clustered. The density of ChAT-immunopositive cells is relatively low (approximately 25 cells/mm^2), yet constant along the rostrocaudal axis. There are differences in the density from medial to lateral. Following injections of PHA-L in the hippocampus, either in the dorsal or the ventral subiculum or the CA1 region, varicosities on PHA-L-labeled fibers occur in close apposition with the dendrites or perikarya of ChAT-immunoreactive neurons in Acc. These close appositions may represent synaptic connections, and at present this possibility is being studied at the ultrastructural level. We conclude that cholinergic neurons in Acc may receive direct allocortical input.

125.15 CHOLINERGIC INNERVATION OF THE MONKEY AMYGDALA: AN IMMUNOHISTOCHEMICAL ANALYSIS USING A POLYCLONAL ANTISERUM TO CHOLINE ACETYLTRANSFERASE.
J.L. Bassett and D.G. Amaral. The Salk Institute, La Jolla, CA, 92037.

The monkey amygdaloid complex receives its primary cholinergic input from cells located in the basal forebrain (Mesulam et al., 1983, 1984; Russchen et al., 1985). The basal forebrain is a heterogeneous region, however, and both cholinergic and noncholinergic neurons are known to project to the amygdala. Nonspecific anterograde tracers are therefore inadequate to define the regions of the amygdala that receive cholinergic termination. With the development of antisera to the specific cholinergic marker choline acetyltransferase (ChAT), a precise map of cholinergic innervation now can be generated. The pattern of ChAT immunoreactivity in the macaque monkey (Macaca fascicularis) amygdala was studied in 5 adult animals. Series of coronal sections were immunohistochemically prepared using the peroxidase antiperoxidase method with a polyclonal antiserum (kindly donated by F. Eckenstein) directed against ChAT.

The density of ChAT staining varied substantially in different regions of the amygdala and the pattern of immunoreactivity was similar to that observed in acetlycholinesterase histochemical preparations. The greatest density of ChAT positive fibers and terminals was seen in the basal nucleus, particularly in the posterior portion of its magnocellular subdivision (Bmg). A decrease in labeling was evident in the parvicellular region of the basal nucleus and in the paralaminar nucleus, particularly near their medial and lateral borders. The nucleus of the lateral olfactory tract (NLOT) also contained dense immunoreactivity. In contrast to Bmg, however, where ChAT immunoreactivity appeared fairly uniform, labeling in the NLOT consisted of varicose fibers that formed pericellular plexuses outlining the somata and proximal dendrites of cells. ChAT immunoreactivity in the accessory basal nucleus ranged from moderately dense in the superficial and magnocellular regions to light in the parvicellular region. The lateral nucleus generally was lightly stained though its ventrolateral region was moderately labeled.

The medial and lateral subdivisions of the central nucleus were clearly distinguished in ChAT preparations. Whereas the lateral division was darkly stained and contained numerous varicosities, the medial division contained mainly stained fibers passing through with apparently low terminal density. Of the remaining corticomedial nuclei, the amygdalohippocampal area demonstrated the greatest density of immunoreactivity; the posterior corticomedial nucleus was moderately labeled and progressively lighter staining was seen in the anterior cortical and medial nuclei. Only the portion of the periamygdaloid cortex deep to the sulcus semiannularis contained appreciable ChAT immunoreactivity.

126.1 6-OHDA LESIONS OF NUCLEUS ACCUMBENS BLOCK THE STIMULANT EFFECTS OF NICOTINE IN RATS. C. Ksir and E.J. Cline*. Department of Psychology & Neuroscience Program, University of Wyoming, Laramie, WY 82071.

After previous exposure, nicotine produces a dose-related increase in locomotor activity in rats. The locomotor stimulation produced by amphetamine and by the opiates has been associated with the mesolimbic dopamine system, which projects from the A10 dopamine cell group in the midbrain ventral tegmental area (VTA) to the nucleus accumbens. Nicotinic cholinergic binding sites are found in the VTA, and there is a recent report that nicotine releases dopamine from the accumbens. Pert and Chiueh (1986 Neuroscience Abstracts) reported that infusions of cytisine, a nicotinic agonist, into the VTA produced locomotor activation. The current study was designed to determine whether the mesolimbic dopamine system is necessary for the expression of the locomotor stimulation produced by nicotine.

Beginning 5 days before surgery and resuming 2 days after surgery, each of the adult male albino rats received daily injections of 0.2 mg/kg nicotine. This type of exposure in necessary if the test injections of nicotine are to produce a robust locomotor response. The rats were anesthetized and injection needles were directed bilaterally into the nucleus accumbens under stereotaxic control. In the control group 2 ul of vehicle was injected into each side. In the lesion group the 2 ul infusions each contained 8 ug of 6-OHDA base.

On the 21st day after surgery the rats were placed into one of 16 identical photocell test cages. These cages measure locomotor activity as alternate breaks of two photocell beams, one near each end of the cage. After a one-hour adaptation period each rat was given an injection of saline and replaced in the test cage for one hour. At the end of that hour each rat was given an injection of 0.2 mg/kg nicotine and again placed in the test cage for one hour. On the 26th post-surgical day this procedure was repeated, except that the second injection was 1.0 mg/kg d-amphetamine.

Nicotine produced an increase in cage crossings during the first 20 min after the injection, and amphetamine produced an increase that lasted the entire hour. The lesion group had lower activity levels after saline than the control group, so the response to each drug was tested using analysis of covariance, with each rat's saline reponse the covariate for its drug response. Data for each rat were summed over 20 min for the nicotine analysis and over 60 min for the amphetamine analysis. ANCOVA found that the lesioned group showed a significantly lower response to both nicotine and amphetamine than the sham control group.

These results indicate that the mesolimbic dopamine system is a critical component of the normal locomotor stimulant response to nicotine seen in rats after several daily nicotine injections.

126.2 ALTERATION IN LICKING PATTERN FOLLOWING CHRONIC HALOPERIDOL: A VALID AND OBJECTIVELY VERIFIABLE MODEL OF TARDIVE DYSKINESIA. S. J. Lytle* and K. M. Kantak. (SPON: J. Stein). Laboratory of Behavioral Neuroscience, Dept. of Psychology, Boston University, Boston, MA. 02215.

Chronic neuroleptic administration can lead to Tardive Dyskinesia (TD). One prevalent theory suggests that TD is caused. by an increase in post-synaptic dopamine sensitivity in the striatum. Evidence indicates that the pars reticulata of the substantia nigra, which projects to the striatum, is involved in the motor control of the oropharyngeal musculature. Since TD is characterized by abnormal movements of the oropharyngeal musculature it is likely that alterations in licking behavior would occur in mice chronically treated with haloperidol.

Baseline licking behavior was recorded in 10 untreated mice until stable performance was achieved. Two groups of mice were then injected with physiological saline or haloperidol (IP. 1.0 mg/kg) for four months. At three-week intervals they were water deprived, habituated to the recording apparatus and tested for 15 minutes under two conditions: a) under the influence of haloperidol and b) after 72 hours of withdrawal from haloperidol. Five measures were recorded: # licks, # bouts, # licks per bout, session length, and latency to first lick.

Overall the # licks did not differ between the saline and haloperidol treated mice. The # bouts, however, were significantly elevated in haloperidol treated mice after the second month under withdrawal conditions and after the third month under spontaneous conditions. Consequently, this led to an abnormal drinking pattern as indicated by the # licks per bout measure. The saline treated mice significantly increased their # licks per bout over time while the haloperidol group showed no change over time or conditions. During the second month there was a significant difference ($p < .05$) between the groups under withdrawal conditions. At the third month the difference between saline and haloperidol # licks per bout became significant under both the spontaneous ($p < .05$) and withdrawal ($p < .01$) conditions. At the fourth month this difference on the # licks per bout between the saline and haloperidol groups became even more pronounced ($p < .01$) for both spontaneous and withdrawal conditions.

These data indicate that this procedure may represent an analogous model of tardive dyskinesia since the effects occurred only over an extended period of time, first upon withdrawal, and later under spontaneous and withdrawal conditions. In addition this design demonstrates a new valid and objectively verifiable animal model for Tardive Dyskinesia.

126.3 EFFECTS OF CAERULEIN AND HALOPERIDOL ON AMPHETAMINE INDUCED BEHAVIORS. K.J. Mueller, E.M. Hollingsworth*, J.L. Peel* and K.L. Rewey* (SPON: J. Babitch) Dept. of Psych., Texas Christian University, Fort Worth, TX 76129.

Caerulein (CL) is an analog of cholecystokinin, a neuropeptide which has been implicated in dopamine neurotransmission. Matsubara & Matsushita (1984, 1985 and others) have reported that the combination of CL and haloperidol (a dopamine receptor blocker) can produce a long-term antagonistic effect on amphetamine (AMP) induced activity in rats. In other words, there is a reduction in AMP induced locomotions even when AMP is given several days after CL + haloperidol (HAL). The present study further examines both the acute and long-term influences of CL on AMP-induced behaviors using the gamma statistic ($\hat{\gamma}$) developed in Hollingsworth, Mueller & Cross as a measure of stereotypy. Rats were pretreated with a combination of drugs, injected with a test drug and observed in an open field. Five days later the subjects were observed again without pretreatment. On test day 1, rats were simultaneously administered one of the following pretreatments: saline (SAL)+SAL, CL (20ug/kg)+SAL, HAL (0.1 mg/kg)+SAL, or HAL+CL. 60 min. following pretreatment rats were injected with either SAL or AMP (2 mg/kg or 4 mg/kg). 25 min. after the second injection, rats were placed in an open field for 20 min. Rears, lines crossed and stereotypic locomotor activity ( ) were recorded. Five days after the first test session, the procedure was repeated but without pretreatments.

We found that 4 mg/kg AMP increased the statistic while HAL prevented this increase. These data support the usefulness of the statistic as a measure of stereotypic locomotor activity. In contrast to the results presented by Matsubara & Matsushita, no long-term effect of CL+HAL on locomotor activity was found. However, CL did produce a short-term decrease in for 4 mg/kg AMP but had no effect on lines crossed. The possible mechanism responsible for the short-term effects of CL administration are discussed in light of evidence of the dopaminergic system's role in locomotor activity.

126.4 A NEW TECHNIQUE FOR MEASURING STEREOTYPIC LOCOMOTOR ACTIVITY IN AN OPEN FIELD, E. M. Hollingsworth , K. J. Mueller, and D. R. Cross*, Psychology Department, Texas Christian University, Ft. Worth, Texas 76129

Amphetamine (AMPH) produces stereotypic behavior in rats; historically this stereotypy has been characterized as particular repetitive movements of head and limbs and licking/biting. The present series of experiments examines stereotypic patterns of locomotions which appear prior to the more traditional stereotypic behaviors. A probability statistic ( ) was derived to quantify stereotypic patterns of locomotor behavior in an open field.

AMPH-induced changes in the statistic were examined in the first experiment. 11 rats were injected SC with saline (SAL), 3.5, 5.0 and 6.5mg/kg AMPH in a repeated measures design. 25 minutes following each injection animals were placed in the open field and the route through the open field was recorded for 20 min. The overall pattern of locomotor activity was broken down into "trips". Trips were defined as the number of lines crossed until 1 of 3 criteria were met. These include when the rat: changes direction, enters center of open field, completes tour of perimeter. represents the number of sequential repetitions of trips divided by the total number of possible repetitions. Lines crossed and rears were also recorded. There were 4 days between each test. Lines crossed and rears tended to decrease as the AMPH dose increased, but tended to increase and then decrease (as the animal became too stereotypic to locomote). Upon further investigation we found that 2.8mg/kg AMPH enhanced lines crossed, rears and , but the change in was not statistically significant. Thus the dose may be near the threshold for reliably producing stereotypic patterns of locomotions.

In the second experiment 11 animals were injected with caffeine (CAF) at 0 (SAL), 5, 10, and 15mg/kg. Although CAF is a well known stimulant, it does not produce stereotypy. As expected, CAF produced a dose-dependent increase in lines crossed and rears without affecting .

A third experiment controlled for multiple exposures to the open field. 13 animals were injected with saline before each of the 4 open field tests. There was little change in lines crossed, rears or .

The present series of experiments suggest that the derived statistic does quantify AMPH-induced stereotypic patterns of locomotions. The statistic will be particularly useful in quantifying stereotypy during the transitional period between enhanced locomotor activity and more traditional stereotypic behavior. Further analysis revealed that AMPH produced specific changes in the types of patterns of locomotions. This information provides a more complete description of the behavioral response to AMPH in rats.

126.5 INCREASED MOTIVATION TO SELF-ADMINISTER APOMORPHINE FOLLOWING 6-HYDROXYDOPAMINE LESIONS OF THE NUCLEUS ACCUMBENS. David C.S. Roberts and G. Vickers*, Department of Psychology, Carleton University, Ottawa, CANADA, K1S 5B6.

We have previously shown that 6-hydroxydopamine (6-OHDA) induced lesions of mesolimbic dopamine (DA) cell bodies or DA terminals in the nucleus accumbens cause extinction of intravenous cocaine self-administration. These data are consistent with the idea that cocaine is an indirect acting agonist at DA receptors, and that the presynaptic element is necessary for cocaine to have a reinforcing effect. By contrast, the self-administration rate of apomorphine, a direct DA agonist, is not affected by 6-OHDA lesions of the accumbens. Indeed, the same lesioned animals which fail to respond for cocaine injections have been shown to self-administer apomorphine at pre-lesion rates.

If the 6-OHDA treatment produces denervation supersensitivity of DA receptors, and if these receptors mediate the reinforcing effects of apomorphine, then the lesion should increase the reinforcing action of the drug. Our previous demonstration that DA denervation fails to affect the rate of apomorphine self-administration suggests that either (1) the reinforcing action of apomorphine is NOT mediated via stimulation of DA receptors in the accumbens or (2) rate of self-administration is not sensitive to changes in reward strength.

We have recently re-investigated the effect of 6-OHDA lesions on apomorphine self-administration using a progressive ratio schedule of reinforcement. At the beginning of each session, the first response produces an injection of apomorphine (i.e. FR 1). With each subsequent injection the number of responses required to earn an injection increases rapidly. The "break-point" was established each day, and was defined as the last reinforcement ratio completed before the behavior extinguished. When tested following surgery, control animals showed no consistent change in break-point, failing to respond on average past a ratio of 15. By contrast, the 6-OHDA treated group displayed a steady increase in the break-point following the lesion, reaching a mean break-point after one week of 60. Several weeks after the lesion, we have found rats that will complete ratios of over 300. These data demonstrate that 6-OHDA-treated animals show an increased motivation to self-administer apomorphine which progresses daily after the lesion and may parallel the development of supersensitive DA receptors.

These data clearly demonstrate that some treatments can induce changes in reward value without affecting the rate of self-administration on simple schedules of reinforcement.

126.6 PRODRUGS ENHANCE THE DURATION OF ACTION OF THE DOPAMINE AUTORECEPTOR AGONIST, CGS 15855A. J.C. Berry*, W.C. Boyar, R.A. Lovell, A.J. Hutchison* and B.S. Glaeser, Research Department, Pharmaceuticals Division, CIBA-GEIGY Corporation, Summit, New Jersey, 07901.

CGS 15855A ([±]trans-1,3,4,4a,5,10b-hexahydro-4-propyl-2H[1]benzopyranol[3,4,-b]-pyridin-9-ol monohydrochloride) has been described as a dopamine autoreceptor agonist having a short to moderate duration of action (Glaeser et al., Soc. Neurosci. Abstr. 11, part 1985). Rapid methylation of the hydroxy group on CGS 15855A may account for the short duration of action. Therefore, derivatives were synthesized by the derivatization of the hydroxy group to form the benzoate (CGS 16475A), pivaloate (CGS 16486A) and the dimethyl carbamate (CGS 16487A) prodrugs of CGS 15855A. These prodrugs were tested for their dopaminergic properties using the gamma-butyrolactone (GBL) model for dopamine autoreceptors (Walters and Roth, Naunyn-Schmiedeberg's Arch. Pharmacol. 296:5, 1976). Previously, in this model it had been shown that CGS 15855A had ED_{50} values of 0.16 mg/kg i.p. and 0.39 mg/kg p.o. (Glaeser et al., Soc. Neurosci. Abstr. 11, part 1, p 500, 1985). In these studies the prodrugs were initially administered at pretreatment times of 15 and 30 min before the administration of GBL (750 mg/kg i.p.). Doses of the prodrugs were calculated to correspond to 5 mg/kg i.p. of CGS 15855A and were based on the assumption that there was 100% hydrolysis of the ester linkage. After a 15 min pretreatment, the benzoate and pivaloate prodrugs reversed the GBL induced accumulation of DOPA by 79 and 90%, respectively. The dimethyl carbamate prodrug was inactive after the 15 min pretreatment, while apomorphine produced an 85% reversal. After a 30 min pretreatment, the benzoate and pivaloate prodrugs produced a 96 and 91% reversal, respectively, while the dimethyl carbamate prodrug did not significantly alter the GBL induced accumulation of DOPA. In related studies with the GBL model, all three prodrugs were administered orally (10 mg/kg) at a pretreatment time of 2 hr. All of the compounds significantly reversed the GBL accumulation of DOPA by 46 to 66%. In metabolite studies, pivaloate and dimethyl carbamate prodrugs were administered orally at doses equivalent to 10 mg/kg of CGS 15855A. Both compounds significantly reduced the striatal concentrations of DOPAC and/or HVA. Both compounds had a more profound effect than CGS 15855A on the reduction of striatal HVA concentrations at 1,2 and 3 hrs post administration. In a similar study CGS 15855A (10 mg/kg p.o.) reduced striatal HVA concentrations at 0.5 and 1 hr post administration (ibid). These studies suggest that certain prodrugs may enhance the dopaminergic autoreceptor agonism properties of the parent compound. More specifically, the benzoate, pivaloate, or dimethyl carbamate prodrugs of CGS 15855A showed a more prolonged duration of action as dopamine autoreceptor agonists when compared to the parent compound, CGS 15855A.

126.7 **DOPAMINE ESTERS AS POTENTIAL PRO-DRUGS FOR DOPAMINE.** **S.M. Tejani-Butt, A. D'Mello*, I. Lucki and D.J. Brunswick. Department of Psychiatry, University of Pennsylvania School of Medicine and Neuropsychopharmacology Unit, Veterans Administration Medical Center and Philadelphia College of Pharmacy and Science, Philadelphia, PA 19104.**

Dopamine (DA) is a hydrophilic neurotransmitter which due to its catechol and ionizable amine moiety is not sufficiently lipophilic to penetrate the brain. A labile, lipophilic derivative of DA which has the ability to penetrate the brain and hydrolyze to DA may have utility in the treatment of Parkinson's disease and may also serve as a tool to study central DA receptor function.

In this study, three esters of DA were synthesized in which the catechol moiety was esterified. These derivatives were the diacetyl (DADA), dibenzoyl (DBDA) and p-chlorobenzoyl (p-CBDA) esters of DA. The ester derivatives were 10-1000 fold more lipophilic than DA itself (log D = -2.8) as measured by their distribution coefficients between phosphate buffer and n-octanol at pH 7.4. The log D values for DADA, DBDA and p-CBDA were -2.0, 1.3 and 0.76, respectively. The kinetics of decomposition of the pro-drugs of DA in aqueous solution at 37° and pH 7.4 was studied to assess their stability and thus their suitability as pro-drugs for further pharmacologic evaluations. The half-lives of hydrolysis for DADA, DBDA and p-CBDA were 194, 423 and 5 min, respectively. DBDA was chosen for further investigation as it was lipophilic and had a usable rate of hydrolysis.

Radiolabeled DBDA was synthesized from (8-^{14}C)DA, and the total uptake of ^{14}C-DBDA into the brain was measured in Sprague-Dawley rats (200-210g) following i.v. injections (9mg/kg) via their tail vein. At various time points (5-240 min), the rats were decapitated and the brain removed, homogenized and its content of radioactivity measured. ^{14}C-DBDA penetrated the brain rapidly giving an uptake of 0.28±0.02% of injected dose/g tissue (n=3) at 5 min. After this time, levels of radioactivity declined with levels at 15 and 45 min being 0.23±0.004% (n=4) and 0.16± 0.02% (n=3), respectively. At 240 min, no radioactivity was detected in brain. By contrast, after i.v. administration of [8-^{14}C]-DA, radioactivity was less than 0.03% of the injected dose/g tissue at these time points.

Behavioral changes were observed when rats were injected with DBDA (12 mg/kg) via their tail vein. At this dose, rats exhibited significantly increased locomotor activity, and increased grooming and rearing behavior as compared with rats injected with saline.

Thus, we have demonstrated that DBDA is a potential pro-drug of DA that is able to penetrate the brain and can be hydrolyzed in aqueous solution at pH 7.4 to form DA. The behavioral effects observed are consistent with increased central dopaminergic activity. Based on these results, DA esters appear to warrant further investigation as potential DA pro-drugs for the treatment of Parkinson's disease. **(Supported by Research Funds from the Veterans Administration, N.I.H. Biomedical Research Support Grant, University of Pennsylvania and MH 36761).**

126.8 COMPARATIVE AUTORECEPTOR AND POSTSYNAPTIC DOPAMINE AGONIST ACTIVITY OF CGS 15855A AND CGS 15873A. J.M. Liebman, R. Gerber, G. Pastor*, B.S. Glaeser, C.A. Altar and P.L. Wood. (SPON: J.J. Welch). Neuroscience/Cardiovascular Research, Pharmaceuticals Division, CIBA-GEIGY Corp., Summit, New Jersey, 07901.

Two novel benzopyranopyridine derivatives, CGS 15855A and CGS 15873A, have been characterized as potent agonists at striatal dopamine (DA) autoreceptors, using the gamma-butyrolactone (GBL) striatal autoreceptor model (Glaeser et al., Soc. Neurosci. Abstr. 11:500, 1985) and other measures (Altar et al., Eur. J. Pharmacol. 134:303, 1987). The present experiments assessed the separation between the autoreceptor and postsynaptic DA agonist activity of these drugs in comparison with apomorphine and (±)-3-PPP.

Drugs were administered i.p. to rats and measurements of postsynaptic DA agonism were performed within the next 30 min. Stereotyped sniffing was assessed by direct observation, and reversal of reserpine-induced akinesia was measured using vibration-sensitive motor activity monitors. Striatal acetylcholine (ACh) levels were measured using the method of Wood and Peloquin (Neuropharmacology 21:349, 1981). Another group of rats received unilateral intranigral injections of 6-hydroxydopamine to induce loss of neostriatal dopamine neurons. Of these rats, only those that manifested a high degree of rotational sensitivity to apomorphine (at least 100 rotations/20 min after 0.03 mg/kg s.c. apomorphine) were used.

In normal rats, CGS 15855A and CGS 15873A were typically eight to thirty times less potent in the stereotypy, reserpine and striatal ACh level assays of postsynaptic activity than in the GBL model. The potency of apomorphine in the postsynaptic models was comparable to its potency in the GBL model, whereas (±)-3-PPP showed no apparent postsynaptic agonism. In lesioned rats, however, the potencies of all four drugs to induce rotation were comparable to those in the GBL model. These results suggest that in the presence of normal dopaminergic innervation, CGS 15855A and CGS 15873A show relative, but not absolute, autoreceptor selectivity. In a DA-denervated preparation, CGS 15855A and CGS 15873A, in common with 3-PPP, have potent postsynaptic activity.

	ED50 or active doses, mg/kg i.p.			
TEST	CGS 15855A	CGS 15873A	APO	(±)-3-PPP
GBL[a]	0.16	0.52	0.56	2.0
Stereotypy	3.1	~30	0.4	>30
ACh levels	4.0	≤3.0	0.9	-
Reserpine	1.0	4.6	0.15	>30

126.9 SELF-ADMINISTRATION OF MIDAZOLAM MAY BE ASSOCIATED WITH A DECREASE IN DOPAMINE RELEASE IN THE NUCLEUS ACCUMBENS.
J.M. Finlay, C. Szostak*, C.D. Blaha, R.F. Lane and H.C. Fibiger. Div. of Neurol. Sci., Dept. of Psychiatry, Univ. of British Columbia, Vancouver, BC, V6T 1W5.

We have previously shown that rats will self-administer the short acting benzodiazepine midazolam. It has been proposed that intravenous self-administration of psychoactive drugs is subserved by increases in the activity of mesolimbic dopaminergic neurons. The present experiments further characterized intravenous midazolam self-administration in the rat and examined the effects of midazolam on mesolimbic dopamine (DA) release.

Following implantation of chronic intrajugular cannulae, rats were given 24 h access to two levers. Each response on the drug lever resulted in a single infusion of midazolam (0.05 mg/0.18 ml/infusion) coincident with the illumination of a cue light located directly above the lever. Responses on the control lever did not produce an infusion but did result in illumination of a cue light. All rats established a preferred level of responding for midazolam that remained stable over subsequent 24 h sessions. Rates of responding were consistently higher on the drug lever than the control lever. As previously reported, maximal responding occurred during the dark phase of the 12 h light/dark cycle. Following acquisition of stable levels of responding for midazolam, rats were tested under reversal conditions. During this phase, each response on the control lever produced an infusion of midazolam coincident with the illumination of a cue light while responses on the drug lever resulted in illumination of a cue light only. Across test sessions, rats tracked the drug-response contingencies such that rates of responding on the newly active lever were similar to levels attained during the initial acquisition of midazolam self-administration.

In vivo electrochemistry was used to evaluate the effects of midazolam on DA release within the nucleus accumbens (NAS) of the unanaesthetized rat. Repeated intravenous infusions of midazolam (0.05 mg/0.18 ml/infusion), delivered in a manner that mimicked the pattern of midazolam self-administration, resulted in a significant decrease in DA release within the NAS. Subcutaneous injections of midazolam also elicited a dose dependent decrease in accumbens DA release in the unanaesthetized rat.

The results of the present experiment: 1) support earlier work demonstrating that rats will self-administer midazolam and 2) provide preliminary evidence that self-administration of midazolam is not mediated by a drug-induced increase in DA release within the NAS.

J.M.F. is a MRC student and C.S. is a NSERC post-graduate scholar. Supported by the Medical Research Council of Canada.

126.10 STUDIES ON SELECTIVE D1/D2 DOPAMINE AGONIST-INDUCED CONDITIONED TASTE AVERSIONS IN RATS.
K.E. Asin and W.E. Montana, Abbott Labs, Dept. 47U,Bldg. AP10, Abbott Park, Il. 60064.

A number of studies have demonstrated that injections of either direct or indirect dopamine agonists are able to produce conditioned taste aversions (CTAs) in animals. To date, however, the selective involvement of the D1 and D2 dopamine (DA) receptor subtypes in the production of CTAs has not been studied. The purpose of the present study was to investigate the ability of selective D1 and D2 agonists to induce the development of CTAs and to examine the effects of selective DA antagonists on these aversions. We also investigated the possible neuronal substrates involved in this behavior by studying D1 and D2 DA agonist-induced conditioned taste aversions in rats with lesions of the area postrema (AP).

The basic procedure for inducing CTAs was the same in all studies. Adult male rats were placed on a 23h water deprivation schedule for 9 days. On the 3rd, 7th and 9th days, rats were presented with a .1% sacharrin solution instead of water. After the first two presentations rats were injected with test compounds or vehicle. Antagonists were injected immediately after the sacharrin was removed; agonists were adminstered 15 minutes later. All water and sacharrin intakes were recorded.

The D2 agonist LY171555 (LY)(.075-.60mg/kg) and the D1 agonist SKF38393 (SKF) (1-20 mg/kg) both produced dose-dependent CTAs. The D2 antagonist haloperidol (.125 &.375mg/kg), which had no effect on its own, blocked the LY but not the SKF induced CTAs. The D1 antagonist SCH23390 (.12,-.60mg/kg) failed to induce a CTA on its own and also failed to block either the D1 or D2 agonist-induced CTAs. These studies suggest that selective stimulation of the D2 DA receptor underlies the ability of LY to induce a CTA since the aversion could be blocked by haloperidol. However, the CTA produced by SKF does not appear to be mediated via the stimulation of either the D1 or D2 DA receptor subtype.

In subsequent studies we investigated the possible neuronal substrates underlying these DA agonist-induced CTAs. Behavioral and neuropharmacological evidence indicate that the AP may be involved in some of the aversive properties of some DA compounds. Therefore, rats were prepared with thermo lesions of the AP under visual guidance using a transcisternal approach. At least three weeks later (by which time body weights had stabilized), rats were tested for the establishment of an LY or SKF induced CTA. Lesions of the AP failed to affect either agonist induced aversion. However, as expected, these lesions did attenuate a scopolamine-induced CTA to a chocolate milk solution. It therefore appears that the area postrema is not importantly involved in the induction of a CTA by either LY or SKF.

126.11 APOMORPHINE-INDUCED REVERSAL IN DIRECTION OF LATERALIZED WALL-FACING AFTER 10 DAYS OF UNILATERAL REMOVAL OF VIBRISSAE IN RATS.
H. Steiner*, S. Morgan* and J.P. Huston (SPON: M. Terman). Institute of Physiological Psychology, University of Düsseldorf, 4000 Düsseldorf, Federal Republic of Germany.

Previous experiments have shown that unilateral removal of the vibrissae (UVR) can induce neural plasticity in the crossed nigrostriatal projection. After 10 days of shaving the vibrissae on one side of the rats' face, more cells were retrogradely labeled in the contralateral substantia nigra (SN) when horseradish peroxidase was injected into the striatum on the side opposite to UVR than when it was applied on the same side as UVR or in normal animals (Huston, et al., Exp. Neurol., 93:380, 1986).

In the present experiment we examined the influence of UVR on rats' wall-facing behavior (i.e., the tendency to locomote along the perimeter of an open field). For this purpose the time the rats moved along the wall of an open field with respect to the side of UVR was measured. Two groups of rats which differed in the duration of experience with this sensory imbalance were compared. The results showed that after UVR wall-facing was lateralized towards the sensory intact side. That is, the rats preferentially moved along the wall with the vibrissae side towards the wall. This asymmetry was seen irrespective of whether the rats had been shaved for 4 hours or for 10 days. After an injection of apomorphine (APO, 0.75 mg/kg, s.c.) the animals that were shaved for 4 hours also spent more time facing the wall with the sensory intact side, whereas the rats shaved for 10 days preferentially moved along the wall with the shaved side of the face facing the wall.

The APO-induced reversal in wall-facing asymmetry found after 10 days of UVR suggests a plasticity in dopamine (DA) transmission after this kind of sensory deprivation. It is reminiscent of the APO-induced reversal in sensorimotor asymmetries that occurs after unilateral lesions of the SN, which has been related to denervation-induced DA receptor supersensitivity. The APO-induced reversal in wall-facing asymmetry after UVR could reflect "deprivation super-sensitivity" of DA receptors.

126.12 DOPAMINE AND OXYTOCIN LINK IN THE EXPRESSION OF PENILE ERECTION AND YAWNING.
A. Argiolas and M.R. Melis. Dept. of Neurosciences, Univ. of Cagliari, Via Porcell 4, 09100 Cagliari, Italy.

Repeated episodes of penile erection and yawning can be induced in experimental animals by the intracerebroventricular (i.c.v.) injection of ACTH-MSH peptides, or by the systemic injection of low doses of dopamine (DA) agonists or by i.c.v. injection of nanogram amounts of oxytocin. The ability of the above unrelated substances, together with their presence in the central nervous system (CNS) to induce the above symptomatology, raises the possibility that a neuronal link between DA, oxytocin and ACTH might play an important role in the expression of penile erection and yawning. In order to test the above hypothesis, several experiments were performed. 1) The effect of DA antagonists such as haloperidol and sulpiride, on penile erection and yawning induced by the DA agonist apomorphine, by oxytocin and ACTH 1-24 was studied. Both haloperidol and sulpiride prevented apomorphine-induced responses, but not that of oxytocin and ACTH 1-24. 2) The i.c.v. injection of the oxytocin antagonist $d(CH_2)_5Tyr(Me)\text{-}Orn^8$-vasotocin was found to be able to antagonize penile erection and yawning induced by oxytocin and apomorphine, but not by ACTH 1-24. 3) The depletion of hypothalamic ACTH and -MSH by neonatal monosodium glutamate was found to be ineffective in antagonizing penile erection and yawning induced either by ACTH 1-24 or oxytocin or apomorphine. 4) Microinjection and lesion studies revealed that the paraventricular nucleus of the hypothalamus is the most sensitive brain area for the induction of penile erection and yawning either by apomorphine or by oxytocin.

Altogether, the present results indicate that DA agonists induce penile erection and yawning by releasing oxytocin in the hypothalamic paraventricular nucleus and that ACTH- derived peptides act either downhill to oxytocin and DA receptors or by a different mechanism to induce such responses. Moreover, the potency of apomorphine and oxytocin suggests a physiological role of hypothalamic DA and oxytocin in the expression of penile erection and that abnormalities in their function might be responsible of penile erection disturbances.

126.13 PENILE ERECTION AND YAWNING INDUCED BY DOPAMINE AGONISTS: SITE OF ACTION IN BRAIN. M.R. Melis and A. Argiolas. Dept. of Neurosciences, Univ. of Cagliari, Via Porcell 4, 09100 Cagliari, Italy.

The systemic administration of low doses of dopamine (DA) agonists, such as apomorphine induces recurrent episodes of penile erection and yawning in rats. In contrast to low doses, high doses of DA agonists induce hypermotility and stereotypy, but not yawning and penile erection. While the striatum and nucleus accumbens have been identified as the brain sites where DA agonists act to induce hypermotility and stereotypy, the site where DA agonists act to induce penile erection and yawning is still unknown. In order to determine such site(s) we microinjected apomorphine into discrete brain nuclei through stereotaxically implanted chronic guide cannulae. The results indicate that the most sensitive brain area for the induction of penile erection and yawning is the paraventricular nucleus of the hypothalamus (PVN). A significant effect was elicited by a dose of apomorphine as low as 5 ng. The symptomatology usually began within 5 min after microinjection, lasted for 30-50 min, and was identical to that induced by the systemic administration of the drug. Hypermotility and stereotypy were never observed after apomorphine microinjection into the PVN, even at the highest dose tested (1 ug). Microinjections of the same doses of apomorphine into the hypothalamic ventromedial and dorsomedial nuclei, preoptic area, caudate nucleus, nucleus accumbens and substantia nigra, were ineffective. LY 171555, a specific D_2-DA receptor agonist, and (+)-3PPP but not (-)-3PPP nor the specific D_1-DA receptor agonist SKF 38393, were as effective as apomorphine when injected into the PVN. Apomorhine-induced penile erection and yawning were antagonized by pretreatment with neuroleptic drugs such as haloperidol, (-)sulpiride, a specific D_2-DA antagonist, and SCH 23390, a specific D_1-DA antagonist.

The present results suggest that the PVN is the brain area where D_2-DA agonist act to induce penile erection and yawning. Moreover, since the PVN contains the cell bodies of a group of incertohypothalamic DA neurons, the above results suggest for the first time a possible involvement of the incertohypothalamic DA system in the expression of penile erection and yawning.

126.14 THE EFFECTS OF D-1 AND D-2 DOPAMINE RECEPTOR ANTAGONISTS ON THE DEVELOPMENT OF SENSITIZATION TO THE LOCOMOTOR EFFECTS OF MORPHINE AND AMPHETAMINE. P. Vezina and J. Stewart. Center for Studies in Behavioral Neurobiology, Psychology Department, Concordia University, Montreal, Canada H3G 1M8.

In the present experiments, a comparison was made between the effects of various selective and nonselective dopamine (DA) receptor antagonists on the development of sensitization of the locomotor activity produced by repeated exposure to intra-VTA morphine or systemic amphetamine.

In experiment one, rats were prepared with bilateral injection cannulae aimed at the VTA and randomly assigned to one of six groups of 6-8 rats each. During the training phase, animals in each group were pretreated with either pimozide (0.5 mg/kg, i.p.), sulpiride (10 or 50 mg/kg, i.p.), Ro22-2586 (0.2 mg/kg, s.c.), SCH-23390 (0.2 mg/kg, s.c.), or saline (1 ml/kg, i.p.) before being administered each of five injections of morphine sulfate (5.0 µg in 0.5 µl saline volume/side) and placed in activity boxes for two hours. Injections were given every other day. On the test day, two days following the last morphine injection, animals were given vehicle injections and tested in the activity boxes following an intra-VTA morphine injection. Animals pretreated during training with the D-1 DA receptor antagonist SCH-23390 as well as those pretreated with the D-2 DA receptor antagonists Ro22-2586 and sulpiride showed, on this test, locomotor activity levels similar to the increased or sensitized activity levels of animals pretreated with saline. Animals pretreated with pimozide, however, were less active than all other groups on this test suggesting that while the effect of pimozide was to block the development of sensitization to the locomotor effects of intra-VTA morphine, the remaining antagonists, selective to D-1 and D-2 DA receptors, were without effect.

In experiment two, different groups of rats were trained as above but with d-amphetamine sulfate (1.0 mg/kg, i.p.). On the test day, rats were given vehicle injections and tested in the activity boxes following an injection of 0.5 mg/kg d-amphetamine. Activity levels on this test suggest that while Ro22-2586 and pimozide had no effect on the development of sensitization to the locomotor effects of d-amphetamine, sulpiride enhanced the sensitization while SCH-23390 attenuated its development.

These results a) suggest that the mechanisms underlying development of sensitization to the locomotor effects of morphine and amphetamine may differ even though these may ultimately result in similar changes in the presynaptic activity of mesencephalic DA neurons, and b) preclude an exclusive role for one DA receptor subtype in the mediation of sensitization to the locomotor effects of opiates and stimulants.

126.15 ACUTE BEHAVIORAL EFFECTS OF MPTP IN RATS ARE MEDIATED BY MPTP ITSELF AND NOT BY MPP^+. R. Schaffner*, M. Da Prada*, P. Polc*, W. Haefely (SPON: K. Bizière). Pharmaceutical Research Department, F. Hoffmann-La Roche & Co., Ltd., CH-4002 Basle, Switzerland.

The preferential degeneration of the nigro-striatal system by MPTP in several mammalian species including primates and mice is dependent on the metabolism of MPTP to MPP^+ by monoamine oxidase (MAO). In rats, however, MPTP induces short lasting behavioral effects of the mixed dopamine (DA)/serotonin-type without influencing brain monoamines to a significant extent.

In an attempt to clarify whether the acute behavioral effects of MPTP in rats are due to MPTP itself or its metabolite MPP^+ and whether they are mediated by pre- or postsynaptic mechanisms at DAergic synapses the following experiments were performed. 1 MPTP was studied for its ability to induce turning behavior in rats with 6-OHDA lesions in the MFB and its antagonistic effect in rats against prochlorperazine (PPZ)-induced catalepsy without or with pretreatment with the selective MAO-B inhibitor Ro 19-6327 (N-(2-aminoethyl)-5-chloro-2-pyridine-carboxamide; Da Prada, M. et al., Pharmacol. & Toxicol. 60 (Suppl. I):10, 1987) and/or the preferential MAO-A inhibitor moclobemide (MOCLO). Furthermore, following the injection of MPTP (10 mg/kg ip, sc), mixed with trace amounts of ^{3}H-MPTP, the striatal content of ^{3}H-MPTP and ^{3}H-MPP^+ was determined by extraction of radioactivity from the striatum, separation of ^{3}H-MPTP and ^{3}H-MPP^+ by TLC and measurement of the radioactivity by scintillation spectrometry (Da Prada, M. et al., Neurosci. Lett. 57:257, 1985). 2 The ability of MPTP to antagonize the cataleptic state induced in rats by the tyrosine-hydroxylase inhibitor alpha methyl-p-tyrosine (AMT) was studied.

MPTP (30 mg/kg sc) induced contralateral turning and dose-dependently antagonized (10-30 mg/kg ip) the PPZ-induced catalepsy. In addition, MPTP (30 mg/kg ip) reduced AMT-induced catalepsy. The turning behavior and the anticataleptic effect of MPTP against PPZ catalepsy were potentiated by Ro 19-6327. A similar potentiation of the anticataleptic effect was observed with MOCLO or a combined pretreatment with Ro 19-6327/MOCLO. Determination of striatal accumulation of ^{3}H-MPTP and ^{3}H-MPP^+ revealed that, within one hour after the injection of ^{3}H-MPTP, ie the time of peak effect, the two MAO inhibitors markedly reduced the formation of ^{3}H-MPP^+ in the striatum of rats.

From these results it is concluded that the acute behavioral effects observed with MPTP in rats are in large part due to MPTP itself and are not dependent on its metabolic transformation into MPP^+. Furthermore, since MPTP induced contralateral turning and antagonized AMT-induced catalepsy it is suggested that these behavioral effects observed with the high doses of MPTP are mediated by a direct effect of MPTP on postsynaptic DA-receptors.

126.16 SENSITIZATION FOLLOWING REPEATED ADMINISTRATION OF THE DIRECT ACTING D_1-DOPAMINE AGONIST SKF-38393 IN NEONATALLY- BUT NOT ADULT-6-OHDA LESIONED RATS. H.E. Criswell, R.A. Mueller, and G.R. Breese. Biological Sciences Research Center, University of North Carolina School of Medicine, Chapel Hill, NC 27514.

Recent work on several fronts has demonstrated that drugs which act on the dopaminergic system can produce sensitization or "reverse tolerance". We examined the effects of repeated administration of the specific D_1- dopamine agonist SKF-38393 in rats lesioned with 6-hydroxydopamine (6-OHDA) either as neonates or as adults. Neonatal-6-OHDA lesions are known to sensitize the animals to D_1-dopamine agonists while adult lesions primarily sensitize animals to D_2-dopamine agonists. Repeated doses of the D_1-dopamine agonist to adult rats which received 6-OHDA lesions as neonates produced a progressive increase in locomotion and several other behaviors following repeated administration of the dopamine agonist at 4 day intervals. Sensitization was still present 90 days after the last administration. Rats which received lesions as adults did not show the progressive increase in locomotor behavior following repeated administration of SKF-38393. Neonatally lesioned rats given repeated doses of SKF-38393 also showed sensitization to the locomotor effects of the adenosine antagonist theophylline and the cholinergic antagonist scopolamine. These two drugs produce increased locomotor activity in neonatally lesioned rats via a mechanism which can be blocked by pretreatment with alpha-methyltyrosine suggesting that it is mediated by catecholamine-containing neurons. Specific sensitization of D_1-dopamine receptors by repeated stimulation may underlie the reverse tolerance and appearance of new symptoms which follow chronic administration of dopamine agonists or drugs which indirectly activate the dopaminergic system. Supported by NS-21355 and HD-03110.

126.17 EFFECTS OF THE D1 AND D2 ANTAGONISTS, SCH 23390 AND SULPIRIDE, ON ORAL MOVEMENTS IN RATS. Edward D. Levin, Ronald E. See, Per Johansson*, David South*, Lars Gunne* and Gaylord D. Ellison Department of Psychology, University of California, Los Angeles, CA 90024.

Two experiments were performed to investigate the actions of the dopamine D1 receptor blocker, SCH 23390, and the D2 receptor blocker, sulpiride, on oral movement in rats. The oral movements were quantified by a human observer and a computerized video analysis system. The first experiment was a dose-response study of the effects of these two drugs (SCH 23390, 0.01-0.25 mg/kg and sulpiride, 4-100 mg/kg) on spontaneous chewing and head movement. Sulpiride was the more effective of the two drugs in decreasing chewing, while SCH 23390 was more effective in decreasing head movement. The low doses of both drugs increased the duration of head movement. The computerized analysis of the slope of movements showed that both drugs decreased the slope of very tiny movements but that only sulpiride decreased the slopes of larger movements.

In the second experiment, the actions of these two drugs were studied in relation to their abilities to block the effects of selective D1 (SKF 38393) and D2 (LY 171555) agonists. The two antagonists had similar effects in relation to the D1 agonist, SKF 38393. Both SCH 23390 (0.25 mg/kg) and sulpiride (100 mg/kg) were effective in eliminating the increases in computer-scored movement induced by SKF 38393 (3 mg/kg). Both drugs were also effective in eliminating the increase in movement slope caused by SKF 38393. In relation to the D2 agonist LY 171555, the two antagonists had differential effects. Sulpiride attenuated the decrease in chewing movement caused by administration of the D2 agonist, LY 171555 (0.1 mg/kg), while SCH 23390 exacerbated it. This differential effect was also seen with computer-scored movements. The increase in oral movement induced by the D1 agonist, SKF 38393, can be reversed by either a D1 or a D2 antagonist, while the decrease in oral movement induced by the D2 agonist, LY 171555, can be reversed by a D2 antagonist but is exacerbated by a D1 antagonist.

126.18 LOCOMOTOR ACTIVITY STUDIES ON D1 AND D2 DOPAMINE RECEPTOR STIMULATION. W.E.Montana and K.E.Asin, Abbott Labs, Dept. 47U, Bldg. AP10, Abbott Park, Il. 60064.

The characterization of D1 and D2 dopamine (DA) receptors has led to a number of investigations on the behavioral functions of these two receptor subtypes. Although neurologically intact animals show relatively few behavioral changes in response to D1 receptor agonists, the DA depleted or denervated rat demonstrates hyperactivity following D1 receptor stimulation. We undertook the following studies to investigate and compare more closely the effects of D1 and D2 DA receptor drugs on locomotor activity in the intact and DA depleted rat. We also examined possible suppressant actions of D1/D2 agonists by studying the effects of D1 and D2 DA drugs on drug-induced hyperactivity.

Adult, male rats were treated with 1mg/kg reserpine (RES) or vehicle (V) for 5 days. Ninety minutes after the last injection rats (N=8-20) were injected with the D2 antagonist haloperidol (H)(.06-.25 mg/kg), the D1 antagonist SCH23390 (SCH) (.05 & .20mg/kg) or with V and placed into locomotor activity cages (tilt boxes) for 40min. Rats were then injected with either V, the D2 agonist LY171555 (LY)(.15-.30mg/kg,sc) and/or the D1 agonist SKF38393 (SKF)(1.25-20mg/kg). Following the agonist injections locomotor activity (LA) was measured for 150 min.

As expected, SKF produced increases in activity only in reserpinized rats; in contrast, increases in LA following LY were similar for the V and RES groups. The activity in response to LY was more potently blocked by H than by SCH in reserpinized rats, and SKF-induced LA in DA depleted rats was more potently blocked by SCH. Injections of SKF and LY at dosages which produced no or only minimal effects on LA on their own led to a robust increase in LA in RES but not V treated rats when administered simultaneously. In contrast, the actions of LY + another D2 agonist, pergolide (5ug/kg), did not appear to be synergistic. Thus, a "supersensitive" LA response in RES rats was only observed after injections of SKF, either alone or in combination with LY. Injections of H or SCH prior to LY+SKF reduced LA in a dose-dependent fashion, although H was more potent. These studies provide additional evidence for interactions between the two DA receptor subtypes in the chronically DA depleted animal.

Finally, we examined possible suppressant actions (as with apomorphine) of selective D1 and D2 agonists. Following a 40min habituation period rats were injected with either V, 2 mg/kg scopolamine HBr (S) or 12 mg/kg caffeine (C), plus LY or SKF. Injections of either the D1 or D2 DA receptor agonist reduced both S and C hyperactivity; lower doses tended to reduce the LA more potently than higher doses. These studies demonstrate locomotor suppressant actions of both selective D1 & D2 agonists.

126.19 EFFECT OF 3-PHENYL-1-ALKYLPYRROLIDINES ON LOCOMOTOR ACTIVITY IN THE RAT. S.C. Sylvestri*, A.M. Crider, and R.M. Dick. (SPON: W.M. Bourn) Division of Pharmacology and Toxicology, School of Pharmacy, Northeast Louisiana University, Monroe, LA 71209.

The 3-phenyl-1-alkylpyrrolidines (3-PAP) are chemical analogs of the neurotransmitter dopamine. Four recently synthesized 3-PAP derivatives were examined for their potential effects on locomotor activity in the rat. The compounds examined included: 3-(3,4-dihydroxyphenyl)-1-n-propylpyrrolidine hydrobromide (Cmpd. 1), 3-(3,4-dihydroxyphenyl)1-i-propylpyrrolidine hydrobromide (Cmpd. 2), Trans-3-(3,4-dihydroxyphenyl)-4-methyl-1-n-propylpyrrolidine hydrobromide (Cmpd. 3), and Trans-3-(3-hydroxyphenyl)-4-methyl-1-n-propylpyrrolidine (Cmpd.4). Previous work by others (Crider, et al., 1984, J. Pharm. Sci. 73:1585-1587) has shown that Cmpd. 1 acts as an effective dopaminergic agonist, demonstrating increased locomotor activity. The current investigation supports their findings. However, of the other compounds examined, only Cmpd. 4 showed a significant increase in locomotor activity when compared to controls. Of the remaining two compounds, Cmpd 2 demonstrated a strong trend towards decreasing locomotor activity and Cmpd. 3 had little if any effect.

127.1 ELECTRICAL STIMULATION OF THE LATERAL HYPOTHALAMIC FEAR/FLIGHT SITES IN RATS PRODUCES CONDITIONAL FREEZING. D.S. Sacks* and J. Panksepp. Dept. of Psych., Bowling Green State University, Bowling Green, OH 43403

Electrical stimulation of the anterior lateral hypothalamus (LH) produces behaviors indicative of underlying emotional states (Behav. Brain Sci. 1982, 5:407). Behaviors associated with stimulation-induced "fear" involve species-typical defensive postures coupled with vigorous escape behaviors. Whether the animal is experiencing a true affective state during such stimulation is not known. This study examined whether conditional freezing would develop to the contextual cues in which "fear" inducing brain stimulation was applied.

12 Long-Evans rats were implantated with bipolar electrodes (-1.0 from bregma, 1.2 lateral, 8.0 ventral). After 2 weeks recovery, each animal underwent 4 days of habituation to the experimental chamber. On the fifth day, the animals in the stimulation group underwent a baseline phase consisting of 5 one-minute observation periods measuring the number of freezing bouts and the time per minute that the animal was immobile. The stimulation phase, consisted of 5 successive 10 sec. periods of LH stimulation (18 to 30μA,sine wave), each separated by a 1 minute observation period. The post-stimulation phase consisted of 5 one-minute observation periods without brain stimulation. This regimen continued for a total of four days. The control group underwent the same procedure but received no electrical stimulation.

Electrical stimulation reliably increased the amount of freezing exhibited by the animals in the stimulation group during the post-stimulation phase of each of the four days of observation. The stimulation group had a mean number of 10.02 freezing bouts across the four days while the control group had .04 freezing bouts ($F(3,40)=10.61$, $p<.0001$). The stimulation group had a mean freezing time of 16.9 sec. across the four days while the control group had a mean time of .1 sec. ($F(3,40)=3.92$, $p<.02$). An increase in the number of freezing bouts during the baseline (pre-stimulation) phase of each of the last 3 days was indicative of conditioning to the experimental chamber. In the stimulation group, the mean number of post-stimulation freezing bouts increased from .4 bouts on the first day to 5.2 to 7.2 and 7.4 on the subsequent 3 days ($F(3,40)=23.041$, $p<.00001$). The stimulation also increased the mean amount of time per period the animal spent freezing. This increase was from 1.3 sec. on the first day to 6.3 to 13.9 and 12.6 on subsequent days ($F(3,40)=9.45$, $p<.00001$).

These results support the claim that electrical stimulation of the LH produces an affective state that induces conditional species typical defensive behaviors, as well as producing an externally referred aversive state that can become connected to environmental cues. We believe this aversive state is reasonably called "fear".

127.2 PRO- AND ANTI-PANIC TREATMENTS AND MEASURES OF ANXIETY IN THE RAT. A. L. Johnston* and S. E. File (SPON: W. A. Friedman) Dept. Pharmacology, The School of Pharmacy, Univ. London, London WC1N 1AX.

Agents useful clinically in the treatment of panic attacks and agents reported to selectively induce panic or anxiety in panic disorder patients were studied in two tests of anxiety: the social interaction test (File, S. E., J. Neurosci. Meths., 2: 219-238, 1980) and the elevated plus-maze (Pellow, S. et al, J. Neurosci. Meths., 14: 149-167, 1985). Anxiolytic drugs increase time spent in social interaction and in the plus-maze they increase the % of entries made onto the open arms and the % of time spent on the open arms; anxiogenic drugs do the reverse.

The anti-panic agents were: the triazolobenzodiazepines (adinazolam 2 & 5 mg/kg, alprazolam 1 & 2 mg/kg, U-43,465 16 & 32 mg/kg), imipramine (5 & 15 mg/kg) and phenelzine (9 & 18 mg/kg). Rats received 5 days pre-treatment with the triazolobenzodiazepines; only adinazolam (5 mg/kg) significantly increased time spent in social interaction and only alprazolam (1 & 2 mg/kg) significantly increased % time spent on the open arms in the plus-maze. Imipramine and phenelzine, tested after 21 days of pre-treatment, reduced the time spent in social interaction but were without effect in the plus-maze.

The pro-panic agents were: sodium lactate (60 & 120 mg/kg), isoproterenol (0.1-0.6 mg/kg) and yohimbine (1.25-5 mg/kg). Rats were also scored for panic-like behaviour following administration of these drugs and following CO_2 (5 & 20% in air). Sodium lactate, isoproterenol and yohimbine were without significant effect on the time spent in social interaction. Sodium lactate had no significant effects in the plus-maze but the highest dose of isoproterenol (0.6 mg/kg) reduced the % of time spent on the open arms and yohimbine (2.5 mg/kg) reduced both the % of entries made onto the open arms and the % of time spent on the open arms. None of the agents produced any behavioural indications of panic.

Our tests appear relatively insensitive to clinical pro- and anti-panic drugs. Effects were observed with the triazolobenzodiazepines and yohimbine (weak anxiolytic and anxiogenic profiles, respectively), however, these drugs are also known to have effects on anxiety levels in normal subjects.

127.3 INCREASED ANXIETY IN BENZODIAZEPINE WITHDRAWAL IS LINKED TO TOLERANCE TO ANXIOLYTIC EFFECTS. Helen A.Baldwin*,Kari Aranko* and Sandra E.File. MRC Neuropharmacology Research Group, The School of Pharmacy, Brunswick Square, London WC1N 1AX. Dept Pharmacology & Toxicology, University of Helsinki.

In a recent paper, (Lader M. and File S.E., Psychol Med, 1987) it was proposed that tolerance and withdrawal were both manifestations of a common mechanism of benzodiazepine dependence. In order to test this hypothesis rats were chronically treated with chlordiazepoxide (CDP) for 5 or 20 days and then tested for tolerance to the anxiolytic effects of a probe dose of CDP (5 mg/kg) in two animal tests of anxiety. Two days after the tests for tolerance the same animals were tested for withdrawal responses, 24-hours after the last dose of CDP.

In the social interaction test, after 5 days of pretreatment with CDP (5 mg/kg/day), there was a significant increase in the time spent in social interaction compared with control in rats tested with the probe dose of CDP. In the elevated plus-maze test, after 5 days of pretreatment with CDP (5 or 20 mg/kg/day), there were significant increases in the number of entries onto, and the time spent on, the open arms, in rats tested after the probe dose of CDP. Thus after 5 days of pretreatment there was no tolerance to CDP's anxiolytic effects. There were no indications of spontaneous withdrawal when the rats were tested, undrugged, for withdrawal responses.

After 20 days of pretreatment there was significant tolerance to the anxiolytic effects of CDP in both tests. There was a decrease in the time spent in social interaction ($p<0.10$) when the rats were tested, undrugged, for withdrawal responses. Similarly in the elevated plus-maze, there were significant decreases in the number of entries onto, and the time spent on, the open arms, by these rats.

In summary, after 5 days of chronic treatment there was no tolerance to the anxiolytic effects of CDP in either test and no indication of spontaneous withdrawal in these rats. However after 20 days of pretreatment there was tolerance to the anxiolytic effects of CDP and evidence for spontaneous withdrawal in both tests.

127.4 EFFECTS OF ANTIPSYCHOTIC DRUGS ON ISOLATION INDUCED INTRASPECIES AGGRESSION BY MALE MICE: A SCREEN FOR ANXIOLYTIC DRUGS. B. A. McMillen, A. H. Song* and E. A. DaVanzo*, Dept. of Pharmacology, School of Medicine, East Carolina U., Greenville, NC 27858.

Inhibition of intraspecies aggression is a sensitive behavioral model for screening potential anxiolytic drugs [1,2]. Several different aryl-piperazine antianxiety drugs potently inhibit aggressive behavior (e.g. buspirone ED50 = 3.5 mg/kg), but are weak or ineffective in other behavioral anxiolytic screens. However, classical antipsychotic drugs are known to be active in this screen [3], which may limit its usefulness. The following experiments were performed to test whether drugs that inhibit dopamine (DA) receptors have antiaggressive activity other than that secondary to akinesia induced by striatal DA receptor blockade.

Male mice (15-18 g) were housed in isolation for 3 weeks and then trained to attack an intruder (group housed) mouse. Only those mice consistently making a sustained attack within 60 sec were used for drug testing. Mice were re-tested 30 min after i.p. injection of drugs or vehicle and 180 sec used as criterion for no attack. Mice were observed for orienting movements and signs of sedation. Additional mice were tested on a rotorod for akinetic effects of drugs. Drugs tested were: haloperidol, sulpiride, SCH 23390, Ro 22-1319, BW 234U, BMY 14802 and (-)-3-PPP. Haloperidol at 1.0 mg/kg had marked akinetic effects, but only 3 of 8 mice were inhibited from attack. (-)-Sulpiride or RO 22-1319 had similar effects at 30 or 3.0 mg/kg, respectively, but the other drugs were ineffective except in large doses. Only BMY 14802 or BW 234U could inhibit aggression at large doses without inducing major motor dyskinesias, but neither of these 2 drugs bind to DA receptors. These data suggest that classical antipsychotic drugs inhibit aggression secondary to induction of akinesia: i.e. a rigid mouse cannot fight. SCH 23390, a D_1 preferring antagonist (in doses less than 0.5 mg/kg), does not inhibit aggression or motor activity in the low dose range. This result suggests that inhibition of D_1 receptors is without anti-aggressive activity. Thus, once the akinetic effects of drugs are accounted for, neuroleptics do not interact in the intraspecies aggression model for screening of antianxiety drugs. These results, combined with previous data which indicate that aryl-piperazines are potent inhibitors of intraspecies aggression, suggest that this animal model is useful for studying the effects of novel anxiolytic drugs.

127.5 REVERSAL OF NEUROLEPTIC INDUCED CATALEPSY BY NOVEL ARYL-PIPERAZINE ANXIOLYTIC DRUGS. S. M. Scott*, E. A. DaVanzo* and B. A. McMillen (Spon. R. B. Graham), Dept. of Pharmacology, School of Medicine, East Carolina University, Greenville, NC 27858.

Buspirone and gepirone, aryl-piperazine anxiolytic drugs, reverse catalepsy induced either by dopamine (DA) receptor blockade or DA depletion (J Neural Trans 57:255 1983) by an unknown mechanism. Both drugs are agonists at 5-hydroxytryptamine (5HT)1a pre- and postsynaptic receptors, which may relate to the antiaggressive (or anxiolytic) effect of these drugs (N-S Arch Pharmacol 335: in press). To determine whether a 5HT action is involved in catalepsy reversal, aryl-piperazine drugs (and other 5HT agonists) and 5HT antagonists were tested for interactions with haloperidol-induced catalepsy assessed on a 4 point scale.

Ipsapirone and 8OH-DPAT reversed haloperidol (1.0 mg/kg s.c.) induced catalepsy. Simple aryl-piperazines, m-Cl-phenylpiperazine (mCPP) and trifluoromethylphenylpiperazine (TFMPP) were ineffective. Antagonists of 5HT receptors, methysergide or methiothepin, are known to potentiate the antiaggressive effect of gepirone or DPAT, but neither inhibited nor potentiated either drug. The beta-adrenoceptor antagonists, propranolol and pindolol, which have 5HT1a antagonist activity did not alter 8OH-DPAT reversal of haloperidol induced catalepsy. Fluprazine, an aryl-piperazine with low affinity for 5HT receptors, did not reverse catalepsy. The results demonstrate that DPAT and alkyl-substituted aryl-piperazine drugs reverse catalepsy in proportion to affinity for 5HT1a receptor binding in hippocampus (Table 1).

	Relative Potency*	IC50 [3H]-5HT nM
8OH-DPAT	0.11	1
gepirone	0.57	58
buspirone	1.0	10
ipsapirone	3.9	20
BMY 14802	13.5	170
fluprazine	no effect	1,429
TFMPP	no effect	100
mCPP	no effect	177

*compared to buspirone = 1.0

Although these data point to the 5HT1a site as the site for catalepsy reversal (either pre- or postsynaptic receptors), the inability of antagonists to interact suggests that another site may be involved. Additional rats had 25 mg/kg s.c. morphine injected to induce a different form of rigid posturing, which is presumably mediated by opiate receptors outside the corpus striatum. Neither buspirone nor gepirone could alter morphine-induced rigidity: thus, their effect on the rat extrapyramidal system did not interact with opiate induced rigidity.

127.6 **THE EFFECTS OF BUSPIRONE AND DIAZEPAM ON RAT CORTICOSTERONE LEVELS.** G. K. Matheson, D. Gage, G. White, V. Dixon & D.Gipson. Neurobiology Laboratory. Indiana University School of Medicine. Evansville, IN 47714

The effects of the anxiolytic agents buspirone and diazepam on the hypothalamic-pituitary-adrenal axis (HPAA) were studied. The HPAA effects were indicated by changes in plasma corticosterone (CS) concentrations obtained from trunk blood. CS levels were measured fluorometrically. The rats were maintained in a temperature and humidity controlled environment. The room lights were on from 0600 - 1800 hours. Both drugs were administered in normal saline. Plasma CS levels were measured 1/2, 1, 2, and 4 hours after drug administration (i.p.). The anxiolytic effects on the HPAA were studied in the mid-morning (0930-1130 hrs) when activity in the HPAA is normally low and in the afternoon (1400-1600 hrs) when the HPAA activity is high. Control levels of CS were measured at 11.5 ± 1.6 S.E. µg/dl (22) during the morning and 20.9 ± 1.2 µg/dl (28) in the afternoon. Animals subjected to a stress, i.e. angular rotation produced by spinning the rat at 30-60 rpm for one minute, 15 minutes before decapitation had morning stress control levels of CS 297% (45.6 ± 2.2 [26]) over unstressed controls. Afternoon stress control levels were increased by 138% to 49.7 ± 2.3 mg/kg (31). At high doses (10 mg/kg) both drugs produced effects that were measurable for at least one hour. The data in table 1 represents the combined 1/2 and 1 hour values. Buspirone had a greater facilitating effect on the HPAA than did diazepam (table 1). In addition, buspirone had a higher maximum effect on CS levels (477% increase after 50 mg/kg) than diazepam (288%). However, they are equipotent since the ED_{50} for buspirone was calculated to be 3.6 mg/kg (8.6 mmol/kg) and for diazepam it is 2.5 mg/kg (8.7 mmol/kg). From the stress data one sees that stress effects and buspirone actions on the HPAA were additive at the higher doses, while stress and diazepam effects were not additive.

Table 1. Percent change in plasma corticosterone levels.

Drug		Buspirone		Diazepam	
Dose (mg/kg)		1	10	1	10
Unstressed	AM	75*	328*	12	265*
Unstressed	PM	-5	166*	14	80*
Stressed	AM	10	20*	13	3
Stressed	PM	5	22*	2	2

127.7 TOLERANCE AND WITHDRAWAL TO THE ANTI-CONFLICT PROPERTIES OF DIAZEPAM FOLLOWING CHRONIC ADMINISTRATION IN RATS. R. S. Rock* and R. J. Barrett* (SPON: M. A. Blackshear). Dept. of Psychology Vanderbilt Univ. and VA Medical Center, Nashville, TN 37203

Although recent clinical evidence indicates that both tolerance and withdrawal occur to the anxiolytic properties of benzodiazepines following chronic administration, animal studies using the Geller and Seifter conflict paradigm have reported either no change or enhanced anti-conflict effects during long term administration. Using a modification of the Geller and Seifter paradigm, the present study further investigated this apparent discrepancy.

Two groups of rats (n=8) were trained to respond on a VI=2' schedule during 30 min test sessions. After stable VI responding, the conflict component was added. This consisted of three 2 min periods, signaled by a 70 db, 1000 cps tone, during which every response produced both food reinforcement and shock. The shock intensity started at .05 mA (0.5 sec duration for all shocks) and increased by .05 mA after every other response made during a tone presentation. The two matched groups were then administered either saline or diazepam (2.5 mg/kg) 30 min prior to testing for 9 consecutive days. On the 10th day no injections were given to animals in either group. On the 11th day both groups were injected with 2.5 mg/kg diazepam prior to testing.

The results showed that intially, diazepam significantly increased responding during the conflict period, but by the 8th day tolerance had developed to these anti-conflict properties. When both groups were tested without drug on the 10th day, the diazepam animals showed a significant increase in conflict, i.e. reduced responding during the tone period. On the 11th day when both groups were injected with diazepam, the chronic saline animals made more conflict period responses than the chronic diazepam animals, but when compared to the previous day's baseline the drug produced comparable changes in both groups.

The results show that tolerance develops to the anti-conflict properties of diazepam following chronic administration. Furthermore, the increased conflict observed following drug termination suggests a withdrawal state analogous to the rebound increase in anxiety observed in humans following discontinuation of benzodiazepine use.

127.8 THE BENZODIAZEPINE RECEPTOR AND HABITUATION. D.H. Aitken*, S.R. Bodnoff, B. Suranyi-Cadotte, R. Quirion, and M.J. Meaney (SPON: S. Young). Douglas Hospital Research Center, Dept. of Psychiatry, McGill Univ., Montreal, Canada, H4H 1R3.

Diazepam is effective in reducing the latency of food-deprived animals to begin eating in a novel environment. Another, non-pharmacological method of reducing fear of novelty is to repeatedly expose animals to the novel environment; animals habituate to the cues associated with novelty and no longer manifest fear. In this sense, the effects of diazepam mimic the process of habituation. Thus, we examined the possible role for the benzodiazepine receptor (BZR) in habituation learning.

Adult, male Long Evans rats were exposed to large plexiglas cages covered with beta chips and 12 evenly-spaced food pellets, for 0 or 4 days. Animals were food-deprived for 48 h and 1 h prior to testing, half of the animals in the 4-day pre-exposure group received a single i.p. injection of the anxiogenic beta-carboline FG-7142 (10 mg/kg). Pre-exposure to the testing apparatus significantly reduced the latency for animals to begin eating relative to controls. FG-7142, completely reversed the effects of habituation. In a second experiment, animals were exposed to the testing apparatus for 0,1,4, or 7 days. Half of the Day 7 animals received a single i.p. injection of the BZR antagonist, Ro15-1788 (20 mg/kg) prior to testing. A final group of non-preexposed animals received a single i.p. dose of diazepam (2 mg/kg). Both 4 and 7, but not 1, day of exposure produced latencies to begin eating that were significantly different from controls, but not from diazepam-treated animals. A single dose of Ro15-1788 was able to completely reverse the anxiolytic property of 7 days of pre-exposure to the test environment. In a separate series of experiments we examined [3H]flunitrazepam binding in post-natally handled (H) and non-handled (NH) rats who differ in their response to novelty. H animals exhibited significantly shorter latencies to begin eating in a novel environment and greater [3H]flunitrazepam binding than did NH animals. Taken together, these data indicate that the BZR plays an integral role in the anxiolytic property of habituation learning and mediate individual differences in response to novelty.

127.9 **BEHAVIORAL WITHDRAWAL FROM CHRONIC ORAL EXPOSURE TO MIDAZOLAM.** **J. TIZZANO, M. HUGGINS*, P. HOPKINS*, J. YARBOUROUGH* AND M. KALLAM. TOXICOLOGY DIVISION, LILLY REASEARCH LABS, GREENFIELD, IN 46140 AND DEPARTMENTS OF PSYCHOLOGY AND PHARMACOLOGY, UNIVERSITY OF MISSISSIPPI, UNIVERSITY, MISSISSIPPI 38677.**

The CNS depressant effects of acutely administered benzodiazepines are well documented (Greenblatt and Shader, 1974), but tolerance to these effects develops rapidly. The benzodiazepines share common pharmacological properties, but differ with regard to various kinetic parameters. Midazolam (MZ) has a pharmacological potency similar to diazepam (DZ) and a broad therapeutic range. However, MZ has a rapid onset of activity and due to rapid metabolic inactivation, a short duration of action. The pharmacokinetics of DZ consists of a rapid absorption followed by distribution and a slow elimination. The present study examined the acute, chronic and withdrawal effects of DZ and MZ on schedule controlled behavior. Sixteen male rats were trained to lever press for sweetened condensed milk on a differential reinforcement of low rates (DRL)-20 schedule. After response rates on the DRL schedule stabilized, animals were randomly assigned to either a DZ or MZ condition (n=8). Initial dose effect data were determined for DZ and MZ (0.0, 1.0, 3.0, 10.0 and 17.5 mg/kg IP.). Animals were then treated with MZ (100 mg/kg/day) in their drinking water for 21 days. Following the period of chronic drug exposure, dose effect functions were redetermined. To investigate the withdrawal effects of MZ, the drug solution was removed and the animals were tested for 10 days on the DRL schedule. Response rate and duration of response were collected via laboratory computer system. The acute effects of DZ and MZ produced a dose dependent decrease in response rate and a dose dependent increase in response duration. When dose effect functions for DZ and MZ were redetermined after 21 days of chronic exposure to midazolam, tolerance was not observed for either drug on the rate measure. However, a non-parallel shift to the right of the dose response curve was obtined with the duration measure indicating the development of tolerance. When midazolam was withdrawn from the drinking water, there was an increase in response rate and a decrease in response duration which began on the first day of withdraval and continued until the fifth day. Eventually response rates and response duration returned to control levels seen before MZ was introduced into the drinking water. These findings suggest that multiple behavioral measures are important in assessing the degree of tolerance obtained with DZ and MZ.

127.10 EFFECTS OF ANXIOLYTIC AGENTS ON CONFLICT BEHAVIOR IN ANIMALS WITH SEPTAL OR AMYGDALOID LESIONS. E. Yadin, E. Thomas, and C.E. Strickland*. Department of Psychology, Bryn Mawr College, Bryn Mawr, PA 19010.

Rats were trained on a drinking conflict test in which unpunished and punished periods were alternately presented. The number of licks was recorded during each time segment which was 2 min long and repeated twice, for a total session time of 8 min. The punished period was signaled by a tone, during which a mild shock (0.2-0.3 ma, 1 sec duration) was delivered to the floor grids after every fifth lick. Animals were pretrained to a stable baseline of suppression of water-licking during the punished period and then were subjected to bilateral electrolytic lesions of the septum, the amygdala, or sham lesions. Beginning at 5 days post-lesion, animals were retested in the conflict paradigm, during 12 consecutive sessions. They were then tested on the conflict test after having been intraperitoneally injected with vehicle, chlordiazepoxide (10 mg/kg, 20 mg/kg), or buspirone (2 mg/kg).

Animals with amygdaloid lesions showed a strong release of the suppression during the signaled, punished period, an effect that diminished over successive sessions. Neither septal- nor sham-lesioned animals showed such a release of the punished response. Both doses of chlordiazepoxide produced a large increase in drinking during the punished period in the amygdala-lesioned animals while neither dose released punished behavior in the septal-lesioned animals. Only the higher dose produced a release of the punished response in the sham animals. Animals in both lesion groups showed suppressed drinking during the unpunished time period and no release in the punished segment after injection of 2mg/kg of the nonbenzodiazepine agent buspirone.

The results would appear to argue against a role for the amygdala as a primary site of action for the anxiolytic activity of benzodiazepines. The combination of release from punishment as a result of amygdaloid lesions and the enhancement of the drug effect in amygdala-lesioned animals is consistent with an interpretation that amygdala lesions remove an inhibitory influence upon a structure which is involved in the active inhibition of fear. The septum might be such a structure. The fact that we observed a diminution of the anxiolytic effects in septally lesioned animals is consistent with such a proposed role for the septum.

127.11 BEHAVIORAL AND NEUROCHEMICAL EVIDENCE FOR SEROTONERGIC MODULATION BY THE ANXIOGENIC β-CARBOLINE FG 7142. N.J. LEIDENHEIMER, B.K. YAMAMOTO AND M.D. SCHECHTER. Dept. of Pharmacology, Northeastern Ohio Universities Coll. of Med., Rootstown, Ohio 44272

FG 7142 (β-carboline-3-carboxylic acid methyl amide) is a β-carboline which binds with high affinity to the benzodiazepine receptor. It has been classified as an inverse agonist at this receptor due to its ability to produce anxiety in several species including man. The present behavioral and neurochemical study sought to investigate the possible serotonergic modulation by FG 7142.

Eight male rats were trained to discriminate between the stimulus effects of FG 7142 (5.0 mg/kg, i.p.) and its vehicle. Testing of various doses of FG 7142, i.e., 5.0, 2.5 and 1.25 mg/kg, produced 100, 78.6 and 42.9% FG 7142-appropriate responding, respectively, and yielded an ED50 of 1.41 mg/kg. Test doses of the serotonergically-active drug tetrahydro-β-carboline (THBC) at 15.0, 10.0 and 5.0 mg/kg produced 92.9, 75.0 and 43.8% FG 7142-appropriate responding.

A separate group of ten male rats were administered either FG 7142 (30 mg/kg) or its vehicle and decapitated thirty minutes later. Their brains were rapidly removed, frozen and hippocampi dissected out. Hippocampal tissue was analyzed for serotonin (5-HT) and 5-hydroxyindoleacetic acid (5HIAA) content by HPLC with electrochemical detection. Tissue indoles are expressed as ng/mg protein (± SEM).

	Vehicle	FG 7142
5-HT	0.74(.06)	1.06(.14)*
5HIAA	1.35(.05)	1.67(.18)

*Significantly different from vehicle, $p<0.05$.

In the present study the discriminative stimulus produced by FG 7142 generalized to THBC. It is unlikely that this generalization to THBC is mediated via the benzodiazepine receptor since THBC shows little affinity for this receptor. Since THBC has been shown to increase 5-HT transmission and FG 7142, as shown here, increases hippocampal levels of 5-HT, it is possible that the similarities of the FG 7142 and THBC cues are based on their abilities to enhance 5-HT transmission.

127.12 **RAUBASINE, A NON-BENZODIAZEPINE COMPOUND WITH ANXIOLYTIC PROFILE .** B Delbarre, G.Delbarre and F.Calinon*.Faculté de Médecine, 37000 Tours, FRANCE.

The efficiency of BZD is established in four distinct behavioural effects : anticonvulsivant, muscle relaxant, anxiolytic and sedative-hypnotic properties. Recently the various actions of BZD have highlighted the role of noradrenergic mechanisms.To elucidate the role of noradrenergic system we have compared on the classical test for BZD, clonidine an alpha-2 presynaptic agent and raubasine an alpha-1 blocking agent which interacts directly at BZD sites.

To test the role of adrenoceptor in the sedative activity of BZD we have used the sleeping time in chicken: sedative effect of clonidine (0.750 mg.kg-1), diazepam (3mg.kg-1), chlordemethyldiazepam (CDD) (4mg.kg-1) and alprazolam (0.750 mg.kg-1) are antagonized by rauwolscine and not by raubasine. Similarly, in the wire test used to test myorelaxant activity of BZD, rauwolscine (0.1 to 0.5 mg.kg-1) antagonizes effect of diazepam, CDD, alprazolam and clonidine. Raubasine (5-10 mg .kg-1) is ineffective alone or to prevent sedative activity of clonidine or BZD. Most of the clinically used BZD display some degree of anticonvulsivant activity . Furthermore, the relative potencies of various benzodiazepines in protecting mice against PTZ-induced seizures correlate well with their relative clinical potencies as anxiolytics. On this test raubasine (5-10 mg.kg-1) but not clonidine (0,2 - 3 mg.kg-1) antagonizes PTZ-induced seizures. In mice, convulsive properties of harmane and yohimbine potent endogenous inhibitors of BZD receptor binding, are antagonized by diazepam (1 mg.kg-1), CDD (1 mg.kg-1) alprazolam (0,150 - 0,30 mg.kg-1) and by raubasine (5 to 10 mg.kg-1) wich interacts directly at BZD sites. Clonidine (3 mg.kg-1) is ineffective.These results may support the hypothesis that harmane and yohimbine specifically act at the BZD receptor. On this test, BZD act at very small doses.

Sedative and myorelaxant activities of BZD and clonidine antagonized by rauwolscine, a presynaptic alpha-2 receptor blocker, may be explained by an action of BZD on alpha-2 presynaptic adrenoreceptor. Convulsive activity of PTZ , which correlates well relative clinical potency of drug as anxiolytic, is antagonized by raubasine and BZD but not by clonidine. Moreover, convulsive activity of yohimbine and harmane with anxiety like effect in humans and animals are antagonized by small doses of BZD and by raubasine but not by clonidine.

In conclusion, sedative and myorelaxant activity of BZD may be explained by an interaction with alpha-2 receptors and anxiolytic activity with alpha-1 adrenoceptors.

127.13 **IS THE 5-HT$_{1A}$ AGONIST, 8-OH-DPAT, AN ANXIOLYTIC?** D. N. Johnson, R. T. Ruckart*, B. F. Kilpatrick, J. H. Porter, H. F. Villanueva*. A. H. Robins Co., Research and Development Division, and Virginia Commonwealth University, Richmond, VA 23261-6609.

Although GABA is involved in the mechanism of action of the benzodiazepines, the newer nonbenzodiazepine anxiolytics (buspirone, ipsapirone) have been proposed to act via a serotonergic (5-HT$_{1A}$) mechanism. Buspirone and ipsapirone are potent partial 5-HT$_{1A}$ agonists: RU-24969, a potent 5-HT$_{1B}$ agonist, does not have anxiolytic activity.

Recently, 8-OH-DPAT (8-hydroxy-2[di-n-propylamino]tetralin) has been reported to be a potent and selective 5-HT$_{1A}$ agonist (Gozlan et al., Nature 305:140, 1983). This study was undertaken to determine if 8-OH-DPAT possessed anxiolytic activity as determined by standard in vivo and in vitro anxiolytic testing procedures.

8-OH-DPAT affected serotonergic systems in displacement studies in vitro, with IC$_{50}$ values of 1.2 nM for 5-HT$_{1A}$ and 1,600 nM for 5-HT$_2$ receptors. It was inactive (>10,000 nM) against D_2, H_1, α_1, GABA$_A$, and BZD receptors. In whole animal studies, 8-OH-DPAT was a potent serotonergic agent, producing signs of neurotoxicity (serotonin syndrome) in rats in doses as low as 1 mg/kg, IP. As has been reported, 8-OH-DPAT is not as potent in mice, requiring approximately 10 mg/kg to produce a similar effect. Anticonvulsant properties of 8-OH-DPAT were determined in mice against clonic convulsions induced by pentylenetetrazol (80 mg/kg, SC) and against tonic seizures induced by maximal corneal electroshock (34 mA, 60 Hz, 2 msec pulse width for 200 msec). Unlike the benzodiazepines, but like buspirone, 8-OH-DPAT (up to 10 mg/kg, IP) was without anticonvulsant activity.

Anxiolytic testing in rats was assessed using the Vogel procedure (Vogel et al., Psychopharmacologia 21:1, 1971) and using the Geller and Seifter conflict test (Geller and Seifter, Psychopharmacologia 1: 482, 1960). In the Vogel procedure, 8-OH-DPAT was ineffective in increasing the number of shocks delivered to the rat in doses of 0.0625 to 1.0 mg/kg, IP. This is similar to the lack of effect of buspirone reported previously in the Vogel procedure (Porter and Johnson, Neuroscience Abs., 11:426,1985). However, when 8-OH-DPAT and buspirone were administered concomitantly, a significant increase in shocks delivered was seen.

In drug-experienced rats (Geller & Seifter conflict test), 8-OH-DPAT was more potent in producing the serotonin syndrome. Doses of 0.125 and 0.25 mg/kg, IP, produced the characteristic stereotypy and abolished, or significantly reduced, lever pressing for food reward during conflict and reward sessions. Still lower doses (0.0125 to 0.0625 mg/kg, IP) were without effect in altering response rates. Oral administration of 8-OH-DPAT (0.1 to 10 mg/kg) similarly failed to indicate any anxiolytic activity. Unlike the results in the Vogel procedure, concomitant administration of 8-OH-DPAT and buspirone did not result in an increase in punished responding in the conflict test.

Thus, in animal models, the 5-HT$_{1A}$ agonist, 8-OH-DPAT, does not show anxiolytic activity.

127.14 NEUROCHEMICAL PROPERTIES OF THE NOVEL ANXIOLYTIC ICI 190,622. B.A. Meiners, R.A. Keith*, V. Justice*, T. Bare*, and A.I. Salama. Department of Pharmacology, Stuart Pharmaceuticals, A Division of ICI Americas Inc., Wilmington, DE 19897.

ICI 190,622 (N-allyl-4-aminopyrazolo[3,4-b]pyridine-5-carboxamide) is a non-benzodiazepine which may have anxiolytic activity (see Patel et al., Neuroscience Abst., 1987). The present studies sought to characterize the interaction of ICI 190,622 with the GABA/benzodiazepine receptor complex and with other receptors. ICI 190,622 competitively inhibited [^{3}H]flunitrazepam (FLU) binding in cerebral cortex (CTX) with an IC$_{50}$ of 81 nM and was 4.3-fold more potent in the cerebellum (CB) (IC$_{50}$ = 19 nM). In contrast, diazepam (DZP) showed similar affinities in both regions (CTZ = 7 nM and CB = 9 nM). GABA caused a 1.2-fold increase in the affinity of ICI 190,622 for the benzodiazepine binding site (GABA shift), which was a typical effect with BZ agonists. However, the GABA shift of DZP was larger (1.6). Photoaffinity labeling receptors with FLU causes a decrease in affinity for agonists but not for antagonists (photo shift). As expected, there was a decrease in the affinity of ICI 190,622 (2.0-fold). Consistent with the GABA shift, photo-labeling caused a greater change in the affinity of DZP (34-fold). It has been reported that benzodiazepine agonists increase the binding of [^{3}H]GABA, and antagonists can block this effect (Meiners and Salama, Eur. J. Pharmacol. 119:61-65, 1985). ICI 190,622 (500 µM) enhanced GABA binding (30%), and this enhancement was blocked by the antagonists RO 15-1788 and ethyl-beta-carboline carboxylate. Ex vivo experiments were conducted to estimate the bioavailability and duration of ICI 190,622. Following oral administration, ICI 190,622 displaced [^{3}H]FLU from cerebellum more potently than DZP (ED$_{50}$ = 3 and 6 mg/kg, respectively, 1 hour after administration). Other ex vivo experiments suggested that the duration of action of ICI 190,622 and DZP were similar. In vivo, as well as in vitro, ICI 190,622 was more potent in cerebellum than in cortex. ICI 190,622 (10 mg/kg, 1 hour) did not alter the steady-state levels of norepinephrine, dopamine, 5-hydroxytryptamine or 5-hydroxyindoleacetic acid in whole brain as measured by HPLC with electrochemical detection. This may suggest that the compound and its metabolites are not monoamine oxidase inhibitors. At 10 µM, ICI 190,622 had no significant effects on the responses of alpha-1, alpha-2, beta-1, beta-2, histamine-1, histamine-2, 5HT-2, and muscarinic receptors as measured in a variety of isolated tissue preparations. In conclusion, ICI 190,622 is a potent agonist at the benzodiazepine receptor and in contrast to DZP is selective for the type 1 (cerebellar) benzodiazepine binding site both in vitro and in vivo. Finally, ICI 190,622 has little activity at sites other than the benzodiazepine binding site.

127.15 ICI 190,622: NEUROPHARMACOLOGICAL PROFILE OF A NOVEL POTENTIAL NON-BENZODIAZEPINE ANTIANXIETY AGENT. J.B. Patel and J.B. Malick. Stuart Pharmaceuticals, A Division of ICI Americas Inc., Wilmington, DE 19897.

ICI 190,622, a pyrazolopyridine carboxamide, demonstrated potent anxiolytic activity in rats, squirrel monkeys, and dogs. In the modified Vogel conflict test in rats, ICI 190,622 (MED = 0.8 mg/kg, p.o.) was at least five times as potent as diazepam (MED = 5.0 mg/kg, p.o.). The duration of anxiolytic activity of ICI 190,622 and diazepam was comparable in this test. In the squirrel monkey and beagle dog conflict tests, ICI 190,622 also exhibited an anxiolytic profile, and it was shown to be approximately one-half as potent as diazepam. Like benzodiazepines (BZP), tolerance did not develop to its anticonflict and anticonvulsant activities following 12 consecutive days of oral treatment. Furthermore, ICI 190,622 demonstrated potent activity as an antagonist of metrazole-induced (ED$_{50}$ = 1.0 mg/kg, p.o.) and bicuculline-induced (ED$_{50}$ = 1.4 mg/kg, p.o.) seizures in rats.

In rats, the sedative liability index (index = rotorod (ataxia) ED$_{50}$/anticonflict-MED) for diazepam is 2.0 whereas it was 31.4 for ICI 190,622; thus, ICI 190,622 should possess a wide safety margin in man. Unlike BZP, ICI 190,622's interaction with ethanol is significantly less pronounced compared to that of diazepam. Neurochemically, ICI 190,622 is a potent (Cortex-IC$_{50}$ = 81 nM and cerebellum IC$_{50}$ = 19 nM) displacer of ^{3}H-flunitrazepam from its binding sites in brain (Meiners et al., this meeting).

In summary, ICI 190,622 is a novel anxiolytic agent that offers significant advantages over BZP.

127.16 SM-3997: A NON-BENZODIAZEPINE ANXIOLYTIC WITH POTENT AND SELECTIVE EFFECTS ON SEROTONERGIC NEUROTRANSMISSION. J. Heym, E. E. Mena and P. A. Seymour, Central Research Division, Pfizer Inc., Groton, CT. 06340.

Buspirone is a clinically efficacious anxiolytic which does not act by a conventional benzodiazepine mechanism of action. In fact, buspirone appears to exert its most impressive effects by a direct action at brain serotonin receptors. However, in addition to its serotonergic actions, buspirone has been shown to possess moderate affinity for D2 dopamine receptors and to produce pronounced increases in forebrain levels of the dopamine metabolites HVA and DOPAC. Efforts to develop second generation agents of this type have focussed on compounds that retain the serotonergic properties of buspirone but reduce the dopaminergic effects.

SM-3997 [3aα, 4α ,5 ,7α, 7aα - hexahydro-2-(4-(4-(2-pyrimidinyl)-1-piperazinyl)-butyl)-4,7-methano-1H-isoindole-1,3-(2H)-dione] is one of a new group of non-benzodiazepine compounds which are characterized by potent and specific effects on brain serotonergic systems. This compound shows anticonflict activity in a modified Vogel paradigm with a minimal effective i.p. dose of 1 mg/kg. SM-3997 binds with high affinity to 5HT1A receptors (Ki = 30 nM) and possesses no substantial affinity (Ki > 1 µM) for 5HT1B, 5HT2, α adrenergic, D2 or benzodiazepine binding sites. Serotonergic neuron firing is potently inhibited by SM-3997 (ID50 = 4 µg/kg i.v.) indicating that it is a very good agonist for somatic 5HT autoreceptors located on serotonergic soma in the dorsal raphe nucleus. In contrast, the behavioral effects elicited in rats by the 5HT1A agonist 8-OH-DPAT are not fully reproduced by SM-3997 and pretreatment with 3.2 mg/kg s.c. of SM-3997 antagonizes the recipricol forepaw treading elicited by a subsequent 8-OH-DPAT challenge. Finally, in contrast to the large increases in dopamine metabolite levels produced by buspirone (200 - 300%), equivalent doses of SM-3997 have only a small effect on these biochemical measures.

These data support the contention that SM-3997 should possess anxiolytic efficacy without producing the side effects associated with benzodiazepine use. It is hypothesized that the anxiolytic profile of this compound stems from its action on serotonergic neurotransmission in the brain. The relatively weak dopaminergic effects of SM-3997 predict that clinical manifestations of altered dopamine function will not occur with this new drug.

127.17 THE EFFECTS OF CHLORDIAZEPOXIDE ON COMPARABLE RATES OF PUNISHED AND UNPUNISHED RESPONDING. S.I. Dworkin, M. J. Blake and S. Izenwasser. Departments of Psychiatry and Pharmacology, Louisiana State University School of Medicine, Shreveport, LA 71130.

Drugs with anxiolytic properties generally increase punished responding. Drug related increases in low rates of behavior not suppressed by punishment have also been reported after the administration of anxiolytic compounds. Thus, these drugs are similar to other behaviorally active agents in that baseline rates of responding can be an important determinant of the behavioral effects of a drug. Therefore, it is important to control for the baseline rate of responding in studies investigating punishment-specific effects of pharmacological agents. Several other variables including temporal patterns of responding and reinforcement density can also alter the behavioral effects of a drug. Procedures developed to determine specific effects of drugs should attempt to control for the potential influences of these factors.

Littermate pairs of male F-344 rats responded under a procedure which generated comparable rates of punished and unpunished responding. One subject of each pair was maintained on a random-ratio (5-100) schedule of food presentation. The interreinforcement intervals from this subject were used to generate a yoked variable-interval schedule of reinforcement for a littermate. A random-ratio (25-200)schedule of electric footshock was then added to the random-ratio schedule of food presentation. Thus, the subject on the ratio schedule received both food and shock, while the rat on the yoked interval schedule received only food presentations. The addition of the punishment contingency resulted in similar rates and patterns of responding by both the punished and yoked unpunished rats. The effects of chlordiazepoxide (3.0-30 mg/kg, i.p.) were determined after stable baselines of responding had been obtained.

Chlordiazepoxide increased punished responding with maximal effects occurring at the 5.6 mg/kg dose. There was, however, little effect of the drug on unpunished responding. These findings suggest the rate increasing effects of chlordiazepoxide can be punishment-specific. Supported by NIH 2 S07 RR05822.

127.18 PUNISHMENT-SPECIFIC CHANGES IN REGIONAL BENZODIAZEPINE RECEPTOR POPULATIONS. M. J. Blake, S. Izenwasser, M. McNulty*, N. E. Goeders and S. I. Dworkin. Departments of Psychiatry and Pharmacology, Louisiana State University School of Medicine, Shreveport, LA 71130.

Benzodiazepines have been shown to increase low rates of responding maintained by several operant schedules of reinforcement. Additionally, these drugs can attenuate the effects of punishment resulting in significant increases in punished responding. Chlordiazepoxide increases punished responding at doses that have little or no effect on similar low rates of unpunished responding. This specific effect on punished responding is most likely the result of alterations in central brain mechanisms that mediate the effects of punished responding. Since the pharmacological effects of benzodiazepines are suggested to result from the binding of these drugs to stereospecific binding sites, changes in these sites may be involved in the punishment-specific effects of these drugs.

Littermate groups of three male F-344 rats responded under a procedure which generated comparable rates of punished and unpunished responding. One subject of each group was maintained on a random-ratio (5-100) schedule of food presentation. The interreinforcement intervals from this subject were used to generate a yoked variable interval schedule of reinforcement for one of its littermates. A random-ratio (25-200) schedule of electric footshock was then added to the random-ratio schedule of food presentation. The addition of the punishment contingency resulted in similar rates and patterns of responding by both punished and yoked unpunished rats. The third animal of each group received noncontingent food and shock yoked to the random-ratio animals. Animals were subjected to the respective treatments for 30 sessions followed by decapitation and dissection of selected brain regions.

Saturation studies were carried out with [^{3}H]Ro15-1788 to characterize changes in benzodiazepine receptors (ie., K_d and B_{max} values) resulting from the treatment conditions. Benzodiazepine receptor binding was significantly increased in the striatum in both the punished and yoked-shock animals as compared to the unpunished controls. Furthermore, the yoked-shock animals had significantly higher binding than the punished animals. In contrast, there were no significant differences in B_{max} in the frontal cortex or hippocampus, nor were there differences in K_d values in any brain region examined. The site-specific alterations of these receptors may underlie the differential effects of benzodiazepines on punished and unpunished responding. Supported by NIH 2 S07 RR05822.

127.19 EFFECTS OF INTRAVENOUS BUSPIRONE AND 8-OH-DPAT ON THE ACTIVITY OF SEROTONERGIC DORSAL RAPHE NEURONS IN FREELY MOVING CATS. C.A. Fornal, L.O. Wilkinson, and B.L. Jacobs. Prog. Neurosci., Dept. Psychol., Princeton Univ., Princeton, NJ 08544

The therapeutic efficacy of non-benzodiazpine anxiolytic agents such as buspirone may involve an action on brain serotonergic neurons. These agents bind to the serotonin-1A receptor and inhibit the discharge of serotonergic dorsal raphe nucleus (DRN) neurons recorded in vitro and in anesthetized animals. Recently, we have extended this observation to serotonergic DRN neurons recorded in freely moving cats (Wilkinson et al. Eur. J. Pharmacol., in press). In the present study, we compare the ability of i.v. buspirone to inhibit the spontaneous activity of serotonergic DRN neurons to that of 8-hydroxy-2-(di-n-propylamino) tetralin (8-OH-DPAT), a specific agonist at the serotonin-1A receptor. Single-unit activity was recorded using movable bundles of 32 and 64 μm diameter nichrome wire electrodes. Serotonergic neurons were identified on the basis of the following established criteria: a) slow and highly regular discharge activity during wakefulness (1-4 spikes/sec); b) long duration action potentials (∿ 2 msec); c) complete suppression of activity during REM sleep and in response to the serotonin agonist 5-methoxy-N,N-dimethytryptamine (250 μg/kg, i.m.); d) histological localization to the DRN. Buspirone hydrochloride and 8-OH-DPAT hydrobromide were dissolved in normal saline and administered remotely via an indwelling jugular catheter. The discharge rate for the one min period beginning 15 sec after drug injection was compared to the one min period immediately preceding the injection. Buspirone and 8-OH-DPAT both produced a dose-dependent inhibition of serotonergic DRN unit activity, however 8-OH-DPAT was approximately 5 times more potent than buspirone. For example, 5 μg/kg buspirone produced a 20-45% suppression of serotonergic unit activity, whereas the same dose of 8-OH-DPAT consistently produced 100% suppression for approximately 3-5 min. Complete suppression of serotonergic unit activity was observed for buspirone at doses of 20-25 μg/kg. These findings are consistent with the greater affinity of 8-OH-DPAT for the serotonin-1A receptor, which may represent the somatic autoreceptor. In addition, in two preliminary experiments, we also examined the responsiveness of DRN neurons to buspirone and 8-OH-DPAT during chronic buspirone treatment (0.5 mg/kg, i.p., 3 times/day, 5-10 days). This schedule was selected to approximate a clinical treatment regimen. In contrast to previous studies, we found no consistent evidence of desensitization following chronic buspirone administration. These data indicate that the delayed clinical efficacy of buspirone is probably not attributable to a desensitization of the serotonin autoreceptor.

127.20 EFFECTS OF SEROTONERGIC COMPOUNDS ON POTENTIATED STARTLE RESPONDING IN THE RAT. R.S. Mansbach* and M.A. Geyer. Department of Psychiatry, University of California, San Diego, La Jolla CA 92093.

The potentiated startle procedure has been suggested as a possible model for the evaluation of anxiolytic compounds. Briefly, this procedure involves the pairing of a noxious stimulus with a neutral light stimulus. When later presented contiguously with an intense acoustic tone, the light induces a respondently conditioned augmentation of the startle response to the tone. This procedure was employed in evaluating the suggested involvement of 5HT1A receptor activation in the behavioral effects of novel, non-benzodiazepine anxiolytic compounds. On two consecutive days, rats were subjected to conditioning sessions in which a light was paired 10 times (mean intertrial interval = 3 min) with a brief 1 mA electric foot shock. Forty-eight hours following the second session, subjects were presented with acoustic startle trials (118 dB(A)), some of which were preceded by presentation of the light stimulus (LT trials) and some of which were not (T-alone trials). Occasional additional trials presented the light alone or no stimulus. In saline-treated animals, the LT trials induced a mean startle 81 percent above that of the T-alone trials. Administration of 8-hydroxy-2-(di-n-propylamino)tetralin (8-OH-DPAT), a prototypic 5HT1A ligand, in doses of 0.125 and 0.50 mg/kg s.c. reduced the potentiation of startle in the LT condition to 17 and 7 percent above the T-alone startle, respectively, despite inducing a moderate increase in T-alone startle. Doses of 0.25 and 1.0 mg/kg of the putative 5HT1B ligand, 1-[3-chlorophenyl] piperazine (mCPP), however, did not markedly change the relative potentiation of startle responding in LT trials (83 and 67 percent above T-alone, respectively), despite a substantial decrease in T-alone startle. The non-startle trial presentations produced very low stabilimeter readings under all conditions. These findings support receptor binding and behavioral studies suggesting that novel non-benzodiazepine anxiolytics such as buspirone and isapirone produce their effects via an interaction with the 5HT1A receptor, and demonstrate, in general, the value of the classically conditioned potentiated startle effect in the evaluation of anxiolytic compounds.

128.1 BMY 20661: A POTENTIAL ANTIPSYCHOTIC AGENT THAT DOES NOT BIND TO D-2 DOPAMINE SITES. Duncan P. Taylor, James S. New*, Michael S. Eison, Deborah K. Hyslop, Rhett Butler*, Lloyd E. Allen*, Frank D. Yocca, Cam P. VanderMaelen, and Joseph P. Yevich. Preclinical CNS Research, Pharmaceutical Research and Development Division, Bristol-Myers Company, P.O. Box 5100, Wallingford, CT. 06492-7660.

BMY 20661, known chemically as 4-{4-[4-(4-furo[3,2-c] pyridinyl)-1-piperazinyl]butyl}-3,5-morpholinedione, was identified as an antipsychotic candidate by its ability to inhibit the conditioned avoidance response in rats with a potency greater than clozapine (ED_{50} values of 11 mg/kg vs 24 mg/kg, p.o., respectively) and its ability to block apomorphine-induced stereotypy (ED_{50} value 34 mg/kg, p.o., compared to 24 for clozapine) and climbing. Moreover, BMY 20661 was active in the Sidman avoidance paradigm at a minimal effective dose of 25 mg/kg, p.o., displaying a clozapine-like profile. Unlike currently-available antipsychotics, BMY 20661 did not produce catalepsy; in fact, it potently (ED_{50} value of 2 mg/kg, p.o.) reversed catalepsy induced by trifluoperazine. Furthermore, whereas chronic administration of haloperidol produced increases in D-2 dopamine binding, administration of BMY 20661 did not. These findings suggest that BMY 20661 should not possess extrapyramidal side effects in clinical use. However, it was not anticholinergic either in vivo or in in vitro binding assays. BMY 20661 appears to have a moderate sedative component as it decreased spontaneous motor activity (ED_{50} value of 9 mg/kg, p.o.), induced rotarod impairment (ED_{50} value of 18 mg/kg, p.o.), and potentiated the hypnotic effects of ethanol (ED_{50} value of 7 mg/kg, p.o.). This may result from its ability to block α_1-adrenergic receptors in vivo: it prevented norepinephrine-induced lethality with an ED_{50} value of 11 mg/kg, p.o. The in vitro receptor binding profile of BMY 20661 is very different from typical antipsychotics: It had no affinity for D-1, D-2, or σ sites, nor did it bind to α_2-adrenergic, opiate, or desipramine sites (IC_{50} values >1000 nM). It displayed very weak affinity for the H_1 histamine site (IC_{50}=660 nM), and it most potently bound at type 1 and type 2 serotonergic sites and α_1-adrenergic sites (respective IC_{50} values of 34, 55, and 41 nM). In contrast to typical antipsychotics, BMY 20661 did not significantly affect the firing of A9 or A10 dopamine neurons. However, BMY 20661 increased the firing rate of noradrenergic neurons in the locus coeruleus, an effect also seen with haloperidol. The pharmacologic profile of BMY 20661 will be compared to those for clozapine and typical antipsychotics. This profile suggests that BMY 20661 possesses antipsychotic efficacy which results from an unusual mechanism, and it appears to be safer than currently available agents.

128.2 THE BINDING OF (+)-[^{3}H]3-PPP AND (+)-[^{3}H]NAN TO HALOPERIDOL-SENSITIVE SIGMA SITES IS INHIBITED BY THE POTENTIAL ANTIPSYCHOTIC BMY 14802. Jennifer Dekleva* and Duncan P. Taylor. CNS Biology, Bristol-Myers Company, P.O. Box 5100, Wallingford, CT 06492-7660

BMY 14802 has been identified as a potential antipsychotic agent. This is based on behavioral testing: (1) It blocks the conditioned avoidance response in rats with a potency similar to that of clozapine, (2) exhibits a clozapine-like profile in the Sidman Avoidance Test (Taylor et al., Soc. Neurosci. Abstr. 11: 114, 1985), and (3) inhibits apomorphine-induced stereotypy and climbing. Unlike currently-marketed antipsychotic drugs, BMY 14802 does not induce catalepsy, in fact, it reverses the catalepsy induced by trifluoperazine. This suggests that BMY 14802 is far less likely to induce the extrapyramidal movement disorders common to this class of psychotherapeutics. Receptor binding studies have previously shown that BMY 14802 exhibits low affinity for D-2 dopamine binding sites in vitro and in vivo. Moreover, BMY 14802 does not bind to D-1 dopamine binding sites (Taylor and Dekleva, Fedn. Proc. 46: 1304, 1987). It has been observed that some conventional antipsychotic drugs inhibit the binding of (+)-[^{3}H]NAN (N-allylnormetazocine, SKF 10,047) in vitro to the "haloperidol-sensitive sigma" site in guinea pig brain. Further, it has been proposed that selective sigma antagonists, devoid of D-2 dopamine antagonist action, may represent a novel class of psychotherapeutic agents in the treatment of schizophrenia. Recently, we have demonstrated that BMY 14802 potently, selectively, stereo-specifically, and competitively inhibits the binding of this ligand (Taylor and Dekleva, Drug. Dev. Res. 10: in press). Interestingly, (+) BMY 14802 displays low affinity for the site labeled by the phencyclidine analog, [^{3}H]TCP (IC_{50}=10,000 nM). It appears that (+)-[^{3}H]3-(3-hydroxyphenyl)-N-(1-propyl)piperidine{(+)-[^{3}H]3-PPP} is a more selective ligand for this site (Largent et al., PNAS 81: 4983, 1984). Our pharmacologic studies confirm this finding. In addition, we have confirmed our earlier work that showed that BMY 14802 inhibits haloperidol-sensitive sigma binding: with this ligand the dextrorotatory enantiomer exhibited a K_I of 28 nM while the levorotatory isomer was ten-fold less potent (K_I=310 nM). It has been suggested that BMY 14802 blocks the behavioral and electrophysiological effects of dopamine agonists by a nondopaminergic mechanism (Matthews et al., JPET 239: 124, 1986). The affinity shown by BMY 14802 for the haloperidol-sensitive sigma site affords support for this suggestion. If clinically efficacious, BMY 14802 would represent a safer alternative to currently available agents for the treatment of schizophrenia.

128.3 THE AUTORADIOGRAPHIC LOCALIZATION OF (±)-[^{3}H]BMY 14802, A POTENTIAL ANTIPSYCHOTIC AGENT. Sandra L. Moon. CNS Biology, Bristol-Myers Company, P.O. Box 5100, Wallingford, CT 06492-7660.

BMY 14802 is a potential antipsychotic agent. In contrast to other antipsychotic drugs, BMY 14802 has low affinity for D-2 dopamine binding sites, and no affinity for D-1 sites. However, like some antipsychotic compounds, BMY 14802 inhibits the binding of sigma ligands (Dekleva and Taylor, Fedn. Proc. 46: 1304, 1987).

Recently we have obtained (±)-[^{3}H]BMY 14802 with a specific activity of 15 Ci/mmol (custom synthesis by NEN). Preliminary in vivo localization experiments were performed by means of auto-radiography. Rats were injected intravenously with 500-900 μCi (±)-[^{3}H]BMY 14802. Cryostat-cut brain sections (20 μm-thick) were opposed to LKB Ultrofilm for 3-12 weeks. Analysis of the resultant autoradiograms revealed a high concentration of label in the anterior cingulate cortex, hippocampus, and the subthalamic region. There was also a widespread distribution of label among cell groups of the pons and medulla.

Preliminary in vitro incubations showed approximately 70 percent decrease in radioactivity in the presence of excess unlabeled (±)BMY 14802. Thaw-mounted frozen brain sections from rat and guinea pig were incubated and apposed to film for 5 weeks or longer. In the rat and guinea pig, labeling was high in cortical regions, including hippocampus and cerebellar cortex. The thalamus concentrated less radioactivity than the subjacent subthalamic region and hypothalamus. The hypothalamus was especially enhanced in the guinea pig. Other labeled regions in both species included the bed nuclei, periaqueductal grey, and superficial layers of the superior colliculus. Labeling in the lower brainstem was relatively less and more heterogeneous in the in vitro conditions than the in vivo experiments.

The pattern of (±)-[^{3}H]BMY 14802 labeling demonstrated many similarities with previously published data on (+)-[^{3}H]3-PPP binding to sigma sites in rat and guinea pig (Gundlach et al., J. Neurosci., 1986).

128.4 BEFIPERIDE, SEROTONERGIC PROPERTIES OF A NEW NON-DOPAMINOLYTIC PUTATIVE ANTIPSYCHOTIC. J.A.M. van der Heyden*, J. Schipper* and M.Th.M. Tulp* (SPON: P. Bevan). Dept. Pharmacol. Duphar b.v., P.O. Box 2, 1380 AA Weesp, The Netherlands.

Befiperide is a novel potential antipsychotic drug on the basis of its inhibition of conditioned avoidance behaviour and apomorphine-induced stereotypy in rats. Unlike the classic neuroleptics, befiperide does not block dopamine (DA) receptors, as established both in vitro (no effect on DA2 receptor mediated release of ^{3}H-DA or ^{3}H-acetylcholine or DA1 receptor mediated c-AMP formation) and in vivo (no increase in DA synthesis rate and DA turnover). As a result, befiperide does not induce the unwanted effects common to most neuroleptics like catalepsy and supersensitivity of the DA system. Since befiperide was developed on basis of a behavioural profile little was known on its mechanism of action except for a lack of DA receptor blocking activity. The most pronounced in vitro receptor affinity of befiperide is for the serotonin (5-HT) type 1A and 2 receptor (22 nM and 45 nM respectively), followed by an affinity of approximately 200 nM for the α_1-noradrenaline and DA2 receptor and 480 nM for the H1 histamine receptor. On basis of its relatively high affinity for 5-HT receptors we have further studied the effects of befiperide and several reference drugs on the serotonin system.

We found that befiperide at a dose of 10 mg/kg orally strongly attenuated 5-HTP accumulation after decarboxylase inhibition in the rat striatum, frontal cortex, hippocampus and nucleus accumbens to about 60% of control. At an oral dose of 15 mg/kg befiperide also lowered 5-HIAA levels in cortex and striatum to about 75% of control. Such effects were not observed for the neuroleptics haloperidol and clozapine. The serotonin agonists TFMPP and 8-OHDPAT produced similar effects in the cortex and striatum whereas no effects were observed with serotonin antagonists such as ketanserin and metergoline. Befiperide did not affect the K^+-stimulated release of 5-HT from rat cortex slices in vitro up to a concentration of 10^{-5}M. TFMPP shows a clear decrease of the K^+-stimulated release, whereas the 5-HT1A agonist 8-OHDPAT showed no effect.

When studying the effects of drugs on the conditioned avoidance behaviour we found that the well known 5-HT1A and 5-HT2 receptor ligands such as 8-OHDPAT, buspirone, quipazine and ketanserin did not inhibit this behaviour at centrally active doses. Like befiperide TFMPP, a 5-HT1B agonist attenuated this behaviour.

In conclusion, the data obtained so far strongly suggest that a 5-HT agonistic activity is present in befiperide, the importance of which for the overall profile remains to be established.

128.5 DOPAMINE AGONIST ACTIVITY OF U-66444B AND ITS ENANTIOMERS: DISCOVERY AND EARLY EVALUATION OF FUNCTIONAL, BIOCHEMICAL AND PHARMACOKINETIC PROPERTIES. P.F.VonVoigtlander, J.S.Althaus*, M.Camacho Ochoa, G.L.Neff* and J.Szmuszkovicz*. CNS Research, The Upjohn Company, Kalamazoo, MI 49001.

Investigation of a novel series of rigid heterocyclic compounds revealed that U-66444B causes hypothermia in mice which is blocked by haloperidol but not by yohimbine. Inhibition of locomotor activity by U-66444B was also blocked by haloperidol and d-amphetamine stimulated motor activity was antagonized by U-66444B. These results suggested that this compound might be a dopamine agonist acting at presynaptic receptors to inhibit the release of dopamine. Evaluation of dopamine release by the measurement of 3-methoxytyramine levels in the corpus striatum revealed that U-66444B does decrease apparent dopamine release. Regarding the involvement of presynaptic receptors in the action of this compound, the ability of U-66444B to reduce the rate of synthesis (DOPA accumulation) and metabolism (DOPAC and HVA) of dopamine in several brain regions was enhanced by gamma butyrolactone and not markedly altered by prior kainic acid lesions. Thus feedback pathways from postsynaptic dopamine receptors did not seem to be principally involved. The measurement of U-66444B brain levels at various time intervals after sc or po administration of the drug to mice revealed that the drug was available by either route and persisted in brain for up to 2 hours. Replication of the above studies with the enantiomers of U-66444B demonstrated that the (+) enantiomer (U-68553B) was by far the more potent and that this was not related to pharmacokinetics as both enantiomers generated comparable brain levels of drug. U-68553B appears to be a structurally novel dopamine agonist that has effects at presynaptic dopamine receptors that may be therapeutically useful.

128.6 **U-66444B AND U-685553B ARE POTENT AUTORECEPTOR AGONISTS AT DOPAMINERGIC CELL BODIES AND TERMINALS.** M.F.Piercey, P.A.Broderick, W.E.Hoffmann* and G.D.Vogelsang. CNS Research, The Upjohn Company, Kalamazoo, MI. 49001 and Pharmacology Dept., CUNY Medical School, NY, NY 10031.

U-66444B and its biologically active stereoisomer, U-68553B, were evaluated for presynaptic and postsynaptic effects in dopaminergic (DA) cell body and nerve terminal regions of chloral hydrate anesthetized rats. To test effects on cell bodies, spikes from DA neurons, identified by long duration (>2.5 msec) action potentials and slow firing rates, were recorded by microelectrodes whose tips were histologically verified as located within cell body regions of the substantia nigra pars compacta (SNPC) or ventral tegmental area (VTA). U-66444B depressed DA neurons in SNPC and VTA in a dose-related manner. ED50 doses depressing firing rates by 50% averaged 3 ug/kg compared to 9 ug/kg for apomorphine and 100 ug/kg for (-)3-PPP. With sufficient dose, all cells were completely silenced. Biological activity for U-66444B resided principally in its (+) stereoisomer, U-68553B, with which it was approximately equipotent. The effects were mediated by DA receptors, since they were promptly reversed by 0.1 mg/kg haloperidol, a DA antagonist. Following 2 weeks of 0.6 mg/kg/day U-66444B, the potency for depressing DA cells was only slightly depressed (ED50=6.6 ug/kg). DA autoreceptor function at nerve terminals was evaluated by in vivo voltammetry. DA release was measured by semi-derivative voltammograms, which were generated every 10 minutes at the tips of stearate graphite electrodes placed directly in the caudate and n. accumbens in vivo. In caudate, 100 ug/kg U-68553B produced a dramatic and prolonged depression of DA release (greater than one hour) compared to weaker and shorter effects of 500 ug/kg apomorphine (less than 20 minutes). In n. accumbens, a similar action occurred following an initial transient (<10 min) increase in DA release. On DA postsynaptic receptors, iontophoretically applied U-66444B and apomorphine were approximately equipotent in depressing caudate neuron firing. It is concluded that U-66444B and its active enantiomer, U-68553B, are more potent, longer acting, and possibly more selective as DA autoreceptor agonists than apomorphine. Moreover, the propensity to produce tolerance is weak.

128.7 **DOPAMINE AUTORECEPTOR AGONIST PROPERTIES OF THE PROPOSED ANTIPSYCHOTIC COMPOUNDS, U-66444B AND ITS (+) ENANTIOMER, U-68553B.** P.J.K.D.Schreur and N.F.Nichols*. CNS Research, The Upjohn Company, Kalamazoo, MI 49001.

Though traditional antipsychotic agents greatly inhibit the symptoms of schizophrenia, their use is often limited by severe or unpleasant side effects which may be an indirect consequence of blockade of the postsynaptic dopamine (DA) receptor. Dopaminergic function may also be decreased presynaptically by a DA autoreceptor (AR) agonist which would decrease the release of DA; thus it may avoid these side effects. U-66444B and U-68553B are potent and selective DA AR agonists with antipsychotic potential.

Exploratory Behavior in Naive Rats. In Omnitech Digiscan Monitors in the dark, DA AR agonists decreased the total distance travelled while paradoxically increasing the number of discrete movements. In contrast, neuroleptics, while decreasing the total distance travelled, also decreased the number of movements (Pharmacol. Biochem. Behav. 25:255-261). U-66444B, U-68553B, apomorphine HCl, and 3-PPP (N-n-propyl-3-(3-hydroxyphenyl)-piperidine) and its two enantiomers decreased the total distance and increased the number of movements in this test.

Locomotor Activity in Habituated Rats. In Digiscan Monitors in the light, DA AR agonists antagonized amphetamine-stimulated locomotor behavior (total distance) without antagonizing apomorphine-stimulated behavior (Pharmacol. Biochem. Behav. 25:255-261). U-66444B, U-68553B, and (+)3-PPP antagonized amphetamine but not apomorphine. Low doses of apomorphine antagonized amphetamine, also.

Turning in Rats with Unilateral Substantia Nigra (6-OH-dopamine) Lesions. DA AR agonists antagonized amphetamine-induced turning (scored visually) at a dose which did not itself cause turning. U-66444B (0.01 mg/kg) or apomorphine HCl (0.01-0.03 mg/kg) antagonized the ipsiversive turning caused by 1 mg/kg d-amphetamine SO4 but did not cause turning alone. A higher dose (0.1 mg/kg) of U-66444B caused contraversive turning and a still higher dose (3 mg/kg) caused ipsiversive turning, both of which could be antagonized by haloperidol HCl. Higher doses of apomorphine HCl (0.1 mg/kg or higher) also caused contraversive turning. U-68553B (0.01-0.1 mg/kg) caused contraversive turning; it was more potent than the racemic mixture. The enantiomers of 3-PPP variably caused contraversive turning.

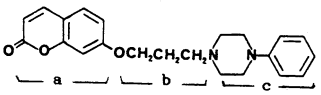
Behavioral Tolerance. After 6 days of continuous U-66444B s.c. infusion (0.3 mg/kg/day) or 14 days of pulsed i.v. infusions (0.6 mg/kg/day), rats showed tolerance to the ability of acute U-66444B (0.1 mg/kg) to antagonize amphetamine-stimulated locomotor activity. This tolerance disappeared by 4 weeks after withdrawal from the continuous infusion.

128.8 OPERANT FORCE-PROPORTIONAL REINFORCEMENT: PIMOZIDE DOES NOT ATTENUATE A RATE-FREE MEASURE OF REINFORCEMENT EFFICACY. M. A. Kirkpatrick and S. C. Fowler. Departments of Psychology and Pharmacology, University of Mississippi, University, MS 38677.

A two step force-proportional reinforcement contingency was used to explore the effects of pimozide (PIM, 0.12, 0.25, and 0.50 mg/kg,ip., injected 4 hr before behavioral tests) on peak force and rate of operant response. Rats (N=4) in the force-proportional group (PRO) learned to press a force-sensing operandum and were rewarded with 8% sucrose solutions for low-force responses (peak forces of 8-23 g) and 24% sucrose for high forces (24 g or more). A second group (N=4) was exposed to an inverse force-proportional procedure (INV); i.e., low forces produced 24% and high forces yielded 8% sucrose solutions, while the third group (N=4) exclusively received 24% sucrose solutions for high forces (NONP). Although the PRO group learned to emit high forces and the INV group learned to make low-force responses, PIM did not reduce the tendency of the PRO group to press harder for more, even though all groups displayed significant dose-related rate decreases ($F[3,27]=9.660$, $p<0.001$). In accord with previous studies, peak force of response was slightly but significantly elevated by PIM ($F[3,27]=2.944$, $p<0.05$). The behavior of groups INV and NONP suggests that the higher concentration of sucrose (24%) did not by itself elicit high-force responding. This observation and the fact that the PRO and INV groups learned to emit forces appropriate for obtaining the sweeter concentration suggest that the PRO group chose the higher concentration because of its relatively greater incentive/motivational value compared to the lower concentration. The failure of PIM to decrease peak force in the PRO group is not consistent with the anhedonia (incentive/motivational) hypothesis of neuroleptics' behavioral effects. These results support the idea that relatively low doses of neuroleptics affect operant responding via motor processes expressed primarily in the temporal domain of behavior.

128.9 7-[3-(4-ARYL-1-PIPERAZINYL)PROPOXY]-2H-1-BENZOPYRAN-2-ONES. A NEW CLASS OF DOPAMINE AUTORECEPTOR AGONISTS. L.D. Wise*, H.A. DeWald*, E.S. Hawkins*, T.G. Heffner, T.A. Pugsley and L.T. Meltzer (SPON: D.K. Boyd). Departments of Chemistry and Pharmacology, Warner-Lambert/Parke-Davis Pharmaceutical Research, Ann Arbor, MI 48105

Dopamine (DA) agonists with selectivity for brain DA autoreceptors have emerged in recent years as a potential therapeutic approach for treatment of cardiovascular and CNS disorders including schizophrenia. PD 116,795, 7-[3-(4-phenyl-1-piperazinyl)propoxy]-2H-1-benzopyran-2-one, is chemically novel as a DA autoreceptor agonist.



PD 116,795

PD 116,795 bound selectively to D_2 DA receptors, attenuated the stimulation of brain DA synthesis induced by gamma-butyrolactone and inhibited firing of substantia nigra DA neurons in rats, all of which indicates that PD 116,795 is a DA agonist. PD 116,795 also inhibited spontaneous locomotor activity in mice after IP administration (ED_{50}: 2.59 mg/kg) and in rats after oral administration (ED_{50}: 2.10 mg/kg). Behavioral stimulation indicative of postsynaptic DA agonist activity was not seen even at doses as high as 100 mg/kg IP in mice. The uniqueness of PD 116,795 led us to examine the structure-activity relationships (SAR) of several related compounds on the basis of their effects on brain DA synthesis. While the benzopyran (a) and propoxy (b) portions of the molecule could be altered significantly without loss of DA agonist activity, the phenylpiperazinyl group (c) was quite sensitive to modifications. For example, addition of chloro or methyl substituents to the phenyl portion of the phenylpiperazine resulted in complete loss of DA agonist activity. Computerized molecular modeling of PD 116,795 and related compounds suggests that the spatial orientation of the phenylpiperazine is quite important in determining DA agonist activity.

128.10 TOLERANCE TO CHRONIC HALOPERIDOL TREATMENT IN THE RAT AS MEASURED BY SPONTANEOUS LOCOMOTOR ACTIVITY. M.A. Notrica*, F.E. Soroko*, B.T. Kenney* and L.E. Boswell* (SPON: A.S. Tadepalli). Department of Pharmacology, Wellcome Research Laboratories, Research Triangle Park, NC 27709.

Chronic administration of Haloperidol (HAL) to the rat produces an augmented behavioral sensitivity to D_2 agonists and hyperplasia of D_2 receptors. Such epiphenomena may influence the interpretation of studies on prolonged neuroleptic treatment and its subsequent withdrawal in the rat. We assessed the effect of 21 days of HAL (2 mg/kg/day) on spontaneous locomotor activity (SLA) in open-field monitors. Significant decreases in SLA were apparent for the first three days of drug treatment with no statistically significant differences, compared to controls, for the remaining 18 days of the study.

Withdrawal of HAL produces a slight rebound in SLA which persists for a period of 10-14 days after cessation of treatment. During this washout period the effects of other neuroleptic agents was explored. The results of these experiments, along with the effects of chronic chlorpromazine treatment on SLA will be discussed.

128.11 EVALUATION OF THE EFFECTS OF CI-943, A POTENTIAL ANTIPSYCHOTIC AGENT, ON DOPAMINE NEURONAL ACTIVITY. L.T. Meltzer[1], C.L. Christoffersen[1]*, A.S. Freeman[2], and L.A. Chiodo[2]. [1]Warner-Lambert/Parke-Davis Pharmaceutical Research, Ann Arbor, MI 48105 and [2]Center for Cell Biology, Sinai Hospital of Detroit, Detroit, MI 48235.

Based on its profile in preclinical behavioral and biochemical tests predictive of antipsychotic activity, CI-943 (8-ethyl-7,-8-dihydro-1,3,5-trimethyl-1H-imidazo[1,2-c]-pyrazolo-[3,4-e]pyrimidine) has been identified as a potential novel antipsychotic agent that does not bind to the dopamine (DA) receptor. The present studies compared the effects of acute and chronic administration of CI-943 and standard antipsychotic agents on the electrophysiological activity of midbrain DA neurons recorded extracellularly in chloral hydrate anesthetized male S-D rats.

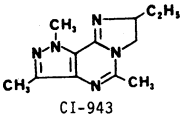
Acute administration of haloperidol (HAL; 0.5 mg/kg, IP) increased the baseline firing rate and antagonized the inhibitory effects of apomorphine (APO) and amphetamine (AMP) on substantia nigra zona compacta (A9) DA neurons. In contrast, CI-943 (20 mg/kg, IP) neither increased the baseline firing rate nor antagonized the effects of APO or AMP.

The effects of acute (PO) and chronic (21 days, drugs administered via drinking water) treatment with HAL (0.5 mg/kg/day), clozapine (20 mg/kg/day; CLZ), and CI-943 (40 mg/kg/day) on the number of spontaneously active DA neurons in A9 and the ventral tegmental area (A10) were evaluated. Acute HAL and CLZ increased the number of active DA neurons in both A9 and A10. In contrast, acute CI-943 did not alter the number of active DA neurons in either region. Chronic HAL decreased the number of active DA neurons in A9 and A10. Chronic CLZ decreased the number of active DA neurons in A10 but increased activity in A9. Chronic CI-943 produced effects that were different than those obtained with HAL or CLZ as it increased the number of active DA neurons in A10 while having no effect in A9.

In this series of electrophysiological studies, CI-943 was differentiated from the typical (HAL) and atypical (CLZ) DA antagonist antipsychotic drugs. These data suggest that the electrophysiological effects of CI-943 are not due to DA receptor antagonism, and are in agreement with in vitro receptor binding data that indicate that CI-943 has no affinity for DA receptors. These data support the hypothesis that CI-943 produces its preclinical antipsychotic-like behavioral effects through non-dopaminergic mechanisms.

128.12 EFFECTS OF THE POTENTIAL ANTIPSYCHOTIC AGENT CI-943 IN PRECLINICAL PREDICTORS OF EFFICACY IN MICE AND RATS. T.G. Heffner, D.A.Downs F.W. Ninteman*, J.N. Wiley*, H.A. DeWald*, L.D. Wise* and F.M. Hershenson*. Departments of Pharmacology & Chemistry, Warner-Lambert/Parke-Davis Pharmaceutical Research, Ann Arbor, MI 48105.

The efficacy of known antipsychotic drugs is commonly attributed to their blockade of brain dopamine receptors. However, dopamine antagonist antipsychotics are incompletely efficacious in man and produce serious neurological side effects. In order to develop improved drugs for the treatment of schizophrenia, we undertook a program to identify agents which display the behavioral profile of antipsychotic drugs in preclinical tests but which do not interact with brain dopamine receptors. CI-943 (8-ethyl-7,8-dihydro-1,3,5-trimethyl-1H-imidazo[1,2-c]pyrazolo-[3,4-e]pyrimidine) is a novel psychotropic agent, unrelated to any known chemical class of antipsychotics.



CI-943

CI-943 is not a brain dopamine receptor antagonist as assessed by receptor binding assays and by in vivo tests. CI-943 inhibits exploratory locomotion in mice (ED_{50} = 26 mg/kg IP & PO) at lower doses than those which impair motor coordination (ED_{50} > 100 mg/kg IP & PO), a profile shared by available antipsychotics but not seen with a variety of non-antipsychotic sedatives. Despite its lack of affinity for brain dopamine receptors, CI-943 inhibits compulsive cage climbing in mice induced by the dopamine agonist apomorphine (ED_{50} = 41 mg/kg IP). However, the finding that CI-943 does not attenuate locomotor hyperactivity produced by d-amphetamine in mice or rats (ED_{50} > 100 mg/kg IP) but instead augments such effects clearly distinguishes this agent from dopamine antagonists. CI-943 shares with dopamine antagonists the ability to produce inhibition of lateral hypothalamic self-stimulation responding in rats (ED_{50} = 10.8 mg/kg PO) and to reduce time spent by rats on a platform on which they receive rewarding brain stimulation passively. CI-943 also resembles antipsychotics in a one-way conditioned avoidance test in rats, inhibiting avoidance responding (ED_{50} = 7.5 mg/kg PO) at lower doses than those which inhibit escape responding (ED_{50} = 32 mg/kg PO). These results indicate that while it differs from dopamine antagonists in tests for mechanism of action, CI-943 displays the profile of known antipsychotic drugs in a variety of preclinical models of antipsychotic efficacy.

128.13 EFFECTS OF THE POTENTIAL ANTIPSYCHOTIC AGENT CI-943 IN PRECLINICAL PREDICTORS OF EFFICACY AND NEUROLOGICAL SIDE EFFECTS IN RATS AND MONKEYS. D.A. Downs, T.G. Heffner, D.J. Johnston*, K.L. Sledge*, A.E. Williams* and J.N. Wiley*. Dept. of Pharmacology, Warner-Lambert/Parke-Davis Pharmaceutical Research, Ann Arbor, MI 48105.

CI-943 (8-ethyl-7,8-dihydro-1,3,5-trimethyl-1H-imidazo[1,2-c]-pyrazolo[3,4-e]pyrimidine) is a potential antipsychotic agent that lacks affinity for brain dopamine receptors as well as other characteristics of dopamine antagonists in neurochemical, neurophysiological, and endocrinological tests. In order to further characterize this novel agent, we compared CI-943 to dopamine antagonist antipsychotics in preclinical tests for efficacy and neurological side effects. Efficacy tests included inhibition of spontaneous locomotion and inhibition of continuous (Sidman) avoidance responding, tests commonly used as preclinical predictors of antipsychotic activity. Liability for extrapyramidal side effects (EPS) was estimated by determining if a behaviorally active dose of test agent elicits acute dystonias in monkeys that have been sensitized to the dystonic effects of haloperidol by its chronic administration. Liability for tardive dyskinesia was estimated by determining if test agents administered chronically to rats induce supersensitivity to the behavioral effects of the dopamine agonist apomorphine. In addition to CI-943, the dopamine antagonists haloperidol (HPD), chlorpromazine (CPZ), and thioridazine (THZ) were examined. Each of the dopamine antagonists tested inhibited continuous (Sidman) avoidance responding in rats and squirrel monkeys at doses that did not impair the ability to respond. CI-943 shared this profile, inhibiting Sidman avoidance responding selectively in both rats (ED_{50} = 19.8 mg/kg PO) and squirrel monkeys (ED_{50} = 7.2 mg/kg PO) with a duration of action in excess of 6 hours. Each of the dopamine antagonists, but not CI-943, produced dystonias in haloperidol-sensitized squirrel monkeys when tested at doses near their ED_{50}s for inhibiting avoidance responding. Each of the dopamine antagonists also inhibited spontaneous locomotor activity in rats (ED_{50}s, mg/kg PO: HPD, 0.2; CPZ, 5.4; THZ, 13.3) at doses that did not produce ataxia and a similar profile of activity was seen with CI-943 (ED_{50} = 15 mg/kg PO). Rats treated daily for 21 days with HPD, CPZ, or THZ at doses equivalent to 3 times the respective ED_{50} for locomotor inhibition displayed augmented locomotor stimulant responses to apomorphine (0.1 mg/kg SC) administered on day 23. However, rats similarly treated with CI-943 (45 mg/kg PO for 21 days) did not display behavioral supersensitivity to apomorphine. These results indicate that although CI-943 shares the preclinical efficacy profile of available antipsychotics, it does not have the profile of dopamine antagonists in preclinical tests for neurological side effects.

128.14 NEUROCHEMICAL PROPERTIES OF CI-943, A NON-DOPAMINE RECEPTOR ANTAGONIST ANTIPSYCHOTIC CANDIDATE. T.A. Pugsley, L.L. Coughenour*, S.L. Myers*, Y.H. Shih*, G.G. Courtland*, W. Berghoff* and S.F. Stewart*. Warner-Lambert/Parke-Davis Pharmaceutical Research, Ann Arbor, MI 48105.

CI-943 (8-ethyl-7,8-dihydro-1,3,5-trimethyl-1-H-imidazo [1,2-c]pyrazolo[3,4-e] pyrimidine) is a novel compound which has been shown to have an antipsychotic profile in animal tests with a low propensity to cause extrapyramidal side effects (EPS). The present study examined some in vivo and in vitro neurochemical properties of CI-943.

CI-943 (40 mg/kg p.o.) caused a significant increase in rat striatal and mesolimbic homovanillic acid (HVA) 2 hours after dosing; striatal but not mesolimbic 3,4-dihydroxyphenylacetic acid (DOPAC) levels were also increased. Lower doses (1 and 10 mg/kg p.o.) were ineffective. CI-943 (20 mg/kg i.p.) caused a significant increase in striatal HVA, DOPAC and 3-methoxytyramine levels. A duration study indicated that CI-943 elevated striatal and mesolimbic HVA content by 0.5 hours after dosing with levels declining to those of control by 4 hours. CI-943 was also shown to increase striatal DA synthesis. As dopamine (DA) levels were unchanged, these findings indicated that DA turnover was increased. These effects are not due to DA receptor blockade as CI-943, unlike known antipsychotics, did not exhibit affinity for DA receptors. CI-943 did not affect rat serum basal levels of prolactin nor did it inhibit in vivo DA neuronal reuptake. Amfonelic acid (AFA) enhanced the action of haloperidol in increasing striatal HVA with no effect on that of CI-943 and clozapine. This suggests that CI-943, like the atypical agent clozapine, would be predicted to have a low risk of EPS as compared to typical antipsychotics like haloperidol. Chronic administration of CI-943 (40 mg/kg i.p.) to rats for 28 days did not affect the affinity or number of striatal DA receptors; in comparison, haloperidol (0.5 mg/kg i.p.) caused an increase in number of DA receptors with no change in affinity. The latter finding suggests that CI-943 does not cause supersensitivity of DA receptors as do known antipsychotics such as haloperidol and thus may have a low propensity to cause tardive dyskinesia in patients. Except for the striatum where levels of 5-hydroxyindoleacetic acid were elevated, measures of serotonergic and nordrenergic function were not affected by CI-943. In addition CI-943 did not exhibit any significant affinity for a number of CNS receptors in vitro. The molecular mechanism by which CI-943 increases brain DA turnover is not known at this time but appears to be unique in comparison to known antipsychotic agents.

128.15 **MECHANISMS OF TOLERANCE TO CLOZAPINE DURING OPERANT RESPONDING IN RATS.** H.F. Villanueva* and J.H. Porter. Dept. of Psychology, Virginia Commonwealth Univ., Richmond, VA 23284.

Previous studies have shown that the atypical neuroleptic clozapine suppresses operant behavior in rats, but that response rates recover to control levels within several days during chronic dosing regimens (Kaempf & Porter, 1985; Villanueva & Porter, 1987). The mechanisms for this tolerance to the rate suppressing effects of clozapine are unclear, however. The present study was designed to determine whether the tolerance to clozapine in operant studies is behavioral, physiological or a combination of these two mechanisms.

Male rats (80%BW) were trained to respond according to a multiple random interval (MULT RI) food reinforcement schedule with four 10-min components (RI 10-sec, RI 40-sec, RI 80-sec and RI 160-sec) separated by 5-min time out periods. One group of rats (N = 7) received 10 mg/kg injections (ip) of clozapine one hour presession for 10 consecutive days. A second group (N = 6) received vehicle injections one hour presession and 10 mg/kg clozapine injections one hour post session for 9 consecutive days. On the tenth day the order of injections was switched, and for the next 10 days the rats in Group Two received the clozapine injections presession and the vehicle injections post session.

Presession injections of clozapine (Group One) produced a significant reduction in responding and number of reinforcers initially in all four MULT RI schedules, but the animals recovered to baseline levels before the end of the 10-day chronic dosing period. For Group Two response rates and reinforcers remained at baseline levels for the first 9 days of post session clozapine injections. On the tenth day when clozapine injections were switched to presession, response rates and number of reinforcers were not significantly suppressed for the RI 40-, 80- and 160-sec schedules. For the RI 10-sec schedule, however, responding and the number of reinforcers were signifcantly decreased but not as much as was seen on day one for Group One. Again, response rates and reinforcers recovered to baseline levels within the 10-day chronic dosing regimen (with presession injections). For response duration, there was no significant change on day 10 when the clozapine injection was switched to presession.

These results suggest that the recovery of operant responding during chronic dosing regimens with clozapine can be attributed primarily to the development of tolerance to the physiological effects of the drug. This recovery can probably be attributed to the development of tolerance to the sedative effects of clozapine, as human studies report that tolerance develops to the sedative, but not to the antipsychotic effects of the drug (Pinder et al, 1976).

128.16 EFFECTS OF CHOLECYSTOKININ AND γ-TYPE ENDORPHIN ON HYPER- AND HYPO-LOCOMOTION INDUCED BY APOMORPHINE. Y.Igarashi, R.Igarashi and J.M. van Ree*(SPON:M.Okamoto), Department of Psychiatry, Saitama Medical School, Saitama, Japan, *Rudolf Magnus Institutute for Pharmacology, University of Utrecht, Utrecht, The Netherlands.

It has been reported that caeruletide, cholecystokinin(CCK) related peptide, and γ-type endorphins have therapeutic effects on schizophrenic symptomes. Apomorphine injected into the nucleus accumbens (NcAcc) of the rat, considered to be one of sites of action of antipsychotic drugs having antidopaminergic actions, produce hypo- and hypermotility depending on the dosage. Pretreatment of CCK or γ-type endorphins modulate hypo- and hyperlocomotion induced by apomorphine. Recently we reported inhibitory effect of naloxone, an opioid antagonist, on the blocking action of CCK on hyperlocomotion induced by high dose of apomorphine (1). To elucidate the further evidence of the relationship between CCK and endorphins, the effects of antagonists and specific antisera against these peptides were investigated. Male wistar rats weighing 120-130g were implanted stereotaxically stainless steel canulae into the NcAcc. Antagonists or antisera were injected at 70min, and peptides were applied at 60min prior to the behavioural observation. Apomorphine was administered at 20min prior to the observation. Locomotion, rearing, glooming and sniffing time in the small open field were evaluated for 3min as reported elsewhere(2). Low dose of apomorphine(10ng/each side) significantly decrease the locomotor activity, and this hypolocomotion was blocked by pretreatments of CCK-8 sulfated form(CCK-8S) and nonsulfated form (CCK-8NS) and des-enkephalin-γ-endorphin(DEγE). Naloxone, an opioid antagonist, and anti γ-endorphin serum inhibited the blocking action of CCK-8NS and DEγE. Proglumide, a CCK antagonist, and anti-CCK serum also showed the inhibitory effect on the blocking action of CCK-8NS and DEγE. High dose of apomorphine(10ug) produced significant increase of the locomotor activity. Hyperlocomotion induced by high dose of apomorphine was blocked by pretretments of CCK-8S and γ-endorphin(γE). Naloxone and anti-γE serum inhibited the blocking effects of CCK-8S and γE on hyperlocomotion. Proglumide and anti-CCK serum inhibited the blocking effect of CCK-8S on hyperlocomotion , though the blocking action of γE did not affect by pretreatments of both proglumide and anti-CCK serum. These data suggest that the blocking action of CCK on hyperlocomotion, postulated the effect of apomorphine on postdopaminergic receptor, mediated through the endorphin system in the rat NcAcc. On the other hands, the actions of CCK and γ-endorphin on hypolocomotion, the effect of apomorphine on predopaminergic receptor, were only obtained under the intact condition of both CCK and endorphin systems.

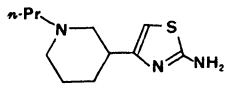
128.17 BUSPIRONE, M-CHLOROPHENYLPIPERAZINE (MCPP), 6-CHLORO-2(1-PIPERAZINYL)PYRAZINE (MK212) AND Wy-47,384 DISPLACE HALOPERIDOL-* SENSITIVE SIGMA BINDING IN MOUSE BRAIN IN VIVO. R.P. Tasse, E.A. Muth and T.H. Andree, Wyeth Laboratories, Inc., Division of Experimental Therapeutics, Philadelphia, PA 19101

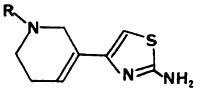
The in vivo binding of 5 μCi/mouse (+)[^{3}H]N-allylnormetazocine (NANM or (+)[^{3}H]SKF 10,047) in brain was examined 15 min following its intravenous injection to vehicle- or drug-pretreated mice. Pretreatment with phencyclidine or one of several sigma receptor ligands displaced the binding of (+)[^{3}H]NANM from that observed following vehicle pretreatment. The putative antipsychotics rimcazole and Wy-47,384, the anxiolytic buspirone, and the arylpiperazine mCPP also inhibited the in vivo binding of (+)[^{3}H]NANM with ID_{50} values of 7.9, 7.3, 4.9 and 4.9 mg/kg i.p., respectively. MK212 produced 40% displacement at 16 mg/kg. Since maximum pharmacologically effective doses of spiperone, (+)SCH23390 and 8-OH-DPAT were each ineffective, the dopamine (D-1 and D-2) and serotonin (5-HT-1A and 5-HT-2) receptor affinities attributed to haloperidol, Wy-47,384 [Andree et al., Soc. Neurosci. Abst. 12:477 (1986)], buspirone and other arylpiperazines fail to account for their in vivo displacement of (+)[^{3}H]NANM. The pretreatment of mice with a maximum, pharmacologically effective dose of the opiate antagonist naloxone, the α_2 adrenoceptor antagonist yohimbine, or the benzodiazepine agonist diazepam also failed to displace the in vivo binding of (+)[^{3}H]NANM. In separate, in vitro receptor binding assays, unlabelled (+)NANM was found to lack affinity at naloxone-sensitive opiate, benzodiazepine, dopamine D-2, cholinergic, noradrenergic (alpha-1, alpha-2 and beta), histamine H-1, and serotonin (5-HT-2 and 5-HT-1A) receptor binding sites. Thus, the displacement of (+)[^{3}H]NANM observed during this investigation appears to have resulted exclusively from the sigma/phencyclidine receptor binding site. These results, combined with the previously reported potential preclinical antipsychotic activity of mCPP and MK212 in conditioned avoidance tests [Moyer and Lucki, Soc. Neurosci. Abstr. 11:1186 (1985)] as well as buspirone's preclinical antipsychotic profile further support a possible role for sigma receptors in antipsychotic drug action.

128.18 DOPAMINE AGONIST PROPERTIES OF AMINOTHIAZOLE BIOISOSTERES OF 3-PPP. J.C. Jaen*, L.D. Wise*, F.M. Hershenson, H. Tecle*, T.G. Heffner, T.A. Pugsley and L.T. Meltzer. Departments of Chemistry and Pharmacology, Warner-Lambert/Parke-Davis Pharmaceutical Research, Ann Arbor, MI 48105.

3-(1-propyl-3-piperidinyl)phenol (3-PPP) is the prototypical dopamine (DA) autoreceptor agonist. Its limited oral activity and short duration of action prompted us to design PD 118,237, a 4-(1-propyl-3-piperidinyl)-2-thiazolamine, as a bioisosteric replacement for 3-PPP. However, PD 118,237 appeared to be a weak DA agonist based on its low affinity for DA receptors in an in-vitro receptor binding assay and its incomplete antagonism of gamma-butyrolactone-stimulated brain DA synthesis in rats. Molecular modeling studies led to the synthesis of two analogs with improved characteristics: PD 118,440 and PD 120,697.



PD 118,237



R = nPr; PD 118,440
R = allyl; PD 120,697

These 4-(1-alkyl-1,2,5,6-tetrahydro-3-pyridinyl)-2-thiazolamines bound selectively to D_2 versus D_1 DA receptors, inhibited the firing of substantia nigra DA neurons in rats and reversed the increase of brain DA synthesis induced by gamma-butyrolactone in rats. This profile of activity indicates that PD 118,440 and PD 120,697 are DA agonists. Both PD 118,440 and PD 120,697 reduced spontaneous exploratory locomotor activity in mice (ED_{50}: 2.9 and 3.0 mg/kg IP, respectively). In rats, both compounds decreased locomotor activity when administered orally (3 mg/kg) but increased locomotor activity at higher doses (30 mg/kg), suggesting both pre and postsynaptic DA agonist activity. In addition, both compounds stimulated locomotion when administered to rats pretreated with reserpine to produce super- sensitivity of postsynaptic DA receptors. Collectively, these results demonstrate that PD 118,440 and PD 120,697 are brain DA agonists with good oral activity. The data also indicate that PD 118440 is more selective than PD 120,697 for DA autoreceptors but that both compounds are less selective for DA autoreceptors than is ±3-PPP.

128.19 EFFECT OF NEUROLEPTIC WITHDRAWAL ON PLASMA PROLACTIN IN SCHIZOPHRENIC PATIENTS. K. Maeda*, B. Kirkpatrick*, G.K. Thaker, D. Jauch*, T.N. Chase and C.A. Tamminga. NINCDS, NIH, Bethesda, MD 20892, and Maryland Psychiatric Research Center, Univ. of Maryland Sch. of Med., Baltimore, MD 21228.

Abrupt withdrawal of treatment with neuroleptics in schizophrenic patients is associated with various withdrawal manifestations. Tardive dyskinesia is the best known example of such a phenomenon. Those manifestations are generally considered to be ascribed to dopamine receptor supersensitivity. However, there has been little direct study in the living human to contribute to our understanding of the mechanism(s) of neuroleptic withdrawal symptoms. Six male patients between the ages of 20 and 30 (mean 25.2) with a DSM III diagnosis of chronic schizophrenia gave a written consent to participate in this study. The patients had received various antipsychotic drugs for at least 12 months. Patients were treated with 0.1 mg/kg haloperidol for 4 weeks. Thereafter, they were abruptly withdrawn from their medication in a placebo-controlled, double-blind design. Clinical assesments of mental status and plasma prolactin determination were done before and thoughout the withdrawal periods. On the morning of the blood sampling, a #19 butterfly needle was inserted into a forearm vein. From a three way stop-cock attached to the butterfly needle, three samples of blood were taken 45 min after insertion of the needle 5 min apart. After all three samples were collected, they were immediately centrifuged and the plasma were stored at -70 C. Plasma prolactin was measured by radioimmunoassay. Mean value for the 3 samples was used for a single prolactin value. The modified BPRS ratings was made by two trained psychiatrist who individually rate the patients' mental status and then develop a concensus rating. As shown in table, marked reduction in plasma prolactin was observed during the first week of drug withdrawal. The prolactin values increased during the later withdrawal phase and the 3rd/4th drug free week as compared to intial withdrawal week. A wide variety of patterns of BPRS changes were observed after neuroleptic withdrawal. These data indicate that dopamine receptor supersensisitivity occurs at the pituitary lactotrophs, and is temporally discordant with any changes in psychosis.

128.20 DOPAMINERGIC ACTIVITY OF SELECTED 3-AMINOCHROMANS. B.S. Glaeser, J. C. Berry,* W. C. Boyar, R. A. Lovell, and A. J. Hutchinson.* Neuroscience/Cardiovascular Research Department., Pharmaceuticals Division, CIBA-GEIGY Corp., Summit, New Jersey, 07901.

The dopaminergic properties of several 3-Aminochromans were studied using the gamma-butyrolactone model for dopamine autoreceptors (Walters and Roth, Naunyn-Schmiedeberg's Arch. Pharmacol. 296:5, 1976). The structures and initial results of these compounds in the GBL model are summarized in the table below. Compound 3 (CGS 14948A) has been previously described as a dopamine autoreceptor agonist (Berry et al., Fed. Proc. Abstract #2807, 1985) with oral activity in the GBL model and a duration of action of 30 to 60 min post ip administration. Compound 6 (CGS 15397A) had also been shown to have properties characteristic of dopamine autoreceptor agonists. Compound 6 (10 and 30 mg/kg, po) was shown to have oral activity in the GBL model, by reversing the GBL-induced accumulation of DOPA after 30 and 60 min. pretreatment. The duration of action of Compound 6 was estimated by the measurement of dopamine metabolites at various time points after a single injection. At a dose of 5 mg/kg ip, Compound 6 significantly reduced striatal concentrations of DOPAC and HVA 30 and 60 min post administration. Also striatal dopamine levels were elevated 60 and 120 min post administration. In summary minimal dopaminergic activity was observed with compounds possessing only a free amino group versus molecules having a nitrogen substituted with methyl or propyl groups. Maximal dopaminergic activity was observed in molecules having a di-propyl substitution on the nitrogen and with hydroxyl groups at positions corresponding to R_1, R_2, or R_3.

129.1 INGESTION-ASSOCIATED CHANGES IN BRAINSTEM SENSORIMOTOR ACTIVITY AS REVEALED IN COMPOSITE [14-C] 2-DEOXYGLUCOSE AUTORADIOGRAPHS FROM 6-DAY-OLD RAT PUPS. C.B. Phifer, L.M. Terry and W.G. Hall (SPON: R.P. Erickson). Department of Psychology, Duke University, Durham, NC 27706.

When infant rat pups are given oral infusions of a liquid diet, the pups exhibit avid ingestion, including vigorous lapping, mouthing and swallowing. Intake by this form of ingestion is usually deprivation-dependent, but when the infusion cannula is appropriately placed in the back of the oral cavity, pups exhibit reflexive swallowing, which is not dependent on deprivation. Using [14-C] 2-deoxyglucose autoradiography (2-DG), we compared changes in relative neural metabolic activity of brainstem sensorimotor systems associated with deprivation-dependent and deprivation-independent ingestion.

Pups used in this experiment were 6 days of age and had been deprived of all nutrient for 24 hr or left nondeprived. Injections of 2-DG (20uCi/100g, s.c.) were given and a 1 hr incorporation period was allowed. During this period, both deprived and nondeprived pups were fed milk through oral cannulas; for comparison purposes, another group of nondeprived pups were not fed. Pups were then sacrificed and their brains were removed, sectioned and autoradiographic images were prepared. Autoradiographic images corresponding to brain sections at the level of the hypoglossal nucleus were selected by matching to the Nissl-stained tissue. Utilizing image averaging techniques, composite images were made from autoradiographs of 6 pups in each of the three conditions. Differences in activity between treatment groups were revealed by subtracting one averaged image from another.

Relative to non-ingesting pups, the brains of ingesting pups, both deprived and nondeprived, showed increased activity in the hypoglossal complex and nucleus tractus solitarius, as well as reticular regions lateral to hypoglossal (parvocellular). There were also clear differences in activity between pups that were deprived and ingesting and pups that were nondeprived and ingesting. The pups exhibiting deprivation-dependent ingestion showed greater activity in the hypoglossal complex, more widely distributed activity in nucleus tractus solitarius, and greater, more-widely distributed activity in reticular regions (particularly in very lateral and ventral areas). Deprived and ingesting pups also showed enhanced activity in the interpolaris trigeminal nucleus (particularly dorsal region) than nondeprived ingesting pups. These results reinforce earlier findings on ingestion-associated activity in sensory and motor nuclei and also reveal corresponding activity changes in known dendritic fields of the brainstem. (Supported by NICHD Grant HD-17458.)

129.2 INTRADUODENAL MEDIUM-CHAIN FATS DECREASE FOOD INTAKE, BUT INTRAPORTAL MEDIUM-CHAIN FATS DO NOT. D. Greenberg, P.A. Foelsch*, P.M. Perez*, and G.P. Smith. Dept. of Psychiatry, Eating Disorders Institute and Bourne Behavioral Research Laboratory, New York Hospital-Cornell Medical Center, White Plains, NY 10605.

Intraduodenal (id) infusions of long-chain triglycerides (LCT, Intralipid, Kabi Vitrum Inc., CA) at physiological rates inhibited feeding and elicited behaviors typical of satiety in rats, but intraportal (iport) infusions did not (Greenberg et al., Abstr. Soc. Neurosci. 10:531, 1984). To determine if this differential satiating potency also occurred with infusions of medium-chain triglycerides (MCT) which are normally absorbed via the hepatic portal system, we investigated the satiating potency of id and iport infusions of the MCT, trycaprylin.

Method: Male Sprague Dawley rats (400-450g) were equipped with chronic gastric cannulas for sham feeding and with chronic Silastic catheters in the duodenum or in the portal vein for tricaprylin infusions. After a 17h overnight food deprivation, rats were permitted to sham feed a high-carbohydrate liquid food (BioServ 40% v:v). All infusions began 12 min after the start of sham feeding and lasted 26 min. Id infusions were 10 ml of tricaprylin (1.25, 1.825 or 2.5 kcal) or 10 ml of 0.15M NaCl. Iport infusions were 1 ml of tricaprylin (1.25 or 2.5 kcal) or 1 ml of 0.15M NaCl. Intakes were measured every 5 min for 60 min.

Results: Id infusions of tricaprylin decreased intake in a dose-related manner, but intraportal infusions did not (see table).

	Percent Inhibition of Intake	
Caloric Load (kcal)	Duodenal Infusion	Portal Infusion
1.25	22.8 ± 8.35	-14.6 ± 10.4
1.825	49.7 ± 8.42	-----
2.5	74.0 ± 6.2	-19.0 ± 20.9

Data are mean ± SE from 5 rats for portal and 7 rats for duodenal infusions. Negative % inhibition indicates larger intake when trycaprylin was infused.

These results demonstrate the same differential satiating potency for tricaprylin (MCT) as we previously reported for Intralipid (98.5% LCT) and support the hypothesis that the major site of the satiating effect of MCT and LCT is preabsorptive.

129.3 RATS SHAM FEED CORN OIL AND MINERAL OIL, BUT PREFER CORN OIL. S. Mindell* and G.P. Smith. Dept. of Psychiatry, Eating Disorders Institute and Bourne Laboratory, New York Hospital-Cornell Medical Center, White Plains, New York 10605.

Rats prefer fatty foods. It is not clear whether this is due to the orosensory stimuli or post-ingestive effects of fats. To determine if the orosensory stimuli are reinforcing in the absence of postingestive effects, we investigated the effect of corn oil or mineral oil on sham feeding in chronic gastric fistula rats.

Rats were maintained on Purina Rat Chow and were tested after an 18-hour, overnight food deprivation. Group A (N=4) got pure corn oil and group B (N=6) got pure mineral oil to sham feed for 30 min each day. Within 8 days both groups sham fed at stable rates with no difference in acquisition time of sham feeding. After 12 days the mean intake (ml) for 2 tests for group A was 25.4±1.3 and for group B was 23.8±3.9. Group A then received mineral oil and group B received corn oil. Within 3 days both groups had relatively stable intakes; the mean intake for 2 tests for group A was 19.5±2.8 and for group B was 31.3±3.5 ($p<.05$).

Both groups were then given a 30-minute, 2-bottle preference test for two days with both oils available. All rats sham fed more corn oil than mineral oil (corn oil $\bar{X}$=31.5±3.1; mineral oil $\bar{X}$=1.3±0.7). Group A then received corn oil and group B received mineral oil for 3 days (mean intake for 2 tests: group A=21.5±3.0; group B=24.2±4.2). The two bottle preference test was then repeated with very similar results (corn oil $\bar{X}$=27.4±3.0; mineral oil $\bar{X}$=0.2±0.1).

Thus, although rats sham feed both corn oil and mineral oil in 1-bottle tests, they have a marked preference for corn oil in 2-bottle tests. These results demonstrate that in the absence of significant postingestive effects, the orosensory stimuli of corn oil and mineral oil are positively reinforcing because they maintained sham feeding in these rats over a period of at least 8 weeks without evidence of extinction.

129.4 SHORT-TERM FOOD INTAKE AFTER REPEATED INTRADUODENAL GLUCOSE INFUSIONS IN MEAL-FED RABBITS. P.J. Geiselman, A. Acevedo-Cruz*, and L. O'Farrell. Dept. Psychol. and Neuroscience Program, UCLA, Los Angeles, CA 90024.

It has been hypothesized that glucose is satiating when it arrives in the duodenum slowly and is absorbed slowly. Conversely, glucose may stimulate hunger when it arrives in the duodenum quickly and is absorbed rapidly. Compared with free-feeding animals, meal feeders absorb glucose more rapidly and clear glucose from their circulatory systems faster. These responses led to the hypothesis that patterns of meal-taking may determine whether glucose produces satiation or hunger. In the present study, meal-fed rabbits were given duodenal glucose infusions at either a slow or a rapid rate, which had been shown to produce satiety and to stimulate hunger, respectively, in free-feeding rabbits.

Female New Zealand rabbits were chronically implanted with duodenal cannulae and were adapted to a schedule in which chow was available for only 4 hrs daily. Rabbits were infused intraduodenally (10 ml/3 kg BW) with 0.3M glucose, 0.15M NaCl, or were given a mock procedure. Infusion rates were either 1 ml/min or 3 ml/min. Glucose, saline, and mock procedures were repeated for three trials each.

As reported in free-feeding rabbits, meal-feeders also increased their food intake at .5, 1, 2, 3, and 4 hrs following rapid glucose infusion into the duodenum. Interestingly, meal-fed rabbits that received slow intraduodenal glucose infusions also showed an increase in food intake at .5, 1, 2, 3, and 4 hrs postinfusion. These latter results are in contrast to the satiating effect of slow intraduodenal glucose infusion found in free-feeding rabbits. Furthermore, after having received their first slow infusion of glucose into the duodenum, meal-fed rabbits ingested more food in subsequent tests in the saline and the mock conditions. A similar trend was observed following the first fast infusion of glucose. This trend was most apparent in subsequent fast saline conditions. These data suggest that conditioning may have taken place.

These results suggest that the daily pattern of meal-taking can determine whether glucose is satiating or hunger stimulating.

129.5 FOOD INTAKE AND PLASMA GLUCOSE LEVEL SHIFTS FOLLOWING GLUCOPRIVIC CHALLENGE IN A DESERT-DWELLING RODENT, THE SPINY MOUSE (ACOMYS CAHIRINUS). D.A. Czech, M.M. Ishii,* L.M. Gehrke* and M.A. LaBar*
Dept. of Psychology, Marquette University, Milwaukee, WI 53233.

We previously reported (Czech & Schrank, Soc. Neurosci. Abstr. 12:1294, 1986) that the spiny mouse, like the hamster, gerbil and several murid rodent species, does not exhibit feeding behavior in response to the glucose antimetabolite 2-deoxy-D-glucose (2-DG) (250, 500 & 1000 mg/kg i.p.). In contrast, 2-DG is a potent feeding stimulus in a wide variety of other mammals. In the present study, we extended these observations, investigating Acomys' feeding response to insulin, as well as the time course of shifts in plasma glucose levels following glucoprivic challenge by both 2-DG and insulin.

In the first experiment, male spiny mice were injected s.c. with 4 doses of regular insulin (Iletin) (1, 3, 10 & 30 U/kg) and normal saline in a within-subject design, and powdered food intake to the nearest 0.1 g was measured at 1, 2, 4, 6 & 24 hours. Water was available ad lib. Tests were separated by one week, and began approximately 2 hr into the light period. Cumulative intakes were evaluated with ANOVA and Dunnett's procedures. Significance level was set at $p<0.05$. By the end of the second hour, all doses of insulin, with the exception of the 30 U/kg dose, led to significantly greater food consumption when compared to baseline (vehicle injection) intake. The 30 U/kg dose reached significance at 4 hours. These data are in sharp contrast to the previously observed lack of feeding in response to 2-DG in this species.

In the second experiment, the effect of several doses of regular insulin (1 & 3 U/kg s.c.), 2-DG (250 & 500 mg/kg i.p.) or normal saline on plasma glucose levels was determined in male spiny mice. Blood samples were drawn by retro-orbital puncture technique under brief ether anesthesia, and plasma glucose concentration was determined at 0 (immediately prior to injection), 0.5, 1, 2, 4 & 6 hr (within-subjects), using the glucose oxidase method (Sigma Chemical kit 510-A). Water, but no food, was available ad lib during the sampling period. Plasma glucose concentration was evaluated at each sampling point with ANOVA and Duncan's procedures. Rejection level was set at $p<0.05$. All treatments produced significant hyperglycemic (2-DG) or hypoglycemic (insulin) responses. Following 2-DG, mean glucose peaked by one hour, with the 250 & 500 mg/kg groups reaching 309 & 303 mg/dl, respectively. Plasma glucose in the 1 U/kg insulin group dropped to a low mean level of 52 mg/dl, also within the first hour, while the 3 U/kg group was lowest (18 mg/dl) at the 2 hr sampling point. Only the 3 U/kg insulin group remained significantly different from the vehicle group at the end of 6 hr. Mean baseline plasma glucose (all animals) was 157 ($\pm$ 5 = 1 s.e.m.) mg/dl.

129.6 CARBOHYDRATE RESTRICTED DIETS EFFECT ON BLOOD GLUCOSE, INSULIN, PYRIDOXAL 5'-PHOSPHATE, DOPAMINE-β-HYDROXYLASE AND AMINO ACIDS IN NORMAL AND IMMOBILIZED CAT. L. Thibault* and A.G. Roberge.
Lab. de Nutrition et de Neurochimie, F.S.A.A., Univ. Laval, Québec, Canada, G1K 7P4.

Adult cats were progressively adapted to hypoglucidic semi-purified diets containing casein or soya as protein source to study the effects of a 2 h immobilization period. Body weight of cats fed hypoglucidic diets was significantly decreased. The control casein group showed higher serum dopamine-β-hydroxylase activity and methionine level but lower pyridoxal 5'-phosphate and ammonia content than control soya group. In cats fed hypoglucidic casein diet, serum glucose, insulin, pyridoxal 5'-phosphate and ammonia levels were increased and methionine decreased whereas in cats fed hypoglucidic soya diet, pyridoxal 5'-phosphate content was decreased and dopamine-β-hydroxylase activity increased, when data were compared to their respective control groups. A 2 h immobilization period induced hyperglycemia in all groups whereas in all cats fed soya diets, serum insulin level and dopamine-β-hydroxylase activity were significantly increased and pyridoxal 5'-phosphate content significantly decreased. Immobilization also induced increased serum leucine, isoleucine, valine, phenylalanine, tyrosine and free tryprophan levels in cats fed control casein diet, unchanged serum amino acids in cats fed hypoglucidic casein diet but decreased serum valine, leucine, isoleucine, methionine, phenylalanine and tyrosine levels resulting in increased free tryptophan and tyrosine: neutral amino acids ratios, in cats fed control and hypoglucidic soya diets. These results demonstrate that dietary casein and soya protein might be differentiated on a physiological basis and immobilization emphasized the biochemical disturbances observed between the groups thus suggesting a more acute response to stress in soya groups.

129.7 SUGAR, FATS AND POLYSACHARIDES INHIBIT DISTRESS VOCALIZATIONS AND ELEVATE PAIN THRESHOLDS IN INFANT RATS. D. Shide*, E.M. Blass. (SPON: R.J. Nelson)
Department of Psychology, Johns Hopkins University, Baltimore, Maryland 21218

The discoveries that: 1) neonatal altricial rats can taste and respond to a variety of substances and, 2) endogenous opioid systems appear to be behaviorally functional in 10-day-old rats led us to evaluate interactions between pleasure, psychological and physiological stress. In one experiment, either 7.5% sucrose, corn oil, 2% or 32% polycose was infused through jaw cannulae into the mouths of Day 10 pups that were separated from their mothers but group-housed as a litter. Paw-lift latencies (PLL) from a 48 C hot-plate were determined either 0, 1, 3 or 5 min after termination of sucrose infusions. In a second experiment, individually housed rats received through the indwelling jaw cannula infusions of the same substances. The number of distress vocalizations (DVs) caused by the isolation was recorded on a minute-by-minute basis for experimental and control isolated groups.

Each of these treatments caused a 30-40% decrease in the number of distress vocalizations emitted by Day 10 rats and a 20-100% increase in paw lift latency. The most potent analgesic was 32% polycose which elevated PLL from 19.5 sec (operated control) to 31.2 sec at the end of the polycose infusion. Analgesia remained elevated in all cases even 5 min after infusion termination. These and other behavioral manifestations parallel those induced by intercerebral injections of morphine. They suggest that the positive hedonic affect and the blunting of negative affect by certain substances reflect the taste-release of central endogenous opioids in infant rats.

129.8 FEEDING RESPONSES TO A TRYPTOPHAN DEVOID DIET: CORRELATION WITH BEHAVIOR BUT NOT PLASMA TRYPTOPHAN OR BRAIN SEROTONIN LEVELS IN THE TERRESTRIAL SLUG, LIMAX MAXIMUS. D.W. Gietzen, A.S. Harris*, A. Caprile*, J.M. Larson*, P.M.B. Leung, and Q.R. Rogers. Depts of Physio Sci, Sch Vet Med, Psychiatry, Sch Med, and Food Intake Lab, UC Davis, CA 95616.

Slugs have been shown to depress intake of amino acid deficient diets, as do other species. Since serotonin (5HT) is recognized as a neurotransmitter, and is dependent on the amino acid, tryptophan (TRP), as its precursor, we fed a TRP devoid diet to specimens of Limax maximus and measured terminal brain 5HT and plasma TRP. Cumulative food intake was depressed 50% in a 3 week feeding trial (complete diet group [COM] = 13.3 $\pm$ 1.5 g [mean $\pm$ SE] cumulative intake, devoid diet group [DEV] = 6.7 $\pm$ 0.9 g), in groups of 7 animals with equal body weights at the beginning of feeding. After the 3 week trial, the COM animals weighed 9.6 $\pm$ 1.3g and the DEV animals weighed 6.3 $\pm$ 1.1g. Over 2 weeks, cumulative food intake was again depressed in DEV, to 66% of control (12.3 $\pm$ 1.6 for COM vs 8.4 $\pm$ 1.7g for DEV), with a trend to depressed body weights (57% of COM). It was also observed that the DEV animals seemed to move away more readily during the measurement of body weight. A subjective grading of activity levels on a scale of 1-5 suggested that DEV animals were more active than COM (COM = 2.0 $\pm$ 0.2; DEV = 3.1 $\pm$ 0.5). This experiment was repeated with an additional control group, pair fed to DEV (PAIR). In this trial, activity, as measured by the number of animals with tentacles extended or retracted, was not different between groups. However, time to righting in DEV animals, as measured by the time to touch the whole mantle border to the cage bottom after being placed on its side, was shorter in DEV than either COM or PAIR (χ^2 = 6.14, $p < 0.05$ for probability of time greater than the median time). Thus, the increased mobility was not due to the food deprivation in DEV. At the completion of the second diet trial, perchloric acid extracts of both plasma and brain were analyzed for 5HT and TRP by HPLC with electrochemical detection. There was no measurable TRP in brain, and no measurable 5HT in plasma. There were no differences in either 5HT or TRP between DEV and COM. Values were: Brain 5HT: COM = 67.3 $\pm$ 4.5 ng/mg protein, N = 8; DEV 66.1 $\pm$ 6.3 ng/mg, N = 5; plasma TRP: COM = 92.9 $\pm$ 11.9 ng/ml, N = 6; DEV = 160.9 $\pm$ 32.3 ng/ml, N = 5. Refractive indices for protein in the plasma samples also did not differ. Thus, although we observed 2 behavioral variables, which may be influenced by 5HT, to be altered in the expected direction in the DEV animals, neither 5HT nor TRP concentrations were different between the 2 groups. The inclusion of the PAIR group suggests that the decreases in both food intake and time to righting were not due to the reduction in food intake. The slug may be able to utilize body stores of free amino acids or metabolize endogenous protein in order to maintain the TRP and 5HT levels, but it is clear that the depression in intake of a TRP deficient diet is not due to changes in brain 5HT or plasma TRP concentrations that could be measured after 2 weeks on a TRP deficient diet. (Supported by NIH Grant AM07557).

129.9 VARIATIONS IN SUCROSE CONCENTRATION AND ITS EFFECT ON FOOD INTAKE IN THE DOMESTIC CAT. I.W Castonguay, I.C. Giles*, J.F. Harrison*, and Q.R Rogers. Food Intake Laboratory and Nutrition Department, University of California - Davis Davis CA 95616

Domestic cats do not prefer sucrose, glucose, maltose, or polycose to water (Harrison et al., 1986). When given access to 10% (w/v) solutions of any of these sugars as supplements to a complete maintenance diet, cats fail to adjust their intake of diet and supplement, so as to overconsume on a caloric basis. The present study was conducted to observe the effects of increased concentrations of sucrose on intake and weight gain. It had already been reported that high concentrations of sucrose promote diuresis and diarrhea in cats. The question asked in the present experiment was: "Does the cat alter its consummatory habits in response to increases in sucrose concentration?" Twelve 3 month old cats (6 female and 6 male) weighing an average of 2145 and 2520 g respectively at the start of the experiment were housed individually in stainless steel metabolism cages. After a preliminary baseline period the cats were tested through four cycles of a 5 day sucrose access period followed by a 2 day recovery period during which only water was available as drinking fluid. Water and maintenance diet were available ad libitum throughout the experiment. An ascending series of sucrose concentrations was used (5%, 10%, 15%, 20%). The positions of the water and sucrose solutions were alternated from left to right daily so as to counterbalance for position preference. The experiment was stopped after the 20% sucrose condition due to significant diuresis and diarrhea in most of the animals. Results from the 5 day test periods reveal that neither male nor female cats adjust their intake of food and sucrose supplement so as to maintain baseline caloric intakes. Rather, both sexes overate in response to the 15% and 20% sucrose solutions. Male cats ate significantly more during these periods than did female cats. With access to the 5% concentration, both males and females consumed approximately 5% of their total calories from sucrose. With access to 10% sucrose, the animals ate approximately 8%; with access to 15%, approximately 13%; and with 20% sucrose, approximately 20% total calories from sucrose. No differences in proportion of calories from sucrose between sexes were noted. Consumption of solid diet remained uniform throughout the four sucrose access period, averaging 110 to 120 g/day in males and 80 to 100 g/day in females. These results suggest that cats are not sensitive to the postingestive effects of consuming significant quantities of sucrose. These results also suggest that the cat may be limited in its sensitivity to the caloric content of its diet. These traits may predispose the animal to some forms of dietary obesity.
(Supported in part by NIH Grant AM 07355)

129.10 METHOD OF COMPUTERIZED MONITORING OF MEAL PATTERNS OF ANIMALS ON MULTIPLE DIETS. C. Ian*, G. Shor-Posner*, and S. F. Leibowitz (Sponsor: N. Miller) The Rockefeller Univ. New York, N.Y. 10021

The microstructure of meal patterns in undisturbed rats maintained on 3 diets (protein, carbohydrate and fat), was automatically recorded by computer, at 30 sec intervals, for 24 hrs. This method employed economical, electronic scales, a PC XT computer, data acquisition hardware and simple, custom software.

Sprague-Dawley, male rats were housed individually in modified 9" by 17", wire mesh, stainless steel cages, under a 12:12 hr light-dark cycle at constant temperature. Pure macronutrient diets in glass food jars rested on OHaus, Port-O-Gram C501 electronic scales (500 g capacity and 0.07 g precision) mounted on adjustable platforms. The jars protruded through the bottom of clear, Plexiglas food module boxes attached to the front of each cage. A horizontal shelf with a round hole directly above the jar provided the animal direct access to the food, with minimal effort, and without applying direct pressure on the jar. The animal reached the food through a rectangular hole in the front of the cage. A spillage tray was positioned under the jar to collect and weigh spilled food. This avoided the use of a more restrictive device that might interfere with normal feeding behavior. The scales, calibrated and tested before each test cycle, sent 16 characters of data with each reading, including a question mark indicating an unstable platform and erroneous reading. Data acquisition was facilitated by use of a Stargate OC 8000, 8 channel, expansion board which merged six serial cables into one serial port on the computer housed in a separate room. This allowed continuous data collection with minimal disturbance to the animals. A program in BASICA collected data as often as every second into a DOS text file on a hard disk.

This simple, computerized technique of data collection permitted a precise, continuous recording of small changes in meal taking events in animals on multiple diets. This allowed subsequent analysis of the microstructure of meal patterns over the course of the entire light-dark cycle.

In initial experiments, rats were adapted for 2 weeks, with fresh food and water provided daily, 6 hours prior to dark onset. Food jars were rotated daily to prevent position preference.

A clear and detailed description of rat macronutrient patterns showed a significant circadian distribution of food intake, with peaks of feeding activity occurring at the beginning and end of the dark period. Additional analysis, as described by Shor-Posner et al., revealed specific phases of the nocturnal period are characterized by identifiable and predictable shifts in macronutrient preference and meal size. This useful procedure has multiple applications in feeding and drinking related research and provides remote analysis of multiple diets as well as single or even liquid diets in undisturbed animals.

129.11 NOCTURNAL PATTERNS OF MACRONUTRIENT INGESTION. G. Shor-Posner*, C. Ian*, C. Guerra* and S. F. Leibowitz. (SPON: I. Abramov). Rockefeller University, New York, NY 10021.

Using automated procedures, natural patterns of food intake and macronutrient selection were examined continuously throughout the course of the dark (active) cycle in undisturbed animals. This computerized-technique permitted us to characterize the full sequence of meal-taking events in animals maintained on multiple diets.

Sprague-Dawley adult male rats were provided with pure nutrient diets (protein, carbohydrate and fat) ad libitum and housed in special food module cages under a 12:12 hr light-dark regime. Their patterns of feeding behavior were recorded via computer-interfaced top loading balances (see C. Ian at this meeting).

Analyses of nocturnal feeding behavior indicated that: 1) Rats initiated feeding within 10 minutes after dark onset and consumed between 10-12 discrete meals during the night. The last meal of the cycle was taken approximately 30 min prior to light onset. 2) Meals at the beginning (hrs 1,2) and end (hrs 11,12) of the night were significantly larger than those ingested during the mid-dark phase (hrs 6,7), reflecting a bimodal distribution of feeding activity. 3) Meal frequency tended to remain stable over the course of the nocturnal cycle, although a trend towards increased number of meals during the first two hours was apparent. 4) Specific alterations in patterns of diet selection occurred throughout the dark cycle. At the beginning of the dark period, meals consisted predominantly of carbohydrate (69%). This strong carbohydrate preference was not apparent during the mid-dark hours when no specific dietary pattern was detected. During the late dark hours, in contrast, a very different selection pattern was observed with meals composed primarily of protein and fat. 5) In addition to this dietary shift from the early to late period, we also observed a meal to meal shift of macronutrient intake with alternating carbohydrate and protein meals. These findings of fluctuating macronutrient intake suggest that feeding over the course of the nocturnal period may be differentially regulated and that composition of a specific meal may affect subsequent intake.

129.12 2-BUTEN-4-OLIDE, TUMOR NECROSIS FACTOR AND INTERLEUKIN-1ß ACTING AS FEEDING SUPPRESSANTS. Y. Oomura, C.R. Plata-Salamán*, S. Nemoto*, A. Niijima and I. Matsumoto*. Dept. of Physiol., Fac. of Med., Kyushu Univ., Fukuoka 812; Natl. Inst. for Physiol. Sci., Okazaki 444, Japan.

Regulation of feeding behavior and control of body weight involve neuronal and humoral factors. We investigated the effects of 2-buten-4-olide (2-B40, a new endogenous sugar acid at 3 µM concentration in blood that increases to 15 µM after 48 hr of food deprivation) recombinant human tumor necrosis factor (rhTNF) and recombinant human interleukin-1ß (rhIL-1ß) on food intake in the rat.

The 2-B40 after intracerebroventricular (1.2 to 5.0 µmole/rat), intraperitoneal (0.4 to 1.7 mmole/kg) or intragastric administration decreased food intake dose-dependently by reducing meal frequency, meal size and eating rate, and prolonging meal duration and post-prandial intermeal intervals. Drinking patterns and locomotor activity were not significantly affected. Electrophysiological studies show that 2-B40 suppressed the activity by hyperpolarization of glucose-sensitive neurons in the lateral hypothalamic area (LHA) and facilitated the activity by depolarization of glucoreceptor neurons in the ventromedial hypothalamic nucleus (VMH). This effect was the same as glucose. In other studies, intravenous administration of 100 pmole of 2-B40 increased the activity of several sympathetic nerves including the adrenal pancreatic, hepatic and renal nerves efferents, whereas the vagal efferent nerve activity decreased. This evidence suggests that 2-B40 produces a sympathetic activation, since blood glucose also increased and insulin level decreased. In other experiments, 2-B40 suppressed gastric acid secretion.

Intracerebroventricular microinfusion of rhTNF (50 to 500 ng/rat) or rhIL-1ß (1.0 to 13 ng/rat) suppressed short- and long-term food intake in a dose-dependent manner. The central infusion of heat-inactivated rhTNF or rhIL-1ß had no such effect. Intraperitoneal administration of rhTNF and rhIL-1ß in similar or higher doses than the central administration had no effect. Short-term rectum temperature was slightly increased by rhTNF and rhIL-1ß. Since TNF and IL-1ß are released by monocytes during inflammatory processes, these results suggest that TNF and IL-1ß play a role in the feeding suppression observed during illness by direct action at the central nervous system. The effects on the LHA and VMH are now being investigated.

These findings suggest that these three endogenous substances, 2-B40, TNF and IL-1ß act as feeding suppressants by action at the level of the nervous system.

129.13 FUNCTIONAL ORGANIZATION OF LATERAL HYPOTHALAMIC GLUCOSE-SENSITIVE (GS) AND GLUCOSE-INSENSITIVE (GIS) NEURONS IN THE MONKEY. Z. Karádi*, Y. Oomura, H. Nishino*, S. Aou* and I. Fujita* (SPON: K. Uchizono) Natl. Inst. Physiol. Sci., Okazaki 444, Japan.

GS- and GIS-neurons in the lateral hypothalamic area (LHA) show characteristic neuronal responses during operant bar-press feeding tasks; i.e. the GS-neurons decrease activity during bar-press and reward phases, while the GIS-neurons increase firing to cue light and cue tone. To elucidate these neurons' input-output organization as well as their specific function in the olfactory and gustatory information processing, LHA single unit responses to electric brain stimulations as well as to various odorants and taste solutions were studied.

Electric shocks to the dorsolateral prefrontal and premotor cortices were followed by similar activity changes of the GS- and GIS-neurons. On the other hand, the GS-neurons responded more often to electric stimulation of the orbitofrontal cortex than did the GIS-neurons, while stimulation of the motor cortex evoked firing changes in more GIS- than GS-neurons.

Odor stimuli elicited excitatory and/or inhibitory responses in almost all of the GS-neurons; however, only less than 50% of the GIS-neurons responded to smells. Manyfold olfactory responsiveness, for two or more odors, of the GS-neurons was observed, whereas the GIS-neurons responded predominantly to one specific smell only.

Gustatory stimulations resulted in firing changes of the most GS-neurons, whereas fewer responses of the GIS-neurons were seen. The GS-neurons responded prevailingly to two or more taste qualities, while the GIS-neurons did mainly to only one. The overwhelming majority of the GS-neurons showed "bimodal" responsiveness to both, gustatory and olfactory stimulations, in contrast with the GIS-neurons that responded predominantly to either taste or odor.

On the basis of the present data different functional organization of the GS- and GIS-neurons in the LHA is suggested. The GS-neurons, having strong orbitofrontal innervation, seem to integrate multimodal, mainly "internal" sensory information in regulating different mechanisms related to food intake. On the other hand, the GIS-neurons, with marked motor cortex connections, distinguish specific "external" sensory cues to modulate selection and acquisition of foods.

129.14 HEAT-INDUCED REDUCTION OF FOOD INTAKE IS ATTENUATED IN CAPSAICIN PRETREATED AND VAGOTOMIZED RATS. E.H. South and R.C. Ritter. WOI Regional Program in Veterinary Medical Education, University of Idaho, Moscow, ID 83843 and Dept. of VCAPP, College of Veterinary Medicine, Washington State University, Pullman, WA 99164-6520.

Rats and other mammals decrease their food intake when subjected to high ambient temperatures. This heat-induced suppression of intake may depend on thermosensitive neurons in the skin, viscera and/or brain. Systemic pretreatment of rats with capsaicin, a neurotoxin that selectively damages some unmyelinated primary sensory neurons in both somatic and visceral nerves, has been reported to attenuate heat-induced suppression of daily food intake in the rat (Cormareche-Leydier, 1981). In an initial effort to assess the thermosensitive substrates damaged by capsaicin we compared heat-induced suppression of 24 hr rat chow intake and the 45 min intake of highly preferred food (cookies) in rats treated with systemic capsaicin or vehicle only.

FOOD INTAKE AT TWO AMBIENT TEMPERATURES

TREATMENT	N	CHOW(24h)	COOKIES(45m)	CHOW(24h)	COOKIES(45m)
Capsaicin	8	20.6±.6g	4.6±.9g	16.3±4g*	4.5±.7g*
Vehicle	8	20.3±.4g	4.3±.6g	13.8±.5g	2.7±.3g

(* significantly different from vehicle intake)

To further investigate capsaicin's effect on thermosensitive mechanisms, we measured rectal temperature and short term cookie intake in hot ambient temperature in rats treated with 175mg/kg capsaicin (HDC), 25mg/kg capsaicin (LDC) or vehicle. Additionally, we evaluated the contribution of vagal damage to alterations of heat-induced suppression of 45 min cookie intake in rats with subdiaphragmatic or sham vagotomy. We found that HDC and LDC rats ate significantly more cookies in hot temperatures than vehicle rats; however, the HDC rats also had significantly elevated rectal temperatures (39.4 ±.2°C) when compared to either LDC (38.4±.2°C) or vehicle (38.0±.2°C) rats. Vagotomized rats, however, not only failed to reduce their intake in the heat, but actually ate 50% more cookies at 32°C than at 24°C. These data indicate that capsaicin damages the substrate(s) responsible for suppressing food intake at high ambient temperatures. Furthermore it appears that dissociation of capsaicin-induced damage to thermoregulatory mechanisms and mechanisms involved in heat-induced suppression of food intake may be possible by varying capsaicin dose. The data also suggest that afferents in the vagus nerve may be involved in suppression of food intake at high ambient temperatures. Such vagal afferents may represent part of the capsaicin sensitive neural substrate mediating heat-induced suppression of food intake. Additional experiments are underway to test this hypothesis. Supported by NIH grants R01 NS20561 and R01 NS21805.

129.15 SUPPRESSION OF SHAM FEEDING BY INTRAINTESTINAL NUTRIENTS IS ATTENUATED FOLLOWING FOURTH VENTRICULAR CAPSAICIN. D. Fear*, D. Yox, and R.C. Ritter (SPON: M. Hyde). Dept. of VCAPP, College of Veterinary Medicine, Washington State University, Pullman, WA 99164 and WOI Regional program in Veterinary Medical Education, University of Idaho, Moscow, Idaho 83843.

Information concerning nutrient arrival in the small intestine is carried to the caudal hindbrain by vagal sensory fibers (Ewart and Wingate, 1985). Most of the vagal sensory fibers from the gastrointestinal tract are small and unmyelinated. Previously, we have demonstrated that intraperitoneal pretreatment of rats with capsaicin, a neurotoxin that destroys a subpopulation of unmyelinated sensory fibers in the vagus nerve and elsewhere, attenuates suppression of sham feeding by intraintestinal infusion of certain nutrients (Yox and Ritter, 1986). In order to determine whether this effect of IP capsaicin is due to damage of vagosensory afferents, we applied the toxin via the fourth ventricle near the central terminals of vagal sensory fibers. Rats were pretreated with 300 µg of capsaicin or injection vehicle (40% DMSO in 0.9% NaCl) via the fourth cerebral ventricle. The rats were subsequently implanted with stainless steel gastric cannulae and Silastic duodenal catheters. Rats sham ingested 15% sucrose while intraintestinal infusions of maltose, sodium oleate or casein hydrolysate were made. The nutrient solutions were all 300mOsm/L with caloric concentrations of 0.13kcal/ml. Percent suppression of intake by the various nutrient solutions was calculated relative to the intake following infusion of NaCl (300mOsm/L). Our results, shown in the table, demonstrate that fourth ventricular capsaicin treatment attenuates suppression of sham feeding by intraintestinal oleate and maltose but not casein hydrolysate.

% Suppression of Intake (Mean ± S.E.)

Infusate	Capsaicin	Vehicle
Sodium oleate (C18)	54.9 ± 8.9	78.1 ± 4.4
Maltose	7.2 ± 6.0	27.8 ± 6.0
Casein hydrolysate	15.4 ± 3.7	15.2 ± 4.1

The effect of fourth ventricular capsaicin is similar to that of IP capsaicin. The proximity of the capsaicin application to the vagal afferent terminals in the nucleus of the solitary tract suggests that the ingestive effect of IP capsaicin is due, at least in part, to its action on unmyelinated vagal afferents. The data are also compatible with the proposition that some nutrients that suppress feeding do so by activating a substrate which is not destroyed by capsaicin. Supported by NIH grants R01 NS20561 and R01 NS21805.

129.16 LATERAL HYPOTHALAMIC LESIONS DO NOT ALTER THE ANOREXIA INDUCED BY CENTRAL INJECTIONS OF ETHANOLAMINE-O-SULFATE (EOS). D.V. Coscina, J. Snow* and J.N. Nobrega. Sect. of Biopsychology, Clarke Insti.-Psychiatry, Univ. of Toronto, Toronto, Ontario, Canada M5T 1R8.

EOS is a drug which inhibits the catabolism of the inhibitory neurotransmitter, gamma-aminobutyric acid (GABA). We have previously shown that intracisternal (i.c.) injections of relatively low doses of EOS produce normal dose-dependent anorexia in three models of chronic overeating plus block the acute overeating induced by systemic injection of insulin or 2-deoxy-glucose (2DG). Given this effectiveness of EOS to reverse or prevent overeating, an understanding of its mechanism of action could prove useful in (a) improving our basic knowledge of the CNS controls over food intake, and (b) perhaps leading to more successful treatments in the prevention of excessive food consumption. Previous work from other laboratories has implicated the lateral hypothalamus (LH) as one brain site which might mediate GABA-induced anorexia. If that is true, one might expect that lesions of the LH would prevent or minimize the anorexia which follows i.c. EOS. To test that possibility, 10 adult female rats received bilateral radiofrequency heat lesions of the LH and 10 other rats received anesthetization as a control treatment. All animals had free access to Purina Lab Chow pellets (4% fat) and tap water at all times during these studies. Following 2 weeks of post-operative recovery, all rats were tested at separate times for their recovery of normal daily feeding and drinking after 0, 100 and 200 ug EOS in 20 ul deionized water injected i.c. under methoxyflurane anesthesia. As in previous work, EOS induced anorexia which increased in magnitude and duration as dosage increased. However, lesioned rats showed the same magnitude and duration of anorexia as controls after each treatment. To determine the functional effectiveness of LH lesions to produce long-term intake deficits, separate tests were conducted of acute feeding in response to intraperitoneal (i.p.) challenge with 2DG (400 mg/kg) or acute drinking in response to i.p. challenge with hypertonic saline (1M NaCl; 1% free-feeding body weight). In both tests, LH-lesioned rats showed only 50% of the intakes shown by controls. These latter data make it unlikely that the lack of differential anorectic response to i.c. EOS was due to insufficient injury to the LH brain axis. Therefore, our data imply that neither the intrinsic cell population of the lateral hypothalamus nor the fibers of passage which normally traverse it represent likely neural substrates upon which EOS acts to induce anorexia.

129.17 MEAL INITIATION FOLLOWING INDUCTION OF TRANSIENT DECLINES IN BLOOD GLUCOSE: EVIDENCE FOR CAUSALITY. L. A. Campfield and F. J. Smith
Neurobiology and Obesity Research, Hoffmann-La Roche Inc., Nutley, NJ 07110

We have recently shown that a brief (3-5 min) rise in plasma insulin (I) (45%) preceded the transient declines (-10%) in blood glucose (BG) which occurred approximately 13 min prior to meal initiation (MI) in free-feeding rats. These studies, together with others from our lab, suggest that transient declines in BG are causally related to MI. This hypothesis was tested using an acetylcholine analog (Ach A) known to cause a brief rise in I with a similar magnitude and time course. Ach A was infused IV in an attempt to induce transient declines in BG and the latency to MI was determined. Sixteen female Wistar rats (220 gms) were implanted with both chronic cardiac (blood withdrawal) and femoral vein (infusion) cannulas. Following a 7 day recovery period and return of food intake and body weight to pre-op values, 21 experiments were performed during long intermeal intervals of the light phase. Fresh water and powdered chow were available ad lib. Following IV heparin (100-300 U), BG and meal pattern were continuously monitored for up to two hours in 15 experiments. In 6 other experiments, meal pattern only was monitored to allow comparison without blood withdrawal. Random sequences of up to 4 doses (45-350 µg/kg BW) of Ach A (carbamyl-β-methylcholine chloride) were infused at least 20 min apart until a fall in blood glucose, if any, was observed. In 9 experiments, Ach A infusion (227±30 µg/kg BW) was followed by a transient decline in BG (-9.4 ± 1.3% at 9.4 ± 1.4 min) with a shape similar to that observed prior to meals and MI occurred 17.1±3.2 min after the beginning of the decline in BG. The average meal size was 1.1±0.3 gm. In contrast, in 6 other experiments BG did not significantly change (<5%) following a smaller average dose of Ach A (168±21 µg/kg BW)and no feeding occurred. In 4 of the 6 experiments without BG monitoring, MI occurred 19.6±3.9 min after Ach A infusion (274±19 µg/kg BW). The frequency of induced feeding was greater in the late (79%) than in the early (28%) light phase. Therefore, infusion of Ach A induced transient declines in BG followed by MI with an average latency of 17 min, while smaller doses of Ach A did not result in significant declines in BG nor feeding. These studies demonstrate the experimental induction of MI during the long intermeal intervals of the light phase in non-deprived rats but only following a brief fall and rise of BG. The latency of MI following Ach A corresponds to the temporal relationship between a rise in I and MI in free-feeding rats. These studies provide strong support for a causal relationship between transient declines in BG and MI under free-feeding conditions. We conclude that transient declines in BG are among the endogenous factors controlling meal initiation.

129.18 SHORT TERM EFFECTS OF FRUCTOSE ON MEAL INITIATION AND BLOOD GLUCOSE DYNAMICS. F.J. Smith, D. M. Whyte* and L. A. Campfield
Neurobiology and Obesity Research, Hoffmann-La Roche Inc., Nutley, NJ 07110

We have previously shown that small (-11%) transient (~18 min) declines in blood glucose (BG) which precede feeding are causally related to meal initiation (MI) under free-feeding conditions. We have also shown that IV infusions of glucose (0.2 ml of 10%) that blunt these declines can delay MI. Since oral and IV fructose (F) have been reported to cause transient hypoglycemia, we used F infusions to test the specificity of glucose to delay MI and to mimic the transient declines in BG. Chronic cardiac and femoral cannulas were implanted in 13 female Wistar rats (250 gm). Following a 7 day recovery period and return of food intake and body weight to pre-op values, continuous monitoring of BG and meal pattern was performed in the light (n = 10) and dark phases (n = 5). Fresh water and powdered chow were available ad lib. Following IV heparin (100-300 U), blood withdrawal (25 µl/min) was begun and continued for up to 2.5 hours. When F (0.2 ml of 10%) was infused IV during a transient decline in BG, MI occurred with a normal latency. Random sequences of F (dose range: 0.05-0.3 ml of 10%), separated by at least 30 min, were then infused IV during intermeal intervals. During the early dark phase, IV F was followed by a slight decrease or increase in BG (-4 to 10% at 6 min). In the light phase, however, three types of dose-dependent declines in BG were observed: a fall to a suppressed level (-6%) for at least 30 min (n = 4); a transient fall (-10% at 8 min) and a delayed return to baseline at 28 min (n = 4); and a transient fall (-9% at 8 min) and return to baseline at 17 min similar to that seen prior to MI (n=3). In these 3 experiments, MI occurred with a latency within the normal range (14.5 ± 1.5 min). No feeding was observed following the other F infusions. Similar effects on BG were observed following oral administration of a range of F doses (0.5-1.5 ml of 50%) in 2-hour fasted rats. These results demonstrate that F was not able to uncouple BG from MI and that both oral and IV F were followed by small, rapid declines in BG in the light but not in the dark. Since the perturbations in BG following F were similar in magnitude to the transient declines in BG prior to meals, these studies suggest that they were detected by peripheral and central glucose receptive elements. Thus, the conclusion that fructose infusions have no effect on the CNS or access to glucose receptive elements in the CNS may have to be re-evaluated.

129.19 EFFECT OF FORCE FEEDING ON WEIGHT AND SUBSEQUENT FOOD INTAKE OF WEIGHT-GAIN "RECOVERED" AREA POSTREMA-LESIONED RATS. * Nancy J. Kenney, Jon N. Kott, C. Shawn Kreig, A. Susan Ruiz and Naomi Tomoyasu. Dept. Psych. Univ. of Washington Seattle WA 98195.

Ablation of the area postrema and subjacent medial commissural nucleus of the solitary tract (APX) of rats results in transient hypophagia and permanent weight loss. We have reported that force feeding APX rats immediately following the ablation (the period of maximum hypophagia and weight loss) results in weight gain similar to that of intact rats. When force-feeding ceases ad lib intakes of the previously force-fed APX rats remain similar to those of intact rats. No weight loss ensues. In this study, effect of force feeding begun one month after APX is examined.

Twelve rats with thermal AP/cmNTS lesions (APX) and 14 sham-lesioned (SHAMX) rats were studied. Five APX and 6 SHAMX rats were fitted with gastric catheters for force-feeding. All surgery was performed under pentobarbital anesthesia. Rats were fed a milk diet throughout the experiment. Force feeding of catheterized rats began 1 month after APX or SHAMX and continued for 14 days. Non-catheterized rats continued to ingest milk ad lib. All rats were returned to ad lib feeding for the last 8 days of the study.

Force-Feed Period: Force-fed APX gained more weight than ad-lib-fed APX or SHAMX rats or force-fed SHAMX rats. Average weight change from the day of lesion to the end of force feeding was significantly greater for force-fed APX rats than for ad lib-fed APX rats ($p< 01$) but did not differ from that of either group of SHAMX rats. Average weight gains and food intakes of ad lib-fed APX and SHAMX rats did not differ over this period.

Period After Force Feeding: Return to ad lib feeding had no effect on intakes or weight gains of previously force-fed SHAMX rats. The two SHAMX groups did not differ in daily intake or weight change over these 8 days. Upon return to ad lib feeding, intakes of the previously force-fed APX rats were reduced compared to those of APX rats fed ad lib throughout the study ($p<.01$). The previously force-fed APX rats lost weight rapidly. At the end of the study, weight change from the day of lesion of previously force-fed APX rats did not differ from that of APX rats fed ad lib throughout.

These results show that APX rats do gain weight in response to elevated caloric intakes. While our previous data indicate that force feeding immediately after APX induces permanent increases of weight, the current findings show that later force feeding has only transient effects on the body weights of APX rats.

129.20 INTRAPERITONEAL BUT NOT INTRAGASTRIC PHENYLALANINE SUPPRESSES SHORT-TERM FOOD INTAKE IN MALE RATS. R.J. Bialik, E.T.S. Li* and G. H. Anderson, Dept. of Nutritional Sciences, University of Toronto, Toronto, Canada M5S 1A8.

Intraperitoneal (ip) administration of amino acids, such as phenylalanine (PHE), suppress short-term food intake (FI) in rats. This effect is generally considered to be the consequence of an increase in the concentration of the amino acids in the plasma and/or brain. If this is the case, other routes of administering PHE should also cause FI suppression when similar increases in plasma and brain levels of PHE are achieved. The present study compared the effects of intragastric (ig) and ip administration of PHE on short-term FI and PHE levels in plasma and brain of male rats. Rats, adapted to a 12 h (1900-0700 h) feeding schedule (food was available only during the dark), received on different days either PHE (as the methyl ester) or an equamolar dose of alanine methyl ester (ALA) 30 min prior to food presentation. ALA, which did not affect FI, served as a control for osmolarity and nitrogen content of the treatment solutions. It was found that 90 mg/kg was the lowest dose that suppressed FI during the first 2 h of feeding when PHE was given by ip injection (mean difference score = 2.0±0.6 grams, $P<0.02$). FI was not affected by ig administration of PHE at any of the doses tested (90,180,360,540 or 720 mg/kg). At the time that food was presented (1900 h), levels of PHE were similar in plasma and brain (approx. 200% and 125%, as % Baseline: Baseline = 7.49 µmol/dl plasma and 52.3 nmol/g brain) following ip and ig administration (90 mg/kg). However, the peak levels of PHE in plasma and brain were higher, and occurred earlier, following ip (411% at 5 min and 157% at 10 min) than following ig administration (188% and 126% at 15 min). The failure of ig PHE to suppress FI was not due to lower plasma or brain levels of PHE. At a dose of 720 mg/kg ig, PHE did not affect FI although, at the time of food presentation, plasma (860%) and brain (215%) PHE concentrations were much higher than were observed following a threshold dose of PHE given by ip injection. We conclude that FI suppression following PHE administration is not determined simply by the peak plasma or brain concentration of this amino acid.

130.1 PREFERENTIAL MOTONEURONAL DENDRITIC GROWTH INTO SYNAPTOGENIC FIELDS: A COMPUTER ASSISTED QUANTITATIVE STUDY OF GOLGI IMPREGNATED DEVELOPING MOUSE SPINAL CORD. J. E. Vaughn and R. P. Barber.* Division of Neurosciences, Beckman Research Institute of the City of Hope, Duarte, CA 91010

The branching of neuronal dendrites may be influenced by initial synaptic relationships formed by afferent axons with dendritic growth cone filopodia. This synaptotropic hypothesis of dendritic branching predicts that dendritic growth will be biased into regions containing numerous prospective presynaptic elements. The developing mouse spinal cord provides a natural experiment to test this prediction because synapses are only found within the marginal zones bordering the motor columns during the early period of synaptogenesis (embryonic days 11-14, E11-14). Therefore, during this time, most motor dendritic growth would be expected to be directed externally into the marginal zones, whereas internally directed growth should become more prevalent later when the formation of synaptic junctions begins to take place within the intermediate zone, i.e., the motor columns proper.

A computer assisted three dimensional reconstruction system has been used to test these predictions in Golgi impregnated preparations of developing mouse (C57BL/6J) spinal cords ranging in age from E13 through postnatal day 1 (P1). Mean dendritic lengths and branch densities are significantly greater ($P < 0.001$ and < 0.01, respectively) for marginal zone dendrites than for intermediate zone dendrites at early ages (E13-14), but there are no significant differences in these measures at later stages of development (P0,1). These results suggest that motor dendritic growth is initially biased into the marginal zone by synaptogenic afferents, but that this preferential distribution is progressively lost as synapses develop within the intermediate zone to attract or stabilize internally directed dendritic growth. Thus, the findings of this study are consistent with predictions of the synaptotropic hypothesis of dendritic branching. Supported by NSF grant BNS-8219831.

130.2 COMPUTER SIMULATIONS OF NERVE FIBRE OUTGROWTH. S.M. Bunt and G. Rowe*. Departments of Anatomy and *Mathematics, University of Dundee, DD1 4HN, U.K.

We have produced a computer simulation of nerve fibre growth in a defined pathway based on the fibres detecting the concentrations of an activator and inhibitor in the environment through which they grow. Manipulations of this simulation have identified the values of certain parameters which cause the model to produce fibre outgrowth in a pattern similar to that observed in vivo.

We have used an adaptation of Gierer and Meinhardt's reaction-diffusion model to set up a two dimensional gradient of activator and inhibitor over which the "nerve fibres" extend, sampling varying areas of the environment as they grow. In this model the activator catalyses both its own production and that of the inhibitor while the inhibitor suppresses the production of activator. The activator is assumed to be a large molecule which can only diffuse slowly and therefore causes short range interactions while the inhibitor is assumed to be a smaller, faster diffusing molecule and therefore causes long range interactions (Gierer, A. and Meinhardt, H., Kybernetik, 12:30, 1972).

We have varied the size of the area sampled by the simulated "growth cone" and the irregularities in the underlying gradients. The ability of the fibres to find their way across a field increases with the size of the area sampled by the growing fibre and decreases as the irregularities of the underlying gradients are increased. We have also varied the speed of growth of the "axon" and the timing of the setting up of the gradients. One of the more interesting results of this procedure has been the observation of moving waves in the underlying gradients which can cause fibres to stop in different parts of the field depending on their time and speed of outgrowth, thus setting up a pattern without any copy of the pattern ever existing in either the underlying gradients or the labelling of the fibres.

130.3 PREFERENTIAL REGENERATION OF SPINAL AXONS THROUGH THE SCAR IN HEMISECTED LAMPREY SPINAL CORD. D.I. Lurie* and M.E. Selzer. David Mahoney Institute of Neurological Sciences and Dept. of Neurology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

Spinal axons of the large larval sea lamprey (4-5 years old) regenerate selectively in their normal rostrocaudal direction and on the correct side of the cord (Yin et al, Science 224:894-896, 1984). The scar in the lamprey, unlike that in mammals, is not an absolute impediment to axonal regeneration and directional specificity is maintained by neurites growing distal to it. We wished to determine whether the scar provides active support for regeneration in the sense that axons would grow preferentially through the scar rather than around it. Therefore, spinal hemisections were made at the level of the 3rd gill in 15 larvae and the animals allowed to recover for 10 weeks. The large reticulospinal neurons (Muller and Mauthner cells) or their giant axons were impaled with HRP-containing mircoelectrodes and injected with label. Wholemounts of brain and spinal cord were stained with the Hanker-Yates reagent and the regenerating neurites visualized. Forty-one of 74 regenerating neurites (55%) grew beyond the level of hemisection. Of these, 33 (80.5%) grew through the scar to remain on the correct side while only 8 (19.5%) crossed the midline growing around the scar.

It is possible that this tendency for axons to regenerate through the scar reflects the greater availability of empty spaces on the hemisected side. In order to rule this out, 14 animals received double simultaneous hemisections at the level of the 3rd gill on the left and the 7th gill on the right. In this case, both hemicords contained large numbers of degenerating axons and potential empty spaces, both rostral and caudal to the scars. Nevertheless, axons grew through their ipsilateral scar rather than around it. Seventy-nine of 132 neurites (60%) regenerated beyond the site of the ipsilateral hemisection. Of these, all grew through the scar and none crossed to the contralateral side.

We conclude that in order to regenerate on their appropriate side, lamprey spinal axons grow preferentially through a scar rather than around it. This suggests that the scar may play a positive role in supporting axonal regeneration. (NIH Grant NS 14837).

130.4 EARLY CROSS-STRIATION FORMATION IN TWITCHING XENOPUS MYOCYTES. Y.Kidokoro and M.Saito*. Jerry Lewis Center,UCLA School of Medicine,Los Angeles,CA 90024.

Growing neurites release acetylcholine (ACh) even before contacting target muscle cells in culture (Young and Poo, Nature, 305:634, 1983; Hume et al., Nature, 305:632, 1983). Physiological significance of this phenomenon is yet to be discovered. In Xenopus myocytes we found that spontaneous release of ACh from growing neurites caused twitches and that these twitching myocytes developed cross-striation earlier than those without nerve contact or those with nerve contact but without twitching in the same culture. This effect was blocked by 0.1 μM α-bungarotoxin.

Nerve-muscle co-cultures were prepared from Xenopus embryos at stage 14 shortly after completion of gastrulation (Nieuwkoop and Faber, Normal Table of Xenopus laevis (Daudin), Elsevier, Amsterdam, 1967). They were plated on the collagen coated cover glass in culture medium (60 % strength of DMEM supplemented with 5 % horse serum). After one day of incubation at room temperature (21-22 °C) many cells attached to the substrate. A great majority of them were myocytes and some of them had a neuron adhered on the surface. About two third of nerve-contacted myocytes twitched spontaneously. These twitches were blocked by α-bungarotoxin indicating that they were caused by spontaneous release of ACh from neurons.

Cross-striation of non-nerve-contacted myocytes first developed at about 23 hours after plating. 44 hours after plating virtually all myocytes were cross-striated. The time for 50 % of non-nerve-contacted myocytes to acquire cross-striation was about 29 hours. Nerve-contacted and twitching myocytes developed cross-striation much earlier. At 23 hours a majority of twitching myocytes showed clear cross-striation. Nerve-contacted but non-twitching myocytes did not develop striation earlier than non-nerve-contacted myocytes.

Iontophoretic application of ACh caused twitches in non-nerve-contacted myocytes. After a few hours of twitching at a rate between 0.1 and 1 Hz these myocytes developed cross-striation. The myofibrils may self-organize to exhibit cross-striation when they are activated to contract.

It is plausible in the animal that successful innervation by motor nerve promotes differentiation of the target muscle cell.

130.5 A POSSIBLE ROLE FOR SOMATOPLEURAL TISSUE IN SPECIFIC MOTONEURON QUIDANCE IN THE EMBRYONIC CHICK HINDLIMB. M. Dias* and C. Lance-Jones, Dept. of Neurobiology, Anatomy and Cell Science, Sch. of Med., Univ. of Pittsburgh, Pittsburgh, PA 15261

Although the formation of motoneuron projections to individual muscles in the embryonic chick limb has been shown to involve the specific recognition of environmental cues, the source of these cues is unknown. Experiments carried out in our laboratory and that of Keynes suggest that the lumbosacral (LS) somites or their derivatives, the limb muscle cells, are not the primary source. Another candidate is the somatopleural mesoderm that lies lateral to the LS somites and gives rise to all limb connective tissues. To examine this hypothesis, the somatopleure (somatopleural mesoderm + overlying ectoderm) adjacent to the LS somites was removed from one side of stage 14-15 chick embryos and shifted anteriorly to replace the last 1-3 segments of thoracic (T) somatopleure. Since muscle cell migration does not begin until stage 16, only prospective connective tissues within the limb are thought to be shifted.

Embryos were incubated until stages 28-36 when limb nerve patterns were examined. Thirteen embryos had limbs which were clearly shifted 1 (n=7), 2 (n=5), and 3 (n=1) segments anteriorly. Within these limbs nerve trunks were positioned appropriately but received spinal nerve contributions from more anterior segments than normal. Crural trunks that normally receive contributions from LS1-3 received contributions from T7-LS2, T6-LS1, or T5-T7. Sciatic trunks that normally receive contributions from LS3 and LS4-8 received contributions from LS2-3, LS1-3 or T7-LS3 and a variable number of more posterior spinal nerves. In every limb 1-3 novel muscle nerves were found coursing from sciatic trunks to anterior muscles that are normally innervated by crural nerves. As the sciatic trunks contained axons that would normally course within crural trunks, an interpretation of these findings is that specific course corrections have been made by mischannelled axons in response to guidance cues from the somatopleure. Two pieces of evidence support this idea. First, in two embryos we have identified motoneuron projections to anterior muscles via horseradish peroxidase labelling and found them to be correct with respect to segment of origin. Second, we find a clear relationship between the extent of the shift and the specific novel muscle nerves present. For example, novel nerves to the femorotibialis muscle were most common. This muscle is normally innervated by axons in LS2 and LS3 or those axons most commonly channelled into the sciatic. While preliminary, these data suggest that axon pathway choices may be made on the basis of cues arising from the somatopleure or its derivatives. Supported by NS-8518864.

130.6 GROWTH CONE INTERACTIONS WITH ANTERIOR AND POSTERIOR SCLEROTOME. K. W. Tosney. Department of Biology, University of Michigan, Ann Arbor, MI, 48109

The somites have long been regarded as important to the development of spinal nerve segmentation. Keynes and Stern (1984, *Nature* 310:786) elegantly showed that axons prefer the anterior of each somite for outgrowth. Axons extend through the ventral portion of the somite, the sclerotome, which is essential for segmentation (Tosney, 1986, *Soc. Neurosci. Abs.* 12:174). I examined anterior (A) and posterior (P) sclerotome populations with scanning electron microscopy to determine if tissue-level differences could be important for segmental outgrowth. I found that differences are of insufficient magnitude or develop too late to explain the absence of outgrowth into P sclerotome. The important population differences may, therefore, lie at the cellular level and be accessible *in vitro*.

Growth cones may avoid growing into P sclerotome because they cease motile activity (become "contact paralyzed") upon contacting P cells. To test this hypothesis, I videotaped interactions between motoneurons and A or P cells on laminin substrata in culture. Motoneurons were labeled by injecting spinal nerves with DiI, a non-toxic fluorescent dye (Honig, and Hume 1986, *J.Cell Biol*, 103:171) 5-8 hours before explanting small pieces of the ventrolateral spinal cord. A or P cells were labeled with rhodamine.

I found that motoneuron growth cones were not contact paralyzed by either population: they continued to extend processes after contact. However, preliminary results show intriguing differences in the interactions. Motoneuron growth cones often extended onto and over the surface of A cells. In contrast, when they encountered a P cell, they generally remained on the substratum. In addition, their forward progress was often delayed. They continued to extend filipodia but remained in place, moved around the side of the P cell or advanced only after the cell moved away. If these preliminary results hold up, they will suggest that motoneuron growth cones prefer anterior over posterior sclerotome cells as a substratum and that their preference may, at least in part, cause their segmental pattern of outgrowth.

#Supported by NIH grant NS 21308 and a Rackham Grant to Augment International Partnerships. I obtained preliminary results using video in the laboratory of Dr. J. Raper, Max-Planck-Institut für Entwicklungsbiologie, Tübignen, West Germany. I am grateful to him, Dr. F. Bonhoeffer and Dr. S. Chang for their kind assistance.

130.7 MONOCLONAL ANTIBODIES RECOGNIZE SEVERAL DEVELOPMENTALLY REGULATED PROTEINS IN THE HAMSTER PYRAMIDAL TRACT. K. Kalil and M. Perdew* Dept. of Anatomy and Neurosciences Training Program, University of Wisconsin, Madison, WI 53706

The hamster pyramidal tract continues to grow into the spinal cord until two weeks postnatal. We were interested in proteins whose expression might be correlated with the late development of the pyramidal tract. We made a series of monoclonal antibodies directed against infant pyramidal tract or a growth cone preparation of young hamster brains, and found that at least three of these recognized developmentally regulated proteins correlated with the late outgrowth of the pyramidal tract.

The first of these was obtained from a fusion in which immunization was carried out using a homogenate of lightly fixed medullary pyramidal tract from 3-day-old hamster brains. The antibody recognized the 200 kDa subunit of the neurofilament protein, as determined by immunoblotting with isolated neurofilament proteins. Indirect immunofluorescence with ammonium precipitated ascites was used to localize the antigen on cryostat sections of the brain and spinal cord of 1 to 23-day-old hamsters. At birth the long tracts, as well as the local fiber systems of the brainstem and spinal cord, were brightly fluorescent. In contrast, the pyramidal tract was almost completely unstained at 2 weeks, and by 23 days contained only sparse punctate labeling. If the 200 kDa subunit serves a cross-bridging function in the neuronal cytoskeleton, then the late appearance of this element of the neurofilament protein may confer upon these fibers an extended period of plasticity in which regrowth after injury can occur.

Additional monoclonal antibodies were obtained from fusions in which mice were immunized with growth cone membranes prepared from 3-day-old hamster brains by subcellular fractionation. Two of these, 3-11G and 6-4E, recognized proteins that appear to be developmentally regulated, since immunofluorescence revealed ubiquitous staining on brain and spinal cord sections up to 1 week postnatal but at 9 days showed restriction of fluorescence in the spinal cord to the pyramidal tract. Within the cerebellum, labeling was restricted to a region of the molecular layer just dorsal to the Purkinje cells. Thus, both antigens appear in pathways that continue to develop relatively late postnatally. The 3-11G antibody recognizes a 30 kDa polypeptide whose developmental decline was quantified by ^{125}I-streptavidin immunoblotting of a crude synaptosomal preparation of hamster brain separated by SDS PAGE. Preliminary results suggest that 3-11G recognizes a membrane associated protein that, in agreement with the immunohistochemistry, shows the steepest decline during the first postnatal week.

Supported by NIH Grant NS-14428.

130.8 ESTABLISHMENT OF A SENSORY PATHWAY IN THE AMPHIBIAN TAIL SPINAL CORD. R.H. Nordlander. Dept. of Oral Biology, Case Western Reserve University, Cleveland, OH 44106.

Dorsal roots are absent in the tails of Xenopus larvae. Instead, central axons of sensory ganglion (SG) neurons of the tail enter the spinal cord via ventral roots (Awwiller and Nordlander, these proceedings, 1985). Once in the cord, these axons take a diagonal path rostrally and dorsally through the substance of the cord to reach the dorsolateral (DL) tract in which they travel to the hindbrain. The purpose of the present study was to characterize the initial ingrowth of central SG axons and, in particular, to describe the morphology and behavior of their growth cones as they find their way across the cord.

Central SG axons and their growth cones were filled with horseradish peroxidase (HRP) applied to the peripheral processes or cell bodies of SG neurons at the level of the 20th myotome in embryos and larvae (stages 32-48). After appropriate diffusion times (20 to 120 min), spinal cords were processed with conventional DAB methods and cleared with glycerine for viewing as wholemounts.

Sensory ganglia of the tail first appeared during late embryonic stages (35-38) as small clusters of fusiform cells sitting on ventral roots at the point of their bifurcation into dorsal and ventral rami. The earliest diagonal central SG fibers were seen in the tail cords several stages later. These early axons had very small diameters, but, later some thicker axons were also observed. SG axons from a single segment traveled in a closely packed arrangement within the ventral root. Upon entering the cord they spread out and traversed the cord individually, recoalescing when they joined the DL tract.

Growth cones at the lead of SG axons were large and showed complex configurations as they navigated from the ventral root entry point to the DL tract. These growth cones frequently extended filopodia rostrally or caudally into longitudinal axon bundles of the lateral marginal zone. Veils commonly appeared at dorsal and rostral borders of the growth cones, sometimes conforming to the contours of axons within the longitudinal bundles they were crossing. Yet, despite these evidences of diversion of dalliance by the growth cones, the axon trailing behind each followed a clear diagonal path as described above. Growth cones retained some complexity as they first entered the DL tract, but became more streamlined and simple at progressively more rostral levels.

130.9 TRANSIENT AXONAL GLYCOPROTEINS DEFINE PATHWAY SELECTION BY DEVELOPING SPINAL CORD AXONS. J. Dodd, S.B. Morton*, D. Karagogeos* and T.M. Jessell. Center for Neurobiology and Howard Hughes Medical Institute, Columbia University, New York, NY 10032.

An initial step in the establishment of specific neural connections is the selection of distinct substrate pathways by developing growth cones and axons. To determine mechanisms that contribute to the guidance of axons in mammalian CNS we have analyzed pathway selection by spinal cord projection neurons. Two major classes of supraspinal projection neurons differentiate in the dorsal region of embryonic rat spinal cord. Association (A) neurons project radially and ipsilaterally in the transverse plane before turning rostrally to form the lateral funiculus. Commisural (C) neurons project ventrally and medially in the transverse plane, cross the midline at the floor plate (FP) and then fasciculate in a rostro-caudal plane to form the contralateral ventral funiculus. Extensive overlap in the spatial location of neuronal cell bodies and in the timing of axon extension of A and C neurons suggests that they respond initially to distinct guidance cues. C axons approach the midline bilaterally, yet project rostrally only after crossing the FP. However, the bilateral symmetry of C axon projections implies that equivalent cues should exist on both sides of the midline. Guidance could be achieved by modification of the surface properties of growth cones and axons during passage across FP cells. Growth cones and axons may, therefore, be capable of responding to guidance cues only after such modification.

To analyze cell surface changes during C neuron pathway selection, we generated monoclonal antibodies (MAbs) that identify antigens expressed selectively by C axons, and FP cells. C axons were identified by expression of a series of cell surface glycoprotein antigens (C-TAGs) with MW's in the range 110-160 Kd. FP cells were identified by expression of keel antigens K1 and K2. C-TAGs are expressed on C neurons as they differentiate adjacent to the roof plate of the spinal cord in E11 embryos and on C axons as they project ventro-medially in the transverse plane. The expression of C-TAGs decreases on C axons after crossing the midline and C axons established in the ventral funiculus do not express C-TAGs. By E15, when all C neurons have projected across the midline, expression of C-TAGs has terminated. The NILE/L1 glycoprotein exhibits a converse distribution; it is not present on C axons projecting in the transverse plane but appears after fibers have passed across the FP. Cell surface glycoprotein expression by C axons is, therefore, modified during passage across FP cells. Such modification may confer or reflect the ability of C axons to respond to guidance cues only after crossing the midline.

Midline guidance cues may involve differential cell adhesion. NCAM is located selectively on FP cells and C axons but not on adjacent neuroepithelial cells in E11 rat spinal cord. The extension of C axons along the contralateral edge of FP cells may involve NCAM-mediated adhesion between C growth cones and FP cells.

130.10 EXPRESSION OF NEURONAL ADHESION MOLECULES ON CULTURED NEURONS. A.N. van den Pol, M. Ellisman#, M. Manthorpe¶, K. Anderson#, W. Stallcup+. Sect. Neurosurgery, Yale Univ. Med. Sch., New Haven, CT 06510; #Dept. Neurosci. and ¶Biology, UCSD, La Jolla, CA 92093; +La Jolla Cancer Res. Ctr., La Jolla, CA 92037.

To examine the distribution of several plasmalemmal molecules involved in adhesion of neurons, we used colloidal gold immunocytochemistry on primary cultures of CNS neurons from rat and chicken. Antisera against rat NILE (Stallcup et al., J. Neurosci. 5:1090, 1985) and against the chicken homologue of rodent L1 (Rathjen et al., J. Cell Biol. 104:343, 1987; gift of Dr. U. Rutishauser) were used. Cells from the rat hypothalamus (E18) or cerebellum (P6), and from the chicken forebrain (E8) were dissociated and grown on polyornithine or laminin/polyornithine treated plastic or glass substrates for light and electron microscopic thin section evaluation. Additionally, cells were grown on formvar coated gold EM grids, stabilized with carbon, and treated with polyornithine and laminin. After several days in culture, cells were fixed with paraformaldehyde and immunolabeled with 5, 10, or 15nm colloidal gold adsorbed to secondary antisera. Following immunolabeling, whole mounts of cells grown on EM grids were further stabilized with a light platinum rotary shadowing which facilitated visualization of plasmalemmal membranes, but did not obscure the gold particles (Ellisman et al., JEMT, in press).

Chicken forebrain cultures contained predominantly neurons as determined with tetanus toxin staining and morphology. These cells grew short neurites with extensive growth cones and filopodia radiating out from the perikaryon. Gold immunolabeling of the L1-homologous antigen was found on neurites, perikarya, and on growth cones including their lamellipodia and filopodia, but was absent from control cells of meningeal origin. Cultures from rat brain contained a heterogeneous population of neurons and glia; long neurites extended from neurons. With both fluorescent microscopy and with ultrastructural analysis of NILE immunolabeling, the high density of colloidal gold varied between neurites but was minimal on underlying astrocytes. Additional experiments using cells grown on grids and labeled with antisera against chick or rodent NCAM confirmed our previous ultrathin section studies (van den Pol et al., J. Cell Biol. 102:2281, 1986) demonstrating the presence of this molecule on neuritic growth cones.

The presence of these antigens (similar or identical to L1, NILE, NgCAM) and NCAM on growth cones and associated filopodia is consistent with hypotheses suggesting that these molecules may contribute to axonal adherence and guidance.

130.11 INTRINSIC DIFFERENCES IN THE GROWTH RATES OF EARLY EMBRYONIC SENSORY NERVE FIBERS Alun M. Davies Dept. Anatomy, St. George's Hospital Medical School, Tooting, London SW17 ORE, U.K.

The distance axons have to grow to reach their targets in development varies form one population of neurons to another. To investigate whether there are intrinsic differences in the growth rates of axons from different populations of neurons at this early stage of development, and if so, whether growth rate is related to the distance the axons have to grow to their targets in vivo, a comparative study of the growth of early embryonic cranial sensory neurons in culture was carried out. The trigeminal (maxillo-mandibular lobe), geniculate, petrosal and nodose ganglia were dissected from chick embryos at the stage of development during which the earliest neurons of these ganglia are being born and the earliest nerve fibers are growing to their targets (at embyronic days 3 and 4). These neurons were chosen because the distance between their peripheral and central targets increases in the order: trigeminal<geniculate<petrosal <nodose. The neurons were grown in low-density, dissociated culture on a laminin substratum in Fl4 medium supplemented with fetal calf and horse sera. These early neurons exhibited a characteristic bipolar morphology with fine, straight, unbranched neurites extending in opposite directions. In each culture the neurite lengths of over 50 individual neurons were measured serially at 2 hourly intervals for the first 18 hours in culture. These measurements showed that there are significant differences in neurite growth rates between these populations of sensory neurons, the rate being slowest for trigeminal neurons and increasing in the order: trigeminal<geniculate< petrosal<nodose. The growth rate of nodose neurons was between 2 and 3 fold greater than trigeminal neurons.

These findings indicate that there are intrinsic differences in the growth rates of nerve fibers from pre-target-encounter sensory neurons, and raise the possibility that these differences are related to the distance the corresponding axons have to grow to reach their targets in vivo (i.e., those that have further to go grow faster).

131.1 REPRESENTATION OF VESTIBULAR AFFERENTS IN FIFTH SOMATIC SENSORY AREA (SV) IN THE CAT. A.Mori, T.Yoshida*, H.Hiraba* and R.Sumino*. Nihon University School of Dentistry, Department of Physiology, 1-8-13 Kanda-surugadai, Chiyoda-ku, Tokyo 101, Japan.

By using the unit technique, we have found that a new and complete somatic sensory area of the body surface of the cat is located in the rostro-caudal part of the medial bank of the anterior suprasylvian sulcus (ASSS). We have designated this area as the Fifth Somatic Sensory Area (Mori et al. Neurosci. Abstr.15, 1985). In the present study we examined projections from the vestibular organ to the SV.

Under ketamine anesthesia a chamber was installed over the skull surrounding the SV. A tungsten in glass microelectrode was inserted into the SV and the receptive fields of neurons were examined by using natural somatic stimulation. The spikes were monitored on the oscilloscope through a window discriminator. A bipolar electrode, which used electrical stimulation, was placed on the round window. The sites of penetration were recorded on photographic prints of the cortical surface, taken through a dissecting microscope. The electrode tracks were reconstructed using the lesions made during the experiments, and analyzed with respect to this region, using the criteria defined by Hassler and Muhs-Clement (1964).

The activity of 278 neurons was recorded through 47 electrode penetrations made in the SV. 82% (228) of the responsive neurons were activated only by somatic sensory stimulation of the contralateral side. 18% (50) of the responsive neurons were activated by both vestibular and somatic stimuli of the contralateral side. Many of these multimodal vestibular neurons were found to be located in the rostral area of the medial bank of the ASSS. However, unmultimodal vestibular activated neurons were not found in the SV. Although multimodal vestibular activated neurons received inputs from a wide area of the face and/or neck and neck and/or trunk of the contralateral side, the forelimb and hindlimb areas of the SV did not converge from the vestibular afferents. In conclusion, these findings suggest that neurons of the SV have an integrational function of inputs of somatic and vestibular afferents.

131.2 ANALYSIS OF THE PERIODICITIES IN SOMATOSENSORY CORTICAL ACTIVITY PATTERNS. M. Tommerdahl,* B.L. Whitsel, E.G. Cox,* M. Diamond, and D.G. Kelly.* Depts. of Physiology and Mathematics, UNC, Chapel Hill, NC 27514

The highly periodic nature of stimulus-evoked C14-2-deoxyglucose (2DG) somatosensory cortical activity patterns suggested the use of spectral image analysis techniques. An image analysis system was developed for this purpose, allowing digitization, storage, display and quantitative analysis of 2DG autoradiographic data. In addition, software was developed to generate high resolution 2- and 3-dimensional reconstructions of the data series provided by sequences of serial autoradiographs. Two types of analyses have been carried out to date. In the first, we sought to quantify the global spatial distribution of labeling within extensive (typically greater than 5mm^2) cortical sectors. In the second, we used spectral analysis techniques to assess the periodicities in the labeling pattern within relatively small tangential (350um) or radial (1500um) sectors of individual high resolution autoradiographs. These two approaches will subsequently be referred to as "low" and "high" resolution analyses, respectively. The low resolution analyses provided new information about the spatial distribution of stimulus-evoked 2DG labeling in the S-I cortex of cats and monkeys. Of special interest is the finding that periodic, low frequency spatial variations (<3 cycles/mm) in C14 uptake occur in two locations: along the long axis of the elongated strips of label which characterize 2DG patterns, and in the cortex adjacent to the strips. This result is seen as consistent with the view that the intrinsic circuitry of the cortex enhances (via cooperative and competitive lateral interactions) local discrepancies in the pattern of afferent input to adjacent cortical columns. The high resolution analyses revealed prominent high spatial frequencies (5 - 40 cycles/mm) in the labeling that exists within individual patches. This is viewed as evidence that the population of neuronal elements within the column-shaped territory occupied by a single patch is activated non-uniformly. Comparisons of the periodicities within 2DG labeled patches with those existing in the same regions in Nissl stained sections suggest that the within-patch 2DG activation pattern is modular (i.e., is made up of active and inactive minicolumns). Other observations show that the within-patch labeling pattern changes systematically with increasing distance from the patch center. It is anticipated that spectral analyses of 2DG data can lead to a detailed 3D view of the spatiointensive patterns of activity that a somatic stimulus evokes within a single cortical column. Supported by NIH grants DE07509 and DE02668.

131.3 PATTERNS OF CORTICO-CORTICAL CONNECTIVITY CAN PREDICT PATCHES OF STIMULUS-EVOKED METABOLIC ACTIVITY IN MONKEY SOMATOSENSORY CORTEX. S.L. Juliano, D.P. Friedman, and D. Eslin*. USUHS, NIDA and Lab. Neuropsych. NIMH, Bethesda, MD.

It has been clearly established that stimulus-evoked metabolic activity in the somatosensory cortex occurs in the form of intermittent, column-like patches. Similar appearing patches revealed by axonal transport are produced by the type of cortico-cortical projection which terminates most heavily in layer IV and appears to sequentially relay sensory information from earlier to later stages in sensory information processing. The relation of the patches elicited metabolically to those formed by cortico-cortical connections, however, is not clear. If the layer IV projection system does indeed transmit sensory information in a sequential manner, it may directly contribute to the definition and location of the individual metabolic "columns". To test this possibility, experiments were conducted in which cortical regions in area 1 of Macaca fasicularis monkeys were defined electrophysiologically. After characterizing the best neuronal response, iontophoretic injections of WGA-HRP were made in the identified cortical sites. The injection sites were 500 - 750 um in diameter and designed to correspond in size to the width of one metabolic "column". Two days later the animals underwent a 2DG experiment, during which they received the somatic stimulus previously determined to best activate the neurons isolated at the injection site. The region of skin stimulated was small (a few mms in diameter) and identical in location and modality to the stimuli which elicited responses in the recording session. Evaluation of both forms of labeling on adjacent sections demonstrated that within areas 1 and 2, but outside the injection sites, the patches of anterogradely labeled HRP terminals were precisely aligned with the stimulus-evoked 2DG patches. However, in area 3b, which contained mainly retrogradely labeled patches of HRP filled cells, the match between the 2DG and HRP distributions was less precise. Control studies in which the stimulus site used during the 2DG experiment did not match the neuronal response properties identified at the site injected during the recording session revealed that the stimulus-evoked metabolic patches were not in alignment with either the retrogradely or anterogradely transported HRP label. Since the relationship between the 2DG and the HRP patches in areas 1 and 2 was stronger than that observed in area 3b, our findings are consistent with the hypothesis that the metabolically activated patches are at least in part defined by cortico-cortical connections that relay information serially. Supported by NS-24014.

131.4 EVIDENCE FOR DISCONTINUOUS BODY SURFACE REPRESENTATION IN SI. O. Favorov*, M. Diamond, and B. Whitsel (SPON. J. Greenspan). Dept. of Physiology, The University of North Carolina, Chapel Hill, NC 27514

The two cornerstones of current views of somatosensory cortical topography -- i) uniformity of the receptive fields (RFs) of the neurons in a cortical column, and ii) continuous representation of the skin within most cortical sectors -- are reexamined. Near-radial microelectrode penetrations were inserted into area 3b of cat and area 1 of Macaca fascicularis monkey. Two RF mapping methods were used: i) single neuron maximal RF mapping in the absence of general anesthesia, and ii) multi-unit minimal RF mapping in the deeply anesthetized subject.

At least 10 maximal RFs were mapped in each penetration and were found to vary markedly in size and locus. In spite of the prominent RF variations, in many penetrations the maximal RFs of all sampled neurons shared in common a very small skin area. In the rest of the penetrations, RFs mapped consecutively in the penetration had in common some small skin area only until a point, after which all the subsequent RFs shared a new skin area, nonoverlapping the first one. The data suggest that: i) all neurons comprising a narrow cell column in SI include in their RFs a common small skin area, and ii) such columns are separated by abrupt boundaries. Statistical analysis supported this view. When the electrode was advanced across such a column (termed a "segregate") no systematic shift in RF position on the skin was detectable. In contrast, the crossing of a segregate boundary was associated with a shift of RFs to a new skin location.

In several penetrations, after the electrode reached the white matter, deep general anesthesia was induced and minimal RFs were mapped as the electrode was withdrawn in 150 um steps. Comparison of maximal and minimal RF data collected in the same penetrations revealed that within a segregate, all minimal RFs mapped essentially the same position on the skin and, furthermore, this position matched closely the skin area common to all the maximal RFs. In addition, crossing of a segregate boundary was marked by a rapid shift in minimal RFs from one position to another. Thus, both RF mapping methods reveal the same plan of topographic organization: a plan in which the body surface is represented by discrete units -- segregates. Supported by NIH grants DE 07509 and DE 02668.

131.5 THE BODY SURFACE IS REPRESENTED IN SI BY A MOSAIC OF SEGREGATES. M. Diamond, O. Favorov*, and B. Whitsel. Dept. of Physiology, University of North Carolina, Chapel Hill, NC 27514

Receptive field (RF) analyses (see preceding abstract by Favorov et al.) have led us to conclude that in SI of cat and Macaca fascicularis monkey the body surface is represented by discrete columnar modules, termed segregates. The questions remain "What is the size and shape of segregates?" and "What is their overall configuration?" We have used two different mapping methods, single neuron maximal RF and multi-unit minimal RF, to arrive at an answer.

Based on the RFs of single neurons in SI of both cat and monkey, collected in the absence of general anesthesia, segregate boundaries often meet at acute angles. This finding eliminated the possibility that segregates are elongated parallel strips. Two shapes remained plausible for segregates: i) complex strips (analogous to the cortical ocular dominance columns), or ii) tiles in a mosaic (analogous to the barrels in rodents).

To choose between the strip and mosaic arrangements, we used the minimal RF method in cats to map all the segregate RF centers and boundaries within a small cortical field of area 3b. Using arrays of closely spaced penetrations, we find in a typical experiment that one segregate (the "central" segregate) is bounded by six other segregates. The data indicate that the central segregate has the shape of an irregular hexagon of approximately 400 um diameter. From the results of these experiments, we conclude that segregates are arranged in the cortex in a mosaic pattern (each segregate a tile). The relation among the RF centers of neighboring segregates suggests a rough somatotopy, but the overall topography of the segregate map is characterized by many reversals.

Several parallels exist between segregates of cat and monkey SI and barrel-based columns of rodent SI: 1) just as every neuron in a segregate responds to a common skin area, every neuron in a barrel-based column responds to a principal whisker; 2) just as the boundaries of segregates are abrupt, so are the boundaries of barrels, 3) no systematic topographic gradient exists within segregates or barrel-based columns, and 4) both segregates and barrels are arranged in a mosaic pattern. Since a similar unit has been identified in SI of cat, monkey, and rodent we propose that representation of the body surface by a mosaic of discrete columns may be a general principle of SI. Supported by NIH grants DE 07509 and DE 02668

131.6 THE MORPHOLOGY OF SINGLE PHYSIOLOGICALLY IDENTIFIED THALAMOCORTICAL AXONS INNERVATING SOMATOSENSORY CORTEX IN MACAQUE MONKEYS. P.E. Garraghty and M. Sur. Dept. of Brain & Cognitive Sciences, M.I.T., Cambridge, MA 02139.

We have studied the morphology of thalamocortical terminal arbors in area 3b of postcentral somatosensory cortex. The structure of thalamocortical arbors presumably underlies many features of somatosensory cortical organization that have been previously described, including the modular segregation of neurons related to rapidly adapting (RA) and slowly adapting (SA) input, and plasticity in cortical maps following alterations in peripheral input.

We recorded from axons in the white matter below the representation of the hand in postcentral cortex in two monkeys (Macaca fascicularis) using micropipettes filled with horseradish peroxidase (HRP). When an axon was recorded, we delineated its receptive field, determined its modality (deep, joint, or cutaneous), and, if cutaneous, its submodality (SA or RA). We then impaled the axon and injected HRP iontophoretically into it.

We report here on the morphology of eight axons that responded to cutaneous stimulation. Axonal arbors within area 3b ramify in cortical layers 3 and 4, and, in many instances, in layer 6 as well. Individual arbor widths range from about 350 to 500 um. We have as yet detected no difference between the SA and RA fibers we have recovered. Seven axons which were injected superficially in the white matter, close to their terminal arbor, arose from parent trunks which we traced to a depth of 1 mm or so in the white matter. One RA axon, injected about 7 mm deep in the white matter very close to what appears to be its most proximal branch point, showed an extensive branching pattern and terminal arbor. This axon's terminal field was composed of four separate zones in area 3b spanning about 2 mm of cortex along its mediolateral axis. The individual arbors, however, were still about 350-500 um in width and were separated from each other by spaces of roughly the same width. Since the branches that give rise to this extended arbor occurred far below the region of termination, it is possible that many thalamocortical axons have quite extensive terminations which would be revealed if their trunks were injected deeper in the white matter.

In any event, individual terminal zones 350-500 um wide are consistent with the hypothesis that they underlie the columnar parcellation of somatosensory cortex. The presence of arbors spanning several such columns suggests that all regions within the arbor may not be equally effective in driving cortical cells under normal conditions, and such arbors may provide the substrate for a cortical response to changes in the pattern of input.

131.7 CORTICAL-STRIATAL PROJECTIONS FOLLOWING INJECTION OF PHA-L INTO A PHYSIOLOGICALLY IDENTIFIED CORTICAL MOTOR OUTPUT REGION IN THE SECOND SOMATO-SENSORY CORTEX (SII) OF CAT. R.S. Waters, E.J. Johnson*, K. Park*. Dept. of Anatomy and Neurobiology, Univ. of Tennessee, Memphis, Sch. of Med., Memphis, TN 38163.

We previously reported that intracortical microstimulation (ICMS) as low as 2-3μA delivered to a physiologically identified cortical motor output region (CMOR) in the second somatosensory cortex (SII) of cat produced contraction of facial muscles. A subsequent investigation of the motor output pathway from SII using anterograde neuroanatomical tracers (tritiated amino acids and WGA-HRP) failed to show terminal labeling in the facial nucleus. However, terminal fields were found in a number of intermediate brainstem nuclei as well as in the neostriatum. In this report we describe the results of our recent investigation of the SII projection to the neostriatum using a more sensitive immunocytochemical tracing technique.

Placing cats under inhalation anesthesia, the dura over the ectosylvian gyrus was removed and the exposed cortical surface was covered with warm mineral oil. The gas anesthesia was then turned off, and the cat was maintained on Nembutal and Ketamine throughout the mapping and injection portions of the experiment.. A tungsten-in-glass microelectrode was inserted into the ectosylvian gyrus and used to deliver a train of cathodal pulses (12-13 pulses/train, 0.2ms duration, 300Hz, 40μA maximum intensity) to the underlying cortical tissue. With this technique, a restricted region of cortex was identified where stimulating currents of 10μA or less were effective in evoking contraction of the facial muslces. Once this zone was clearly delineated, a 2.5% solution of phaseolus vulgaris leucoagglutinin (PHA-L) was iontophoresed into the center of this region with anodal pulsed current of 5 μA for a period of 20-40 minutes. Following a survival time between 14-21 days, the animals were anesthetized with Nembutal and perfused through the aorta with buffered acetate and borate fixatives. The brain was removed and sectioned at 50 micron thickness on a vibratome. The tissue was processed in accordance with the method Gerfen and Sawchenko (84).

All injections sites were localized to the deep layers of SII cortex. Following the injection of PHA-L into SII, labeled axons and terminal processes were found in the caudate, putamen, and claustrum. Within the caudate, long cruciform-like axons were most often seen running in a dorsal-lateral direction in the most lateral portion of the caudate. Axons were observed to branch extensively and most often showed a beaded appearance suggestive of boutons en passant. Discrete clusters or patches of terminals in the caudate were not obvious. Long axonal terminals were also found in the putamen and nearby in the claustrum. These results suggest that cell bodies in SII cortex exert influence over a large portion of the striatum and may play an important role in controlling or modulating motor output to the facial muscles.

131.8 AN ANTEROGRADE TRACING STUDY OF THE PROJECTION FROM A PHYSIOLOGICALLY IDENTIFIED LOW THRESHOLD REGION IN THE SECOND SOMATOSENSORY (SII) CORTEX TO THE FOURTH SOMATOSENSORY CORTEX (SIV) IN CAT USING PHA-L. E.J. Johnson*, R.S. Waters, K. Park* (SPON: A. GRANATA). Dept. of Anatomy and Neurobiology, Univ. of Tennessee, Memphis, Sch. of Med., Memphis, TN 38163.

Cortical motor output regions (CMORs) have been identified in the primary motor, second somatosensory (SII), third somatosensory (SIII), and fourth somatosensory cortex (SIV) where low threshold intracortical microstimulation is effective in producing contraction of the facial muscles controlling eyeblink, ear movement, and vibrissae deflection. The results of studies where tritiated leucine/proline or WGA/HRP was injected into each CMOR suggest that these regions are highly interconnected. However, the details of these projections, particularly the pattern of axonal terminations, were not previously available using the earlier anterograde tracing techniques. In this report, we describe the results of our examination of the cortico-cortical projection from a physiologically identified low threshold site in SII, to SIV using the recently developed phaseolus vulgaris leucoagglutinin (PHA-L) tracing technique. Iontphoretic injections of a 2.5% solution of PHA-L were delivered through a micropipette (tip diameter 40-60 microns) into the center of a physiologically mapped region in SII cortex where currents of 10 mA or less were effective in producing contractions of the facial muscles. Anodal constant current was pulsed (5uA, 7s duration) through the micropipette for a period of 20-40 minutes. With these parameters the central core of the injection varied between 200-1000 μm in diameter. Following survival times of 14-20 days, cats were sacrificed and the PHA-L visualized by the avidin-biotin immunoperoxidase procedure of Gerfen and Sawchenko (84).

PHA-L injections were localized to the deep layers of SII cortex where the lectin was incorporated into the cell bodies and dendrites of a central core of neurons. Labeled cells were also observed in the immediate vicinity of the injection site but outside the central core. A few labeled neurons were found at distances greater than 5 mm from the injection site suggesting retrograde transport by damaged axons at the injection site.

Cortico-cortical fibers in SII show two distinct pattens of projection to SIV. The majority of the axons leave the injection site but remain within the gray matter to enter the superficial layers of SIV. These axons branch extensively in the upper layers and are characterized by a beaded appearance suggestive of wide spread terminal fields. In the second pattern, fibers leave the injection site and enter the white matter where they travel several millimeters before reentering SIV in a distincitive columnar type arrangement. These axons ascend to the more superficial layers of cortex, branch extensively, show characteristic beading at their terminal portions, and do not appear to overlap with axons originating in the gray matter. It remains to be determined whether the projection from SII to SIV serves to link together cortical areas sharing similiar motor control over the facial muscles.

131.9 ORGANIZATION OF CORTICOSPINAL PROJECTIONS IN THE MACAQUE: EXTENT OF PROJECTIONS FROM THE PARIETAL LOBE. R.P. Dum and P.L. Strick. V.A. Med. Ctr. and Depts. of Neurosurg. and Physiol., SUNY-HSC at Syracuse, Syracuse, NY 13210.

We have examined the origin of corticospinal projections from the parietal lobe using retrograde transport of HRP. In 2 monkeys (Macaca nemestrina), tracer was placed in the dorsolateral funiculus at C2. The distribution of labeled neurons in the parietal lobe was reconstructed from serial sections.

All of the cytoarchitectonic fields of primary somatosensory cortex (areas 3a, 3b, 1 and 2) contribute to the corticospinal tract. However, the density of projections from individual areas varies. The highest peak density of labeled neurons is in parts of areas 1 and 2 (140 neurons/mm^2) and the lowest peak density is in parts of areas 3a and 3b (76 neurons/mm^2).

Except for area 3a, most corticospinal neurons are not uniformly distributed within a single area. For example, the density of corticospinal projections is particularly low in the lateral portion of areas 3b, 1 and 2 near the end of the intraparietal sulcus. Based on current maps of somatosensory cortex, this region appears to correspond to the representation of the forelimb digits. In contrast, the highest density of corticospinal projections originates from the portions of areas 1, 2 and 5 which are adjacent to the postcentral sulcus. This region is bordered medially and laterally by regions with sparse corticospinal projections. The densely labeled region at the postcentral sulcus appears to correspond to the rostrocaudal strip in areas 1, 2 and 5 which contains a sequential cutaneous representation of the arm (Pons et al., J. Comp. Neurol. '85).

Corticospinal projections also originate from dorsal and lateral portions of area 5 and from multiple areas in and around the lateral sulcus (area 7b, SII, retroinsular and granular insular cortex). These projections all appear to originate from cortical regions which are responsive to peripheral afferent input (e.g., Robinson and Burton, J. Comp. Neurol. '80).

These observations indicate that the parietal lobe contribution to the corticospinal tract originates from multiple and diverse cytoarchitectonic areas. These cortical areas are thought to be at different levels in the processing of somatosensory information. Furthermore, based on their corticospinal projections, specific regions within some cytoarchitectonic areas appear to be preferentially involved in the processing of sensory information at the spinal level.

131PO SUBCORTICAL EFFERENT PROJECTIONS FROM CELLS IN THE INFRAGRANULAR LAYERS OF THE RAT BARREL FIELD

B.E. Mercier*, C.R. Legg* and M. Glickstein
Department of Anatomy and Biological Development, University College, Gower Street, London W1, U.K. and Psychology Division, City University, London, U.K.

The rat barrel field provides the opportunity to ask fundamental questions about connections between sensory and motor areas of the brain. We studied efferent projections of cells in Layers V and VI by injecting the tracers wheat germ agglutinated HRP, diamidino yellow, or true blue into subcortical target structures and reacting sections through the barrel field cortex to reveal retrograde labeled cells. An alternate series of sections was processed for cytochrome oxidase. Our results confirm and extend the previous report of Wise and Jones (J. Comp. Neurol. 175, 129, 1977). Layer V is readily subdividable into a superficial, cytochrome- oxidase pale sublamina Va, and a deep, darkly staining Vb. Cells in these sublaminae differ strikingly in their efferent targets. Most, probably all pyramidal cells in sublamina Vb project to the pontine nuclei. Double retrograde labelling reveals that the axons of a subset of the cortico-pontine cells in sublamina Vb bifurcate with a branch to the superior colliculus. Another subset of Vb corticopontine cells send a branch to non-relay thalamic nuclei. The major subcortical target of cells in sublayer Va is to the caudate/putamen. Cells in layer VI are labeled only after injections are made which include the ventrobasal thalamus.

Recent physiological studies report that cells in the two sublaminae of layer V are activated at different latencies following vibrissal stimulation (Armstrong-James et al., J. Physiol. in press). Anatomical studies (Keller et al., Brain Research 343, 159, 1985) demonstrate that Vb but not Va of mice receives a direct thalamic afferent projection. Our own results combined with these physiological and anatomical findings suggest that sensory information is processed in parallel by the two sublaminae of layer V. Cells in one sublamina project principally to the cerebellum by way of the pons, the other mainly to the basal ganglia.

SOMATOSENSORY CORTEX AND THALAMOCORTICAL RELATIONSHIPS III

132.1 **RESPONSES OF CUTANEOUS MECHANORECEPTORS TO STRIPE PATTERNS ON THE OPTACON.** J.A. Santoro*, C.I. Palmer and E.P. Gardner (SPON: M. Bak). Dept. of Physiology, NYU Sch. Med., New York, NY 10016.

The OPTACON (144 miniature probes arranged in a 6 x 24 matrix) simulates motion across the skin by sequentially strobing adjacent probes. Although widely used as a reading aid for the blind, and in psychophysical studies of tactile discrimination, almost no electrophysiological studies of the neural activity generated by the OPTACON have been published. We now report the responses of the three major classes of cutaneous mechanoreceptors to moving stripe patterns displayed on the OPTACON. Single fiber recordings were made from 98 cutaneous afferents innervating the glabrous skin of the anesthetized monkey's hand. Four ms pulses were applied simultaneously to one or two rows; active rows were shifted in 1.1 mm steps across the OPTACON at 10, 20 or 40 ms interpulse intervals.

Meissner's afferents (RAs) (n=33) were extremely responsive to OPTACON stimulation, firing one or two impulses to stimulation of each row within their receptive field (RF). Most RAs fired one spike/pulse, yielding uniform sensitivity throughout the RF; the remainder fired two spikes, to probe indentation and retraction. RAs responded in an all or none fashion to repetitive activation of 2-5 rows, with identical latencies on each trial. Sequence of receptor activation determined RF boundaries, which stretched one row in the direction of motion. **Pacinian corpuscles** (PCs) (n=12) had larger RFs (5-24 rows), but more irregular responses; intertrial variability was greater than for RAs. Multiple spike bursts were more common; PCs fired up to 4 spikes/pulse. **SA mechanoreceptors** (n=53) responded only to contact of the RF with the tactile array, but none responded to dynamic patterns. Thus SAs contribute only noise to the CNS from skin contact, but provide no useful information concerning spatial patterns.

Firing rates of RAs and PCs were tightly linked to frequency of stimulation at 25-100 Hz; average rates were highest to 100 Hz, and decreased exponentially. Most RAs showed no change in total spikes/sweep over these frequencies. PCs displayed slight decreases in total spike output at high frequency, due to occlusion of multiple spike responses from subsequent stimuli.

Responses to pairs of rows separated by 1-12 mm were similar to those evoked by single rows. RAs did not sum inputs from two rows within their RFs, responding only to the shorter latency row. Individual stripes could be resolved only when their spacing exceeded the diameter of the RF. RAs had better spatial resolution than PCs, due to their smaller RFs, and more regular responses.

Although use of the OPTACON as a reading aid depends crucially upon the ability to resolve spatial characteristics of letters displayed, we have shown that it is ineffective for SA receptors, which most clearly resolve Braille dots. The OPTACON is highly selective for RAs and PCs, which accurately transmit information about temporal frequency of stimulation.

132.2 **FREQUENCY FILTERING OF SENSORY INFORMATION IN SI CORTEX.** E.P. Gardner, H.A. Hamalainen and S. Warren. Dept. of Physiology, NYU Sch. Med., New York, NY 10016.

Santoro, Gardner and Palmer (*Soc. Neurosci. Abstr. 13:* (this vol.)) have demonstrated that dynamic patterns on the OPTACON (144 miniature probes arranged in a 6 x 24 matrix) excite only RA and PC mechanoreceptors, whose firing rates are tightly linked to the frequency of stimulation over the range 25-100 Hz. Average rates of RAs and PCs were highest to 100 Hz stimuli, decreasing exponentially as a function of frequency. Most RAs showed no change in total spikes per sweep when the frequency was raised from 25 to 100 Hz, while PCs displayed slight decreases at high frequencies. We now report that a remarkable transformation of sensory information occurs between the periphery and cortex, involving enlargement of receptive fields (RFs), and filtering of high frequency responses in SI cortex of alert rhesus monkeys.

Four ms pulses were applied simultaneously to the central four columns of a single row on the OPTACON; the active row was shifted proximally or distally to the immediately adjacent row (1.1 mm), or to rows 2.2 or 4.4 mm away, at intervals of 10, 20, 40, or 80 ms. Single unit responses in areas 3b, 1 and 2 integrated information from at least 16 rows; most cells responded to rows covering an entire digit, or a large fraction of the palm.

Temporal frequency of stimulation seems to be the major determinant of cortical firing patterns. Phase locking of spikes was most apparent in low frequency responses consisting of short highly regular bursts of 3-5 spikes, separated by silent periods. The spike train changed to continuous, low amplitude, frequency modulated activity at high frequencies. Unlike peripheral afferents whose firing rates mimic stimulus frequency, average firing rates of cortical neurons were relatively uniform at all frequencies. Over the range 100-25 Hz, we observed a linear increase in total spikes/sweep of the bar across the RF, due to increased spikes/pulse, and RF expansion along the path of stimulation. Unlike RAs whose responses were constant, cortical average spikes/pulse rose from 0.5 at 100 Hz, to 3 at 25 Hz. No further increases in spikes/pulse or RF dimensions occurred at lower frequencies. High frequency attenuation of firing rates and RF size suggest a time dependent central inhibitory process, which is maximum at 10 ms, and terminated by 40 ms. Thus high frequency stimuli are selectively attenuated by central neuronal processing, which smooths out variations in firing during the period of stimulation.

High frequency stimuli are perceived as moving stimuli by humans and elicit continuous, regular firing by cortical neurons. Low frequency stimuli feel pulsatile or punctate; their cortical responses are burstlike. Thus the difference between punctate and moving sensations may be encoded by the properties of the cortical spike train.

132.3 SENSORY RESPONSES AND PREMOVEMENT ACTIVITY CHANGES IN PRIMARY SOMATOSENSORY CORTEX DIFFER WHEN MONKEYS MAKE HAND MOVEMENTS IN RESPONSE TO VISUAL VS. VIBRATORY CUES. R. J. Nelson. Department of Anatomy and Neurobiology, College of Medicine, University of Tennessee, Memphis, Memphis, TN 38163.

Changes in the sensory responsiveness of primary somatosensory (SI) cortical neurons to peripheral input occur when monkeys make stereotyped wrist movements with the stimulated hand in response to a vibratory "Go-Cue", as compared to when no movement was required (Nelson, Brain Res., 304 [1984]:143-148). This indicates that "motor-set" influences SI neuronal responses to sensory input. As well, premovement activity changes in SI neurons often greatly precede movement, suggesting that these neurons receive centrally generated modulatory inputs (Nelson, Brain Res., 406 [1987]:402-407). The current experiments were designed to determine if premovement activity changes in SI neurons, and those associated with the vibratory Go-Cue onset, are related in general to the Go-Cue itself and not modality specific.

Rhesus monkey made flexion or extension wrist movements with their stimulated hand in response to palmar vibratory stimulation of either 27, 57 or 127 Hz. This was the trigger stimulus for the movements which the animals made at reaction time latencies. It remained on until the animal moved at least 5° from a previously held position in this self-paced task. The animals viewed a visual display of their current wrist position at all times. In requesting visually triggered movements, the display of current position, shown by LEDs, was shifted from the center zone by an amount equal to a 5° wrist movement. Animals learned to move in the direction opposite the lamp shift. Movements of at least 5° in the appropriate direction were rewarded with fruit juice. The animals began the next trial by repositioning the handle in the center zone. The activity of single SI cortical neurons and the wrist position were digitized by conventional means. Reaction times, stimulus related responses, and premovement activity changes were analyzed to compare vibration vs. visually triggered movements.Visual reaction times averaged about 100 ms slower than for vibratory cued trials for the 59 SI neurons analyzed to date. Some 24/59 (41%) responded at short latency (<30ms) to a vibratory Go-Cue, whereas 1/59 (2%) showed any change in discharge with the visual trigger stimulus. The 24 neurons often responded differently to vibration if it was the Go-Cue, as opposed to when the movements were extinguished. Of the sampled neurons, 55/59 (93%) exhibited some premovement suppression or facilitation in firing rate. Of these, 51/59 (86%) had activity changes for vibratory cued trials that led those for visually cued trials; the opposite was true for 4/59 (7%). The magnitude of premovement activity changes also differed under the two conditions. Some 37/59 (63%) neurons had a greater change in activity for vibratory vs. those triggered by visual stimulation; the reverse was true for 17/59 units (29%) and 5/59 cells (8%) showed similar magnitude or no change.

These results indicate that set-dependent changes in sensory responsiveness, occuring at stimulus onset, vary with different behavioral contingencies . They also suggest that premovement, centrally generated modulatory influences differ depending on the modality of the stimuli present. Since vibratory stimulation, under some circumstances, is know to alter muscle spindle responses, perhaps, these differences depend upon whether the present peripheral inputs might be capable of disrupting the monitoring of performance of a required movement.

Supported by USAF Grant AFOSR 85-0217.

132.4 COMPARISON OF HUMAN AND MONKEY ESTIMATES OF ROUGHNESS. R. Sinclair and H. Burton. Department of Anatomy & Neurobiology, Washington Univ. Sch. of Med., St. Louis, Mo. 63110

Humans and Rhesus Macaques discriminated the "smoother" of pairs of textured surfaces presented on 16cm long rectangular blocks "stroked" in a distal-proximal fashion (Sinclair & Burton, Soc. Neurosci. Abst. 12:1431,1986), with specified force and velocity. Each block contained two 8 cm gratings of nyloprint etched with ridges oriented transverse to the direction of stroking. Gratings varied in spatial period from 650 to 3050 μm, with ridge-groove ratios (RG) of 10, 25 & 50%. All combinations of surfaces were presented as paired comparisons. Humans were instructed to identify the "smoother" of each pair. Monkeys were first trained to make easy discriminations to the 80% criterion level, and then progressively given harder discriminations. Human psychophysical data indicated that perceived roughness increased with increasing spatial period. For comparisons of surfaces with the same RG, monkeys were required to choose the surface with the lower spatial period. The effect of varying RG across spatial period was not as clear. To obtain a less biased estimate of what the monkey considered the "smoother" of two surfaces of differing RG ratio, trials where monkeys were required to make a correct response were interspersed with trials where they were rewarded for either choice. Only easy discriminations were presented for correct response trials. The purpose of these was to keep the animal from adopting a random strategy on the free choice trials. The assumption for the free choice trials was that since monkeys were trained to choose the "smoother" of any two surfaces, they would do so even when not required. Results from these free choice trials were used to calculate the monkey's estimate of roughness for comparisons across RG.

The order of surfaces from smoothest to roughest was the same for both species. To date, monkeys have been able to discriminate at the 75% correct level, two surfaces differing in spatial period by 15%. Other studies indicate that humans can, on average, discriminate a difference of 5%. In both species, surfaces with the same spatial period were identified as smoother as groove size decreased. This is consistent with human psychophysical and with recent electrophysiological studies in somatosensory cortex in which larger groove size resulted in greater response when spatial period was held constant.

This study attempted to minimize methodological differences between the two species studied. Humans and monkeys apparently perceive roughness in a similar fashion. This provides support for generalizing to man, the findings of electrophysiological/ behavioral studies in monkey. (Funds from NS09809)

132.5 MODULATION OF SOMATOSENSORY CORTICAL UNITARY RESPONSES DURING ACTIVE TACTILE DISCRIMINATION IN THE MONKEY. C.E. Chapman. Centre de recherche en sciences neurologiques and Ecole de réadaptation, Université de Montréal, Montréal, CANADA

It has been reported that somatosensory input to primary somatosensory cortex is diminished during movement. Paradoxically, the ability to discriminate differences in texture is reportedly uninfluenced by movement. These two findings could be reconciled if the modulation of afferent input during movement varied with the task. The purpose of this study was to characterize the discharge properties of neurones in primary somatosensory cortex of the awake monkey during the performance of a task requiring the animal to actively explore and discriminate between two different surfaces.

A monkey, macaca mulatta, was trained to perform a scanning movement over two different surfaces. One surface was smooth while the other was initially smooth, becoming textured (embossed Braille characters) over the second half of its length. Following a visual cue, the animal made a scanning movement, monitored with LEDs set into the walls of the groove, over the surface. Following completion of the movement, the monkey signalled the type of surface encountered by pushing (smooth throughout) or pulling (smooth/rough) a lever with the contralateral arm.

Recordings have been made from 38 neurones in the cutaneous hand representation of primary sensory cortex and evidence was obtained to suggest that somatic input to sensory cortex is indeed modulated as a function of the task. 23 of the 38 units were modulated during the scanning movement. Of 18 cells whose discharge increased during the scanning movement, 7 showed no discharge or a decrease in discharge as the digits were moved back over the surface. Such units were not obviously directional when their receptive field was determined. Furthermore, passive movement, in the same direction as the scanning movement, had only weak excitatory effects or no effect in 4 of 5 cells tested. Such observations indicate that somatic input to some cells is enhanced during the scanning movement. The opposite effect, diminished transmission of somatic input to cortex, was also observed. Five units showed a decrease in discharge during the scanning movements yet all showed evidence of an excitatory receptive field on one or more of the digits. Of a further 15 cells, unmodulated during the scanning movement, 5 showed an increased discharge as the monkey resumed the initial position. These results indicate that peripheral input from the hand can be enhanced or diminished during a task requiring the animal to discriminate different surfaces. Supported by the FRSQ and the Canadian MRC.

132.6 A Comparison Between Asleep and Waking Cortical Depth Profiles of Somatosensory Evoked Field Potentials (SEP), Multiple Unit Activities (MUA) and Current Source Densities (CSD) in the Postcentral Gyrus of Behaving Rhesus Monkeys. L.J. Cauller* and A.T. Kulics* (spon: L. Fechter). Dept. of Neurobiology, N.E. Ohio Univs' College of Medicine, Rootstown, OH 44272

Multiple electrode arrays (15 tips; 200 um fixed separation) were constructed to simultaneously record the somatosensory evoked electrical signals from fifteen, equally spaced levels from dura to white matter through cortex. A detachable, screw-type microdrive permitted multiple penetrations through postcentral gyrus in the awake or sleeping monkey. The multi-channel responses to electrocutaneous or mechanical stimulation of the contralateral hand was saved on FM tape for offline digital analysis. Records were high pass filtered (>500Hz) and then integrated (5ms time constant) to determine the profile of MUA. For penetrations that were found to be perpendicular to the cortical surface, depth profiles of SEPs were digitized and processed for CSD analysis. These methods are an elaboration of those reported previously (Kulics and Cauller, Exp. Brain Res. 62:46-60, 1986) and have led to a model of the sleeping cortical process.

The somatosensory cortical response consists of two distinct components, a surface positivity at 12 ms (P1) that is a reliable measure of stimulus strength, and a later suface negativity at about 50 ms (N1) that predicts the monkey's performance on a stimulus strength discrimination task. Both P1 and N1 are associated with peaks of MUA through layers III-V. P1 is thought to reflect the synchronous activation and discharge of middle layer pyramidal cell bodies and N1 is generated by a massive postsynaptic sink into the layer I/II distal apical dendrites of pyramidal cells whose bodies are in layers II-V.

The sleep state was identified when a monkey's eyes closed and the cortical electroencephalograph (EEG) displayed large slow wave activity while wakefulness was defined as low amplitude, high frequency EEG activity with eyes opened. While the P1 component of the SEP, and the associated early MUA was increased during the sleep state, the late MUA that is associated with N1 during the awake state, is replaced by inhibition as indicated by a level of MUA that falls below prestimulus activity. That late inhibition during sleep is associated with a massive late current source in layers II-IV which lasts about 100ms following the P1 excitatory response. Occasionally, a rebound burst of MUA follows the long inhibitory phase at about 125ms post stimulus which is associated a surface positive-negative wavelet. The possibility that the sleeping cortical response could result from a voltage-sensitive potassium conductance (ie. M-current) that is inactivated by cholinergic inputs during wakefulness is considered in the model of the cortical sensory process. Supported by NIMH grant MH38157.

132.7 SEP AND MUA RESPONSES TO MECHANICAL STIMULI IN SI AND SII CORTICAL AREAS OF AWAKE MONKEYS. H. Hämäläinen, M. Sams*, S. Carlson*, A. Pertovaara , K. Reinikainen*, and R. Näätänen*. Dept. of Psychol. and Dept. of Physiol., Univ. of Helsinki, Finland.

We measured simultaneously local early and late somatosensory evoked potentials (SEPs) and multiple unit activity (MUA) elicited by mechanical pulses and vibration. The recordings were obtained from hand projection areas of cortical regions SI and SII. Our aim was to compare the responses of these cortical areas to different stimuli, and to evaluate the relationship between neuronal spike-activity and evoked potentials.

Awake monkeys (Macaca Arctoides) were used in the experiments. The recordings were obtained with glass-coated tungsten macroelectrodes, and the signals were fed to different filters for SEP and MUA measurements (600 ms analysis period). The MUA was converted to trains of 0.4 ms pulses by a window discriminator, and the average firing probabilities were calculated by a computer. The stimuli were single tactile pulses and vibration (duration 400 ms of 24 or 240 Hz frequency.

In SI only responses to stimulation of the contralateral hand were obtained, and largest responses were measured to slow pulses and low-frequency vibration. The main SEP components measured to single pulses were a large negative deflection - often consisting of several peaks - at 40 ms, followed by a slower positivity which returned to the baseline within 200 ms after the stimulus onset. Usually the large negativity was preceded by a short-latency (13 ms) positive deflection, the amplitude of which was dependent on the recording depth. With low-frequency vibratory stimuli similar initial deflections were recorded, but they were followed by oscillation tuned to vibration frequency, and by an off-response at the end of vibration. The SEPs to high-frequency vibration showed the same pattern except that no oscillations tuned to vibration frequency could be seen. The onset of the pulse-elicited MUA responses (duration about 75 ms) corresponded to that of first SEP components. The distinct peaks in MUA often elicited by low-frequency vibration were time-locked to the SEP oscillations.

In SII completely different responses were measured. A basic pattern to all stimulus types consisted of a slow positivity starting immediately at the onset of the stimulus (peaking at 100-200 ms), followed by a large slow negativity (peaking at 270-400 ms). Sometimes also a distinct negative peak (at 70-100 ms) was seen together with the slow positivity. SEPs to ipsilateral hand stimulation were usually weak in SII with all but high-frequency vibration which elicited similar responses to both contra- or ipsilateral stimulation. In contrast to SI responses, the MUA usually increased rather smoothly after stimulus onset, and its decay corresponded to the increasing negativity in the simultaneously measured SEP.

132.8 MOVEMENT CORRELATED MODULATION OF SENSORY TRANSMISSION TO SINGLE UNITS IN THE VPL THALAMUS H.-C. Shin and J.K. Chapin, Hahnemann University, Philadelphia, PA 19102.

We have previously shown that cutaneous sensory transmission to single neurons in the rat somatosensory cortex is reduced a mean 71.2% during locomotion, and is phasically modulated over the step cycle. As part of an effort to determine the level(s) in the somatosensory system at which this modulation occurs, similar studies have now been carried out in the ventroposterolateral (VPL) thalamus. The experiments involved recording single units in the forepaw area of the VPL thalamus in awake, freely moving rats in which stimulating electrodes had been chronically implanted under the skin of the forepaw. This allowed standardized low current stimulation pulses to be applied during different phases of the forepaw step cycle.

Initial studies showed that transmission to single neurons in the VPL was depressed by mean 32% during movement as compared with rest; much lower than the 71% reduction observed at the cortical level. The next step was to determine the degree to which this modulation varied over the step cycle. Using frame-by-frame video tape analysis to define the step cycle phase, "peri-footfall sensory gating histograms" were constructed to graphically illustrate the variation over the step cycle in the neurons' sensory responsiveness to the applied forepaw stimulation. The results showed that while some VPL neurons were subject to a tonic reduction in sensory responsiveness over the step cycle, many cells were phasically modulated. An average of peri-footfall gating histograms from all 30 units in this sample showed a strong sensory inhibition during the 50 msec just following footfall, and a sensory facilitation during the late-stance-to-foot-off phase of the step cycle. The post-footfall inhibition was strongest in the 10 neurons which also responded to the footfall itself, and thus may have resulted partly from an interaction between the test stimulation and the natural stimulation caused by footfall. In the 20 cells which did not respond to footfall, sensory inhibitions were also observed during the entire swing phase of the step cycle. We conclude that phasic somatosensory modulation occurs in the VPL thalamus as well as the cortex, but that the modulations are distinctly different in their temporal patterns, polarities, and magnitudes. 132.9 PHARMACOLOGICAL ACTIVATION OF LOCUS COERULEUS NEURONS BY LOCALLY INFUSED CARBACHOL: EFFECT ON CORTICAL NEURON EVOKED ACTIVITY. L.M. Adams and S.L. Foote. Department of Psychiatry, Univ. of California, San Diego, La Jolla, CA 92093.

Previous studies have revealed a modulatory action of iontophoretically applied norepinephrine (NE) on cortical neuron responsiveness, suggesting a role for the cortically projecting NE-containing nucleus locus coeruleus (LC) in modulating cortical function. As an alternate means of determining the effects of NE release in cortical target areas, LC neurons were activated by local infusion of the cholinergic agonist bethanechol (BCHOL) while simultaneously monitoring the spontaneous and sensory-evoked activity of cortical neurons. Utilizing a previously described cannulae-microelectrode assembly (Soc Neurosci Abst. 12:154,1986), BCHOL was infused into the LC of halothane-anesthetized rats and its effect on firing rate monitored by means of a metal microelectrode. A 12-25 ng infusion (50 nl/1 min) produced a 4-fold increase in firing rate with 30-60 second latency to maximum effect and 3 min duration. A second microelectrode was lowered into the hindlimb region of primary somatosensory cortex and the appropriate receptive field activated either electrically or by air-puffs. Post-stimulus-time histograms (PSTHs, 50 sweeps) were computed on-line to determine the effect of LC activation on cortical neuron response profiles. PSTHs were accumulated over 50 sweeps (3 min) before and at 6-min intervals following BCHOL infusion. Infusion of BCHOL produced one of two effects depending on the baseline response properties of the cortical neuron being recorded from. The most typical baseline response consisted of a transient, short-latency (15-20 ms) excitation followed by a prolonged period (50-150 msec) of post-stimulus inhibition (PSI). One minute after BCHOL infusion, the number of short-latency spikes and the duration of PSI were reduced, and there was a corresponding increase in the number of longer latency spikes. Recovery occurred over a period of 6-12 min. The other type of cortical baseline response was a short latency burst not followed by PSI. For these cells, BCHOL infusion reduced both the spontaneous firing rate and the short-latency evoked response. Since the reduction in spontaneous activity occured at lower doses and was slower to recover than the reduction in evoked responding, the ratio of evoked to spontaneous activity was enhanced. The majority of units tested were found in layers IV or Va. Infusion of BCHOL 400-500 µg below the LC failed to alter cortical activity. Intravenous clonidine in a dose (10-20 µg/kg) which completely inhibited LC firing for 30-60 min, antagonized the BCHOL effects on cortical evoked responses. The spatial restriction and pharmacological specificity of BCHOL effects suggest a direct mediation by LC activation. Studies are underway to attempt to further define the relationship between cortical neuronal response types and the effects of LC activation.

132.10 SOMATOSENSORY EVOKED POTENTIALS FOLLOWING INTRATHECAL DYNORPHIN A (1-13) INJECTION IN THE RAT. D.D. Rigamonti, J.B. Long, F.C. Tortella, R.P. Gussio*, A. Martinez-Arizala* and J.W. Holaday. Neuropharmacology Branch, Department of Medical Neurosciences,Division of Neuropsychiatry, Walter Reed Army Institute of Research, Washington, D.C. 20307.

Pharmacological exposure of the rat spinal cord to several endogenous peptides [dynorphin A (DYN), arg-vasopressin, and somatostatin] has been observed to produce neural injury, blood flow reductions, and neurological impairments. Among these peptides, DYN has been specifically implicated as a mediator in spinal cord injury. Cortical somatosensory evoked potentials (SEP) have been routinely used to assess spinal cord integrity and functional status following trauma and ischemia. Therefore, the SEP was employed as an adjunctive test to assess the time course and extent of spinal cord dysfunction following DYN (1-13) exposure. Adult male Sprague-Dawley rats anesthetized with ketamine and xylazine were placed in a stereotaxic frame, and cortical evoked potentials were averaged (N=50-2000) using either forelimb or hindlimb stimulation (Nicolet Pathfinder II). The control SEP altered with changes in strength, frequency, and duration of the stimulus, and location of the cortical recording electrodes. These parameters were adjusted to obtain the optimum cortical response. Following intrathecal injection of DYN (50 nmoles) into the lumbar subarachnoid enlargement, alterations in the SEP were observed. These were mainly in the amplitude and shifts in the latency of major cortical responses. Changes in amplitude varied from slight to total disappearance of the cortical response. The forelimb evoked potential following DYN injection also was generally increased in amplitude. Following recovery from anesthesia, neurological impairments were compared with SEP alterations. This neurophysiological test is a powerful tool to correlate neuropathological and functional changes following peptide injury to the rat spinal cord.

133.1 IDENTIFICATION OF DECUSSATION SITE OF LOCUS COERULEUS (LC) AXONS WHICH AFFECT LHRH NEURONAL ACTIVITY. M. S. Gitler * and C. A. Barraclough. Dept. of Physiology, University of Maryland. Sch. of Medicine, Baltimore, MD 21201.

Electrical stimulation (ES) of LC amplifies luteinizing hormone (LH) release after medial preoptic nucleus (MPN) LHRH neurons have been partially depolarized. We also observed that these stimulatory LC fibers must decussate to reach contralateral LHRH neurons for the LH amplifying effect to occur. The purpose of this study was to determine where the decussation of these LC axons occurs. Estrogen-treated ovariectomized rats were anesthetized with chloral hydrate. One group of control rats received right MPN electrochemical stimulation (ECS) (0.1mA/60 sec d.c.) at 0 time. In a second group, the right MPN was ECS and 30 min later the left LC was electrically stimulated (0.1 mA, 10 Hz, 1 msec duration, 15 sec on/off) for 15 min. Blood was collected at various times and plasma LH levels were measured by RIA. In different experimental groups one of the following brain transections was made with a knife blade: (I) unilateral (left) cut of medial forebrain bundle (MFB) at the level of the posterior hypothalamus. This transection spares the tegmental and posterior commissural decussations of LC fibers; (II) a midline transection in the MPN region which coursed through the anterior commissure (AC) to the top of the third ventricle. This cut should disrupt AC decussation of LC axons; (III) a midline cut in the MPN region which passed through both AC and optic chiasma (OC) to the sphenoid bone. This transection should interrupt both AC and OC decussations by LC axons. In rats receiving cut I (MFB), the transection was placed either 10 min before or 25 min after MPN-ECS. LH responses to MPN-ECS did not differ from controls in either group. In other rats, the MFB cut was placed 25 min after MPN-ECS and 5 min later the LC was ES. The normal amplifying effect produced by LC-ES was completely abolished by this transection. In all of the remaining groups, transections were made 25 min after MPN-ECS. Cut II (AC): after MPN-ECS, LH levels remained slightly elevated from 60-90 min in transected vs. control rats. In other AC-transected rats which received combined MPN+LC stimulation, peak LH concentrations were markedly amplified to the same extent as controls. However, while control LH levels approached baseline values at 180 min, they remained significantly elevated from 60-180 min in the AC transected rats. Cut III (AC+OC): This transection did not affect LH responses to MPN-ECS. In contrast, this cut completely blocked the amplifying effects of LC-ES. We concluded that: (1) stimulatory LC axons cross midline via the supraoptic commissure to affect LHRH neuronal activity in the contralateral MPN; (2) By disrupting neural elements in the AC region we have unmasked an inhibitory component which affects LHRH neuronal responsiveness to LC-ES. Whether this inhibitory effect is exerted via LC input to MPN or is the consequence of our disrupting inhibitory rhinencephalic tracts to MPN remains to be resolved.

133.2 **EXCITATION OF LOCUS COERULEUS FROM PARAGIGANTOCELLULARIS MAY BE MEDIATED BY AN AMINO ACID TRANSMITTER.** M. Ennis and G. Aston-Jones, Dept. Biol., New York University, NY, 10003.

Recent studies reveal that the major afferent to rat locus coeruleus (LC) is nucleus paragigantocellularis (PGi) in the medulla. We have also recently reported that PGi inputs are predominantly excitatory on LC. PGi-induced excitation of LC is resistant to the muscarinic antagonist **scopolamine**, but is abolished by kynurenic acid, an antagonist of excitatory amino acid (EAA) transmission. Here we further specify the transmitter and receptor involved in PGi-induced excitation of LC.

Extracellular recordings were obtained from single LC neurons with micropipettes in anesthetized rats. Subcutaneous 26 g needles were used for electrical footpad stimulation (FS) and 250-uM wires were used for bipolar electrical stimulation of PGi.

The nicotinic antagonist **mecamylamine** (1.0 mg/kg, i.v.) had no effect on PGi-evoked excitatory responses in 5 LC neurons. Similarly, this agent had no effect on responses of LC cells to FS, and did not change the firing rate of LC cells. **Kynurenic acid** (0.53 umols, icv) completely blocked PGi-induced excitation of LC neurons, and this agent also abolished excitation of LC by FS ($p<.01$ for both). **D-glutamylglycine (DGG)**, a preferential NMDA-kainate antagonist, blocked PGi-LC excitation in a dose-dependent manner in all 8 neurons tested, markedly attenuating ($p<.01$) excitation at 0.1 umols and completely blocking excitation at 0.32 umols (icv). Similarly, DGG exerted a dose-dependent antagonism of FS-excitation in LC, reaching significance at 0.18 umols ($p<0.2$). DGG also decreased spontaneous discharge ($p<.05$) for 6 cells tested with 0.32-1.0 umols.

The specific NMDA antagonist **2-amino-7-phosphonoheptanoic acid (AP7)** also attenuated PGi- ($p<.01$) and FS-elicited ($p<.05$) excitation in LC, but at a relatively high dose (0.1 umols; icv). Also, this agent was less effective than kynurenic acid or DGG, failing to completely block PGi or hindpaw responses in any cell.

In contrast to DGG and AP7, the preferential quisqualate antagonist **glutamate diethyl ester (GDEE)** (15 umols, icv) did not block LC responses to PGi or FS stimulation ($p>.1$).

Although additional tests are needed to exclude other possible effects of EAA antagonists (e.g., on peptide transmission), the present results suggest that an EAA mediates the activation LC by its major afferent, PGi. The ability of EAA antagonists to attenuate FS-responses in LC is consistent with our hypothesis that sensory stimuli activate LC through PGi, and implies an EAA in this pathway. However, it is also possible that EAA antagonism of FS responses was effected prior to PGi. DGG and AP7, but not GDEE, antagonism of LC responses implicates kainate or NMDA subtypes. Supported by PHS MH09381, Alz. Dis. Related Dis. Assoc., Am. Fed. Aging Res., and ONR Contract N00014-86-K-0493.

133.3 RESPONSE OF LOCUS COERULEUS NEURONS TO SOMATOSENSORY STIMULI IS NOT BLOCKED BY LESIONS OF TWO MAJOR AFFERENT INPUTS. Kurt Rasmussen and George K. Aghajanian. Depts. of Psychiatry and Pharmacology, Yale Univ. Sch. Med., New Haven, CT 06508.

Stimulation of somatosensory nerves is known to have strong excitatory effects on noradreneragic neurons of the locus coeruleus (LC); indeed their burst-pause response to somatosensory nerve stimulation is an identifying characteristic of these neurons. A recent study (Aston-Jones et al., Sci., 234 (1986) 734) has reported that direct afferents to the LC are almost exclusively restricted to two medullary nuclei, i.e., the paragigantocellularis (PGi) and the prepositus hypoglossi (PrH). These findings raise the possibility that somatosensory input to the LC is relayed through one, or both, of these two medullary nuclei. In order to test this hypothesis, we lesioned each of these nuclei to see if we could block the effects of stimulating the sciatic nerve on the LC. We also lesioned the paraventricular hypothalamic nucleus (PVH), a possible minor afferent to the LC, and the ipsilateral medullary lateral reticular nucleus (LRN), a structure which is contiguous with the PGi and was suggested to be an afferent to the LC in an earlier study (Cedarbaum & Aghajanian, J. Comp. Neurol., 178 (1978) 1).

LC single unit recordings were obtained from chloral hydrate anesthetized male rats. Electrolytic lesions were made with a radiofrequency lesion maker, and the extent of the destruction was evaluated by examining histological sections. The sciatic nerve was stimulated at three different current settings with a bipolar hook electrode. The responses of five LC cells to each current level were examined in each animal. Although the projection to the LC from the PGi is predominantly ipsilateral, we also destroyed the PGi bilaterally in some animals. As compared with sham operated controls, destruction of ipsilateral PGi, bilateral PGi, PrH, ipsilateral LRN, or PVH did not alter the effects of sciatic nerve stimulation on the LC, indicating that afferent information from the sciatic nerve to the LC is not relayed through these nuclei. Alternatively, afferent information to the LC from the sciatic nerve could project directly from the spinal cord. This view is consistent with anatomical evidence for a possible direct projection to the LC from lamina X (Aston-Jones et al., Sci., 234 (1986) 734) and both anatomical and electrophysiological evidence for a direct projection to the LC from lamina I (Cedarbaum & Aghajanian, J. Comp. Neurol., 178 (1978) 1; McMahon & Wall, Brain Res., 333 (1985) 19).

In conclusion this study indicates that the strong excitation of the LC produced by somatosensory nerve stimulation is not mediated through relay nuclei in the medulla (PGi, PrH, LRN) or hypothalamus (PVH), but is probably a result of a significant direct input from the spinal cord.

133.4 THE ANTERIOR HYPOTHALAMUS PROVIDES STIMULATORY INPUT TO TUBEROINFUNDIBULAR DOPAMINE NEURONS WHICH IS NOT MEDIATED BY PROLACTIN. A.C. Barton, K.T. Demarest and K.E. Moore. Dept. of Pharmacol./Toxicol., Mich. State Univ., E. Lansing, MI 48824.

Tuberoinfundibular dopamine (TIDA) neurons in the medial basal hypothalamus (MBH) receive both stimulatory and inhibitory afferent input. For example, prolactin stimulates the neurosecretory activity of the TIDA neurons which, in turn, release DA into the hypophysial portal blood to inhibit further secretion of prolactin from the anterior pituitary (Endocrinol. 106: 526, 1980; Neuroendocrinol. 38: 467, 1984). The objective of the present study was to determine the role played by putative afferent neuronal connections (1) in maintaining basal neurosecretory activity of TIDA neurons, and (2) in the stimulatory actions of prolactin on these neurons. The neurosecretory activity of TIDA neurons was estimated by measuring the rates of synthesis, turnover, or metabolism of DA in the terminals of these neurons in the median eminence. DA synthesis and turnover were determined by measuring the rate of accumulation of dihydroxyphenylalanine (DOPA), following NSD 1015 (100 mg/kg, i.p.) and by the alpha-methyltyrosine(250 mg/kg free base, i.p.) induced decline in DA, respectively. DA metabolism was estimated by measuring the concentration of the DA metabolite, dihydroxyphenylacetic acid (DOPAC). Complete and retrochiasmatic (RC) deafferentations of the MBH were made to either completely isolate TIDA neurons from the rest of the brain or to interrupt rostral neuronal connections to the TIDA neurons, respectively (Endocrinol. 80: 608, 1967). Complete deafferentation of the MBH reduced the basal rate of DA synthesis, and RC deafferentation decreased the rates of synthesis, turnover and metabolism of DA in the median eminence of female but not male rats. A knife cut 1 mm rostral to the RC cut failed to alter basal TIDA neuronal activity. These results suggest that afferent neuronal inputs originating in or coursing through the caudal portion of the anterior hypothalamus mediate a tonic stimulatory influence on TIDA neurons in the female rat while this influence is either absent or repressed in the male. Since TIDA neurons in the female rat receive tonic stimulation by prolactin, it was investigated whether the RC deafferentation-induced decrease in TIDA neurosecretory activity was a direct consequence of the interruption of afferents mediating the action of prolactin. In intact female rats, intracerebroventricular (ICV) administration of rat prolactin (10 µg/3 µl) or systemic administration of haloperidol (2.5 mg/kg, s.c., which increases circulating levels of prolactin) increased DA synthesis in the median eminence. This stimulatory action of prolactin was not blocked by RC deafferentation. Decreasing circulating levels of prolactin, induced by the administration of bromocriptine (3 mg/kg, s.c.), reduced the rate of DA synthesis in the median eminence of both sham and RC deafferentated rats; in both groups this bromocriptine-induced decrease in DA synthesis was reversed by ICV administration of prolactin. These results suggest that the RC deafferentation-induced decrease in TIDA neurosecretory activity is a consequence of removing stimulatory afferent input to these neurons which is mediated by something other than prolactin. (Supported by NIH Grant NS09174.)

133.5 INTERACTIONS OF DOPAMINE AND ACETYLCHOLINE ON PREFRONTAL CORTEX(PFC) NEURONS AND THE EFFECTS OF GABAERGIC AND ENKEPHALINERGIC STIMULATIONS OF VENTRAL PALLIDUM ON PFC ACTIVITIES. C.R.Yang* and G.J. Mogenson (SPON: W.T.Blume). Dept. of Physiology, Univ. of Western Ontario, London, Canada N6A 5C1.

The prefrontal cortex (PFC), innervated directly by the mediodorsal thalamus (MD), receives prominent inputs from mesocortical dopaminergic (DA) neurons and from cholinergic (ACH) neurons of the ventral pallidum/substantia innominata (VP/SI). In turn, efferents from the PFC project to the nucleus accumbens (NAC). From the NAC, GABAergic and enkephalinergic output neurons synapse onto the VP/SI neurons which ascend directly to the PFC, or indirectly via the MD. Hence, PFC is an important site where interactions of the DA and ACH systems occur and where the output from the NAC may be fed back via the NAC-VP/SI-MD-PFC 'loop'. These possibilities were studied using extracellular single-unit recordings in urethane- or ketamine-anaesthetized rats.

145 PFC neurons 2-4mm below the surface of the cortex (layer III-VI) were identified as PFC-NAC neurons by their antidromic responses to NAC stimulation (onset latency=15±2 ms). 36 of these neurons were also inhibited by MD stimulation. Iontophoretic application of ACH (5-80 nA, 40-70s) to 32 of 87 PFC neurons produced a gradual increase in firing which outlasted the application period. When DA or its D-2 receptor agonist (LY171555) was applied iontophoretically onto 27 PFC and 5 PFC-NAC neurons, there was a significant (p 0.001) increase in the firing rate and duration of the response to ACH. The doses of DA or the D-2 agonist used (2-7nA)produced only minimal changes (±20%) of baseline firing of the PFC neurons. Furthermore, following blockade of of the D-1 receptors by SCH23390 (2mg/kg,i.p.) the potentiation of the cholinergic response by the very small amount of D-2 agonist on the PFC neurons persisted suggesting a sensitive and selective D-2 receptor mechanism which potentiates cortical cholinergic transmission.

Muscimol (1-2ug/0.5ul), a GABA agonist, or D-ala-D-met-ehkephalin (lug/0.2ul) microinjected into the VP/SI mimicked the actions of the NAC output. Muscimol increased the firing rate in 11 of 25 PFC-NAC neurons by 70-400%, perhaps by disinhibition. Injection of procaine (40ug/0.2ul) into the MD (to block the transmission of ascending VP-PFC neurons relayed via the MD)further enhanced the discharges in 4 of these PFC neurons but 4 others were inhibited. Met-enkephalin in the VP/SI produced no clear response in the PFC, but the opioid inhibited the spontaneous firing of 10 of 20 MD neurons. Taken together these results suggest GABAergic and enkephalinergic neurons from the NAC may regulate ascending VP/SI neurons which influence the activities of PFC-NAC neurons directly, or indirectly via the MD. The potentiation of the cholinergic transmission by mesocortical DA may be part of a mechanism for cognitive processes involving the ascending VP/SI cholinergic neurons.(Funded by M.R.C. of Canada)

133.6 LACK OF EFFECT OF L-PHENYLALANINE ON PHOTICALLY-INDUCED MYOCLONUS IN THE BABOON, Papio papio. B.S. Meldrum. Department of Neurology, Institute of Psychiatry, London, SE5 8AF, U.K.

Administration of L-phenylalanine (PHE) to rodents can modify reflexly-induced seizure responses in susceptible strains (Truscott, Pharmac. Biochem. Behav. 3: 939, 1975). It is thought that PHE competes with tyrosine for uptake into the brain and decreases the synthesis of catecholamines. Direct evidence for an effect of PHE on seizure threshold in primates is so far lacking. We have studied the effect of the acute oral administration of PHE on photically-induced myoclonic responses and on plasma levels of large neutral amino acids in Papio papio from the Casamance region of Senegal. Four highly photosensitive adolescent baboons each received (in random order, at weekly intervals) PHE 0 (=alkali solution), 50,150 or 450 mg/kg orally. Myoclonic responses to a standardised 5 min period of photic stimulation prior to and at hourly intervals after drug administration were scored according to Meldrum et al, Electro. clin. Neurophys. 29: 333,1970. Similar decreases in seizure score over time were observed after each of the four treatments. Ranking of the decreases in seizure score showed that there was no significant difference in dosage effects (Friedman's test on ranks).

Peak plasma PHE concentrations of 60, 93, 561 and 2155 umoles/l were observed approximately 120 min after administration of PHE, 0,50, 150 and 450 mg/kg, respectively. In contrast plasma tyrosine levels did not exceed 78 umoles/l in any baboon throughout the 4 hour sampling period. Calculation of the plasma PHE: large neutral amino acid ratio (a predictor of the competitive uptake of phenylalanine into brain) revealed a dose-related 2-, 11 and 34-fold increase compared to control. Thus even at extremely high concentrations of plasma PHE, neither pro- nor anticonvulsant effects were observed in baboons.

133.7 DIABETES-INDUCED DECREASES IN BRAIN TYROSINE LEVELS RESULT IN DECREASED SYNTHESIS IN MESOPREFRONTAL CORTICAL DOPAMINE NEURONS. D.H. Karasic, C.W. Bradberry, A.Y. Deutch and R.H. Roth. Yale Univ. Sch. Med., New Haven, CT 06510.

Hydroxylation of the amino acid tyrosine (Tyr) is the rate-limiting step in the synthesis of dopamine (DA). The activity of Tyr hydroxylase is influenced by precursor availability in DA neurons that are activated pharmacologically or physiologically.

It is known that subsets of midbrain DA neurons exhibit different basal firing rates. A large amount of work in our laboratory has been directed towards characterization of the regulatory features of the mesoprefrontal cortical (mPFC) DA neurons. We have recently demonstrated that DA synthesis in these rapidly firing mPFC DA neurons is dependent on Tyr availability, while other mesotelencephalic DA neurons, such as the mesostriatal neurons, under normal conditions do not show such a dependence.

Brain Tyr levels are significantly reduced in the streptozotocin (STZ)-induced model of diabetes in the rat. Using this model, we have examined whether diabetes-induced changes in brain Tyr can result in alterations in in vivo Tyr hydroxylation in mesotelencephalic DA neurons. Diabetes was induced by administration of 65 mg/kg STZ i.v., and confirmed by blood glucose levels of 400 mg% at time of sacrifice three weeks later. As an index of in vivo Tyr hydroxylation, tissue levels of L-DOPA 30 min. following NSD-1015 treatment (100 mg/kg i.p.) were measured in the prefrontal cortex and striatum, as well as in the DA cell body regions of the ventral tegmental area (VTA) and substantia nigra (SN). Cortical and striatal Tyr levels were also determined in the same animals.

A significant decrease in L-DOPA accumulation in the prefrontal cortex but not in the striatum of diabetic animals was observed. In both regions, in vivo Tyr hydroxylation correlated with the levels of endogenous Tyr. A corresponding significant decrease in L-DOPA accumulation was seen in the VTA but not in the SN. This finding is consistant with the fact that projections to the prefrontal cortex arise primarily from the VTA while the SN projects mainly to the striatum. These data suggest that changes in brain Tyr availability may result in significant alterations in DA synthesis in mPFC DA neurons, but not in nigrostriatal DA neurons. Our results are consistant with previous characterizations of metabolic differences between various midbrain DA neuronal populations. The susceptibility of mPFC DA neurons to diabetes-induced alterations in cortical Tyr is of special interest due to the possible role of this subset of DA neurons in cognitive function, and the knowledge that some cognitive deficits may occur in patients with uncontrolled or long-lasting diabetes.

133.8 CEREBRAL INFARCTION AND CSF MONOAMINE METABOLITES IN THE RAT. R.M. Parikh*, A. Justice, T.H. Moran, J.A. Bowersox*, R.G. Robinson. Dept. of Psychiatry, Johns Hopkins Univ. Baltimore, MD 21205.

As an extension of our investigations in a rat model of stroke, we have studied the effects of unilateral middle cerebral artery (MCA) ligation on cerebrospinal fluid (CSF) monoamine metabolites at different intervals over a 40 day post-operative period.

Male Sprague-Dawley rats were divided into five groups: an unoperated control group (n=9), a right craniotomy group (n=5), a left craniotomy group (n=4), a right MCA ligation group (n=10) and a left MCA ligation group (N=10). CSF (100 ul) was collected percutaneously from the cerebello-medullary cistern on the day of surgery just prior to the operative procedure and at days 5, 20 and 40 following the surgical procedure. The measurements of CSF catecholamine metabolites - MHPG, 5-HIAA and HVA were carried out using a high pressure liquid chromatography (HPLC) assay. At the end of the experiment,brain chemistry measures were obtained using an HPLC assay for NE, DA, 5HT and 5-HIAA in 7 brain regions.

There was significant depletion in CSF MHPG levels in the right lesion group at days 5 ($p<.05$), 20 ($p<.01$) and 40 ($p<.05$) post-operative, when compared with the control group. No such depletion was observed in the left lesion animals. Similarly, there was reduction in CSF 5-HIAA levels at days 5 ($p<.01$) & 20 ($p<.01$) in the right lesion group compared with the left lesion group. There was a significant correlation between CSF 5-HIAA levels at day 40 and brain concentrations of 5HT in the frontal cortex on both the left ($r=.42$, $p<.05$) and right sides ($r=.34$, $p<.05$) across all 38 animals.

This study has demonstrated a time-dependent differential effect of unilateral ischemic stroke on CSF neurochemistry in the rat dependent on the cerebral hemisphere involved. It has also demonstrated a significant relationship between CSF neurochemistry and brain transmitter concentrations. It is hoped that by establishing relationships between CSF metabolite and brain transmitter concentrations in the rat, we will be able to make inferences about the relationship between these measures in human stroke.

133.9 NOREPINEPHRINE RECEPTOR AGONISTS AND ANTAGONISTS INFLUENCE RATE AND MAINTENANCE OF RECOVERY OF FUNCTION AFTER SENSORIMOTOR CORTEX CONTUSION IN RAT. M.S. Weaver*, L.J. Farmer* and D.M. Feeney. Depts. of Psychol. and Physiol., Albuquerque, NM 87131.

A single dose of amphetamine, combined with task relevant experience, produces an enduring acceleration of recovery of locomotor ability after unilateral sensorimotor cortex ablation. Norepinephrine (NE) has been implicated in mediation and maintenance of this effect (CRC Critical Reviews in Neurobiology, 1987, 3: 135-197). We examined effects of NE receptor agonists and antagonists on beam-walking ability after cortical contusion (Br. Res., 1981, 211: 67-77). Rats were given a single drug or saline injection (i.p.) 24h after a 400g/cm focal contusion of the right sensorimotor cortex. Beam-walking tests were conducted 1, 3, 6 and 24 hours postinjection continuing every other day for 15 days. Prazosin (4mg/kg) retarded recovery and a trend toward accelerated recovery was observed for yohimbine (10 mg/kg; p=.13). Propranolol (10 mg/kg) and methoxamine (1, 4 or 8 mg/kg) showed no effects. The lack of an effect of methoxamine may be due to its short half-life. These results indicate a role for NE in recovery after cortical contusion but do not clarify the receptor type mediating this effect. After recovery from this cortical injury, continued NE function may be important for maintaining locomotor ability. Therefore, fully recovered sham or contused rats were injected 30d post injury with either propranolol (10 mg/kg), clonidine (.4 mg/kg), prazosin (4 mg/kg) or phenoxybenzamine (PBZ; 10 mg/kg). Beam-walking tests were conducted 1, 3, 6, 24 and 48 hours postdrug. Clonidine, prazosin and PBZ, but not propranolol, reinstated deficits.

Comparing these results to previous data using ablation of the same cortical area, the contused brain appears less responsive to drugs that promote recovery and more responsive to drugs which slow recovery. This could be due to more severe remote effects of the impact injury because of greater edema and/or shock forces. However, reinstatement of symptoms by drugs affecting alpha- but not beta-NE receptors is identical in the two models of hemiplegia.

133.10 PROSTAGLANDINS AND NOREPINEPHRINE IN PERIPHERAL NERVE OF EXPERIMENTAL CHRONIC PROGRESSIVE DIABETIC NEUROPATHY. Kim K. Ward*, James D. Schmelzer*, Phillip A. Low Department of Neurology, Mayo Foundation, Rochester, MN 55905

Electrophysiologic studies on motor, sensory and sympathetic nerves of chronic progressive experimental streptozotocin diabetes of 4 months duration were done. Significant slowing of motor, sensory and sympathetic nerve conduction velocities was found associated with a reduction in amplitudes of caudal nerve and sciatic-tibial muscle compound action potentials.

The norepinephrine (NE) levels of superior cervical ganglion and sciatic nerve were significantly reduced in diabetic animals. Sciatic nerve sheath in vitro biosynthesis of 6-keto $PGF_{1\alpha}$ was significantly reduced in diabetic nerves. All studies were done on groups of at least 7 rats.

Table

Blood Glucose, Nerve Norepinephrine and Prostaglandins in Chronic Diabetes

Group	Control	Diabetes
Blood glucose (mg/dl)	120±6[d]	500±27[c]
HbA_{1c} (%)	5.36±0.1	17.8±0.5[c]
6-keto $PGF_{1\alpha}$ (pg/mg)	856±47	521±54[c]
TxB_2 (pg/mg)	640±130	319±50[a]
NE (ng/mg/wt) Cx Sym Gangl	35.6±2.1	24.6±1.5[c]
Sciatic	0.63±0.05	0.48±0.03[b]
Tibial	0.86±0.07	0.74±0.06[d]

a, $p<0.05$; b, $p<0.01$; c, $p<0.001$; d, SEM

We conclude that chronic diabetes results in a neuropathy involving motor, sensory and sympathetic nerve fibers. The findings of altered nerve NE and prostacyclin metabolism suggest that vasoregulation may be perturbed in chronic progressive experimental diabetic neuropathy. (Supported in part by grants from NINCDS (NS-14304; NS-22352) MDA, Mayo and Mogg funds.

133.11 DECREASED SPEED OF AN INTERNAL CLOCK IN PARKINSON'S DISEASE (PD). S. Corkin, A. Gruber, G. Desclos, and J.H. Growdon. Department of Brain and Cognitive Sciences and Clinical Research Center, MIT, Cambridge, MA 01239, and Department of Neurology, Massachusetts General Hospital, Boston, MA 02114.

Maricq and Church (1983) reported that rats given methamphetamine (which enhances release of dopamine, DA, and norepinephrine, NE) showed acceleration of an internal clock, whereas rats given haloperidol (which blocks DA release) showed deceleration of the clock. We therefore predicted that patients with PD, who have a DA deficiency, would show a decrease in clock speed and that this deficit may constitute an objective measure of bradyphrenia (slowness of thought). Sixteen patients with idiopathic PD who were not demented and 13 age-matched, healthy control subjects (HCS) were trained on a time estimation task modeled after that used by Maricq and Church. All PD patients were receiving anti-parkinson medication. During training subjects viewed a series of squares on a computer screen that remained in view for either 1.0 sec. or 4.0 sec. After each square had disappeared, subjects reported whether the square had stayed on the screen for the shorter time or for the longer time. Then the correct response appeared on the screen. In the test phase, squares were presented for 1.0, 1.3, 1.6, 2.0, 2.5, 3.2, and 4.0 sec. A tone preceded each trial as a signal to attend to the screen. Subjects were told to say "short" if the stimulus duration seemed short based upon their training or "long" if the stimulus duration seemed long. The correct response was given for the 1.0 and 4.0 sec. durations but not for the others. The 7 stimulus durations were presented 10 times each for a total of 70 trials. In the results for normal subjects, the mean point of indifference (PI, the duration to which subjects responded "short" and "long" equally often) was at the geometric mean of the two extreme durations, i.e. 2.0 sec. In contrast, the mean PI for the PD group fell at 2.5 sec. The control and PD groups differed significantly at three stimulus durations in mean percentage of "long" responses (1.6 sec. -- HCS = 22.3%, PD = 3.8%; 2.0 sec. -- HCS = 52.3%, PD = 31.8%; 2.5 sec. -- HCS = 82.3%, PD = 56.3%). These results suggest that timing was altered in the PD group such that stimulus durations were consistently underestimated. Our findings support Maricq and Church's view that decreases in levels of DA cause decreases in internal clock speed.

133.12 NEUROTRANSMITTER METABOLITE LEVELS IN EQUINE AND CANINE CSF: COMPARISON OF CISTERNAL AND LUMBAR CSF. D.M. VAUGHN, G.B. SMYTH*, E. COLEMAN*, B. WHITMER*, S. SIMPSON*, AND C. SATJAWATCHARAPHONG*. Scott-Ritchey Res. Prog., Small and Large Animal Clinics, Coll. of Vet. Med., Auburn Univ., Auburn, Al 36849.

Cerebrospinal fluid (CSF) is often collected from the lumbar region in clinical medicine. Biochemical and cytological evaluation of lumbar CSF is used to help evaluate neuronal status in disease or after drug administration. In clinical veterinary medicine, CSF is primarily obtained from the cisterna magna in dogs, and from the lumbo-sacral region in horses. The present studies were undertaken to determine if there was a significant difference in the concentration of Dopac, HVA, and 5-HIAA in cisternal versus lumbar CSF of dogs and horses.

CSF samples were collected from adult mixed breed dogs and horses within 10 min of induction of general anesthesia. With the dogs in sternal and the horses in lateral recumbancy, separate spinal needles were inserted into the lumbar subarachnoid space and into the cisterna magna. Canine CSF was removed first from the the lumbar then the cisternal region. Equine CSF was removed simultaneously from both regions. CSF was deproteinized by centrifugation over deproteinizing filters at 5°C. Neurotransmitter metabolites were evaluated by HPLC and electrochemical detection.

Equine and canine cisternal CSF contain measurable amounts of Dopac, HVA, and 5-HIAA. Lumbar CSF from dogs contains significantly lower amounts of HVA (cisternal= 108.0 ± 13.7 ng/ml vs. lumbar= 8.8 ± 0.7 ng/ml). In addition, canine lumbar CSF contained 24% less 5-HIAA (cisternal= 46.3 ± 8.1 ng/ml vs. lumbar= 36.6 ± 4.0 ng/ml). Opposite alterations in protein content occured within canine CSF. Lumbar CSF contained a significantly higher protein content (27.2 ± 2.3 mg/dl) than cisternal CSF (16.1 ± 1.8 mg/dl).

Equine cisternal CSF contained an average of 2.4 ± 0.2 ng/ml Dopac, 43.7 ± 3.4 ng/ml HVA, and 48.8 ± 3.7 ng/ml 5-HIAA. Dopac and HVA were not present in equine lumbar CSF. A significant 67.6% decline in 5-HIAA content (15.8 ± 3.7 ng/ml) was present in equine lumbar CSF. These data indicate cisternal CSF is a better indicator of brain neurotransmitter output and that opposite concentration gradients may exist between protein content and neurotransmitter metabolites in CSF.

133.13 GENETIC DIFFERENCES IN BRAIN CATECHOLAMINE LEVELS IN THREE TYPES OF DOMESTIC DOGS AND THEIR F_1 HYBRIDS. C. Arons*, D. Corry*, B.E. Ginsburg*, D. Morse*, and W.J. Shoemaker (SPON: K. Yurko). Dept. of Psychiatry, Univ. of Connecticut Health Center, Farmington, CT 06032

Genetic differences in CNS catecholamine systems have been reported for various strains of inbred mice and other laboratory species. In several instances these differences have been correlated with behavioral differences among the strains. In this study, we extend the brain-behavior correlation to another species, the dog. We have assayed catecholamine levels in 3 types of purebred dogs which have distinct behavioral characteristics and in their F_1 hybrids. The purebred types are: 1) Shar Planinetz, a livestock guarding dog that is non-aggressive toward livestock; 2) Border Collies, a livestock herding dog that displays components of predatory behavior but does not attack livestock; and 3) Siberian Huskies, a northern type dog that shows full predatory behavior towards livestock and other prey. We have used HPLC with electrochemical detection to analyze regional brain extracts for dopamine (DA), norepinephrine (NE), epinephrine (EPI) and serotonin. The results show little variation in EPI, it is found in low levels in all brain regions in all dogs. In contrast, some trends are apparent among the purebreds when key regions of the DA and NE systems are considered. In all major cell body regions of DA-containing neurons, Shars possessed the lowest levels of this transmitter compared to Border Collies and Huskies: substantia nigra, ventral tegmental area, and hypothalamus. In the Shars the NE level in the nucleus locus ceruleus is also the lowest among the 3 purebreds. Shars display low transmitter levels in the terminal regions of these amine systems as well: septal nuclei, hypothalamic regions, hippocampus and amygdala for NE; caudate nucleus, septum and locus ceruleus for DA. However, in two prominent DA regions, the globus pallidus and the nucleus accumbens, transmitter levels are quite high in the Shars. Border Collies show the opposite pattern; high transmitter levels in cell body regions and most terminal regions for both DA and NE. The Huskies show no clear trend in amine levels but rather show a mixture of both high and low levels in both cell body and terminal areas. Among the hydrids, one apparent trend was that the amine levels of the Border Collie x Shar Planinetz hybrids was intermediate between the two parental breeds. While we can suggest that some of the trends in transmitter levels might be correlated with general behavioral characteristics such as the low dopamine levels in Shars and their less active nature compared to Border Collies and Huskies, we cannot, at this time, draw any correlations with specific behavioral differences.

133.14 EFFECTS OF INHIBITION OF MAO SUBTYPES ON PLASMA AND STRIATAL LEVELS OF CATECHOLS AND HOMOVANILLIC ACID. D. Hovevey-Sion,* I.J. Kopin, R.W. Stull*, D.S. Goldstein*, NINCDS and NHLBI, National Institutes of Health, MD.

Deamination by monoamine oxidase (MAO) is a major route of metabolism of endogenous catecholamines. Two types of MAO -- MAO-A and MAO-B -- have been described. In the present study we measured plasma and corpus striatum levels of catechols and homovanillic acid (HVA) during inhibition of MAO-A (clorgyline 2 mg/kg, i.p.), MAO-B (deprenyl 1 mg/kg, i.p.) or both MAO-A and MAO-B (nialamide 75 mg/kg), and peripheral neuronal MAO (debrisoquin 40 mg/kg, i.p.) in pentobarbital-anesthetized rats. Levels of catechols in vena cava plasma and in the left corpus striatum were assayed using liquid chromatography with electrochemical detection. Samples were obtained at 1.5 hrs after drug treatment, except after debrisoquin, where sampling was at 4 hrs. Plasma norepinephrine (NE) was unaffected by all the treatments. Plasma dihydroxyphenylglycol (DHPG) was reduced significantly by clorgyline (28.1% of saline control), nialamide (32.4%), and debrisoquin (33.4%) but not by deprenyl (114.6%). Decreases in plasma DHPG were greater than decreases in HVA. In striatum, clorgyline and nialamide increased levels of dopamine (DA, 174.8 and 193.8% of control) and decreased levels of dihydroxyphenylacetic acid (DOPAC, 34.6 and 29.5%) and HVA (25.1 and 36.6%), whereas deprenyl and debrisoquin had no effects. The results indicate that plasma DHPG mainly reflects MAO-A activity and that striatal DA is also mainly metabolized by MAO-A. Thus rat plasma HVA and DHPG can be influenced in parallel by inhibition of MAO-A and not MAO-B.

133.15 Genetic Regulation of Catecholamine Enzyme Synthesis in Fischer-344 and Buffalo Rat Adrenals. A. C. Towle, H. Paivarinta, M. J. Evinger and T. H. Joh. Dept. of Neurol., Lab of Mol. Neurobio., Cornell Univ. Med. Coll., 1300 York Ave., N.Y., NY 10021.

Previous investigators have shown that Fischer 344 strain rats have much higher levels of blood epinephrine and adrenal phenylethanolamine n-methyl transferase (PNMT) than Buffalo strain rats. Recently, Evinger et al. (Mol. Brain Res. 1, 63-73, 1986) demonstrated that Fischer adrenals contain 5-fold more PNMT protein and 2-4 fold more PNMT mRNA than Buffalo rat adrenals.

In this study we sought to determine if the genetic differences between these two rat strains was due to a difference in (1) the amount of mRNA per cell, (2) the number of chromaffin cells, or (3) an interaction between mRNA content and cell number. To perform this investigation, rats were perfused with 4% paraformaldehyde and one adrenal was used for immunocytochemistry and the other was used for in situ hybridization. For immunocytochemistry, 25 micron sections through the entire adrenal were first incubated with PNMT antiserum and the immunostaining was shown using DAB. The sections were further incubated with TH antiserum and stained with aminoethylcarbazole. Thus, in the same section, the adrenergic cells were brown and the noradrenergic cells were red. Significantly, the total number of cells in the adrenal medulla appears to be the same for both rat strains. However, the number of cells containing PNMT immunoreactivity was greater in the Fischer than the Buffalo rat adrenals. Approximately 84% of the chromaffin cells contain PNMT in the Fischer rat compared to 60% in the Buffalo rat.

To investigate the possibility that the amount of PNMT mRNA per cell was lower in the Buffalo rat we performed PNMT and TH in situ hybridization. Densitometric quantification of the X-ray film and emulsion coated slides revealed that the number of cells containing PNMT mRNA was lower in the Buffalo than in the Fischer rat adrenal. Furthermore the amount of PNMT mRNA per cell was lower in the Buffalo adrenal. TH mRNA did not appear to be different in the adrenals from the two rat strains.

Thus, the decreased PNMT enzyme activity in the Buffalo rat adrenal is due to a decrease in the number of cell expressing PNMT as well as a decrease in the amount of PNMT mRNA in those cells.

133.16 The Distribution and Dynamics of Epinephrine-Containing Neurons in the Rat Brain: Influence of Adrenocortical State. K.L. Johnson*, C.M. Anderson*, J.K. Nishita, J.C. Ritchie, C.D. Kilts (SPON: R.D. Weiner) Duke Univ. Med. Ctr., Durham, NC 27710.

Epinephrine, a quantitatively minor catecholamine in the CNS, is localized in a variety of hypothalamic, telencephalic, and brainstem nuclei. The topographic distribution of epinephrine(EPI)-containing cells suggests the involvement of these neurons in the regulation of physiological processes such as blood pressure and respiration, neuroendocrine secretions, food and water intake, and thermoregulation. A focal innervation of the parvocellular division of the paraventricular nucleus (PVN) of the hypothalamus by EPI-containing neurons suggests a role in the regulation of the hypothalamic-pituitary-adrenal (HPA) axis. Immunocytochemical studies indicate that EPI-containing and corticotropin releasing factor(CRF)-containing neurons make discrete synaptic connections in the PVN (Liposits et al., Histochem. 84:201, 1986) Pharmacological studies using inhibitors of phenylethanolamine-N-methyltransferase (PNMT) have demonstrated an increase in CRF immunoreactivity in the PVN (Mezey et al., Nature 310:140, 1984) and dose-related increases in circulating corticosterone (Roth et al., Life Sci. 28:2389, 1981), suggesting an inhibitory role of central EPI upon the HPA axis. The goals of the present study were to further investigate the distribution of EPI at the level of discrete nuclei and to biochemically estimate the rate of activity of these populations under normal conditions and under defined alterations of the activity of the HPA axis. The EPI content of micropunch dissected brain nuclei was determined by on-line trace enrichment HPLC with electrochemical detection and the activity of EPI neurons was estimated from the rate of depletion with time following administration of a PNMT inhibitor (LY134046). Of the nuclei examined, the following were found to have detectable and significant levels of EPI: PVN> tuberal periventricular nucleus> dorsomedial nucleus> pretuberal periventricular nucleus> C1> lateral hypothalamic nucleus> ventral bed nucleus> arcuate nucleus> C2. The arcuate followed by PVN demonstrated the greatest rates of estimated neuronal activity while cell body rich brainstem nuclei exhibited a significantly slower turnover rate. The collective findings of this study indicate that populations of EPI neurons innervating discrete brain nuclei differ in the estimated density of innervation and the estimated rate of tonic activity. The effects of the administration of glucocorticoids, bilateral surgical adrenalectomy and adrenalectomy plus glucocorticoid supplementation on the biochemically estimated activity of populations of EPI neurons innervating the PVN and other nuclei will be discussed.

133.17 **PRODUCTION OF POLYCLONAL ANTISERA THAT RECOGNIZE NON-GLYCOSYLATED DOPAMINE β-HYDROXYLASE.** *O. Hwang, A. Towle, and T. H. Joh.* Laboratory of Molecular Neurobiology, Cornell Univ. Med. College, New York, N.Y. 10021.

Dopamine β-Hydroxylase (DBH) is the only enzyme in the catecholamine biosynthetic pathway that has not been characterized by molecular biological cloning. This is partially due to the fact that polyclonal antibodies to native glycosylated DBH have not been effective in recognizing the non-glycosylated enzyme produced in bacterial expression systems. We sought to develop efficient tools for cloning DBH, specifically, to prepare antisera that recognize the non-glycosylated enzyme.

We have previously reported purification of DBH to homogeneity and the sequence of 15 amino acids from the N-terminus (Hwang et al. *Soc. Neurosci. Abst. 12*:602, 1986) To obtain internal peptide sequences purified DBH was digested with trypsin, several peptides were purified by HPLC, and their sequence determined. Based on these sequences, peptides were synthesized and conjugated to Limulus hemocyanin with glutaraldehyde. Antisera were raised in rabbits by immunization at monthly intervals with 1mg of conjugate in complete Freunds adjuvant. Specificity of each antisera was tested by immunobloting, Western blot analysis, and immunocytochemistry. To obtain deglycosylated DBH, 40μg of enzyme was incubated with 0.4 units of glycopeptidase F in the presence of 20 mM potassium phosphate, pH 7 and 10 mM EDTA in a final volume of 50μl; reactions proceeded for 1 - 24 hours. For immunocytochemistry, rats were perfused with 4% paraformaldehyde and 20 micron vibratome sections were incubated with antisera diluted 1:500.

As determined by immunoblot analysis, each of the peptide antisera recognized their respective peptide conjugate both before and after preabsorption with carrier protein, hemocyanin. Surprisingly, highly purified glycosylated DBH was not detected by any of the antisera tested. Thus antisera recognized the synthetic peptides but not the glycosylated enzyme. In order to determine whether these antisera recognize the deglycosylated enzyme, DBH was treated with glycopeptidase F. This treatment resulted in complete deglycosylation as determined by periodic acid Schiff reaction and a decrease in MW from 75, 72, and 69 kD to 66 kD as determined by SDS-PAGE with silver stain detection. Similiar results were reported by Wong and Ciaranello (Soc. Neurosci. Abst. 12:1152, 1986) using a different endoglycosidase. Western blot analysis demonstrates that the anti-peptide antisera recognize the intact, deglycosylated enzyme but not un-treated DBH. Furthermore, none of the peptide antisera stained cell bodies in the locus coeruleous although some nerve terminal were stained indicating that *in vivo* almost all the enzyme is glycosylated. Native DBH antisera, in contrast,stained the cells and nerve teriminals very strongly.

Thus we have produced antisera that are efficient recognizing the non- glycosylated form of DBH, the form that would be present in bacterial expression systems. We are presently using these antisera to identify potential DBH clones from a cDNA expression library.

133.18 ANALYSIS AND ISOLATION OF DOPAMINERGIC NERVE TERMINALS BY FLUORESCENCE-ACTIVATED CELL SORTING. M.E. Wolf and G. Kapatos. Laboratory of Neurochemistry, Center for Cell Biology, Sinai Research Institute, Detroit, MI 48235.

The availability of pure preparations of dopamine (DA) nerve terminals would enable many basic questions about dopaminergic function to be answered. We have developed methods for the analysis and isolation of striatal nerve terminals (synaptosomes) using fluorescence-activated cell sorting techniques (FACS). Synaptosomes were distinguished from free mitochondria and other types of particles based on the following criteria: 1) lysis eliminated the signal attributed to synaptosomes, indicating an osmotically-sensitive compartment 2) synaptosomes, but not free mitochondria, exhibited increased fluorescence after incubation with a voltage-sensitive fluorescent dye, indicating that they possess a membrane potential; furthermore, the fluorescence signal decreased in response to incubation with the depolarizing stimuli 75uM veratridine or 55mM potassium chloride 3) synaptosomes were sorted onto membrane filters and subsequently shown by Western blot techniques to contain TH, a protein previously shown to be localized to DA terminals. Subpopulations of intact synaptosomes were separated by the cell sorter based on differential recognition by fluorescein-conjugated plant lectins and found to contain different amounts of TH. However, no surface marker which selectively identifies DA nerve terminals is presently available. Thus, sorting of dopaminergic synaptosomes was based on immunofluorescent labeling of an intracellular antigen specific to DA terminals, TH, after fixation of synaptosomes to allow penetration by antibodies. A highly fluorescent subpopulation of synaptosomes (9-12%) was detected after sequential incubation with a monoclonal antibody to TH and a fluorescein-conjugated second antibody. Specific labelling was eliminated if synaptosomes were prepared from 6-OHDA lesioned rats. TH-positive nerve terminals were isolated by FACS and proteins separated by SDS-PAGE. Sorted terminals were found to contain 8 times as much TH as an equal number of control terminals. These studies verify the dopaminergic identity of the sorted synaptosomes. This approach will enable DA terminals to be analyzed for the presence of co-transmitters, components of signal transduction systems, and unique protein constituents.

CATECHOLAMINES II

134.1 AUGMENTATION OF AMPHETAMINE-STIMULATED [^{3}H]-DOPAMINE RELEASE AFTER ONE INJECTION OF COCAINE: DO OTHER DOPAMINE UPTAKE BLOCKERS, DOPAMINE RECEPTOR AGONISTS AND LOCAL ANESTHETICS MIMIC THIS EFFECT? J. Peris and N. R. Zahniser. Dept. Pharmacology, Univ. Colorado Hlth. Sci. Ctr., Denver, CO 80262.

We have reported that a single injection of cocaine augments amphetamine-induced release of tritium from rat striatal slices preloaded with [^{3}H]-dopamine (DA) without affecting electrically-stimulated release (Peris, J. et al. Pharmacol. Biochem. Behav. in press, 1987). This augmentation appears within 24 hrs and persists for 2 weeks even though cocaine is eliminated from brain 2 hrs after injection. It has been suggested that a change in dopaminergic synaptic transmission coincides with this augmentation and could explain sensitization to the behavioral effects of cocaine which appear over the same time course (Lin-Chu, G. et al. Pharmacol. Biochem. Behav. 22:901, 1985). Cocaine has a number of effects on the CNS, including blockade of DA uptake, indirect DA receptor activation and local anesthesia. Therefore it was of interest to determine whether drugs sharing one or more of these actions with cocaine would also augment amphetamine-stimulated [^{3}H]-DA release. Mazindol, a DA uptake blocker and indirect DA receptor agonist (10 mg/kg, i.p.), or lidocaine, a local anesthetic (20 mg/kg, i.p.), was administered to rats 24 hrs before sacrifice. [^{3}H]-DA release from striatal slices of these animals was compared with that from animals which had received either an injection of cocaine (10 mg/kg, i.p.) or an equivolume injection of saline. Release was defined as tritium overflow which is the net result of both DA release and reuptake. While cocaine treatment increased tritium release evoked by 2, 6 and 20 μM D-amphetamine compared to the saline control, mazindol treatment resulted in lower levels of amphetamine-induced release at all doses of amphetamine tested. In addition, whereas cocaine did not affect electrically-stimulated [^{3}H]-DA release, mazindol significantly increased tritium evoked in this manner. These data indicate that mazindol, unlike cocaine, is still present in brain 24 hrs after i.p. injection in sufficient concentrations to block DA uptake. Therefore in subsequent studies, mazindol will be injected 1 week before sacrifice to eliminate drug from brain. If mazindol produces the same long-term augmentation as cocaine, it should be apparent 1 week after injection, once mazindol has been eliminated from brain. Lidocaine treatment 24 hrs previous to sacrifice also caused augmentation of tritium release but, unlike cocaine, only in response to 20 μM amphetamine. It is also possible that lidocaine is present in brain 24 hrs after injection, and the effects of this drug will also be studied 1 week after injection. Similar experiments will be carried out using a selective DA uptake blocker (GBR 13069), another local anesthetic (procaine), and two direct DA receptor agonists (levodopa and apomorphine). From these studies, the mechanism for the augmentation in release and possibly the acute sensitization to the behavioral effects of cocaine may be identified. (Supported by USPHS grants MH 09387, DA 04216 and NS 09199)

134.2 SYSTEMIC OR CEREBRAL ADMINISTRATION OF p-HYDROXYAMPHETAMINE REDUCES DOPAMINE AND SEROTONIN CONCENTRATIONS IN THE RAT CNS. L.A. Matsuda, G.R. Hanson and J.W. Gibb. (SPON: J.A. Madsen) Dept. Pharmacol. & Toxicol., University of Utah, Salt Lake City, UT 84112

In rats treated with amphetamine, the major metabolites formed are p-hydroxyamphetamine (pOHA) and p-hydroxynorephedrine (pOHNor). The ability of these metabolites to deplete norepinephrine stores in both the brain and the periphery has been well characterized. In comparison, however, little is known about the actions of these compounds on central dopaminergic or serotonergic systems. Local administration of pOHA or pOHNor decreased striatal dopamine and its major metabolites, DOPAC and HVA, in a dose-dependent manner. We previously reported that local administration of methamphetamine (100 μg), into the striatum, had no effect on dopaminergic or serotonergic systems (Matsuda et al., Fed. Proc.: 399, 1987). However, as little as 1.0 μg (6.6 nmoles) of pOHA produced significant changes in striatal dopamine (68% of control) and its metabolites 3 hrs after treatment. This effect was reversible; maximal dopamine depletion (43% of control) occurred between 3 and 6 hrs after an intrastriatal injection of pOHA (5 μg) and returned to control levels within 48 hrs after treatment. In addition to their effects on dopamine, local injections of these para-hydroxylated compounds also reduced serotonin concentrations in the striatum; although, compared to dopamine, serotonin stores were less sensitive to the depleting actions of both pOHA and pOHNor. The pOHA-induced effects on striatal dopamine and its metabolites were also observed in animals treated with pOHA systemically. Three hrs after pOHA (15 or 30 mg/kg, s.c.) striatal dopamine decreased to 66% and 53% of control, respectively. This decrease in striatal dopamine was attenuated significantly in rats pretreated with the dopaminergic uptake inhibitor, amfonelic acid (1 mg/kg). Following systemic administration, however, serotonin concentrations were not altered in the striatum or cerebral cortex but were reduced in the hypothalamus and hippocampus. It appears, therefore, that in various regions of the brain, serotonergic neurons display a differential sensitivity to the actions of pOHA. Although the catecholaminergic effects of these para-hydroxylated metabolites of amphetamine have been the focus of numerous studies, a pOHA-induced behavioral response in mice, has recently been demonstrated to be a serotonin-mediated effect (Tadano et al, 1986). Thus, this observation, along with the present results, indicate that additional studies are necessary to appreciate fully the CNS effects of these metabolites of amphetamine. (Supported by USPHA grants DA 00869, DA 04222 and American Foundation for Pharmaceutical Education).

134.3 DOPAMINE (DA) AGONIST ACTIONS ON IDENTIFIED A9 DA NEURONS - ANESTHETIC ACTIONS AND D1/D2 INTERACTIONS. M.D. Kelland, A.S. Freeman and L.A. Chiodo, Lab. of Neurophysiology, Center for Cell Biology, Sinai Research Institute, Detroit, MI 48235.

We have utilized electrophysiological techniques in order to address two issues pertaining to DA agonist actions on the activity of rat A9 DA-containing cells identified by antidromic activation as nigrostriatal DA neurons. First, does the anesthetic condition of the subject alter the actions of DA agonists, as has been reported for DA antagonists? Second, might the selective D1 agonist SKF 38393 exert subtle actions on the activity of A9 DA neurons, either directly or on D2-mediated inhibition of these cells, that have previously gone undetected.

Standard extracellular single-unit recording techniques were used to monitor the activity of A9 DA neurons in vivo. Dose-response curves for the following DA agonists were compared in both the anesthetized and the locally anesthetized, paralyzed preparations: LY171555 (D2 selective), apomorphine (mixed D1/D2) and d-amphetamine (indirect agonist). For each compound, a significantly higher dose was required to achieve inhibition of DA cell discharge in the paralyzed animals (overall basal firing rates of the cells in each condition were not significantly different). Mean ED50 comparisons (anesthetized; paralyzed) were as follows: LY171555, 6.4 $\pm$ 2.4; 24.0 $\pm$ 8.3 ug/kg; apomorphine, 6.5 $\pm$ 4.8; 28.0 $\pm$ 6.3 ug/kg; d-amphetamine, 1.0 $\pm$ 2.8; 1.8 $\pm$ 1.7 mg/kg.

The ability of LY171555 to inhibit A9 DA neuronal firing rate was dependent upon the baseline firing rate of the neuron studied (i.e. faster cells required higher doses in order to achieve either 50% or complete inhibition). Pretreatment with SKF38393 (1.0 mg/kg i.v., 4 minutes) eliminated the rate-dependency of LY171555-induced inhibition of A9 DA neurons. Hemitransections of the forebrain prevented the SKF38393-induced effects, without eliminating the presence of slow or fast firing DA neurons. The selective D1 antagonist SCH23390 also blocked the SKF38393 effects.

The mechanisms underlying the results concerning anesthesia vs. paralysis are unclear at this time. It does appear, however, that anesthetic conditions are an important issue in DA agonist as well as DA antagonist research. The observations in the second set of experiments suggest that the direct-acting D1 agonist SKF38393 exerts a subtle modulatory effect on the responsiveness of A9 DA cells to D2 stimulation via actions it has in the forebrain. Further studies are required to more fully characterize this action of SKF 38393. Moreover, rate-dependent sensitivity of DA neurons to DA agonists is not dependent upon intact long-loop feedback pathways from the striatum.

134.4 EFFECTS OF MIXED AND SELECTIVE DOPAMINE D-1 AND D-2 AGONISTS ON CAUDATE NEURON ACTIVITY. C.L. Christoffersen* and L.T. Meltzer (Spon: R.J. Anderson) Warner-Lambert/Parke-Davis Pharmaceutical Research, Ann Arbor, Michigan 48105.

Dopamine (DA) D-1 receptors are located on neurons intrinsic to the caudate nucleus (CN), while DA D-2 receptors are located on both intrinsic neurons and terminals of DA neurons which project to the CN (DA autoreceptors). Using extracellular single-unit recording techniques, we have evaluated the effects of mixed and selective DA D-1 and D-2 agonists on the firing activity of spontaneously active neurons in the CN of chloral hydrate anesthetized rats. Recordings were made from both type 1 (negative-positive action potentials) and type 2 (positive-negative action potentials) caudate neurons. In general, no differences were noted between the two neuronal types so the data were combined. Baseline firing rates ranged from 0.3-13.6 Hz with a mean +/- SEM of 2.8 +/- 0.2 Hz (n=65). Drugs were administered i.v. via a tail vein.

An initial bolus injection of apomorphine (APO; 100 ug/kg), a mixed D-1/D-2 agonist, induced increases (n=8) and decreases (n=7) in neuronal firing. Cumulative doses (up to 800 ug/kg) did not produce inhibitions in neurons that were excited by APO. Both the excitatory and inhibitory effects were reversed by haloperidol.

An initial bolus injection of LY 171555 (quinpirole hydrochloride; 500 ug/kg), a selective DA D-2 agonist, induced increases (n=6), decreases (n=2), and no change (n=2) in neuronal firing. Similar to APO, increasing cumulative doses, up to 2 mg/kg, only increased the magnitude of the response, and did not change excitations into inhibitions.

SKF 38393, a selective D-1 agonist, had essentially no effect on CN neuron activity (cumulative dose response from 4-32 mg/kg, n=5).

The doses of APO and LY 171555 tested are much higher than the doses required to completely inhibit DA neuron activity; thus the excitations may be due to a direct effect on CN neurons and not due to disinhibition produced by DA autoreceptor stimulation. It appears that DA D-2 receptors are important for modulating CN neuron activity. The role of DA D-1 receptors is at present unclear.

134.5 EFFECTS OF ACUTE THIORIDAZINE, METOCLOPRAMIDE AND SCH 23390 ON THE BASAL ACTIVITY OF A9 AND A10 DOPAMINE NEURONS. Timothy H. Hand, Richard J. Kasser and Rex Y. Wang, Department of Psychiatry and Behavioral Science, SUNY, Stony Brook, NY 11794.

In a recent paper (Hand et al., Brain Res., in press), we reported that the acute administration of clozapine (considered an "atypical" antipsychotic drug because of its low potential for producing extrapyramidal side effects) elevated the basal firing rate of A10 but not A9 dopamine (DA) cells. By contrast, the neuroleptic haloperidol increased the firing rate of both A9 and A10 DA cells. These acute studies were consistent with previous chronic studies (White and Wang, Science, 1983), which had shown that while clozapine inactivates A10 but not A9 DA cells, haloperidol inactivates DA units of both subpopulations. The agreement between the acute and chronic effects of these two DA antagonists on DA cell subpopulations suggested the potential usefulness of the acute effects of these drugs in predicting their chronic effects. It was also proposed that the differing pharmacological and clinical properties of these two drugs might be related to their respective actions on DA cell subpopulations.

We therefore used this same acute procedure to test three other DA antagonists (thioridazine, TDZ; metoclopramide, MET; SCH 23390) with very different pharmacological and clinical properties, to determine whether there is a consistent relation between these properties and acute electrophysiological effects on DA cell subpopulations. TDZ, like clozapine, is considered an "atypical" antipsychotic drug. MET is a DA antagonist whose antipsychotic properties are weak except at very high doses. SCH 23390 is a selective D-1 receptor antagonist.

MET and TDZ both reversed the suppression of A9 and A10 DA cell activity by the DA agonist apomorphine (APO). SCH 23390 produced only a partial reversal of this suppression. When the antagonists were given alone (eg., with no APO pretreatment), TDZ increased the firing rate of 6/7 A10 cells (mean dose 0.6 mg/kg, i.v.) but only 1/9 A9 cells. On the other hand, MET activated 5/6 A9 cells (1.0 mg/kg) but only 3/7 A10 cells (0.8 mg/kg). SCH 23390 elevated the firing rate of 0/5 A9 cells and 1/5 A10 cells (up to 6.4 mg/kg). These data support the hypothesis that the "atypical" antipsychotic drugs act preferentially on the A10 DA system. They also support the position (White and Wang, JPET, 1984; Napier et al., JPET, 1986) that DA cell activity is not directly regulated by D-1 receptors. Taken together with the results from our previous acute (Hand et al., in press) and chronic (White and Wang, 1983) studies, it appears that the acute and chronic effects of a number of DA antagonists coincide very well, and that the chronic effects of these drugs may be predicted from their acute effects.

134.6 EFFECTS OF DOPAMINE D1 AND D2 RECEPTOR AGONISTS ON THE SLEEP-AWAKE CYCLE OF RATS. K.A. Serpa and L.T. Meltzer, Warner-Lambert/-Parke-Davis Pharmaceutical Research Division, Ann Arbor, MI 48105.

Apomorphine (APO), a mixed D1-D2 dopamine (DA) receptor agonist, has a biphasic effect on the behavior of rats. Low doses produce sedation, characterized by locomotor inhibition and a synchronized EEG, while high doses produce increased locomotion, stereotypies, and a desynchronized EEG. The sedative effect of APO has been postulated to be due to selective activation of DA D2 autoreceptors, while the hyperactivity and the stereotypies are attributed to postsynaptic DA D1 and D2 effects. To further characterize the pharmacology of these responses, we have examined the effects of various selective DA agonists and antagonists on the sleep-awake cycle of rats.

Rats implanted with cortical screw electrodes and temporalis muscle wire electrodes were connected via a mercury pool commutator to a polygraph for EEG and EMG recording. Testing was done during the rats' light phase and began immediately following transfer to the recording chamber. EEG records were scored visually for minutes of awake, slow-wave sleep (SWS) and REM sleep. Latencies to first occurrence of deep sleep (S2) and to REM were also measured.

APO decreased latency to S2 and increased total SWS at low doses and decreased SWS and produced stereotypies at high doses. (+)-3PPP, a D2 agonist, had a biphasic effect similar to that of APO. (-)-3PPP, a weak autoreceptor agonist with post-synaptic antagonist activity, increased SWS at all doses. LY 171555, a selective D2 agonist, reduced latency to S2 at all doses. Low doses of LY increased SWS in both the 1st and 2nd h post injection, while higher doses decreased SWS in the 2nd h. The selective D1 agonist SKF 38393 had no effect on latency to S2, and produced a slight decrease in SWS. Both the decrease in latency to S2 and the increase in SWS produced by low doses of APO were antagonized by (-)-sulpiride, a selective D2 antagonist. SCH 23390, a selective D1 antagonist, increased sleep and reduced latency to S2 when administered by itself, and blocked the decrease in SWS and the stereotypy induced by a high dose of APO.

These results confirm and extend the evidence that the sedative effects of DA agonists are mediated by the DA D2 autoreceptor, arousal results from postsynaptic D2 stimulation, and that production of stereotypies requires stimulation of both D1 and D2 receptors.

134.7 DOSE-DEPENDENT EFFECTS OF REPEATED APOMORPHINE TREATMENTS ON LOCOMOTOR ACTIVITY IN RATS. B.A. Mattingly, J.E. Gotsick*, and K. Salamanca*. Dept. of Psychology, Morehead State Univ., Morehead, KY 40351.

In two experiments, the effect of repeated injections of apomorphine on locomotor activity of rats was determined. In each experiment, different groups of rats were injected with either apomorphine (0.2, 1.0, or 5.0 mg/kg) or vehicle at either 24 or 72 hr intervals and tested for locomotor activity in photocell arenas. In Experiment 2, following 13 treatment sessions with various doses, all groups were first tested for activity following a 5.0 mg/kg dose of apomorphine and then given vehicle only prior to the final activity test session. Major findings were as follows: a) repeated injections of 1.0 and 5.0 mg/kg apomorphine produced a progressively greater increase in activity with each injection (i.e., sensitization); b) injections of 0.2 mg/kg of apomorphine produced a slight inhibition of activity which did not change with repeated injections; c) prior treatment with 0.2 mg/kg of apomorphine resulted in a significantly greater activity increase following a 5.0 mg/kg dose of apomorphine than did prior vehicle treatments; and d) chronic pretreatment of rats with apomorphine did not affect their activity level following a vehicle injections. These findings suggest that sensitization to apomorphine is a graded, rather than an all or none, phenomenon dependent on the dose of apomorphine repeatedly administered. In addition, these results are inconsistent with autoreceptor tolerance and conditioning explanations of dopamine agonist-induced sensitization effects.

134.8 DOPAMINE (DA) COMPLEXES WITH TYPICAL ANTIPSYCHOTIC DRUGS (AD) AND WEAKLY OR NOT AT ALL WITH THE ATYPICAL ANTISYCHOTIC DRUGS. J. O. Schenk and T. Patterson (SPON: C. Hughes). Dept. of Chemistry, Program in Biochemistry, Washington State Univ., Pullman, WA 99164-4630.

Acute treatment with AD's increases DA cell firing rates, the number of spontaneously active DA cells, DA release, and DA synthesis and metabolism. Repeated administration of AD's results in a cessation of DA cell firing with decreased spontaneous and depolarization induced release while synthesis and metabolism return to near control levels.

During voltammetric (VA) assessments of the acute effects of AD's on release from striatal tissue in vivo and in vitro we observed negative alterations in the VA assessed [DA] in direct proportion to the [AD]. These effects were observed over 0.27-1.1 uM [AD], the tissue [AD] after a single ca. 0.2 umol/kg i.p. dose (Öhman et al. N.-S. Arch. Pharmacol. 299: 105 (1977)).

This phenomina was then examined chemically in either bicarbonate based buffers (pH 7.0 to 8.0) or in commercial ultra pure water. The following observations were made: 1. the half wave potential (E(1/2)) for the oxidation of DA shifted as a function of [AD] 2. E(1/2) shifts were not observed for methoxylated catechol derivatives 3. u.v.-visible absorption features of DA shift as a function of [AD] 4. no spectral shifts for DA after adding AD were observed at acid pH's and 5. the difference spectra of AD's in the presence of DA (less the spectra of DA) have features that are not found in the spectra of AD alone.

In the case of haloperidol (HAL) (where one can test the commercially available butyrophenone and piperidinyl moeities separately) we found that the basic piperidinyl moeity was essential for the interaction to occur. Phenothiazine AD's also appear to undergo complexation with DA. Based on the data above it is hypothesized that the interaction between AD's and DA is based on acid-base association. However, sulpiride, a basic but so called atypical AD did not complex with DA. The dissociation constants of the complexes that do form is in the range 10^{-4} to 10^{-3} mol/l, values smaller than expected for the simple acid base association between an acidic catechol moeity and the nitrogen based basic sites on AD molecules. The order of ability of individual AD's to complex with DA is Fluphenazine > HAL > SULP.

In conclusion, complex formation between AD's and DA should not appreciably alter DA concentrations in vivo (because of the low [AD] needed for physiological effects) but almost all typical AD molecules would be complexed with DA (due to its excess conc.). This phenomina could be important in the pharmacology of typical AD's and in some of the differences between typical and atypical AD's. Supported by MH-42759 and the State of WA.

134.9 ACTION OF COCAINE ON DOPAMINE (DA) AND SEROTONIN (5HT) CONTAINING NERUONS, M.J. Keegan*, J. Stahl*, and M.P. Galloway (SPON: H. Altman) Lafayette Clinic and Wayne State Univ., Detroit MI

The ability of cocaine (COC) or amphetamine (AMPH) to inhibit neuronal reuptake of monoamines is thought to be one mechanism that contributes to their psychotropic effects. In light of the autoregulatory mechanisms associated with monoaminergic neurons (i.e., modulation of transmitter release, synthesis, and impulse flow), inhibition of reuptake takes on added significance in these neurons. Our studies are focused on the effects of COC and AMPH on 5-HT or DA synthesis (measured after inhibition of decarboxylase with NSD-1015). Monoamine synthesis is utilized as a presynaptic function responsive to autoreceptor (AR) stimulation.

We have previously reported that acute COC dose-dependently suppresses DA and 5HT synthesis in vivo in medial prefrontal cortex (PFC), n. accumbens (NAC), and the striatum (STR). We have recently observed that administration of the D2 antagonist sulpiride (60 umol/kg, ip) blocked the inhibition of DA, but not 5HT, synthesis afforded by cocaine (60 umol/kg, ip) suggesting that the inhibitory effect is D2 receptor mediated. Pretreatment with reserpine (2.5 mg/kg,sc, 6 hrs) depletes striatal DA by 96% (5HT by 88%) but does not block the COC (60 umol/kg, ip) induced attenuation of 5HT or DA synthesis in the accumbens (37% and 22% decrease respectively) or other tissues studied. Inhibition of DA release by administration of GBL prevents the inhibitory effect of COC on striatal DA synthesis.

In striatal slices, DA, but not 5HT, synthesis is dose dependently inhibited by COC and GBR 13098 (EC50 = 0.5 & 1.0 uM, respectively). Curiously, COC (1 uM) induced inhibition of DA synthesis was not blocked by sulpiride, haloperidol, or SCH 23390 (1 uM). In addition, the potency of COC to inhibit DA synthesis was increased in slices from reserpine pre-treated animals.

Repeated administration of COC (10 mg/kg, ip, bid, x14 days) does not substantially alter basal levels of parent monoamines or metabolites in several DA projections, except a 23% increase in striatal DOPAC. However, a consistent observation after repeated COC is a modest increase (15-25%) in the basal rate of in vivo DA synthesis. In addition, in striatal slices obtained from animals treated subchronically with COC (10 mg/kg, ip, tid, x3 days), the ability of the DA agonist quinpirole to inhibit DA synthesis is diminished. Similar decrements in the efficacy of quinpirole in vitro were noted after subchronic treatment with AMPH in vivo.

Taken together, the findings support the hypothesis that COC is an indirect DA agonist capable of altering levels of synaptic DA. Moreover, repeated exposure to COC may lead to a decreased responsiveness of synthesis modulating DA ARs. Support (MPG) from DA-04120, MH-41227, and the State of Michigan-DMH.

134.10 STIMULATION OF MIDBRAIN DOPAMINE NEURONAL ACTIVITY BY RITANSERIN, A NOVEL 5-HT_2 ANTAGONIST. L. Ugedo*, J. Grenhoff* and T.H. Svensson. Dept. of Pharmacology, Karolinska Institutet, S-104 01 Stockholm, Sweden.

Anatomical, histochemical and biochemical studies have for long indicated the existence of a projection from the 5-hydroxytryptamine-(5-HT)-containing brainstem raphe nuclei to the substantia nigra (SN) and ventral tegmental area (VTA). However, functional evidence regarding this suggested serotonergic influence on the dopamine (DA) cell groups in the SN and the VTA is still sparse. In the last few years, several new drugs with a purported selectivity for the different 5-HT receptor subtypes have been synthesized. We have used one of these, ritanserin (R 55667, Janssen Pharmaceutica), a selective 5-HT_2 antagonist (see Mol. Pharmacol. 27:600, 1985), to study the serotonergic influence on the DA neurons in the SN and the VTA, which give rise to the nigrostriatal and mesolimbic DA systems, respectively.

Electrophysiological single cell recordings were made from identified DA neurons in SN and VTA in male rats anesthetized with chloral hydrate. Neuronal activity was characterized with respect not only to firing rate, but also to amount of firing in bursts and regularity of firing, respectively, by means of inter-spike interval analysis. One cell per rat (n=24) was recorded before and after intravenous administration of ritanserin (0.5-2.0 mg kg^{-1}).

In SN-DA neurons, 0.5 mg kg^{-1} of ritanserin produced increased burst firing and deregularization of firing pattern without altering the firing rate of the neurons, i.e. a modulatory effect. However, larger doses (1.0-2.0 mg kg^{-1}) increased the firing rate without changing the regularity of firing, i.e. an excitatory effect. In VTA-DA neurons, all doses (0.5-2.0 mg kg^{-1}) increased firing rate and burst firing without altering the regularity of firing. The inhibition (30-100 %) of firing produced by the DA agonist apomorphine after ritanserin indicates that the effects of ritanserin are not due to DA receptor antagonism.

Thus, the following interpretations of our results seem warranted:

1) Midbrain DA neuronal activity may be under tonic, inhibitory 5-HT-mediated control, executed by means of 5-HT_2 receptors.
2) In the SN, the 5-HT influence seems to include a modulatory component, controlling the regularity of firing, as judged by the effects of differential doses of the selective 5-HT_2 antagonist ritanserin.

134.11 CHANGES IN BRAINSTEM NORADRENALINE AND ADRENALINE TURNOVER DURING CLONIDINE TREATMENT AND ITS WITHDRAWAL. L. Lambás-Señas*, J. Atkinson*, J.P. Fluckiger*, M. Sonnay* and B. Renaud. Lab. Neuropharmacologie-UA CNRS 1196, Faculté de Pharmacie, Université Claude Bernard, Lyon (France), Lab. Pharmacodynamie, Faculté de Pharmacie, Université de Nancy I, Nancy (France) and Institut de Pharmacologie de l'Université-CHUV, Lausanne (Switzerland).

This study was undertaken to determine, in the spontaneously hypertensive adult rat, the brain regions involved and the changes occurring in noradrenaline (NA) and adrenaline (A) metabolism i) during a chronic clonidine treatment and ii) at the beginning of the withdrawal syndrome which appears after cessation of a prolonged clonidine treatment. NA and A turnovers (estimated by measuring NA and A depletions after FLA 63 administration) were determined in the A1-C1 and A2-C2 brainstem regions after seven days of treatment with clonidine (0.1 mg/kg/day, i.v., via osmotic minipumps) and at a early (16h), intermediate (40h) and late (64h) delay after withdrawal from a 10 days' treatment. The doses of clonidine and the protocol used have previously been reported to lower blood pressure and produce cardiovascular hyperactivity upon withdrawal (Atkinson et al., Eur. J. Pharmacol., 1986, 121, 97-107).

After a seven days' treatment with clonidine, the NA and A turnovers were unchanged both in the A1-C1 and A2-C2 regions. During withdrawal, the NA turnover was also unchanged in these regions. However, the A turnover was significantly increased 16h ($p < 0.01$) and 40h ($p < 0.05$) after withdrawal in the A1-C1 region and 16h after withdrawal ($p < 0.01$) in the A2-C2 region.

These results show that the NA metabolism is unchanged both during clonidine treatment and during its withdrawal in the brainstem catecholaminergic regions analyzed. In contrast, the increase in A turnover found in the A1-C1 and A2-C2 regions suggests that the adrenergic neurons of the brainstem could be activated during clonidine withdrawal. The adrenergic C1 neurons have been shown by various approaches to be a key element of the sympathetic vasopressor system. Thus, the increase in the A turnover we observed during withdrawal could be at the origin of the sympathetic hyperactivity found after cessation of a prolonged treatment with clonidine.

134.12 FG 7142, AN ANXIOGENIC BETA CARBOLINE, SELECTIVELY INCREASES TYROSINE HYDROXYLATION IN THE MEDIAL PREFRONTAL CORTEX. A.M. Knorr, A.Y. Deutch, and R.H. Roth. Yale Univ. Sch. Med., New Haven CT 06510.

We have previously demonstrated that footshock stress leads to a selective activation of dopamine (DA) metabolism in the prefrontal cortex of rat. A similar effect is elicited by administration of the anxiogenic beta carboline FG 7142. The activity of tyrosine hydroxylase (TH), the rate-limiting enzyme in DA synthesis, increases in the prefrontal cortex following stress exposure (Iuvone and Dunn, 1986), suggesting that an increase in DA synthesis may occur concomitantly with the increase in metabolism.

The current experiments examine FG 7142-induced alterations in DA synthesis as reflected by DOPA accumulation following L-aromatic amino acid decarboxylase inhibition with m-hydroxybenzylhydrazine (NSD 1015). NSD 1015 was administered to rats 30 minutes prior to sacrifice; FG 7142 or vehicle was administered 5 minutes after NSD 1015. Catecholamine levels were measured by HPLC with electrochemical detection. DOPA accumulation was significantly increased in the medial prefrontal cortex but was not altered in the nuc. accumbens or striatum. DA levels in the prefrontal cortex of FG 7142-treated animals were significantly lower than in control subjects, thus confirming an enhancement of DA turnover and metabolism induced by FG 7142. Neither the striatum nor the nuc. accumbens exhibited lowered DA levels. The observed increase in DOPA synthesis in the prefrontal cortex may therefore be secondary to a decrease in feedback inhibition. Alternatively, FG 7142 may influence the kinetic properties of TH by increasing the functional activity of the mesoprefrontal DA neurons. This possibility is consistent with our previous data demonstrating an FG 7142-induced increase in DA metabolite levels in the ventral tegmental area, but not substantia nigra. These data therefore suggest that FG 7142 may be acting directly on the cell body region of mesoprefrontal cortical DA neurons. However, in vitro studies in which prefrontal cortical slices from untreated rats were preincubated with FG 7142 (1-10 um) demonstrated a concentration-dependent increase in tyrosine hydroxylation similar to that observed in vivo. In striatal slices, in contrast to the lack of effect in vivo, DOPA accumulation was significantly decreased. This is consistent with the possibility that FG 7142 may also exert a presynaptic effect on DOPA synthesis which is dependent on the intrinsic organization of the terminal regions. These studies confirm and extend previous data on the effects of the anxiogenic beta carboline FG 7142 by demonstrating that synthesis and metabolism in the mesoprefrontal DA system is preferentially altered by this inverse benzodiazepine agonist.

Supported in part by MH-14092, the National Science Foundation, and the American Parkinson's Disease Association.

134.13 YOHIMBINE INCREASES PLASMA NOREPINEPHRINE APPEARANCE RATE WITHOUT ALTERING CLEARANCE. M.M. Murburg*, E. Villacres*, D.M. Dorsa, G.N. Ko, R.C. Veith* (SPON: D. Bowden). GRECC, Seattle VAMC and University of Washington, Seattle, WA 98108.

The α_2-adrenergic antagonist yohimbine hydrochloride has been reported to increase plasma norepinephrine (NE) in humans. We investigated whether yohimbine increases plasma NE solely by causing a dose-dependent increase in the rate of NE appearance into plasma, or whether it also decreases the rate of NE clearance. Seventeen fasting supine, healthy, nonobese, drug-free men, aged 20 to 34, participated. Plasma catecholamines and basal NE kinetics were measured in arterialized plasma 30, 40 and 50 minutes after a 15μCi/m^2 bolus, followed by a 0.35μCi/m^2/min infusion, of tritiated l-norepinephrine ([^{3}H]-NE). Subjects then randomly received (double-blind) placebo, or yohimbine 20 or 40 mg po. Ninety minutes after the drug, a second bolus and infusion of [^{3}H]-NE were given, with sampling again at 30, 40 and 50 minutes (120, 130, 140 minutes after drug). Plasma NE appearance and clearance rates were calculated using a [^{3}H]-NE isotope dilution technique. Average basal and post-drug steady state catecholamine levels, NE appearance and clearance rates, and vital sign measurements were calculated. One way ANOVA was used to compare mean percent of baseline achieved after each drug treatment for each of these measures.

Basal NE and epinephrine (EPI) levels, NE kinetics and mean arterial pressure (MAP) did not differ among the three drug groups. Placebo, yohimbine 20 mg, and yohimbine 40 mg, respectively, raised plasma NE to 99±25, 157±33 and 213±58 ($\bar{x}$±SD) percent of baseline ($F=11.31$; $p<.005$). The yohimbine-induced increases were accompanied by dose-dependent increases in NE appearance rate, which was 104±27, 175±53 and 230±72% of baseline after placebo, yohimbine 20 mg and yohimbine 40 mg, respectively, ($F=8.12$; $p<.01$). NE clearance was not altered by yohimbine (all 99-108% of basal). EPI levels were 99±17% after placebo, 138±50% after yohimbine 20 mg, and 187±50% after yohimbine 40 mg ($F=6.89$; $p<.02$). Yohimbine increased MAP to (101±4.3; 102±4.7; 108.9±3.6 percent of baseline; ($F=6.01$; $p<.05$) after placebo, yohimbine 20 mg and yohimbine 40 mg, respectively. Increases in human plasma NE levels following yohimbine reflect dose-dependent increases in NE appearance rate, and not alterations in NE clearance, compatible with increased sympathetic outflow in response to blockade of α_2 adrenergic receptors.

134.14 THYROID HORMONE AND NOREPINEPHRINE: EFFECTS ON RECEPTOR REGULATION AND Na,K-ATPase. Alan C. Swann and Jeffrey S. Steketee. Dept. of Psychiatry, University of Texas Medical School, Houston TX 77225, USA.

Thyroid hormone produces metabolic effects similar to those of stimulation of noradrenergic receptors. It has been reported, however, that norepinephrine turnover is reduced during thyrotoxicosis and that beta-receptor number is increased. Metabolic effects of thyroid hormone may therefore reduce noradrenergic activity by a feedback mechanism. We examined effects of thyroid hormone administration or of production of hypothyroidism with methimazole on receptors associated with regulation of noradrenergic function. Since both norepinephrine and thyroid hormone increase Na,K-ATPase activity, we also examined interactions between effects of thyroid hormone and noradrenergic activity on this enzyme. Treatment with thyroid hormone increased beta-receptor binding, increased alpha-2 receptor binding, and decreased desipramine binding, opposite to effects of hypothyroidism produced by methimazole. Heart was more sensitive than brain to these effects. Treatment with the beta-adrenergic antagonist propranolol or with 6-hydroxydopamine did not prevent the increase in heart Na,K-ATPase associated with thyrotoxicosis. Thyroid hormone also did not prevent the decrease in Na,K-ATPase associated with propranolol or 6-hydroxydopamine. Administration of methimazole did not prevent the stimulation of heart or cerebral cortex Na,K-ATPase by yohimbine; consistent with the increase in alpha-2 receptor number, thyroid hormone increased sensitivity to yohimbine slightly. These data are consistent with reduced noradrenergic activity during hyperthyroidism, possibly mediated by increased alpha-2 receptor function. Thyroid hormone and norepinephrine appear to affect Na,K-ATPase activity by independent mechanisms.

134.15 EFFECTS OF CHLORAL HYDRATE ANESTHESIA ON LHRH NEURONAL RESPONSIVENESS TO NOREPINEPHRINE. R.D. Hartman* and C.A. Barraclough. (SPON: A. M. Mans) Dept. of Physiology, Sch. of Med., Univ. of Maryland, Baltimore, MD 21201.

Electrical stimulation (ES) of locus coeruleus (LC) or the A1 noradrenergic cell groups, in chloral hydrate (CH) anesthetized rats, amplifies LH release. This effect occurs only after LHRH neurons are partially depolarized by initial electrochemical stimulation (ECS) of the medial preoptic nucleus (MPN). In contrast, plasma LH levels remain basal if only LC or A1 are stimulated. These observations suggest that: (a) inadequate norepinephrine (NE) is released by these stimuli to activate dormant LHRH neurons, or (b) CH elevates thresholds of excitability of LHRH neurons to NE. Accordingly, we evaluated the effects of CH on LH release after infusion of NE into the third ventricle (3V) of control and MPN-ECS rats.

Seven day ovariectomized (OVX) rats (day 0) received Silastic capsules containing estradiol (150 ug/ml in oil, s.c.). On day 2 control rats were anesthetized with ether, whereas experimental rats received CH (400 mg/kg, i.p.). Infusion cannulae were inserted into the 3V and thereafter, NE was infused in 2 ul artificial CSF containing 0.2% ascorbic acid over 1 min. In controls, NE elicited peak LH responses of 250 $\pm$ 30 (5 ug) or 600 $\pm$ 80 ng/ml (15 ug) within 10 min, whereas ACSF alone did not affect basal LH levels. In contrast, in CH-treated rats, peak LH responses reached only 233 $\pm$ 50 (30 ug NE) or 304 $\pm$ 46 ng/ml (45 ug NE). Consequently, one reason why neither LC or A1 ES evoke LH release may be due to the marked suppression of LHRH neuronal responsiveness to NE by CH.

A similar protocol was used to ascertain whether 3V NE infusions would mimic the amplifying effects of LC or A1 ES on LH release. Estrogen-primed OVX rats were anesthetized with CH and the MPN was ECS (100 uA/60 sec, d.c.). Thirty min later ACSF was infused into the 3V of control rats, whereas other groups received either 150 ng, 15 or 45 ug NE in ACSF. Following MPN-ECS, plasma LH rapidly increased from 103 $\pm$ 9 to 597 $\pm$ 42 ng/ml, and this response was not affected by ACSF. Neither 150 ng or 15 ug of NE altered this LH response. However, 45 ug NE markedly amplified MPN-ECS-induced LH release. Within 30 min after NE, plasma LH rose to 1380 $\pm$ 236 vs. control values of 668 $\pm$ 143 ng/ml. By 45 min LH reached levels of 2545 $\pm$ 860 vs. 636 $\pm$ 101, and by 60 min LH was still elevated to 2625 $\pm$ 732 vs. 582 $\pm$ 91 ng/ml for controls. Seemingly, LHRH neurons become more responsive to NE after MPN-ECS compared to unstimulated controls. It is possible that even after MPN-ECS, LHRH neuronal responsiveness to NE is markedly reduced by CH. We currently are searching for other anesthetics which only minimally affect LHRH neuronal responsiveness to NE. Supported by Research Grant HD-02138.

134.16 **NEUROTENSIN EFFECTS ON DOPAMINE RELEASE IN THE STRIATUM AND NUCLEUS ACCUMBENS: SITE SPECIFICITY AND MECHANISMS OF ACTION.** **C.D. Blaha, A.G. Phillips, H.C. Fibiger and R.F. Lane, Depts. of Psychology, Psychiatry and Chemistry, Univ. of British Columbia, Vancouver, B.C. Canada V6T 1Y7.**

The tridecapeptide neurotensin (NT) and dopamine (DA) have been shown to be co-localized in mesolimbic neurons. The observation that intracerebroventricular (i.c.v.) injections of NT produces behavioral effects similar to those of atypical antipsychotics (e.g. blockade of locomotion but not stereotypy induced by amphetamine) has prompted hypothesis about the role of NT in the etiology of schizophrenia. Using in vivo electrochemical techniques (Lane & Blaha, Ann.N.Y.Acad.Sci. 473:50, 1986), we have previously shown that typical antipsychotics (e.g. haloperidol, HAL) increase DA release in both mesolimbic (accumbens) and nigrostriatal (striatum) DA terminal regions, whereas atypical antipsychotics (e.g. clozapine, CLOZ) selectively increase DA release in the accumbens. The present study compares the effects of NT with those of HAL and CLOZ, on DA release in the striatum and accumbens on anesthetized rats. In an effort to understand the mechanisms of action of NT on DA release, the effects of NT and these antipsychotics in combination with apomorphine (APO) and amphetamine (AMP) were also examined.

Administration of various doses of NT (0.1-10 ug/10ul i.c.v.) induced immediate dose-dependent increases in accumbens DA release, whereas striatal DA release was unaffected at these doses. Similar to NT, CLOZ (20 mg/kg s.c.) selectively increased accumbens DA release while having no effect on striatal DA release. In contrast, HAL (0.5 mg/kg s.c.) produced increases in DA release in both brain regions. γ-butyrolactone (GBL) is known to block DA neuronal impulse flow and induce concomitant reductions in forebrain DA release. Dependent upon the time of injection, GBL (200 mg/kg i.p.) either prevented or reversed NT-induced increases in accumbens DA release. Both CLOZ- and HAL-induced increases in accumbens DA release were similarly affected by GBL. APO (50 ug/kg i.v.) was also effective in antagonizing both NT- and antipsychotic-induced changes in DA release. Additionaly, AMP (1 mg/kg i.v.), administered during peak DA stimulatory effects induced by NT or the antipsychotics, produced further increases in release that was comparable in magnitude to that produced after AMP administration alone.

These in vivo results provide evidence that (1) at the doses tested, NT selectively stimulates mesolimbic DA release (2) NT selective effects and interactions with GBL and DA agonists parallel CLOZ effects suggesting common mechanisms of action with atypical antipsychotics and (3) the inability of NT to alter AMP-induced increases in DA release indicates that NT blockade of AMP elicited behaviors is mediated by mechanisms postsynaptic to the DA nerve terminal. **Support: MRC Program Grant-23 and USPHS NS 13556.**

134.17 (-)-3PPP HAS TWO EFFECTS ON DOPAMINERGIC (DA) NEURONS IN THE SUBSTANTIA NIGRA PARS COMPACTA (SNC) OF THE RAT. C.B. Davis* and P.S. Blum. Department of Biological Research, McNeil Pharmaceutical, Spring House, PA 19477.

(-)3-(3-Hydroxyphenyl)- N-n-propylpiperidine ((-)-3PPP) has been proposed to be an agonist at DA autoreceptors. Part of the evidence for this conclusion includes the observation that a dose-dependent decrease is seen in the activity of DA neurons following administration of (-)-3PPP (ED_{50} 300 µg/kg i.v.). Recently, we investigated the effects of (-)-3PPP on DA neurons in the SNC of chloral hydrate anesthetized Wistar rats. A simple, dose dependent decrease in firing rate was rarely seen. Rather (-)-3PPP produced either no change or an erratic change in neuronal activity. To characterize the effects of (-)-3PPP, therefore, we examined the relationship between neuronal activity and extracellular spike amplitude following (-)-3PPP for 10 DA neurons in the SNC. DA neurons were identified by standard criteria including firing frequency, and duration and shape of the action potential. All recording sites were in the SNC. The total analysis period for each neuron (7-33 min) was divided into 20 sec segments in which the number of spikes was counted and the average spike amplitude and variability in amplitude was determined. Two neurons showed a simple dose-dependent decrease in activity. Twenty µg/kg of (-)-3PPP produced an observable decrease, and inhibition reached 40% with cumulative doses of 75 and 40 µg/kg. There was a reciprocal relationship between frequency and spike amplitude, and there was little second-to-second variability in amplitude. These results are consistent with an action at DA autoreceptors. In three neurons, administration of (-)-3PPP resulted in an abrupt decrease in both frequency and spike amplitude. In two neurons this occurred after one dose of 10 µg/kg and in the other after a cumulative dose of 170 µg/kg. These data suggest that (-)-3PPP has a direct toxic effect on DA neurons that is not receptor mediated. Four neurons showed an intermediate effect; initially there was a dose dependent decrease in activity with an increase in amplitude. This was followed by an abrupt decrease in amplitude and frequency. The threshold for the initial decrease was 10 µg/kg and the threshold for abrupt change was 40-135 µg/kg. One neuron showed no effect of (-)-3PPP (30 µg/kg). These data suggest that (-)-3PPP has two different effects on DA neurons when administered systemically. The first is a decrease in activity mediated by action at DA autoreceptors. The second is a direct effect on the neuronal membrane. Depending upon the sensitivity of the individual neuron, one effect or the other may predominate.

135.1 INTRANIGRAL ANTIEPILEPTIC DRUGS PREVENT SEIZURES INDUCED BY PILOCARPINE. L. Turski, J.S. Andrews*, P.A. Löschmann*, D.N. Stephens*, Z.A. Bortolotto* and E.A. Cavalheiro*. Dept. of Neuropsychopharmacology, Schering, 1000 Berlin 65, West Germany; Dept. of Neurology and Neurosurgery, Escola Paulista de Medicina, CEP-04023 Sao Paulo, Brazil.

Seizures produced in rodents by systemically administered pilocarpine provide a model for studying the generation and spread of convulsive activity in the forebrain. Pilocarpine hydrochloride, 380 mg/kg, induces a sequence of behavioral and electroencephalographic alterations indicative of motor limbic seizures and status epilepticus which is followed by widespread damage to the limbic forebrain resembling that occurring subsequent to prolonged intractable seizures in humans. The efficacy of anticonvulsant drugs in preventing seizures induced by pilocarpine in rats correlates well with their ability to depress the firing rate of neurons in the substantia nigra pars reticulata (Turski et al., Soc. Neurosci. Abstr., 12: 898, 1986; Waszczak et al., J. Pharmacol. Exp. Ther., 239: 606, 1986). Systemic administration of benzodiazepines, barbiturates, trimethadione and valproate prevents seizures produced by pilocarpine, 380 mg/kg, and depresses the firing rate of nigral neurons. In contrast, ethosuximide increases susceptibility of rats to seizures elicited by pilocarpine, while diphenylhydantoin and carbamazepine remain inactive. These effects also correlate with the action of ethosuximide, diphenylhydantoin and carbamazepine on substantia nigra unit activity.

The present study was undertaken to determine whether antiepileptic drugs share an ability to modulate seizures induced by pilocarpine following microinjections into the substantia nigra. Pretreatment of rats with midazolam, ED_{50} 0.038 µmol (0.029-0.052), and phenobarbital, 0.016 µmol (0.007-0.039), prevented the evolution of limbic seizures induced by pilocarpine, 380 mg/kg, while diphenylhydantoin (up to 0.1 µmol) remined inactive. Ethosuximide, 0.038 µmol (0.022-0.065), lowered the threshold for seizures induced by pilocarpine, and converted a non-convulsant dose of pilocarpine, 200 mg/kg, into a convulsant one.

These results show that microinjections of antiepileptic drugs into the substantia nigra are sufficient for an anticonvulsant action.

135.2 EFFECTS OF M1 AND M2 MUSCARINIC AGONISTS ON SEPTO-HIPPOCAMPAL AND OTHER CENTRAL NEURONS IN THE RAT. O. Rascol* and Y. Lamour, INSERM, U. 161, 2 rue d'Alésia, 75014 Paris, France.

The functional role of M1 and M2 muscarinic binding sites in the central nervous system is still poorly understood. It has been suggested that the M1 binding sites could be post-synaptic whereas the M2 sites could be presynaptic. In the present series of experiments the effects of muscarinic M1 (pilocarpine, McN A 343) and M2 (oxotremorine - M, carbachol) agonists and antagonists (pirenzepine, gallamine) applied by iontophoresis were studied on several neuronal populations in the central nervous system of rats anesthetized with urethane. Septo-hippocampal neurons and neurons from hippocampus, subiculum and somatic sensory cortex were studied. Septo-hippocampal neurons (SHNs), taken as example of "presynaptic neurons", were identified by their antidromic response to the electrical stimulation of the fimbria-fornix. Only cholinoceptive neurons (i.e. neurons excited by the iontophoretic application of acetylcholine) were studied. The qualitative (percentage of excitations and inhibitions) and quantitative (current-responses curves) aspects of the effects of the various drugs in the various structures were investigated. Conventional amplification methods were used to record extracellular neuronal activity, using micropipettes filled with 1M NaCl and 2 % pontamine skye blue that were rigidly attached to multibarreled micropipettes (tip diameter 8-10 um) filled with solutions for testing by iontophoresis.

The proportion of SHNs excited by carbachol and oxotremorine-M was close to 90 % whereas only 7 to 9 % of the SHNs were inhibited by these drugs. In contrast pilocarpine and McN A 343 inhibited 25 and 52 % of the SHNs, whereas excitations were observed in only 41 % and 13 % of the SHNs respectively. In the hippocampus and subiculum, the picture was essentially the same with some minor variations. In the cerebral cortex, carbachol and oxotremorine-M were also potent excitants whereas inhibitions were frequent with McN A 343 (41 %) but less so with pilocarpine (11 %). Pirenzepine blocked more easily the M1 than the M2 effects.

These results suggest i) that the "presynaptic" septo-hippocampal neurons as well as the "post-synaptic" hippocampal or cortical neurons both bear M1 as well as M2 receptors which are able to modify neuronal discharge rate. ii) and that M1 and M2 agonists induce changes in neuronal discharge rate in opposite directions. They might therefore act through different mechanisms.

135.3 DISINHIBITORY ACTION OF ACETYLCHOLINE MEDIATED BY M_1 MUSCARINIC RECEPTOR IN THE LATERAL SEPTAL NUCLEUS OF THE RAT *IN VITRO*. H. Hasuo, J.P. Gallagher, P. Shinnick-Gallagher. Dept. of Pharmacol. & Toxicol., Univ. Texas Med. Br., Galveston, TX. 77550.

Intracellular recording were made from neurons of the dorsolateral septal nuclei (DLSN) contained within a transverse slice of a rat and superfused *in vitro* with artificial cerebrospinal fluid (ACSF). Orthodromic focal stimulation applied to the fimbrial afferents in the slice could generate either a fast inhibitory postsynaptic potential (IPSP) or a fast IPSP followed by a late hyperpolarizing potential(LHP). Bath application of muscarine(0.5-30 µM) either hyperpolarized (70 % neurons tested) or depolarized(20 %) the resting membrane potential of the DLSN neurons; each effect accompanied with decrease or increase in input membrane resistance,respectively. In either case the amplitudes of IPSP and LHP were markedly depressed by muscarine in a dose dependent manner. When we measured the amplitudes of IPSP and LHP, depolarizing or hyperpolarizing dc current was applied to nullify the membrane potential change by muscarine. The amplitudes of IPSP and LHP were depressed by muscarine (10 µM) by 45.2 ± 3.9 % (n=16) and 53.8 ± 2.2 %(n=22), respectively, although the input membrane resistance change was about 10 %. These results indicate that the inhibition of both IPSP and LHP is not simply due to the shunting action caused by a conductance change. Oxotremorine (0.1-10 µM) and bethanechol (10-100 µM) also showed effects similar to muscarine. The membrane potential change and inhibition of IPSP and LHP by muscarine(10 µM) were blocked completely by atropine(1 µM), but were unaffected by mecamylamine (10 µM). In the rat DLSN neuron, IPSP and LHP are considered to be mediated ,at least in part, by GABA receptors (Stevens et al. Synapse, 1:184-190 ,1987). GABA induced potentials produced by pressure application of exogenous GABA were little affected by muscarine(10 µM). Pirenzepine caused a parallel shift in the muscarine dose-response curve. The analysis by the Gaddum-Schild method indicated that pirenzepine blocked competitively the effect of muscarine on IPSP, LHP and resting membrane potential with a K_D value of 30 nM, 40 nM,and 6 nM,respectively. These results suggest that M_1 muscarinic receptors, highly pirenzepine sensitive, may be involved in the presynaptic regulation of GABA release as well as in the muscarine induced resting membrane potential changes of dorsolateral septal neurons. The physiological significance of muscarinic action in the dorsolateral septal neurons is not clear, however since theta rhythm has been shown to be both atropine sensitive and resistant, one type of theta rhythm could be modulated by muscarinic receptors in the dorsolateral septum. 135.4 DIFFERENTIAL EFFECTS OF CHOLINERGIC AGONISTS UPON THE COMPONENTS OF THE COMPLEX EVOKED DISCHARGE OF AUDITORY CORTICAL NEURONS. T.M. McKenna, J.H. Ashe, G.K. Hui, and N.M. Weinberger. Center for the Neurobiology of Learning and Memory, University of California, Irvine, CA 92717.

This experiment studied the effects of cholinergic agents upon responses to controlled pure tone stimulation in the primary auditory cortex of the unanesthetized cat. Because previous reports of physiological plasticity in auditory cortex have noted that learning may differentially affect spontaneous vs. evoked discharges, and various components of evoked discharges, (cf. Weinberger & Diamond, Prog. Neurobio.,1987), and since acetylcholine has been implicated as a factor in neural plasticity, special attention was devoted to these parameters of cellular activity.

Multibarrel micropipettes were used to record activity from 115 acoustically-responsive single neurons and to apply cholinergic agonists acetylcholine (ACh, 2M) or methacholine (MCh, 20 mM), or antagonist atropine (.2M) by micropressure. Most of these neurons had more than one response component to tones (i.e. on, through, or off component).

The most prominent effect of the agonists was a facilitation of "on" discharges, ACh and MCh being equally effective. They also generally produced an increase in "off" responses, but they had opposite effects on "through" responses; ACh was more likely to depress "through" responses than was MCh. Agonist effects on spontaneous activity often paralleled those on "through" responses, but were different from the effects for "on" or "off" components.

Furthermore, agonists had different effects on various response components; in many cases opposite effects (increases and decreases). Moreover, "on" and "off" components were usually changed together. In contrast, changes in "on" responses were weakly related to changes in "through" discharges. Effects of agonists could be blocked by atropine, and atropine effects for "on" and "off" responses also directly covaried.

These findings indicate that ACh and MCh modify evoked activity in a manner more subtle than simple increase or decrease in discharge rate during an acoustic stimulus. Comparison of the effects of cholinergic agents on the different response components revealed that the "on" and "off" responses were modified in concert.

We are currently extending this investigation to neurons tested with a range of tone frequencies.

135.5 MICROINJECTION OF ATROPINE COMPETITIVELY ANTAGONIZES THE CARBACHOL INDUCED ENHANCEMENT OF DESYNCHRONIZED SLEEP SIGNS. H.A. Baghdoyan, R. Lydic, C.W. Callaway* and J.A. Hobson. Laboratory of Neurophysiology, Harvard Medical School, 74 Fenwood Road , Boston, MA 02115.

Microinjection of cholinergic agonists or an acetylcholinesterase inhibitor into the pontine reticular formation of conscious cats produces a behavioral and electrographic state similar to physiologically occurring desynchronized (D) sleep. This cholinoceptively evoked D sleep-like state is dose dependent and is blocked by centrally administered atropine, indicating that this phenomenon is mediated by muscarinic cholinergic receptors. The purpose of the present study was to determine quantitatively whether the effects of carbachol on D sleep signs can be competitively antagonized by microinjection of the muscarinic receptor blocker atropine.

Three dosages of carbachol (0.4, 1.0, 4.0 micrograms in 250 nl saline) were used. For each injection trial, 15 min prior to carbachol administration cats were pretreated with either atropine (5 micrograms in 250 nl) or saline (250 nl). There were 2 trials per dosage of carbachol, 2 trials of atropine alone, and 2 saline controls, for a total of 16 injections. The percentage of time spent in the carbachol induced D sleep like state (D-carb) was measured for 4 hrs following carbachol administration.

A double reciprocal plot of D-carb percentage (y) vs. carbachol dosage (x) showed the equation for the line to be $y=(0.08)x+0.07$ following microinjection of carbachol, with an x intercept of -0.85; and $y=(0.83)x+0.11$ following the atropine pretreatment trials, with an x intercept of -0.13. Thus, the maximal effect of carbachol was not decreased by atropine, however this pretreatment did reduce the affinity of carbachol for the acetylcholine receptor.

This is the first time that centrally administered atropine has been shown to competitively antagonize the D sleep sign enhancement induced by microinjection of carbachol into the pontine reticular formation. Therefore, these quantitative data provide a new demonstration that D-carb is mediated by muscarinic cholinergic receptors, and support the hypothesis that physiologically occurring D sleep is generated by cholinergic/cholinoceptive mechanisms of the pontine reticular formation.

135.6 LOCALIZATION OF MUSCARINIC AND GABA RECEPTORS TO APICAL DENDRITIC TUFTS IN CINGULATE CORTEX WITH LAMINAR NEUROTOXIN LESIONS. Brent A. Vogt. Depts. Anatomy and Physiology, Boston University School of Medicine, Boston, MA 02118

Dissociation of adult neurons in combination with radiolabeled ligand binding techniques provide a powerful assay for the localization of receptors to specific classes of cortical neurons and parts of the dendritic tree. This approach, however,includes wet emulsion autoradiography and so requires the use of a limited number of irreversible ligands. In addition, the apical tufts of pyramidal neurons and dendritic spines are pulled off during dissociation.One solution to these problems is to make neurotoxin lesions which are restricted to one or two layers followed by cryostat sectioning, radioligand binding, coverslip autoradiography and quantification of alterations in binding above and below the lesion. Alterations in layer I binding are of particular interest because this is where the apical dendrites of almost all cortical pyramids arborize.

Lesions of either layers II-IV or Vb and VI were made with ibotenic acid in adult, male rats. Two weeks later the animals were perfused with Krebs-Henseleit buffer, the brains removed and frozen and sectioned with a cryomicrotome. The sections were incubated in either pirenzepine (PZ, 15 nM) for localization of M_1 sites or muscimol (20 nM) for localization of GABAa receptors. Nonspecific binding was determined with 1 μM atropine or muscimol,respectively. The sections were then washed, dryed and exposed to emulsion-coated coverslips. After the autoradiograms were developed, single grains were counted in area 29c of posterior cingulate cortex in normal, i.e. unablated, and experimental cases.

In three cases in which layers II-IV were destroyed, there was a reduction in specific PZ binding in layers Ia, b and c of almost 80% in comparison to three normal cases, while reductions in specific muscimol binding were between 32 and 40%. Losses in what remained of layers II-IV were 40-55% for PZ binding and 15-30% for muscimol binding. No significant alterations occurred in layers V and VI for either ligand. Lesions in layers Vb and VI produced 15-20% reductions in PZ binding in layers I-IV.

One of the principal structural heterogeneities in area 29c is the dense dendritic arborizations of pyramidal cell apical tufts in layer I. Pyramids in layers V and VI have apical dendrites which arborize evenly in layer I, while many cells in layers II-IV have a selective termination of their dendrites in layer Ia. The present findings indicate that both M_1 and GABAa sites are on these apical dendritic tufts.

This research was supported by NIH grant 18745.

135.7 CHARACTERIZATION OF MUSCARINIC AUTORECEPTORS IN THE RAT HIPPOCAMPUS AND FRONTAL CORTEX. P. Supavilai*, I. Bobirnac* and M. Karobath (SPON: G. Engel). Preclinical Research, Sandoz Ltd., CH-4002 Basle, Switzerland

Presynaptic muscarinic autoreceptors can regulate acetylcholine release from cholinergic nerve terminals in the central and peripheral nervous system. Studies on electrically evoked release of acetylcholine from brain slices (e.g. Szerb et al, Brain Research 1977; 128:285-291) have shown that inhibitors of acetylcholinesterase (AChE) decrease ^{3}H-acetylcholine release, which is restored by the addition of muscarinic antagonists. The latter drugs added alone have no effect or even slightly enhance ^{3}H-acetylcholine release. Further studies using K^+-evoked release from brain slices and synaptosomes also suggested that acetylcholine release can be inhibited by the stimulation of presynaptic muscarinic autoreceptors. Recently it has been proposed that muscarinic receptors can be divided into 2 major pharmacologically distinct subtypes ie. M1 and M2 receptors with further subdivisions also suggested. Currently it is not clear whether presynaptic muscarinic autoreceptors in a given brain area are of the M1 or M2 type. We therefore investigated the effects of muscarinic agonists, partial agonists, antagonists and AChE inhibitors on electrically-evoked acetylcholine release from rat hippocampus and frontal cortex slices. In some experiments we also studied muscarinic drugs on electrically-evoked acetylcholine release from monkey hippocampus slices. Our results show that the activation of muscarinic receptors can lead to a complete suppression of acetylcholine release, and that the efficacy of muscarinic agonists is similar in rat hippocampus and rat frontal cortex slices. In agreement with observations from other laboratories using currently available receptor subtype selective drugs we suggest that presynaptic muscarinic autoreceptors in rat hippocampus and frontal cortex are of the M2 subtype. Results with brain slices obtained from the hippocampus of squirrel monkeys indicate that no marked species differences in the functional importance and properties of presynaptic muscarinic autoreceptors exist.

135.8 REGULATION OF BRAIN ACETYLCHOLINE (Ach) CONCENTRATION BY MUSCARINIC RECEPTORS. V.H.Sethy and J.W.Francis*, CNS Research, The Upjohn Company, Kalamazoo, Michigan 49001 USA

There is substantial evidence indicating that the function of cholinergic neurons in the central nervous system is subject to a number of regulatory mechanisms. These regulatory mechanisms could involve various neurotransmitter systems making synaptic contact with cholinergic neurons and/or muscarinic receptors located at cholinergic synapses. While the effect of cholinergic drugs on brain Ach levels and the release of this transmitter has already been extensively investigated, very little is known about the relationship between the occupation of muscarinic cholinergic receptors and changes in brain Ach levels. Therefore, it was decided to investigate this relationship after intravenous (i.v.) administration of muscarinic agonists to mice. The peak effect of arecoline (10 umol/kg i.v.) on inhibition of (3H)-oxotremorine-M (3H-OXT) binding and on the increase in brain Ach levels was observed at 1 and 3 minutes, respectively. The maximum effect of i.v. oxotremorine (3 umol/kg) on inhibition of (3H)-OXT binding and on the increase in brain Ach was observed at 30 and 60 minutes, respectively. There was a significant (p 0.001) and dose-dependent inhibition of (3H)-OXT binding and an increase in brain Ach levels after i.v. administration of arecoline (0.3, 1, 3, 10, and 30 umol/kg), oxotremorine (0.1, 0.3, 1, and 3 umol/kg), oxotremorine-1 (0.1, 0.3, 1, 3, and 10 umol/kg), and oxotremorine-3 (0.3, 1, 3, 10, and 30 umol/kg). The correlation coefficient between the ED50 for inhibition of (3H)-OXT binding and the increase in brain Ach levels was 0.94. These results suggest that the muscarinic cholinergic receptor system involved in the regulation of brain Ach levels may lack spare receptors.

135.9 MUSCARINE INCREASES THE DIACYLGLYCEROL CONTENT OF PC12 CELLS. J. Horwitz (SPON: R.L. Perlman) Kennedy Mental Retardation Research Center and Dept. of Pediatrics, Univ. of Chicago, Chicago,IL 60637

Stimulation of muscarinic receptors on PC12 pheochromocytoma cells increases the hydrolysis of inositol containing phospholipids by phospholipase C. The hydrolysis of these phospholipids is thought to lead to the formation of inositol phosphates and diacylglycerol. Previous experiments from this laboratory and others have shown that muscarine increases inositol phosphates in these cells. Diacylglycerol has been shown to activate protein kinase C in vitro. The effect of receptor stimulation on diacylglycerol in cells is usually assessed by measuring the accumulation of [^{3}H]diacylglycerol in cells whose phospholipids have been prelabeled with [^{3}H]arachidonic acid. Muscarine increases [^{3}H]diacylglycerol formation in PC12 cells differentiated with nerve growth factor. After a 5 min incubation at 27°C, muscarine at 100 μM caused approximately a 2-fold increase (cpm/10^6 cells, control: 605±76; muscarine: 1073±49). This, method, however, may not give an accurate indication of diacylglycerol content because [^{3}H]arachidonic acid is incorporated unevenly into all phospholipids. Preiss et al. (J. Biol. Chem. 261, 2597, 1986) have developed an assay that measures the actual amount of diacylglycerol. This assay involves phosphorylation with diacylglycerol kinase and [γ-^{32}P]ATP and measurement of [^{32}P]phosphatidic acid formed. Using this assay, I have measured the effect of muscarinic receptor stimulation on diacylglycerol levels in differentiated PC12 cells. The basal level of diacylglycerol in several experiments ranged from 75 to 200 pmol/10^6 cells. A 5 min incubation with muscarine at 37°C caused a 35% increase in diacylglycerol over basal levels (pmol/10^6 cell, control: 76±4; muscarine: 103±2). Lower temperature (27°C) seemed to enhance the effect of muscarine (control: 115±6; muscarine: 180±6). Thus, muscarine stimulates diacylglycerol formation in PC12 cells and would, therefore, be expected to activate protein kinase C under these conditions. (Supported by NIH grants NS22694 to J.H., HL29025 to R.L.P. and HD04583 to KMRRC)

135.10 CHARACTERISTICS OF MUSCARINIC RECEPTORS AND SECOND MESSENGER RESPONSES OF STRIATAL NEURONS IN PRIMARY CULTURE. J. Ellis, D.E. Kemp*, M. Seidenberg*, R.H. Lenox, and S. Weiss. Neuroscience Research Unit, Department of Psychiatry, University of Vermont, Burlington, VT 05405.

Our preparations of striatum, generated from the fetal mouse brain, are predominantly (>93%) neuronal and are maintained in serum-free monolayer culture. Some advantages of such cultures are: (1) diffusional barriers and contributions from non-neuronal cell types are minimal; (2) the characteristics of these cells are not exclusive to a single cell type, as may be true of cloned, transformed, cell lines; (3) differential distributions of cell types and receptor-mediated responses may be obtained by culturing selected regions of the brain.

Quinuclidinyl benzilate (QNB) and N-methylscopolamine (NMS) bind to these intact neurons in a saturable manner and with high affinity. The values for Bmax and K_D for [^{3}H]QNB are 450 fmol/mg protein and 210 pM; as in many other studies, [^{3}H]NMS has been found to label significantly fewer sites (150 fmol/mg protein, K_D=70 pM). The difference in Bmax between [^{3}H]QNB and [^{3}H]NMS is not likely to be due to uptake or sequestration, because similar values have been obtained from binding assays performed on membranes derived from these cells. In the presence of lithium, carbachol produces a dose-dependent (EC_{50}, 80μM) increase in the accumulation of [^{3}H]inositol monophosphate (IP) in neurons that have been prelabeled with [^{3}H]inositol. At 0.3mM lithium, 1mM carbachol yields greater than 10-fold elevation of IP levels; the presence of 1 μM atropine abolishes this elevation. In identical preparations, carbachol inhibits the accumulation of cyclic AMP (EC_{50}, 0.5 μM). At a concentration of 10 μM, carbachol inhibits about 70% of the stimulation of cyclic AMP accumulation that is produced by the D-1 dopamine agonist SKF 38393 (1 μM). This effect of 10 μM carbachol is reversed by atropine (IC_{50}, 70 nM). Carbachol also reduces basal levels of cyclic AMP by 20%, but has not been found to reduce the elevation of cyclic AMP levels that is induced by forskolin or isoproterenol.

We have also been able to identify cell types immunocytochemically, according to neurotransmitter, and to autoradiographically label muscarinic receptors on the same neurons. It is expected that future studies of this model system will contribute to identifying which subtypes of muscarinic receptors are associated with given cell types, second messengers, and cellular responses such as the regulation of neurotransmitter release.

Supported by PHS R01 AG05214, PHS R01 MH41571, NSF-VT EPSCoR Project 5, and an MRC of Canada fellowship to S.W.

135.11 Facilitatory and disfacilitatory actions of acetylcholine in the rat hippocampus may be mediated by M 1 muscarinic receptors. Yanguo Hong* and Kresimir Krnjević, (SPON: D. Watt) Departments of Anaesthesia Research and Physiology McGill University, 3655 Drummond St., Montreal, Que., H3G 1Y6 Canada

In rats under urethane anaesthesia, several cholinergic agonists and antagonists were iontophoretically released in the pyramidal layer and in the apical dendrites of area CA1 (in fewer cases in CA3). The somatic population spike (P.S.) and the dendritic negative field (field EPSP) were evoked by fimbrial and/or commissural stimulation (3.5-6 V, 0.2 ms, 0.7 Hz). Cholinomimetics applied included acetylcholine (ACh), acetyl-B-methylcholine (MeCh), oxotremorine, diphenylpiperazinium iodide (DMPP) and tetramethylammonium hydroxide (TMA).

Local ejection of pirenzepine (PRZ) strongly depressed or fully blocked the effects of muscarinic agents on responses to fimbrial stimulation, but had little or no effect on the action of DMPP when they were applied at the same site. Conversely, local applications of curare antagonized the effect of DMPP and TMA without significantly affecting the action of MeCh. At the somatic level, PRZ depressed the facilitatory action of MeCh, ACh and oxotremorine by 67.6 + 18.6% (Mean + SD n=14), 76.5 + 25.6% (n=47), 85.4 + 18.0% (n=14) respectively. At the apical dendritic level, PRZ reduced the effects of Ach by 70.0 + 19.3% in 14 tests. These results were compared with those of atropine. There was no statistically significant difference between PRZ and atropine in respect of their depressant efficancy (76.5 + 25.6%, n=47; 81 + 24%, n=31, respectively), suggesting that the muscarinic receptors involved in chrolinergic facilitation of population spike in the pyramidal layer as well as those responsible for disfacilitation at the dendritic area belong to the M 1 subtype.

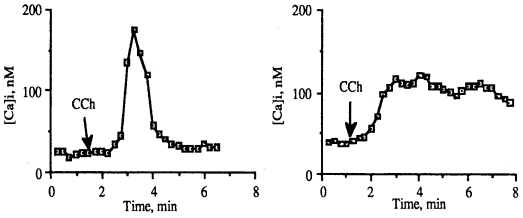
135.12 CARBACHOL INCREASES CYTOPLASMIC FREE CALCIUM IN RAT BRAIN CORTICAL CELLS VIA MUSCARINIC RECEPTORS. LJ. Reynolds, G.S. Shangold*, E. Lee* and R.J.Miller. Dept. Pharmacol. and Physiol. Sci., Univ. Chicago, Chicago IL 60637.

Many studies have demonstrated that muscarinic agonists can increase the metabolism of polyphosphoinositides. Generation of inositol triphosphate and inositol tetrakisphosphate is believed to be coupled to the increase of intracellular free calcium ([Ca^{2+}]i) by release from intracellular stores or by opening of a membrane channel. However this process has not been demonstrated directly in neurons. We have measured [Ca^{2+}]i in single cells in monolayer cultures of fetal rat cortex using the calcium sensitive dye fura-2.

Cortical cells were taken from embryonic day 18 rat fetuses and grown in vitro for 14 days. At this age the cells have muscarinic receptors demonstrated by [^{3}H] QNB binding (kD 50pM, Bmax 338fmoles/mg protein). Addition of 100uM carbachol to cortical cells produced a rise in[Ca^{2+}]i in approximately 50% of the cells examined. The average peak response seen was an increase of 77nM above baseline. Broadly, the responses could be equally divided into two types; a fast transient response and a slower more sustained response. Typical responses from single cells are shown below.



In the presence of atropine (1mM) the frequency of response to carbachol diminished to about 10% , while the response was not altered in the presence of hexamethonium (100mM). This suggests that the response was mediated by muscarinic acetylcholine receptors. This conclusion is supported by the observation that oxotremorine produced similar responses. Similar results have also been obtained in cultures of striatal cells.

We have demonstrated that muscarinic receptors in cultures of rat brain cortex can produce a rise in [Ca^{2+}]i. The source of the Ca^{2+}that produces the rise is not clear at this time and may originate from release of intracellular stores or from entry following cell depolarization. Possible mechanisms are currently under investigation.

135.13 THE AFFINITY RATIO FOR ANTAGONIST AND AGONIST LABELED BINDING SITES PREDICTS MUSCARINIC RECEPTOR AGONIST/ANTAGONIST ACTION IN CENTRAL AND PERIPHERAL TISSUES. L.L. Coughenour*, W.G. Berghoff*, S.L. Myers*, R.D. Schwarz, W.H. Moos, and R.E. Davis (SPON: R.F. Bruns). Warner-Lambert/Parke-Davis, Pharmaceutical Research, Ann Arbor, MI 48105.

Numerous studies have shown that muscarinic agonists bind to multiple affinity states of the muscarinic receptor. In contrast classical muscarinic antagonists usually detect only a single affinity state of the receptor. Using a rapid filtration assay (Vickroy et al. JPET 229, 1984), we have selectively labeled the high affinity state of the muscarinic receptor with [^{3}H]cismethyldioxolane (CMD) and the antagonist state of the receptor with [^{3}H]quinuclidinyl benzilate (QNB) and determined the antagonist/agonist affinity ratio (QNB/CMD ratio) in these two assays for a number of cholinergic agents.

The QNB/CMD ratio was about 1000 or greater for efficacious agonists such as carbachol, muscarine, oxa-22, and cismethyldioxolane. It was markedly lower for partial agonists, such as pilocarpine, BM-5, RS-86 and AF-30 and approached one for antagonists such as atropine, scopolamine, pirenzepine and AF-DX-116. The QNB/CMD ratio was correlated with agonist efficacy in decreasing the release of [^{3}H]acetylcholine and in stimulating phosphatidylinositol turnover in vitro and the ability to reverse scopolamine induced swimming activity in vivo (R.D. Schwarz et al., this meeting).

The M1 selective agonists, McN-A-343 and pilocarpine, could be distinguished by their higher affinity for [^{3}H]CMD binding in the cortex (M1) compared to [^{3}H]CMD binding in the heart (M2) but not by [^{3}H]QNB binding in the cortex and heart. On the other hand, the M1 selective antagonists, pirenzepine and trihexyphenidyl, could be distinguished using [^{3}H]QNB binding in the cortex and heart but not by [^{3}H]CMD binding.

Various classes of compounds including acetylcholinesterase inhibitors (AChEI) have been reported to perturb binding to the muscarinic receptor. There were differences among the binding interactions of AChEIs. Physostigmine and miotine exhibited high affinity for CMD binding and QNB/CMD ratios like those of muscarinic agonists. Ambenonium exhibited high affinity for both CMD and QNB binding and a QNB/CMD ratio like that of a muscarinic antagonist. In contrast tacrine did not exhibit high affinity for either CMD or QNB binding. Since all of these are about equipotent as AChEIs (R. Davis et al., this meeting), these findings suggest that interactions of these agents with the muscarinic receptor may not be related to their acetylcholinesterase inhibition. In conclusion the QNB/CMD ratio in these two assays appears to predict the agonist efficacy of the agent.

135.14 EFFICACY AT CENTRAL MUSCARINIC RECEPTORS: CORRELATION OF RECEPTOR BINDING WITH PHOSPHATIDYLINOSITOL TURNOVER, ^{3}H-ACETYLCHOLINE RELEASE, AND IN VIVO BEHAVIORAL ACTIVITY. R.D. Schwarz, L.L. Coughenour, R.E. Davis, W.H. Moos, and C.J. Spencer*. Warner-Lambert/Parke-Davis, Pharmaceutical Research, Ann Arbor, MI 48105.

Muscarinic agonists (e.g. arecoline, oxotremorine) have been shown in both humans and rodents to produce significant positive effects on cerebral activity while muscarinic antagonists (e.g. scopolamine, atropine) decrease cognitive function. These findings gain importance with the recent observations that marked cholinergic dysfunction occurs in age-related memory disorders such as senile dementia of the Alzheimer type (SDAT). Greater understanding of molecular events at central muscarinic receptors and their relationship to in vivo behavioral activity will aid in the development of more efficacious cholinergic agents useful in the treatment of age-related memory disorders.

In a series of binding experiments it was found that muscarinic agonists showed higher affinity for sites labeled by the agonist ^{3}H-cis-methyldioxolane (CMD) than those labeled by the antagonist ^{3}H-quinuclidinyl benzilate (QNB), while antagonists displayed equal affinity for both sites. Calculation of the QNB/CMD ratio for agonists extended from 5500 (carbachol) to 100 (RS-86), whereas antagonists produced ratios of 1.0. Compounds having a mixed profile, such as BM-5, had ratios between 1-100 (L.L. Coughenour et al., this meeting). As a measure of muscarinic postsynaptic activity, the stimulation of phosphatidylinositol (PI) turnover was determined in rat cortical slices. Full agonists such as carbachol, muscarine, and CMD produced maximal stimulation while all other agonists displayed partial activity. Muscarinic presynaptic activity was assessed by measuring K^+-stimulated ^{3}H-ACh release from rat cortical slices. While a maximal inhibition of 45-50% was observed for any agonist tested, in general as the QNB/CMD ratio decreased, the amount of inhibition was also reduced. The ability to reverse scopolamine-induced swimming (SIS) activity was used as an index of in vivo cholinomimetic activity. Of those compounds which are centrally available upon systemic injection, SIS activity was also predicted by the QNB/CMD ratio. The greater the ratio, the greater the ability to reverse scopolamine.

In conclusion, the ratio of QNB/CMD binding may be used as a predictor of efficacy at central muscarinic receptors as defined both in vitro and in vivo.

135.15 EVALUATION OF THE CENTRAL PHARMACOLOGY OF TACRINE (TETRAHYDROAMINOACRIDINE: THA). R. E. Davis, L. L. Coughenour*, E. Gamzu, W. H. Moos and R. D. Schwarz, Pharmaceutical Research, Warner-Lambert/Parke-Davis, Ann Arbor, MI 48105.

Within restricted dose ranges cholinomimetics can improve learning and memory in animals. In addition, senile dementia of the Alzheimer's type (SDAT) in man is associated with forebrain cholinergic hypofunction and the cholinesterase inhibitors, physostigmine and tacrine, may ameliorate the cognitive deficits accompanying senile dementia. Because of the recent claims of dramatic improvement in cognitive performance of SDAT patients after tacrine, we reevaluated the 'in vitro' and 'in vivo' pharmacology of tacrine in comparison to other known cholinesterase inhibitors.

As a cholinesterase inhibitor tacrine was equipotent to physostigmine and miotine (3-(1-dimethylaminoethyl)-phenyl-N-methylcarbamate). All three also decreased K+-stimulated release of acetylcholine from cortical slices. However, unlike physostigmine and miotine, tacrine did not bind to muscarinic sites labelled by [3H]-cis-methyldioxolane (L. L. Coughenour, this meeting). These compounds reverse scopolamine-induced swimming activity in rats, demonstrating 'in vivo' cholinomimetic activity. The onset of this effect was rapid for physostigmine and miotine (< 15 min) but was delayed for tacrine (2 hr). Both tacrine and physostigmine improved the performance of hippocampally-deficient, C57/B10jsnc mice in a water maze but with extremely steep dose effect curves. In the water maze, effective doses were only slightly below toxic doses. Neither tacrine nor physostigmine improved delayed response performance of aged-rhesus monkeys. These cholinesterase inhibitors also increased local cortical blood flow in rats through a central cholinergic mechanism.

These data demonstrate that tacrine is a potent cholinomimetic 'in vitro' and 'in vivo' working through inhibition of acetylcholinesterase. It has a much longer duration of action than physostigmine and miotine in rats.

135.16 NEUROTOXIN (AF64A) MODEL OF CHOLINERGIC HYPOFUNCTION: AN IMPROVED SYNTHETIC PROCEDURE FOR AF64A. C.J. Spencer*, W.H. Moos, R.E. Davis, R.D. Schwarz, J. Kinsora*, M.E. Smith* (SPON: J. Symons). Departments of Chemistry and Pharmacology, Warner-Lambert/Parke-Davis, Pharmaceutical Research, 2800 Plymouth Road, Ann Arbor, MI 48105.

The cholinergic deficit that accompanies aging and dementia has prompted a search for appropriate preclinical models of cholinergic hypofunction. One model that has received particular attention involves the use of aziridinium salts such as AF64A (1-ethyl-1-(2-hydroxyethyl)aziridinium). In an effort to both simplify and improve the reproducibility of the AF64A model, we have developed a new and straightforward synthetic procedure using stoichiometric base.

Within 45 min of its preparation, AF64A was injected bilaterally into the lateral cerebral ventricles (ICV) of male Long-Evans rats (3 nmoles/side, 1 nmole/ul over 15 min). An additional group received ICV injections of 0.9% saline vehicle. Five weeks later, these rats were tested in a hidden platform water maze task. An additional group of rats previously trained on a discrete trial delayed alternation task received similar AF64A or vehicle ICV injections. One week later, these animals were retested and if necessary retrained on the delayed alternation task. To biochemically assess the lesions, cholineacetyltransferase (ChAT) activity then was determined by the method of Fonnum (J. Neurochem 24: 407, 1975) in the corpus striatum, hippocampus and cerebral cortex from all rats, some at 6 weeks, others at 6 months after injection.

AF64A reduced hippocampal but not cortical or striatal ChAT activity. Hippocampal ChAT activity was inversely related to the latency in the water maze task with latencies increasing with decreasing ChAT activity. AF64A lesioned rats also were impaired on the delayed alternation task.

The behavioral and biochemical observations thus confirm the effectiveness of the lesions produced by the AF64A synthesized by this improved procedure.

135.17 **CENTRAL MUSCARINIC PHARMACOLOGY OF A SERIES OF ARECAIDINE ESTERS.** W.H. Moos, L.L. Coughenour, R.E. Davis, C.C. Humblet*, and R.D. Schwarz. Warner-Lambert/Parke-Davis Pharmaceutical Research, Ann Arbor, MI 48105.

It is now well established that the muscarinic receptor agonist arecoline (arecaidine methyl ester) can improve learning and memory in animals within restricted dose ranges. These findings gain additional importance from evidence that senile dementia is associated with forebrain cholinergic hypofunction. Despite this association, clinical trials with muscarinic agonists have yet to produce unequivocal, clinically relevant improvement in the symptoms accompanying senile cognitive decline. Limitations of arecoline in treating human cognitive dysfunction arise largely from pharmacokinetic liabilities such as a short duration of action. As a preliminary step toward developing more suitable agents for treating senile dementia, we have studied the central cholinergic pharmacology of a series of arecaidine esters whose cholinomimetic activity in cardiac and smooth muscle preparations is known.

Using the finding that known muscarinic receptor agonists exhibit higher affinities for sites labeled by the quaternary muscarinic receptor agonist [^{3}H]-cis-methyldioxolane (CMD) than for sites labelled by the quaternary muscarinic receptor antagonist [^{3}H]-quinuclidinyl benzilate (QNB) (Schwarz, et al., 1987), relative affinities (ratio of binding affinities (QNB/CMD)) of compounds from this series were determined for rat cerebral cortical muscarinic sites. Muscarinic receptor agonists decrease potassium-stimulated release of acetylcholine from cortical slices (NTRA), stimulate phosphatidylinositol turnover (PIT), and reverse scopolamine-induced increases in swimming activity (SIS). Agonist activity in NTRA, PIT, and SIS was reduced as the QNB/CMD ratio decreased.

Arecoline and arecaidine esters with electron-donor moieties (e.g., propargyl and butynyl esters) displayed potent agonist-like activity in NTRA, PIT, and SIS, as predicted by the QNB/CMD ratio. Increasing the size of the ester group, however, generally decreased agonist-like activity in this series. Meaningful correlations amongst biological data and physicochemical properties were observed.

These data demonstrate the QNB/CMD ratio in this series of arecaidine esters to be predictive of both in vitro and in vivo central muscarinic cholinergic activity.

DOPAMINE RECEPTOR FUNCTIONS

136.1 OPPOSING ACTIONS OF D-1 AND D-2 DOPAMINE RECEPTORS ON cAMP FORMATION DURING NEURONAL DOPAMINE RELEASE: THE PREDOMINANCE OF D-1 RECEPTOR ACTIVATION. A.J. Azzaro, J. Liccione and J. Lucci* Departments of Neurology, Pharmacology/Toxicology and Psychiatry, West Virginia University Medical Center, Morgantown, WV 26506.

The results of many studies have provided strong evidence for a functional interaction between D-1 and D-2 dopamine (DA) receptors in brain tissue. At the molecular level, activation of D-1 or D-2 DA receptors (with selective DA receptor agonists) leads to opposing actions on the formation of cAMP. Evidence that such interactions between D-1 and D-2 receptors occur under conditions of neurotransmitter release are presented here in studies with d-amphetamine (AMPH) in rat striatal brain slices. AMPH (0.1uM to 20uM), an agent which releases newly-synthesized DA from DA nerve terminals, stimulated the formation of cAMP in a concentration-dependent manner. This action of AMPH was related to the release of the endogenous DA since experiments performed in the presence of 3-iodotyrosine (an inhibitor of DA synthesis) + reserpine (an inhibitor of DA storage) failed to demonstrate a change in cAMP formation at all concentrations of AMPH.

To examine the nature of this DA mediated response, a variety of DA, norepinephrine and serotonin receptor antagonists were examined. Only the D-1 (Sch 23390) or D-2 (sulpiride) DA receptor antagonist were able to alter the AMPH-induced change of cAMP formation. Sch 23390 (10uM) completely abolished while (-)sulpiride (10uM) potentiated (2 fold) the actions of 20uM AMPH on cAMP formation.

The relationship between the amount of DA released and the change in cAMP formation seen after AMPH was examined by simultaneous assay of DA and cAMP in superfusates of striatal brain slices. A strong correlation was observed between the increase in DA release, by each concentration of AMPH, and the stimulation of cAMP formation. Moreover, when synaptic catabolism of DA was inhibited with 0.1uM clorgyline (a selective type A MAO inhibitor), the larger concentration of synaptic DA was reflected in an enhanced stimulation of cAMP formation by AMPH.

Superfusion experiments were performed in the presence and absence of 50uM (-)sulpiride in order to determine the role of each DA receptor subtype in the formaton of cAMP. At each concentration of AMPH, (-)sulpiride significantly potentiated cAMP formation but was without effect on DA release. With increasing concentrations of AMPH, the inhibitory role of D-2 receptors on cAMP formations rose from 10% at 5uM AMPH to 30% at 20uM AMPH.

These experiments demonstrate that opposing actions of D-1 and D-2 receptors are seen under conditions where DA is released from DA nerve terminals. However, D-1 induced activation always greatly exceeded D-2 induced inhibition of cAMP formation, suggesting a modulator role for D-2 DA receptors in this striatal second messenger system. (Supported by WVU. Corp. & F.O.E.)

136.2 EFFECTS OF CHRONIC DOPAMINE RECEPTOR ANTAGONIST TREATMENT ON THE BEHAVIORAL AND BIOCHEMICAL PROPERTIES OF D_1 AND D_2 DOPAMINE RECEPTORS. Ellen J. Hess*, Andrew B. Norman*, Diane Swick* and Ian Creese, Dept. of Neuroscience, UCSD School of Medicine, La Jolla, CA 92093.

We have investigated the effects of chronic dopamine receptor antagonist treatment on the behavioral and pharmacologic properties of D_1 and D_2 dopamine receptors. Rats were treated with 0.5 mg/kg/day SCH23390, 0.2 mg/kg/day spiperone, 1 mg/kg/day cis-flupentixol, or 0.5 mg/kg/day SCH23390 plus 0.2 mg/kg/day spiperone for 21 days. During the treatment, rats were tested for the cataleptic response to their administered drug. Chronic treatment with SCH23390 resulted in a significant increase (16%) in D_1 receptors, labeled by [^{3}H]SCH-23390, but no change in D_2 receptors, labeled by [^{3}H]spiperone, was observed. Conversely, treatment with spiperone resulted in no significant change in D_1 receptors while D_2 receptors were significantly increased (24%). Paradoxically, chronic treatment with the mixed D_1/D_2 receptor antagonist cis-flupentixol resulted in a significant increase in only D_2 receptors (24%) with no change observed in D_1 receptors. Treatment with SCH23390 plus spiperone resulted in a significant increase in both D_1 (19%) and D_2 (32%) receptors. Thus, under these conditions, simultaneous D_1 and D_2 receptor antagonism did not appear to modulate D_1 receptor regulation, as one might hypothesize from the results of chronic cis-flupentixol treatment. In fact, our studies utilizing in vivo cis-flupentixol administration followed by in vivo EEDQ treatment demonstrate that cis-flupentixol preferentially interacts with D_2 receptors in vivo.

Catalepsy scores for rats chronically treated with spiperone decreased over the course of treatment with a significant reduction in catalepsy scores occurring by day 5. Rats receiving chronic administration of SCH23390 for 21 days demonstrated no tolerance to its potent cataleptogenic action. Rats receiving chronic cis-flupentixol demonstrated no tolerance to its cataleptogenic action two hours post-injection. However, the pattern of catalepsy observed over the two hour catalepsy scoring session changed over the duration of treatment; in the first 80 min of the scoring session, the animals appeared to become progressively tolerant to the cataleptogenic effects of cis-flupentixol. Those rats receiving SCH23390 plus spiperone demonstrated no tolerance to the cataleptogenic effects of these drugs. Rats treated with SCH23390 for 21 days and then administered an acute injection of spiperone on day 22 demonstrated tolerance to the cataleptic effects of spiperone. Conversely, rats challenged with an acute dose of SCH23390 after 21 day spiperone treatment were profoundly cataleptic. Thus, although there is a reciprocal interaction between D_1 and D_2 receptors, apparently behavioral tolerance may only occur through D_2 receptors. Additionally, it appears that D_2 receptor upregulation is not a prerequisite for the development of tolerance to neuroleptic-induced catalepsy. Supported by MH32990,MH09535 & Scottish Rite Schizophrenia Res. Prog

136.3 BEHAVIORAL EFFECTS OF CHRONIC EXPOSURE TO SELECTIVE D-1 AND D-2 DOPAMINE RECEPTOR ANTAGONISTS AND AGONISTS ADMININSTERED ALONE AND IN COMBINATION A.R. Braun*, M.M. Mouradian* and T.N. Chase (SPON: H. Weinstein) Experimental Therapeutics Branch, NINCDS, NIH, Bethesda MD 20892

Dopamine receptor antagonists alter spontaneous motor activity, catalepsy and behavioral responses to apomorphine when they are administered chronically. In order to identify the roles played by D-1 and D-2 dopamine receptors in the generation of such effects, experiments were performed utilizing the selective D-1 receptor antagonist SCH-23390 and agonist SKF-38393 and the selective D-2 receptor antagonist metoclopramide and agonist LY-171555.

Six groups of ten male Sprague Dawley rats were injected i.p. twice daily for 28 days with one of the following regimens: SCH-23390 1 mg/kg; metoclopramide 20 mg/kg; SCH-23390 plus metoclopramide; SCH-23390 plus LY-171555 1.5 mg/kg; metoclopramide plus SKF-38393 8 mg/kg; or saline. Spontaneous motor activity was rated blindly on a scale of 0-3, 18 hours after the first and last drug treatment. Catalepsy was assessed by measuring the time animals remained suspended by all four paws on a wire grid, 45 minutes following the first and last treatment. Stereotypic behavior elicited by 675 mg/kg apomorphine s.c. was rated using a modified Ernst scale prior to chronic treatment and after a 72 hour drug-free interval which followed the last injection.

Spontaneous motor activity did not differ from that observed in saline treated controls 18 hours following the initial dose of any drug combination. Following chronic treatment, however, activity was significantly reduced in animals that had received either the D-2 antagonist metoclopramide alone or metoclopramide plus SKF-38393 and was significantly increased in animals that had received the D-1 antagonist SCH-23390.

Acute treatment with all drug combinations produced elevated catalepsy scores which did not significantly differ from one another except for the group which received both SCH-23390 and metoclopramide, in which scores were on the average 350% higher. All animals showed habituation of the cataleptic response following chronic treatment except those receiving SCH-23390 plus metoclopramide or metoclopramide plus SKF-38393.

Chronic treatment with either metoclopramide or SCH-23390 alone resulted in a supersensitive behavioral response to subsequent apomorphine challenge (Ernst scores were 213% and 198% of saline controls, respectively). Chronic treatment with both selective antagonists produced a significantly greater response (325% of control animals). The induction of behavioral supersensitivity by either selective antagonist, however, was blocked by concurrent treatment with the complementary receptor agonist: scores in animals treated with SCH-23390 plus LY-171555 or metoclopramide plus SKF-38393 did not significantly differ from those of control animals.

Evaluation of spontaneous motor activity suggests distinct and opposing effects of chronic D-1 and D-2 receptor blockade. Results of all three behavioral experiments illustrate a complex synergistic interaction between D-1 and D-2 receptor subtypes in the generation of chronic behavioral effects in the intact rat.

136.4 **DOPAMINERGIC RECEPTORS IN YOUNG CHICKENS.**

G.Delbarre, B.Delbarre, V.Bernard* and L.Gauvin*.
Faculté de Médecine, 37000 Tours, FRANCE

Apomorphine (0,05 -0,5 mg.kg-1 I.M) induced in young chickens a compulsive type of behavior pecking which could be easily quantified. Pecking was dose dependant. Other dopaminergic agonists have been studied. D1 agonist bromocriptine (1-4mg.kg-1) induces pecking. D2 agonist Lylli 171555 (1-10 mg.kg-1) is ineffective. Amphétamine (1-10 mg.kg-1) and amantidine (1-10 mg.kg-1 I.M), which release dopamine , are ineffective . Pecking response to apomorphine (0,25 mg.kg-1 I.M) was antagonised by the neuroleptic agents pimozide (1 mg .kg-1) and spipérone (1 mg.kg-1), by the sympathomimetic agents clonidine (0,3 mg.kg-1) and clenbuterol (2 mg.kg-1), by the alpha-adrenoceptor blocking agent yohimbine (2 mg.kg-1), by the ß adrenoceptor blocking agent propranolol (5 mg.kg-1) and by the antiserotoninergic agent methysergide (1mg.kg-1).

Methylphenidate (12 mg.kg-1), imipramine (12 mg.kg-1) but not amitriptyline (1-12 mg.kg-1) induce a very strong pecking .

This model specific for D1 agonists allows to study dopamine receptors D1 involved in the release of other neurotransmitters

136.5 DO D-1/D-2 RECEPTOR INTERACTIONS OCCUR DIRECTLY IN THE SUBSTANTIA NIGRA PARS RETICULATA? B.G.Weick and J.R.Walters. Experimental Therapeutics Branch, NINCDS, Bethesda, MD 20892.

Recent behavioral and neurophysiological studies have suggested that concurrent stimulation of D-1 and D-2 receptors is necessary for the expression of apomorphine-like postsynaptic effects in the rat; the two dopamine (DA) receptor subtypes appear to interact in a synergistic way to affect basal ganglia output[1-4]. To gain insight into where the interacting receptors may be located, we have explored the possibility that D-1 and D-2 receptors within the substantia nigra pars reticulata (SNpr) might be involved in mediating the synergistic effects induced by coadministration of D-1 and D-2 receptor selective DA agonists on SNpr neurons.

D-1 and D-2 agonists were co-iontophoresed onto cells in the SNpr and their ability to affect the firing rates of these neurons was determined in conjunction with their ability to attenuate the inhibitory effects of GABA. Previous studies have shown that iontophoresis of DA in both the globus pallidus and the SNpr results in a modest increase in the activity of pallidal and SNpr neurons, and, more consistently, effectively attenuates the inhibitory effects of GABA in these brain regions[5-6]. The D-2 selective agonist quinpirole produced modest increases in SNpr firing rate in chloral hydrate anesthetized rats and attenuated the inhibitory effects of GABA iontophoresis. These effects did not appear dependent on the presence of endogenous DA providing simultaneous D-1 receptor stimulation since they were not attenuated in animals pretreated with alpha-methyl-para-tyrosine; thus they did not appear to involve D-1/D-2 receptor interactions. Both the selective D-1 agonist R-SKF 38393 and the selective D-1 agonist R-fenoldopam (R-SKF 82526) produced increases in firing rate in approximately 85% of neurons tested. With increasing currents, both R- and RS-SKF 38393 induced complete diminution of spike amplitude in 85% of reticulata neurons examined (n=13). Both R-fenoldopam and R-SKF 38393 also attenuated the effects of GABA in 50% of the cells recorded. However, none of these effects were potentiated by co-iontophoresis of quinpirole. Moreover, the mechanism underlying these effects is unclear: in 66% of the cells recorded (n=15), the D-1 inactive enantiomer, S-SKF 38393, also produced increases in firing rate that preceded complete diminution of spike amplitude and produced significant attenuation of the effects of GABA in 41% of neurons (n=17). The effects of the R-and S-enantiomers of SKF 38393 on spike amplitude and GABA mediated inhibition occurred at similar currents for both enantiomers in all neurons in which both enantiomers were tested (n=5).

These results do not support the idea that local interactions of D-1 and D-2 receptors in the SNpr are involved in mediating the potentiated responses in SNpr activity observed with systemic coadministration of D-1 and D-2 dopamine agonists.

[1]Braun and Chase, Soc. Neurosci. Abstr. 11:671, 1985. [2]Carlson et al., Brain Res. 400: 205, 1987. [3]Weick and Walters, Brain Res. 405: 234 1987. [4]Walters et al, Science, in press. [5]Waszczak and Walters, Science 220: 218, 1983. [6]Bergstrom and Walters, Brain Res. 310: 23, 1984.

136.6 APOMORPHINE'S EFFECTS ON THE ACTIVITY OF GLOBUS PALLIDUS NEURONS ARE RELATED TO ROTATIONAL BEHAVIOR IN RATS WITH UNILATERAL QUINOLINIC ACID LESION OF THE STRIATUM. H.S. Pan, D.A. Bergstrom, J.H. Carlson, T.M. Engber, T.N. Chase and J.R. Walters. NINCDS, Bethesda, MD 20892.

Doses of postsynaptically active apomorphine (APO) which cause behavioral activation in rats also induce marked increases in firing rates of neurons in the globus pallidus (GP). GP receives a sparse but widespread direct dopamine (DA) input from substantia nigra pars compacta as well as an extensive indirectly mediated DAergic influence via the striatopallidal pathway. The relative importance of the direct versus the indirect DAergic influence on GP is not known. It is also unclear to what extent the electrophysiological changes in GP and any of the behavioral phenomena induced by APO are related. To examine these issues, we studied APO's effects on GP neuronal firing rate and rotational response to APO after unilateral quinolinic acid lesion of the striatum.

Male Sprague-Dawley rats (300 g) received an injection of quinolinic acid (300 nmol/0.5 ul/min) in the left striatum. After 1 week of recovery, rotational behavior induced by APO (0.5 mg/kg, s.c.) was measured in a rotometer for 1 hour. One week after the behavioral testing, extracellular single unit recording techniques were used to study the effects of APO (0.3 mg/kg, i.v.) on GP cell firing rates in locally anesthetized, gallamine treated and artificially respired rats. Only rats with histologically confirmed recording sites and lesions affecting at least the rostral half of the striatum with minimal involvement of the cortex and GP were used in the data analyses.

Lesioned animals were divided into two groups on the basis of turning response to APO administration; nonturners were those which rotated less than 60 turns/hr (mean ± SEM: 13.3 ± 3.8 turns/hr, n=14), and turners were those rotating more than 60 turns/hr (mean ± SEM: 113.6 ± 14.8 turns/hr, n=12). In control nonlesioned rats, APO induced firing rate increases of at least 20% baseline in 27 of 30 (90%) cells, yielding an average increase of 93 ± 9%. In nonturners, APO induced increases in firing in 11 of 14 (79%) GP cells, yielding an average increase of 63 ± 17%. In contrast, in turners, only 4 of 12 (33%) GP cells showed firing rate increases of more than 20% baseline and 3 of 12 (25%) cells showed decreases of more than 20% baseline with APO administration. The overall rate change induced by APO in turners was an increase of 10 ± 19% over baseline, an effect which was significantly different from that of both controls and nonturners.

These results indicate that unilateral lesions involving the rostral half of the striatum can cause changes in both behavioral and GP electrophysiological responses to APO. The appearance of rotational behavior seems related to an altered pharmacological response of GP cells to APO in turners. The absence of rotational response in nonturners appears related to increased GP cell firing, as seen in normal rats. The data suggest that the influence of DA via the striatum plays a more important role than the direct nigropallidal DA input in mediating DA and DA agonists' effects on GP neuron activity.

136.7 EVIDENCE FOR DOPAMINE D-1 RECEPTOR RESERVE IN RAT STRIATUM AND SUBSTANTIA NIGRA. M.S. Ackerman*, L.D. Artman*, R.G. MacKenzie and J.W. Kebabian. Abbott Laboratories, Abbott Park, IL 60064.

The presence of receptor reserve or "spare" receptors in a system means that a maximal response can be evoked by a full agonist at submaximal receptor occupancy. The maximal response of a partial agonist, however, is only achieved at full receptor occupancy and is thereby limited by receptor number (Ruffolo, R.R. J. Auton. Pharmacol. 2:277, 1982). Therefore, in systems with receptor reserve, reducing receptor number should have a greater impact on the maximal response evoked by a partial rather than a full agonist. Results from a recent study based on the above approach suggest the existence of a dopamine D-1 receptor reserve in rat striatum (Hess, E.J. et al. Mol. Pharmacol. 31:50, 1987). In the present study, we compare the effects of reducing D-1 receptors on the maximal stimulation of adenylate cyclase by a partial and a full agonist in rat striatum and substantia nigra.

Rats were injected i.p. with 3 mg/kg of the irreversible receptor antagonist N-ethoxycarbonyl-2-ethoxy-1,2-dihyroquinoline (EEDQ), sacrificed the following day, and the striata and nigra were removed and frozen. Adenylate cyclase activity and D-1 binding parameters were measured in the same tissue homogenates. In the striatum, EEDQ reduced B_{max} by 51% whereas maximally stimulated adenylate cylase by dopamine (a full agonist) was reduced by 19% and the maximal effect of SKF-38393 (a partial agonist) was reduced by 31%. In the substantia nigra, B_{max} was reduced by 36% and the maximal effects of dopamine and SKF-38393 on cyclase were reduced by 35% and 64%, respectively. In both tissues, EEDQ treatment had no effect on basal or forskolin-stimulated cyclase or D-1 receptor affinity, indicating that the effects of the treatment were confined to reductions in receptor number. We suggest that these results are consistent with the existence of a D-1 receptor reserve in both striatum and substantia nigra and that this reserve might be greater in the striatum.

136.8 DOPAMINE AUTORECEPTOR RESERVE ON SUBSTANTIA NIGRA DOPAMINE NEURONS CAN MASK PARTIAL AGONIST PROPERTIES OF PUTATIVE AUTORECEPTOR AGONISTS. D.A. Bergstrom, J.H. Carlson, H.S. Pan and J.R. Walters. NIH, NINCDS, Bethesda, MD 20892 and Univ. of Calif. San Diego, La Jolla, CA 92093.

Studies have suggested that pharmacologically exploitable differences exist between dopamine (DA) autoreceptors and postsynaptic DA receptors in the CNS. Indeed, certain drugs appear selective for DA autoreceptors. A more substantial DA receptor reserve at the presynaptic site would tend to increase relative autoreceptor agonist potency and efficacy and might explain these findings.

In the present neurophysiological study, the effects of 2 putatively selective DA autoreceptor agonists, BHT 920 and EMD 38362, on DA autoreceptors and postsynaptic DA receptors were compared with those of the nonselective DA agonist apomorphine (APO) in normal rats and in rats pretreated with the irreversible receptor inactivating agent EEDQ to decrease DA receptor number. Extracellular single unit activities of substantia nigra DA neurons and globus pallidus (GP) neurons provided indices of pre- and postsynaptically mediated DA receptor effects, respectively. Drugs were administered intravenously. Like APO, BHT 920 and EMD 38362 were effective agonists at DA autoreceptors, producing haloperidol-reversible inhibitions of DA cell firing. Maximal inhibitions (99-100%) of DA cell activity were observed with doses of 160 ug/kg APO and 40 ug/kg BHT 920 or less; ED_{50}s for APO and BHT 920 were 6.3±1.6 (n=13) and 2.3±0.5 (n=16) ug/kg, respectively. EMD 38362 was slightly less effective with an ED_{50} of 13.8± 4.6 ug/kg (n=12) and typically inhibited activity 95-100% with doses of 80 ug/kg or less. In the GP, BHT 920 and EMD 38362 were not as effective as APO in increasing neuronal firing rates. Maximal firing rate increases of 93±9% (n=30), 54±10% (n=22) and 25±14% (n=17) were induced by 0.3 mg/kg APO, 2.8 mg/kg BHT 920 and 0.4 mg/kg EMD 38362, respectively. EMD 38362, but not BHT 920, antagonized the effects of APO on GP cell activity.

In rats treated with EEDQ (6 mg/kg, i.p.) 24 hr. prior to recording, the dose-response curve for APO on DA cells was not significantly shifted (ED_{50}=11.6±2.9 ug/kg, n=8) and maximal inhibition of DA cell firing was still observed. In contrast, the dose-response curves for BHT 920 and EMD 38362 were shifted to the right by EEDQ pretreatment. Moreover, the activities of fewer neurons were completely inhibited by these drugs and thus, the maximal inhibitions induced by BHT 920 (92%, n=10) and EMD 38362 (77%, n=6) were significantly less than those in control rats. In the GP, pretreatment with this dose of EEDQ markedly attenuated the rate-increasing effects of APO; an average increase in pallidal neuron activity of 35±14% (n=10) was induced by 0.3 mg/kg APO in the EEDQ-treated rats.

These results lend neurophysiological support to the idea (Meller et al., Eur. J. Pharmacol. 123: 311, 1986) that a greater DA receptor reserve on DA neurons, as compared to postsynaptic cells, may explain the apparent autoreceptor selectivity of drugs like BHT 920 and EMD 38362 which appear, relative to APO, to be partial DA agonists.

136.9 COMPARISON OF IN VITRO AND IN VIVO MODELS OF STRIATAL DOPAMINE (DA) AUTORECEPTOR FUNCTION. K. Bohmaker,* M. Goldstein and E. Meller. Department of Psychiatry, New York University Medical Center, New York, NY 10016.

We have recently determined the relative potencies and relative efficacies of several DA agonists, including N-propylnorapomorphine (NPA) and the DA autoreceptor selective agents (+) and (-)3-PPP, utilizing the in vivo γ-butyrolactone (GBL) method (Meller et al., Eur. J. Pharmacol. 123:311-314, 1986; ibid., Mol. Pharmacol. in press, 1987). A large receptor reserve was also found at the autoreceptor for full agonists such as NPA. We have now examined these drugs using an in vitro model in order to compare their potency ratios and intrinsic activities in vivo and in vitro.

Strait and Kuczenski (JPET 29:561-569, 1986) recently studied DA agonist inhibition of synaptosomal TH after its activation by forskolin. Their results, unlike those of several recent studies (Fowler et al., Naunyn-Schmied. Arch. Pharmacol. 331:12-19, 1985; Brautigam et al., Mol. Pharmacol. 8:515-520, 1985) were consistent with an autoreceptor model, presumably because they measured DA agonist inhibition of an "activated" form of the enzyme similar to that obtained after treatment with GBL in vivo.

As previously reported (Strait and Kuczenski, op. cit.), incubation of striatal synaptosomes with forskolin (0.15-100 uM) elicited a dose-dependent increase in the activity of TH subsequently solubilized and assayed; activation of the enzyme was associated with an apparent change in forms of the enzyme with multiple Km's for tetrahydrobiopterin (BH_4) (curvilinear Lineweaver-Burk plots) to a single form with a low Km (30 uM) for the cofactor (linear Lineweaver-Burk plots). Forskolin (1.5 uM) stimulated TH activity about 70-80 percent at low BH_4 concentrations (33 uM). NPA dose-dependently inhibited forskolin (1.5 uM) stimulated TH activity with an IC_{50} of 5 nM; maximal reversal was about 80 percent. (+)3-PPP had an IC_{50} of 2 uM, and maximal reversal (appx.75%) was not significantly different from that elicited by NPA, whereas the IC_{50} for (-)3-PPP was about 1 uM and its maximal effect was only about 35% reversal. The relative potencies of NPA, (+)3-PPP and (-)3-PPP in vitro (1, 0.0025 and 0.005, respectively) were very similar to those obtained in vivo (1, 0.0007 and 0.001). Likewise, the relative intrinsic activities were also nearly identical (1, 0.9 and 0.4 in vitro and 1, 1 and 0.5 in vivo). These results support the idea that unlike inhibition of basal TH activity, which yields IC_{50} values for NPA and (+) and (-)3-PPP at least 100 times larger (Fowler et al., op. cit.), inhibition of forskolin-stimulated TH in vitro may be an accurate reflection of autoreceptor-mediated regulation of DA synthesis in rat striatum in vivo. Supported in part by grants NS-23618, MH-02717 and MH-35976.

136.10 K+-INDUCED DEPOLARIZATION OF RAT STRIATAL NEURONS IN VITRO ALTERS FUNCTIONAL EFFECTS OF DOPAMINE (DA) AGONISTS AT DA SYNTHESIS-MODULATING AUTORECEPTORS: DEPENDENCE ON THE RELATIVE EFFICACY OF DOPAMINE AGONISTS? D. Clark*1, R.S. Salah2 and M.P. Galloway2. (SPON: R.B. Holman) 1Center for Cell Biology, Sinai Research Institute, Detroit, MI 48235, and Neuropsychopharm. Lab., Dept. of Psychology, University of Reading, England, 2Neurochemical Pharmacology Research Unit, Lafayette Clinic, Detroit, MI 48207.

Previous in vivo biochemical and electrophysiological evidence indicates that the enantiomers of 3-hydroxyphenyl-N-n-propyl-piperidine (3-PPP) act as agonists at dopamine (DA) autoreceptors, with (-)-3-PPP exhibiting lower relative efficacy (Clark et al., J. Neural Transm. 62: 171, 1985; Meller et al., Soc. Neurosci. Abstr. 12, Part 1: 194, 1986). In the present study, we have investigated the effects of these compounds on DA synthesis in rat striatal slices. Comparisons were made with the selective D2 DA agonist quinpirole, and the putative partial DA receptor agonist transdihydrolisuride (TDHL; Kehr, Eur. J. Pharmacol. 97: 111, 1984). The enantiomers of 3-PPP concentration-dependently reduced basal DA synthesis, measured as DOPA accumulation after decarboxylase inhibition by NSD 1015, although they were considerably less potent (IC50: 1.8-3.2 uM) than quinpirole (IC50: 0.1 uM) and TDHL (IC50: <0.1 uM) in this regard. Similar inhibitory effects of the 3-PPP enantiomers were observed in slices depleted of DA by a prior in vivo pretreatment with reserpine. Although both (+)-3-PPP and quinpirole were able to completely reverse the increase in DA synthesis in normal slices produced by addition of excess K+ (30uM) to the incubation medium, (-)-3-PPP and TDHL were ineffective in this regard. Instead, the latter compounds reversed the inhibitory effects of quinpirole under these conditions. This switch in pharmacological profile of (-)-3-PPP and TDHL may be related to their previously demonstrated low relative efficacy, and to the presence of varying synaptic DA concentrations under our different conditions. This hypothesis is currently being further investigated. The present findings suggest caution in interpreting the profile of novel DA receptor agonists in certain DA autoreceptor models. Thus, the previously reported antagonist profile of (-)-3-PPP at DA release-modulating autoreceptors may be related to a partial agonist action of the drug at these sites and significant receptor concentrations of competing endogenous transmitter. (The present research was supported by grants MH-41227 and DA-04120 to MPG).

136.11 COMPARISON OF STRIATAL D1 DOPAMINE RECEPTORS AND ENDOGENOUS DOPAMINE RELEASE IN AGING MICE. K.A. Young [1], J.A.Severson [2], J.J.Woodward [1], S.W.Leslie [1], P.K. Randall [2] and R.E.Wilcox [1]. [1] Institute for Neurological Sciences Research, College of Pharmacy, University of Texas, Austin, TX, 78712. [2] University of Southern California, Los Angeles, CA.

While D2 DA receptors decrease in the aged rodent, there is controversy concerning age effects on neuronal [and especially synaptic] markers of DA neuronal function in striatum. We have previously demonstrated in C57BL/6 mice that high-affinity binding of DA to D2 dopamine receptors in striatum is reduced with age. It was of interest to compare effects of age on the D1 DA receptor and on the release of endogenous DA in the same strain.

Male, C57BL/6 mice were used. For D1 binding studies the ages were 3,8, and 24 mo., for up uptake/release studies the ages were 3,12, and 24 mo. Striata from 3 mice were pooled for each receptor binding or calcium uptake/DA release assay. In both D1 receptor and uptake/release assays sets of three experiments were conducted at one time, with tissue from each of the three ages represented in each assay. For D1 binding, 8 experiments in duplicate were run for each age. The procedure of Hess et al. [Eur. J. Pharmacol., 121:31, 1986] was used for the D1 binding assay. Saturation isotherms using 6 concentrations of 3H-SCH23390 [250-3000pM] and displacement of 750pM 3H-SCH23390 by 15 DA concentrations [0.1mM to 0.1nM] were run in duplicate with 300nM cis-flupentixol as a blank to define nonspecific binding. Six 45Ca++ uptake/DA release experiments were conducted in duplicate. The procedure of Leslie, S., et al., Brain Res., 325: 99, 1985] was used in the present experiment. Synaptosomes were prepared and separate portions were incubated in microcentrifuge tubes for 1, 3, 5, 15, or 30 sec. Uptake/release under resting conditions [5mM K+] was subtracted from uptake/release under depolarizing conditions [30mM K+] to provide net uptake/release through voltage-sensitive channels.

The Bmax for D1 DA receptors was unchanged from 3 to 8 mo., but was reduced by 24 mo. [1606 ± 207, 1637 ± 207, and 1119 ± 105 fmole/mg protein, respectively]. Kd's were unchanged from 0.74 nM. The percentage of D1 receptors exhibiting high-affinity binding for DA was unchanged from 54.6 ± 5% under our assay conditions. However, the capacity of the high affinity agonist state of the D1 receptor were significantly reduced between 8 and 24 mo. [by 22%]. Thus, when 3H-SCH23390 and cis-flupentixol are used for D1 DA receptor assays, clear cut reductions in both high-affinity binding of DA and in total D1 sites occur with aging.

Neither 45Ca++ uptake through voltage-sensitive channels nor DA release was altered by aging. The expected increases in 45Ca++ uptake and in DA release from 1 through 30 sec. occurred, with most of each over by the end of the 1-3 sec. fast-phase period as we have previously described. Also, values for 45Ca++ uptake and DA release which we obtained in 3 mo. old C57BL/6 mice were found to be comparable to those which we had previously obtained using 3 mo. CD-1 mice. Thus, values obtained in all 3 age groups were similar to those observed in the 3 mo. group: (1) 45Ca++ uptake [nmoles/mg protein were 1 sec. 89 ± 16, 3 sec. 260 ± 23, 5 sec. 413 ± 23, 15 sec. 515 ± 35, and 30 sec. 527 ± 24; [2] DA release [pmoles/mg protein] were 1 sec. 12 ± 2, 3 sec. 21 ± 2, 5 sec. 25 ± 2, 15 sec. 34 ± 3, and 30 sec. 34 ± 3. The coupling ratios for calcium/DA were also found to be the same in the 3 age groups. Total DA levels in striatum were also found to be constant across the 3 ages in the present study. Thus, when the fast-phase endogenous release of the transmitter coupled to 45Ca++ entry is used an index, aging to 24 mo. does not appear to reduce either process.

Overall, our previous results on age effects on the striatal D2 DA receptor in conjunction with the present results suggest that, in mice of this strain assayed under the described conditions, age produces reductions in the high-affinity binding of DA to the D1 and D2 sites without altering the stimulus-secretion coupling process for the transmitter. 136.12 EFFECTS OF CHRONIC APOMORPHINE TREATMENT ON MEASURES OF STRIATAL DOPAMINE FUNCTION. R.E.Wilcox [1], W.H.Riffee [1], J.A.Severson [2], J.J. Woodward [1], S.W.Leslie [1], and D.M.Vaughn [3]. [1] Dept. of Pharmacology & Toxicology, College of Pharmacy, and Neuropharmacology Research Program, Institute for Neurological Sciences Research, University of Texas, Austin, TX 78712. [3] Scott-Ritchey Research Program, School of Veternary Medicine, Auburn University, Wire Road, Auburn, AL 36849.

Subchronic [14 once daily injections] treatments of mice with apomorphine [APO] induce a behavioral sensitization to the stereotypic effects of challenge doses of APO. In the present report we attempted to establish a biochemical basis for the behavioral effect by evaluating the effects of subchronic vs. single APO treatments on striatal dopamine (DA) metabolites, DA synthesis, in vitro DA release, and on the high-affinity agonist binding of DA to the D2 DA receptor. Mice received 14 daily injections of APO (30 mg/kg, ip; a subchronic injection routine) or saline. Three days after the last subchronic dosing (which is the time of peak behavioral sensitization) mice were challenged with saline or APO (2 mg/kg, ip). In parallel experiments, the effects of a single APO treatment 24 hr prior to euthanasia on striatal DA metaboism, synthesis, release and on D2 DA receptors were evaluated to suggest rates of adaptation to the agonist for these markers. Subchronic APO administration (1) increased the stereotypic response to APO in a dose-dependent manner for the 1 and 2 mg/kg challenge doses of APO, but not the 4 mg/kg dose; (2) increased basal striatal levels of dihydroxyphenylacetic acid (DOPAC), homovanillic acid (HVA) and the ratios of DOPAC/DA and HVA/DA; (3) attenuated the ability of APO challenge to lower DOPAC/DA and HVA/DA ratios; (4) increased striatal l-dopa accumulation after decarboxylase inhibition; (5) left unaltered the ability of APO challenge to lower l-dopa accumulation; (6) left unaltered fast-phase (3 sec. depolarization) endogenous DA release; and (7) left unaltered the percentage of D2 DA receptors binding DA with high-affinity. Single APO pretreatments (24 hr prior to euthanasia) (1) did not affect striatal DA metabolites or DA synthesis but (2) reduced fast- (but not the slow-) phase release of DA and (3) increased the percentage of D2 DA receptors binding DA with high-afinity. These results are consistent with an ability of subchronic APO treatment to induce altered synaptic DA content in striatum independent of receptor mechanisms. Our findings suggest that alterations in dopamine synthesis or metabolism in response to subchronic DA agonist treatment may occur at different rates than changes in DA release and binding and that such neuronal alterations may play a role in the behavioral changes which are associated with multiple dopamine agonist pretreatments. These results are also consistent with a rapid development of tolerance to the nigrostriatal neuron and D2 receptor effects of APO in which a reciprocal pattern of changes occur in DA release and in the percentage of D2 DA receptors in the high-affinity agonist state. [Supported by MH33442 (WHR & REW), NS20827 (REW & WW Spirduso), MH09269 (JJW), AA05809 (SWL) and a Texas Technology Grant (SWL & REW)].

136.13 AMPHETAMINE-INDUCED INHIBITION OF VENTRAL TEGMENTAL AREA DOPAMINERGIC NEURONAL IMPULSE FLOW: IN VITRO STUDIES IN THE MOUSE. E. Viscardi, G. Bernardini and D. C. German. Depts. of Psychiat. and Physiol., Univ. of Texas Health Sci Cntr., Dallas, TX 75235.

The effect of d-amphetamine (d-AMP) on ventral tegmental area (VTA) dopamine (DA)-containing neurons is thought to be critical for the enhanced motoric effects of this drug. d-AMP is a potent releaser of DA and inhibits VTA DA neuronal impulse flow in vivo. The inhibition of cell firing is thought to be due to a local effect of d-AMP in releasing dendritic DA onto cell body autoreceptors (Groves et al.,Science 190:522, 1975; Wang, Brain Res. Rev.,3: 153,1981). The purpose of the present study was to investigate whether d-AMP inhibits mouse VTA DA neuronal impulse flow in vitro. We have previously demonstrated that mouse midbrain DA neurons exhibit spontaneous activity in vitro and that DA inhibits neuronal impulse flow (Sanghera et al. Neurosci. 12:793, 1984). Using the in vitro slice preparation, the effects of d-AMP can be studied directly without the influence of feedback and afferent inputs to the VTA neurons. Brains from BALB/c and CBA mice were rapidly removed from the skull and sectioned in the coronal plane at a thickness of 400 um. Recordings were obtained from neurons in the VTA whose firing characteristics resembled those previously described for DA neurons. The tissue was superfused with d-AMP in increasing doses (12.5, 25, 50, 100 uM). In 12 cells examined, doses as low as 25 uM induced over 90% inhibition of cell firing. This inhibition was reversed by superfusion with the DA type-2 receptor antagonist, (-) sulpiride (0.1 uM). Pretreatment of mice with the DA-synthesis inhibitor, alpha-methylparatyrosine (250 mg/kg, i.p.), 90 min. prior to sacrifice, blocked the inhibitory effects of d-AMP, yet superfusion with DA still inhibited cell firing. These data are consistent with the hypothesis that d-AMP releases newly synthesized dendritic DA to inhibit VTA DA neuronal impulse flow. Research supported by grants from the NIMH (MH-30546) and the Dallas Area Parkinsonism Society.

136.14 DOPAMINE RECEPTOR BLOCKADE ANTAGONIZES AMPHETAMINE-INDUCED ASCORBATE RELEASE IN THE NEOSTRIATUM. George V. Rebec, Choonjeong Oh*, and Thomas W. Gardiner. Dept. Psychol., Indiana Univ., Bloomington, IN 47405.

Ascorbate (AA), which exists in high concentration in the extracellular fluid of the neostriatum, appears to modulate both the firing rate of neostriatal neurons (Gardiner et al., Brain Res. 344:181, 1985) and behavioral responses mediated by neostriatal dopamine (Rebec et al., Science 227:438, 1985). Amphetamine, a well-known dopamine agonist, nearly doubles the extracellular concentration of neostriatal AA. Although this effect is not abolished by destruction of dopaminergic terminals in the neostriatum, several studies suggest that dopamine receptors may play a role in AA release. The present study was designed to examine this hypothesis.

Electrochemically-modified microvoltammetric electrodes were positioned in the neostriatum of urethane-anesthetized rats. These electrodes yield a voltammetric wave for AA that is resolved easily from that for catechols and all other electroactive species in the mammalian brain. Voltammetric scans, displayed in a differential form, were obtained at 2-min intervals. The animals received 2.5 mg/kg d-amphetamine and were challenged 30 min later with one of several dopamine antagonists or with vehicle. Both haloperidol and clozapine reversed the amphetamine-induced rise in AA. This was not the case following administration of either SCH-23390, which selectively blocks D-1 dopamine receptors, or sulpiride, a selective D-2 dopamine antagonist. When administered together, however, these drugs blocked AA release. It appears, therefore, that a blockade of both D-1 and D-2 dopamine receptors is required to reverse the increase in neostriatal AA produced by amphetamine.

137.1 EXTERNAL ENVELOPE PROTEIN (gp120) of HIV PRODUCES NEURONAL DEATH IN HIPPOCAMPAL CULTURES. D.E. Brenneman, C. Pert and G.Westbrook Lab. of Develop. Neurobiol., NICHD and Section on Brain Biochem., Clin. Neurosci. Branch, NIMH, Bethesda, MD 20892.

Cognitive impairment and neuronal deficits are clinical features of Acquired Immune Deficiency Syndrome. Previous studies have indicated that several of the immunological defects associated with Human Immunodeficiency Virus (HIV) infection are mediated by nonviable viral proteins (Pahwa,S. et al.,PNAS,82: 8198,1985). We have tested if the 120-kDa external HIV envelope glycoprotein (gp120) produced neuronal death when incubated with dissociated cultures from the hippocampus.

Hippocampal neurons obtained from 16-17 day old fetal mice were plated on confluent hippocampal feeder cultures prepared from newborn mice. The neuronal cultures were maintained in defined medium supplemented with 5% horse serum/MEM and the feeder cultures were grown in 10% fetal bovine serum/MEM until seeded with neurons. Gp120 and peptide treatments were added to 7 day old cultures and treatment was continued for 5 days. To assay, the neurons were immunocytochemically identified with antibodies to neuron specific enolase and counted. Gp120 was purified from HIV isolate $HTLV\text{-}III_B$ by immunoaffinity chromatography and preparative PAGE as described (Robey,W. et al., PNAS,83:7023,1986).

Addition of gp120 to hippocampal cultures produced a concentration-dependent decrease in neuronal survival as compared to control cultures. Decrements were evident at 10^{-13} M, with maximal neuronal deficits (67-75% of control values) being observed with 10^{-12} M. However, neuronal losses associated with gp120 treatment were attenuated at concentrations of gp120 greater than 10^{-11} M.

Vasoactive intestinal peptide (VIP) has been shown to increase neuronal survival during development in culture (Brenneman,D. et al.,PNAS,83:1159,1986). A five amino acid sequence of VIP (TDNYT) shares homology with sequences of the gp120 molecules. Because of this similarity, we have examined the effect of VIP and an analog of an octapeptide sequence from the envelope, ($D\text{-}Ala^1$) Peptide T amide, on gp120-induced neuronal death. Addition of 0.1 nM VIP to hippocampal cultures produced a significant increase (25%) in the number of neurons and also prevented losses produced with gp120. Treatment with the Peptide T derivative alone had no effect on hippocampal neuron survival; but this substance, like VIP, also attenuated gp120 associated neuronal death. These data indicate that in cell culture, the nonviable external envelope protein of HIV can produce neuronal death. The attenuation of gp120-induced death by VIP and the Peptide T derivative suggests an important link between the action of these substances and protection against HIV-associated neurotoxicity.

137.2 NEUROCHEMICAL CHANGES IN THE CORTEX OF HUNTINGTON'S DISEASE PATIENTS: POSSIBLE BASIS FOR AFFECTIVE DISORDER. J.C. Hedreen and G.L. Wenk. Departments of Neuropathology and Psychology, The Johns Hopkins University School of Medicine, Baltimore, MD 21205

Huntington's Disease (HD) has four principal clinical manifestations: (1) Chorea and other involuntary movements; (2) Disturbances in voluntary motor control; (3) Dementia; and (4) Emotional (affective) disorders including depression, irritability, aggression hallucinations and suicide. The principal histopathologic change in HD is a loss of the small/medium projection neurons in the caudate and putamen. The neurochemical changes in the striatum include decreased levels of gamma-aminobutyric acid, acetylcholine, substance P, and dynorphin, and increased levels of somatostatin and neuropeptide Y. Few investigators have examined changes in neocortical neurochemistry. In the present study, we have examined the levels of various biochemical markers for the cholinergic, serotonergic, dopaminergic, and noradrenergic neurotransmitter systems in neocortex of patients with pathologically confirmed HD and in age-matched controls. These measures include choline acetyltransferase activity, endogenous levels of dopamine, serotonin, norepinephrine, 5-hydroxyindoleacetic acid, homovanillic acid, and the number of serotonergic type-2 receptors (as determined by [^{3}H]-ketanserin), as well as the density of high-affinity norepinephrine uptake sites (as determined by [^{3}H]mazindol). There was no correlation between levels of the biochemical markers and post-mortem delay or drug therapy. The ratio of 5-hydroxyindoleacetic acid to serotonin, and the number of serotonergic type-2 receptors were decreased, suggesting decreased activity in raphe neurons. Levels of dopamine metabolites were increased, and levels of dopamine were decreased, suggesting increased activity in mesocortical dopaminergic systems. The density of norepinephrine uptake sites was decreased, consistent with decreased release of norepinephrine. The data support the hypothesis that alterations in cortical monoamine neurotransmitter systems may underlie some of the affective disorder symptomatology associated with HD.

137.3 HUNTINGTON'S DISEASE: STUDIES ON BRAIN FREE AMINO ACIDS. E. Bonilla, A.L.N. Prasad* and A. Arrieta*. Instituto de Investigaciones Clínicas and INBIOMED-FUNDACITE. Apartado 376. Maracaibo, Venezuela.

Huntington's disease (HD) is a chronic neurodegenerative disorder characterized by involuntary choreiform movements, psychological symptoms and dementia. It is inherited in an autosomal dominant fashion with complete penetrance. Although a genetic marker linked to the Huntington's disease locus located in chromosome 4, has been identified (Gusella, J.F. et al, Nature 306: 234, 1983), the affected gene and the resultant biochemical deficit is unknown. In this report, we investigated the changes in free amino acid levels in putamen and Brodmann's area 10 of patients who died with Huntington's disease.

Brains were obtained from 12 patients with HD (7 male, 5 female; mean age, 60.5 years; range 36-80 years) and 13 non-neurologic controls (9 male, 4 female; mean age, 67.7 years; range 34-84 years). The diagnosis of HD was confirmed by neuropathologic examination. Free amino acids were detected using a high performance liquid chromatographic procedure (Jones, B.N. et al Liquid. Chromat. 4: 565, 1981).

Gamma-amino-butyric acid (GABA), glutamate and alpha-amino-n-butyric acid levels were found to be significantly reduced in the putamen of HD patients. In Brodmann's area 10, the concentrations of glutamate, histidine and lysine were highly decreased, but the levels of aspartate, GABA, glycine, serine and taurine were increased.

We have confirmed previous reports stating that the concentration of GABA decreases in the putamen of HD patients. A reduction in GABA neurons has been considered to be responsible for the disinhibition of the dopamine nigrostriatal system and would explain the improvement of choreic movements by dopaminergic antagonists. However, the fact that GABA levels are normal in other brain regions or increased, as we have found in Brodmann's area 10, makes it unlikely that GABA is solely responsible for the pathogenesis of HD. The reductions in the levels of glutamate do not necessarily preclude the possible role of glutamate in the pathogenesis of HD since its buildup at the synaptic cleft of excitatory synapses is all it takes to produce the neurotoxic effect of this amino acid on postsynaptic neurons. The increase in glycine content observed in Brodmann's area 10 may be a direct consequence of the elevation in serine levels. Further work is needed to define the significance of the changes in these amino acid for the development of the neurologic and psychiatric symptoms in HD.

Supported by FUNDACITE-ZULIA. Human brain samples were kindly provided by E.D. Bird, Brain Tissue Resource Center, McLean Hospital, Belmont, Massachusetts.

137.4 PHARMACOKINETICS AND METABOLIC DISPOSITION OF THE COGNITION ACTIVATOR ^{14}C-CI-933 IN DOGS. A. Black and T. Chang*, Warner-Lambert/Parke-Davis Pharmaceutical Research, Ann Arbor, MI 48105.

CI-933, 1-(4-methoxybenzoyl)-5-oxo-pyrrolidinepropanoic acid, is a cognition activator currently undergoing Phase 1 clinical evaluation. A two-way crossover study in beagle dogs was performed by giving single 10 mg/kg IV and PO doses of ^{14}C-CI-933. Heparinized blood, urine and feces were collected at specified time periods. Total radioactivity was determined in plasma, urine and feces by liquid scintillation spectometry. Plasma CI-933 concentrations were assayed by a validated HPLC method. Plasma protein binding was determined by ultracentrifugation. HPLC with radioactivity detection (RAM) was used to detect metabolites in urine and plasma.

Following single IV doses, plasma ^{14}C activity declined in a polyexponential manner with a mean $t_{\frac{1}{2}}$ of 4 hours. By six hr postdose ^{14}C concentrations were 0.1 ug/ml or less. After single PO doses, mean peak ^{14}C activity (20.9) ug/ml) occurred 0.6 hr postdose. Similar concentration-time profiles were obtained and mean elimination $t_{\frac{1}{2}}$ was 3.5 hrs. RBC ^{14}C activity was approximately one-third of plasma ^{14}C activity after either route of administration. Plasma CI-933 concentrations declined in a monoexponential manner after single IV doses and were undetectable by 6 hr. Following single PO doses, peak CI-933 plasma concentrations (19.9 ug/ml) were observed less than one hr post dose. Elimination $t_{\frac{1}{2}}$ was approximately 0.5 hours and independent of route of administration. Plasma protein binding of CI-933 over a 100-fold concentration range averaged 25%. Based on plasma AUC comparisons, absolute oral bioavailability of CI-933 was 82%.

Excretion patterns of ^{14}C activity were similar after either route of administration indicating complete oral absorption. Urinary excretion was the major route of elimination accounting for 88% of the radioactivity by 24 hr post dose. Fecal recovery ranged from 1-7% of the dose. HPLC-RAM analysis of urine after IV and PO doses indicated that intact CI-933 accounted for approximately 76% of the dose. The remainder of radioactivity (11.7%) was in the form of 5-oxo-2-pyrrolidinepropanoic acid metabolite. This metabolite was also detected in plasma at later time intervals.

137.5 Early Leukocyte Migration into a Bacterial Cerebritis. W. Lo and D. McNeely Department of Pediatrics, Columbus Children's Hospital, Columbus, Ohio 43205.

The initial steps by which bacteria impair blood-brain barrier integrity and eventually cause edema are not well understood. We hypothesized that bacteria stimulate neutrophils to migrate from the blood to the brain, the neutrophils phagocytose the bacteria, and the chemical products of phagocytosis damage microvessel integrity, thereby the blood-brain barrier is damaged. We examined the first step of this hypothesis in a rat model of a bacterial brain abscess (Winn, H.R. et al., J. Neurosurg 51:685-690, 1979). Sprague-Dawley rats, (250-300 gms) were anesthetized with pentobarbital (40mgs/kg), and intracerebrally inoculated with a 10^4 colonies/ml suspension of log phase Staphylococcus aureus (PG-114-1, a non-delta-, and non-alpha-toxin producing strain). The animals were perfused and sacrificed at 3, 6, 12, 24, and 48 hours after inoculation (n=3-4), and the brains were prepared for hematoxylin and eosin staining. The experimental animals showed little cellular change at 3 hours except for a scant amount of neutrophil margination in microvessels near the inoculation site. By six hours after inoculation, neutrophils accumulated into a measurable volume, 0.136 ± 0.090 mm^3 (n=3), and the volume of leukocyte infiltration steadily increased in size, to 0.385 ± 0.142 mm^3 (n=3) by 48 hours. In contrast, control animals injected with sterile medium showed only a slight collection of red blood cells along the needle path at the early time points. A few neutrophils appeared only 24 to 48 hours after inoculation, and never achieved measurable volume.

Our results indicate that Staphyloccous aureus produces chemotactic factor(s) that stimulate neutrophil chemotaxis across the microvascular wall. Neutrophil migration begins as early as three hours after inoculation. The migration occurs when there is no histologic evidence of tissue destruction or necrosis.

Our results suggest that neutrophil chemotaxis across the microvessel wall is an early step in the development of a cerebritis. Our findings suggest that neutrophil migration may precede alteration of the blood-brain barrier, and that the barrier may be affected by the products of neutrophils phagocytosing bacteria.

137.6 INDUCTION AND SUPPRESSION OF AUTOIMMUNE NEUROPATHIES F. C. Westall and R. S. Root-Bernstein. Institute for Disease Research, 6171 Kinlock Ave., Rancho Cucamunga, CA 91730.

Post-infectious and post-vaccinal neuropathies (PINs and PVNs) occur very rarely (1/10,000 to 1/500,000 per infection or injection). Like other autoimmune diseases, they are usually regarded as resulting from "mistakes" in the self-recognition system. However, under experimental conditions, autoimmunity can be induced in many species with almost 100% success. This observation suggests that the induction of autoimmunity is not a mistake, but due to factors not normally encountered. Experimental autoimmune diseases, including experimental autoimmune encephalomyelitis, thyroiditis, and castration, all require both a protein "antigen" and one or more bacterial "adjuvants" for their induction. It is not possible to induce any of these autoimmune diseases with the protein or peptide alone, or with the "adjuvant" alone. Furthermore, the "adjuvant" induces a separate immune response from the protein or peptide "antigen". As with "antigen", the pretreatment of animals with large doses of "adjuvant" can prevent induction of autoimmunity, and large doses of either "antigen" or "adjuvant" can suppress the disease once induced. In short, the "adjuvant" has all of the properties of a second "antigen", and both antigens must be present concurrently to induce an autoimmune response. A dual antigen mechanism for the induction of autoimmunity would explain many currently puzzling facts concerning PINs and PVNs. Viruses, including measles and Epstein-Barr, have coat-protein sequences similar to myelin basic protein. Injection of animals with these viruses alone does not, however, lead to autoimmune neuropathies. As with other autoimmune diseases, we suggest that an appropriate second antigen, bacterial in origin (e.g., a Mycoplasma or B. pertussis), is necessary to induce PINs and PVNs. The necessity for concommitant viral and bacterial infections would explain the very low incidence of PINs and PVNs; is supported by hospital records of patients admitted with PINs and PVNs; and suggests the possibility of treatment of such patients with suppressive doses of bacterial "adjuvants" or myelin basic protein. (Westall and Root-Bernstein, Mol Immunol 20 (1983) 169-77; Lancet (2 Aug 1986) 251-2).

137.7 INHIBITORY EFFECTS OF PHENIDONE ON COLD-INDUCED VASOGENIC EDEMA AND LEUKOTRIENE PRODUCTION IN RODENT BRAIN. L. J. Robichaud* and F. W. Marcoux. Department of Pharmacology, Warner-Lambert/Parke-Davis Pharmaceutical Research, Ann Arbor, MI 48105.

Extracts from sections of guinea pig and rat brains cryogenically injured 15 or 60 minutes before sacrifice were assayed for leukotriene (LT)C_4 by radioimmunoassay. LTC4 levels in injured brain extracts were elevated as compared to controls. The lipoxygenase inhibitor, phenidone (30 mg/kg, IP), was tested in guinea pigs and completely blocked the cold-induced increase in LTC_4. LTC_4, which was not detected in normal rodent brains, increases cerebral vascular permeability in rats (Black & Hoff, 1985), and has been implicated in post-ischemic reperfusion injury in gerbil brain (Kiwak et al, 1985). We hypothesized that LT might also be an important mediator in cold-induced vasogenic brain edema.

Transcranial cold injury induced extravasation of albumin (A) labeled with either ^{125}I or Evans-blue (EB) dye. Assessments of ^{125}I-A and EB-A in tissue after injury were interpreted as measures of the intensity and extent of edema, respectively. Phenidone (30 and 100 mg/kg, IP) inhibited cerebral tissue accumulation of ^{125}I-A and reduced the extent of EB-A accumulation in rats and guinea pigs subjected to cold injury.

Phenidone has various pharmacological actions (e.g. oxyradical scavenger and inhibitor of ornithine decarboxylase activity). In order to further characterize the edema model and the mechanisms involved, additional pharmacologic agents were tested. Several inhibitors of oxy-radicals and/or their effects were inactive in the edema model: allopurinol (100 mg/kg IP 48, 24 and 0.5 hrs before challenge), mannitol (4mg/kg IV), DMSO (1%, 4 ml/kg IP), catalase-PEG (3600 IU/kg, IV) and superoxide dismutase-PEG (3600 IU/kg, IV). Catalase and superoxide dismutase combined potentiated the intensity of the edema (73%). The ornithine decarboxylase inhibitor 3400 MDL (100 mg/kg IP) had no effect on vasogenic edema. These data further support a role for leukotriene as a mediator of cold-induced vasogenic brain edema in rats, and suggest that the inhibitory effects of phenidone on edema may be due to inhibition of lipoxygenase but not to inhibition of oxy-radicals.

137.8 CALCIUM HOMEOSTASIS IS ALTERED IN SYNAPTOSOMES FROM CATS WITH GM_1 GANGLIOSIDOSIS. M.L. Koenig, R.S. Jope, H.J. Baker, and J.A. Monti. Dept. of Pharmacology and Neuropsychiatry Program, Univ. of Alabama at Birmingham, Birmingham, AL 35294 and Dept. of Comparative Medicine, Bowman Gray School of Medicine, Winston-Salem, NC 27103.

GM_1 gangliosidosis is one of several lysosomal storage diseases which are characterized by severe, progressive dysfunction of the central nervous system (CNS). Although much has been learned about the specific defects in lysosomal biochemistry associated with these diseases, the underlying pathogenetic mechanisms responsible for CNS dysfunction remain poorly understood. Our previous studies of cholinergic metabolism in a well characterized feline model of GM_1 gangliosidosis have shown that the depolarization-dependent release of acetylcholine is increased in diseased cats relative to controls (J. Neurochem. 46:1567, 1986). Subsequent studies of calcium fluxes in synaptosomes prepared from cats with GM_1 gangliosidosis and from phenotypically normal controls have shown that both the fast and slow phases of voltage dependent calcium influx as well as Na^+ dependent efflux are reduced significantly in the diseased cats (Brain Res., in press). These results suggest that the intrasynaptosomal calcium concentration might be increased chronically in cats with GM_1 gangliosidosis.

The intra synaptosomal free Ca^{2+} concentration ($[Ca^{2+}]_i$) in diseased and control cats, measured using the fluorescent Ca^{2+} indicator indo-1, was higher under resting conditions, was less affected by a high K^+ (50 mM) induced depolarization of the synaptosomal membrane, and appeared to be less effectively buffered in synaptosomes prepared from GM_1 mutant cats. Subsequent studies of the sequestering capacity of synaptosomal mitochondria and endoplasmic reticulum have indicated that the ATP-dependent uptake of calcium into the endoplasmic reticulum of synaptosomes from GM_1 mutants is 30-40% lower than controls.

Because altered intrasynaptosomal calcium concentrations will affect both the rate and extent of protein phosphorylation and dephosphorylation, we also are investigating the possibility that phosphorylation of synaptosomal proteins is altered in cats with GM_1 gangliosidosis. Differences in the phosphorylation patterns of at least five synaptosomal proteins have been identified. Our present effort is focused on determining the extent to which these changes can be attributed to changes in the activities of the well characterized Ca^{2+} dependent protein kinases, Ca^{2+}-calmodulin dependent protein kinase and Ca^{2+}-phospholipid dependent protein kinase (protein kinase C).

137.9 IMMUNOPATHOLOGY OF THEILER'S VIRUS DEMYELINATION.
I. N. Montgomery, G. Nabozny*, S. Cola*, H. C. Rauch. Wayne State Univ., Dept. Immunology/Microbiology, Detroit, MI 48201.

We are investigating the immunopathology of the demyelinating process associated with Theiler's murine encephalomyelitis virus (TMEV). We have previously shown [J. Immunol. 136:2136, 1986] that some splenocytes are infected with the virus following intracerebral inoculation. We suggested, as have others [Clatch, et al J. Immunol. 136:920, 1986], that the macrophages were the most likely cell type to be infected. Using both a bioassay and immunocytochemical staining, we have identified plastic-adherent, esterase positive cells in the spleen that are infected. After 10-12 weeks, spleens from intracerebrally infected mice showing clinical signs of demyelination were removed. Following separation into plastic-adherent and non-adherent populations, the plastic non-adherent cells were passed over a nylon-wool column and the remaining non-adherent cells recovered. An aliquot of the adherent and non-adherent cells were subjected to repeated freeze-thawing and the supernatant injected intracerebrally into 2 day old suckling mice for a bioassay. The remainder of the two cell populations were fixed, treated with saponin to permeabilize the cell membrane, and immunocytochemically stained for TMEV protein. The primary antibody was a rabbit anti-TMEV with a fluoresceinated goat anti-rabbit-IgG secondary antibody. After identification of fluorescent positive cells, the coverslips were removed and the cells stained for esterase. Infected cells were found in the plastic-adherent, esterase-positive cell population. Only the freeze-thaw supernatant from the plastic-adherent cell population was infective in the bioassay. We have also reported [J. Neuroimmunol., In press] immune responses directed against both the TMEV and myelin basic protein (MBP) in these infected mice. To further investigate the immunopathology of this disease we sought cytotoxic lymphocytes from TMEV-infected mice. Using a modification of the method of McCarthy and deVellis [J. Cell Biol. 85:890, 1980; Knapp et al, Dev. Biol. In press], we prepared a monolayer of cells, rich in oligodendroglia, from a primary culture. The plastic non-adherent, nylon-wool non-adherent cell population is the source of cytotoxic lymphocytes. Expression of MHC antigens on target cells is induced using a concanavalin A conditioned media eluant and verified by immunocytochemical staining. In cytotoxic assays the oligodendroglia, after lymphocyte exposure, are monitored for the integrity of their membrane sheets and characterized by immunocytochemical staining for MBP and galactocerebroside. Controls are identical cultures exposed to ConA eluant only or to nylon-wool non-adherent lymphocytes from CFA immunized donors.

137.10 PLATELET PROTEIN MAPPING IN NORMAL AND AUTISTIC SUBJECTS USING TWO-DIMENSIONAL "GIANT GEL" ELECTROPHORESIS.
G.M. Anderson*, L.B. Hall*, F.R. Volkmar*, B.A. Shaywitz, and D.J. Cohen*. Depts. of Lab. Med., Neurology, and the Child Study Center, Yale University School of Medicine, Box 3333, New Haven, Ct 06510

One successfull approach to determining genetic defects in inherited disorders has been to identify and characterize specific disease-related proteins and to then determine their corresponding genes. Recent work in Alzheimer's Disease has demonstrated the feasibility of this approach in the molecular analysis of neuropsychiatric disorders. In most cases the most difficult step in this process would appear to be the initial identification of altered proteins. Several groups have employed standard two-dimensional gel electrophoresis in attempting to locate altered proteins in CSF, lymphocytes, or fibroblasts obtained from patients with neuropsychiatric disorders.

In order to perform as complete as possible mapping and inventory of cellular protiens in CSF, fibroblasts, platelets and brain we have used the "giant gel" methodology of Young (Clin. Chem. 30:2104) and Klose & Zeindl (Clin. Chem. 30:2014). Two-dimensional "giant gel" were obtained using 32 cm isoelectric focusing tube gels (3 mm I.D., ampholytes 4:1, pH 5-7 : pH 3-10) followed by 35 cm SDS-PAGE seperation in the second dimension (12-17% acrylamide, exponetial gradient) Typically 0.5-1.0 mg of brain, fibroblast, or platelet protein has been electrophoresed and approximately 1200 discrete protein spots have been observed after silver staining. Results of "giant gel" mapping of brain (cortex), fibroblast, and platelet proteins using silver staining will be presented as will mapping studies of fibroblast proteins metabolically-labeled with ^{35}S-methionine.

Our first clinical application of the method has been to the study of platelet proteins in autism. Recent research on the mechanism of the well-replicated increase in platelet serotonin (5-HT) levels seen in autism has stongly indicated that some aspect of the platelet's uptake or storage of 5-HT is altered in autism. This has suggested the platelet as a potentially fertile area for the molecular analysis of autism. We will present results of the "giant gel" inventory of platelet proteins, as well as more specific studies of 5-HT related proteins, in autistic and normal subjects.

137.11 AKINESIA AND CATALEPSIA INDUCED BY CARBACHOL INJECTED INTO THE PONS AND EEG CORRELATES.
Z. Elazar and M. Paz. Department of Physiology and Pharmacology, Sackler School of Medicine, Tel-Aviv University, Israel.

The basal ganglia are considered as the anatomical substrate of catalepsia induced by systemic administration of neuroleptic drugs. However, it was reported that the mesencephalic reticular formation may also be a site for the cataleptic effect of neuroleptics (Hartgraves and Kelly, Brain Res., 307:47, 1984). Here we report our findings about the role of the pons in catalepsia.

Carbachol (4-10 ug in 1 ul saline) was injected unilaterally into the mesencephalon and pons of freely moving male Wistar rats. The effect obtained in the two brain areas was similar, but stronger in the pons. Several minutes after the injection the animals acquired a characteristic standing immobile posture. The horizontal bar test revealed an intense, long standing cataleptic state. The bracing, clinging and righting tests indicate a state similar with the neuroleptic induced catalepsia (De Rick et al., Brain Res. 201:143, 1980).

Higher amounts of Carbachol induced EEG epileptiform seizures recorded from the injection site. The seizures were associated with strong catalepsia which was the first motor correlate observed. Generalized convulsions started later from a backgroung of catalepsia and were followed by catalepsia.

Intraventricular injections of 6-hydroxydopamine decreased, after two weeks, the noradrenaline content of the pons by 50 percent. No spontaneous catalepsia was seen in these animals but correspondingly smaller amounts of Carbachol were necessary to induce both catalepsia and epileptiform seizures. Atropine injected in the same pontine sites abolished both catalepsia and seizure activity induced by Carbachol.

Our findings show: 1. the pons may be a site for the generation of catalepsia; 2. cholinergic pontine mechanisms may be involved in the generation of catalepsia; 3. the association between catalepsia and epileptiform activity and the parallel facilitation of both phenomena by reduction of the noradrenaline content suggest a relation between the pontine mechanisms of catalepsia and generalized seizures.

137.12 2,5 HEXANEDIONE AFFECTS THE POSITION SENSITIVITY OF DE-EFFERENTED MUSCLE SPINDLES.
T.C. deRojas* and B.D. Goldstein. Department of Pharmacology and Toxicology, Medical College of Georgia, Augusta, Georgia 30912.

The neurotoxicants acrylamide (ACR) and 2,5 Hexanedione (HD) induce a distal axonopathy (DA) with an accumulation of 10nm neurofilaments distally prior to axonal degeneration. ACR has previously been shown to effect muscle spindle afferents. In this study the effect of HD on the position sensitivity of primary and secondary muscle spindles was studied in cats to determine if a similar functional pathogenesis occurs. The neurotoxicant was administered as a 0.5% solution in distilled water. Cats drank ad libitum, either distilled water or until either 2.5 or 5.0 ml/kg HD was consumed. On the following day the cat was anesthetized and a dorsal laminectomy was performed. The soleus nerve and muscle were isolated in situ, and a hindlimb de-afferentation was performed. The cat was mounted on a spinal unit and the leg was held rigid. L6-S1 dorsal and ventral roots were sectioned proximally. Single soleus muscle spindle afferents were recorded from the teased L7 dorsal root and isolated via an amplitude discriminator coupled to a frequency analyzer. Afferents were classified as primary or secondary muscle spindle endings based on their conduction velocities (CV) and their characteristic response to stretch. Static discharge frequencies were determined by stretching the soleus muscle from 0 to 14 mm in 2 mm increments. Frequency-response curves (stretch vs. frequency) were generated and comparisons made between control and HD groups.

Animals displayed behavioral signs of DA in a dose-dependent manner. The length-frequency relationships of both the primary and secondary muscle spindle afferents were significantly depressed when compared to control at both doses studied. Mean slopes of the frequency-response curves for the primary muscle spindle afferents were 4.4±0.22, 1.3±0.20, 1.4±0.19 Hz/mm and their mean peak frequency response (at 14 mm) were 71±3.4, 24±3.6, 24±3.6 Hz for control, 2.5 and 5.0 ml/kg HD, respectively. Mean slopes of the frequency-response curves for the secondary muscle spindle afferents were 4.1±0.56, 1.3±0.54, 1.8±0.18 Hz/mm and their mean peak frequency response were 75±8.1, 33±7.9, 30±5.8 Hz for control, 2.5 and 5.0 ml/kg HD, respectively. Mean CV of both the primary, and secondary muscle spindle afferents were depressed in a dose-dependent manner.

In summary, these data show that HD affects the position sensitivity of primary and secondary muscle spindle afferents. There was no difference in the frequency-response relationship between the two doses studied. However, the mean CV exhibited a dose-response relationship. Supported by NS 18664.

137.13 COMPARISON OF BRAIN SIZES OF CATS WITH AN INHERITED SPINOCEREBELLAR DISEASE WITH NONAFFECTED CATS-Gerald A. Hegreberg. College of Veterinary Medicine, Washington State University, Pullman, WA 99164.

An inherited progressive neurodegenerative spinocerebellar disorder which is transmitted as an autosomal recessive trait has been recognized in cats. Intention tremors, the earliest clinical manifestation, are observed in kittens as early as 11 days of age. The tremors are apparent in all affected kittens by the age of 4-5 weeks. The tremors progress in severity with age and are throbbing, rhythmical tremors of high amplitude at the clinical apogee, usually reached by 16 weeks of age. Other neurologic and behavioral changes occur as the disease progresses, including hypermetria, posterior ataxia, posterior paresis, generalized seizures, limb rigidity, moderate to severe visual impairment, unprovoked agitation and rage, dementia, catatonia, stereotypy, and apparent hallucinations.

Brain sizes were examined from 5 adult affected female cats and compared to 23 nonaffected adult female cats. Brains were removed immediately after necropsy and were weighed. Visual examination suggested that the brain of the affected cats were smaller than the brains from nonaffected cats and that all regions of the brain appeared involved to some exte Comparisons of the brain weights were made using the students test for grouped data. The results indicated that the mea brain size of the affected cats was smaller than the mean brain size from the nonaffected cats and that this change is highly significant ($P<0.001$). The mean and 1 standard deviation of the brain sizes from the affected cats and nonaffected cats were 12.6 Gm $\pm$ 0.15 Gm and 23.8 Gm $\pm$ 1.5 Gm respectively.

Based on these studies, we could not ascertain whether this change involves a disturbance in growth of the brain or atrophy after maturation. Although the disease is first associated with young developing animals, morphologic changes observed in mature affected animals indicate that there is severe neuronal degeneration. This feline disorder may provide a means of unraveling mechanisms resulting in neurodegeneration and the relationship of this disorder to human spinocerebellar diseases and epilepsy.

Supported in part by NIH RR00515 and Washington State University.

137.14 EFFECT OF INTERLEUKIN ADMINISTRATION ON GROWTH OF TRANSPLANTED C_6 GLIOMA CELLS

M.J. Politis and J.K.S. Lindsay, Dept. Med. Anat., U. Saskatchewan Sask. CANADA

Studies in a number of laboratories underlie the importance of lymphokines in glial function. The present study was conducted to determine if exogenous interleukin 1 (IL-1) or 2 (IL-2) can alter the growth of transplanted C_6 glioma cells in the rat.

Aggregates of C_6 cells were injected into caudates of Sprague-Dawley rats. Elvax pellets containing IL-1, IL-2 or no additives were inserted into cortical tissue uverlying the caudate at time of C_6 cell injection or 9 days later. Animals were sacrificed 16 days after initial cell injection. Brains were fixed in formalin, embedded in parafin, and sections taken every 250 microns. Tumor cross-sectional area was determined in H and E stained sections and volume of tumor tissue ascertained. Results showed that insert ion of low dose IL-2 pellets (50 units/brain) at time of C_6 injection markedly prevented establishment of tumors when compared to rats in which additive-free pellets were employed (three-fold differences observed between groups). In contrast, IL-1 pellet insertion at time of cell injection resulted in tumors with volumes of more than 2 times that of controls. Implantation of high dose IL-2 pellets (200 units) at 9 days after C_6 cell injection significantly decreased tumor growth by approximately 40%, low dose pellets having no effect.

Subsequent studies were conducted to determine if these effects were due to (a) direct inhibitory action on C_6 cells, or (b) alteration of "host" brain tissue. The former involved growing C_6 cells on 35 mm dishes in the presence or absence of IL-1 or IL-2 (200 U/ml) for 24 hours. No significant effect on proliferation was noted with IL-2, whereas IL-1-treated cultures contained approximately 50% less cells than control cultures.

In vivo experiments were conduted to determine the extent to which lymphokine pellets affect host brain tissue. Saline was injected into caudates of rats and IL-1, IL-2 or additive-free pellets implanted. Five days later, serial sections of brain were obtained and assessed for infiltration by inflammatory cells. Increased infiltration was noted in IL-2-exposed brains, IL-1 rats displaying less of this effect than in additive- free pellet groups.

Results obtained indicate that exogenous IL-2 can inhibit establishment and growth of transplanted C_6 cell tumors, whereas IL-1 appears to enhance tumor growth. These studies (a) offer an approach to deliver exogenous interleukins to tumor tissue and (b) describe an experimental model tha can be used to study the mechanisms underlying interleukin-directed changes in tumor growth.

137.15 CHARACTERIZATION OF THE DIVERSITY OF MURINE BRAIN REACTIVE AUTOANTIBODIES.

A. Narendran*, A. Heitkemper* and S.A. Hoffman. Dept. of Microbiology, Arizona State Univ., Tempe, AZ 85287.

Autoantibodies to brain antigens have been demonstrated in patients with systemic lupus erythematosus (SLE). In addition, sera from murine models of autoimmunity have also been shown to contain such antibodies. If these autoantibodies play a role in the neuropsychiatric manifestations associated with SLE, then it is important to properly characterize them and determine their diversity in order to better understand their relationship to disease activity. Toward these ends, we have studied the antigen binding specificities and isotypes of anti-brain antibodies, reactive with cell surface antigens, from one non-autoimmune and three autoimmune strains of mice.

Integral brain membrane proteins of a non-disease manifesting autoimmune strain of mouse (viz., MRL/mp) was isolated by detergent extraction and phase separation. These proteins were separated on polyacrylamide gels under non-reducing conditions, transferred onto nitrocellulose membranes and incubated with sera from Balb/c, MRL/l, BXSB and NZB/W mice. Positions of reactive antigens were visualized using an indirect immunoenzymatic technique, with enzyme labeled, heavy chain specific, anti-mouse immunoglobulin antisera. The results of these assays, testing large numbers of sera, indicate the following: (1) Not all individuals of these autoimmune strains produced detectable antibodies against brain membrane antigens. (2) Autoantibodies of both IgG and IgM isotypes were produced in all three strains. (3) Considerable heterogeneity in binding specificities was observed in MRL/l and BXSB mice. Interestingly, a high proportion of NZB/W mice produced IgM antibodies against two high molecular weight proteins and IgG antibodies to a peptide with an apparent molecular weight around 75KD. Further information on the biochemical properties of these NZB/W autoantibody reactive brain membrane antigens are presented. We will discuss the implications of these findings.

137.16 **Cerebral Glucose Metabolism in Cortical and Subcortical Regions of Drug-Free Schizophrenic and Normal Brain using PET/FDG**

C.A. Tamminga, H. Burrows, L.D. Alphs*, G.K. Thaker, K.M. Lyons*, T.N. Chase, (SPON: W.T. Carpenter) Maryland Psychiatric Research Center, Baltimore, MD 21228 and Experimental Therapeutics Branch, NINCDS, NIH, Bethesda, MD 20205

Schizophrenia is a chronic psychotic illness whose mechanism and etiology remain unknown. Studies of its pathogenesis have focused on brain dopamine systems because of the potent antipsychotic effect of neuroleptic drugs. Until recently, no consistent abnormality of CNS dopamine systems had been identified in schizophenic patients. But, now, an increase in striatal DA receptors identified by in vivo 11C-NMSP binding and PET, has been reported in schizophrenia by Wong and his colleagues (Science 234:1558, 1986). This finding has refocused interest in a potential pathophysiologic role of DA in schizophrenia. In the studies reported here, that question has been further explored by measuring glucose metabolism in several DA terminal areas of mesencephalic DA-containing neurons (Table 1). Eleven neuroleptic-free psychotic patients with a DSM-III diagnosis of schizophrenia and eleven normal controls received 18F-2-deoxyglucose and were scanned with a NeuroPET scanner (5-7 mm resolution); data in μmoles glucose/100 gm tissue/min were calculated from the Brooks modification of the Sokoloff equation. Subjects were scanned at rest with eyes closed and ears plugged.

Results indicate no metabolic differences in this group of schizophrenics in caudate or various cortical areas containing DA receptors. However, significant decreases in glucose utilization were apparent in the anterior cingulate cortex, and the parahippocampal gyrus. These results are in agreement with postmortem morphometric studies in schiozphrenia. And they serve to focus our attention and studies on the hippocampus and related subcortical structures in schizophrenia.

Table
Glucose Utilization in Human Brain
μmole glucose/100 gm tissue/min)
(mean $\pm$ SD)

Area	Schizophrenic (N=11)	Normal (N=11)	P
Caudate	10.2 $\pm$ 2.3	11.9 $\pm$ 3.6	NS

137.17 THROMBOSPONDIN: QUANTITATION AND DISTRIBUTION ON MUSCLE BASEMENT MEMBRANES IN NEUROMUSCULAR DISEASES. J.S. Rao*, D. Hantai*, B.W. Festoff (SPON: L.T.Giron). Dept. of Neurology, UKMC, Kansas City, KS. and Neurobiology Research Laboratory at VAMC, Kansas City, MO. 64128.

We have studied the distribution of thrombospondin (TSP), fibronectin, laminin, heparan sulfate proteoglycan (HSPG) and collagen types I, III and IV by immunofluorescence in frozen sections of muscle from normal, disease control and amyotrophic lateral sclerosis (ALS) patients. In ALS, normal and disease control muscle, types I and III collagen were localized to the endomysium and the perimysium. Type IV collagen and laminin precisely delineated each muscle fiber (basement membrane) but did not stain the perimysium. We found no marked qualitative difference in the distribution of these ECM proteins, or HSPG, in ALS patients compared to controls. However, TSP showed a marked increase in its distribution in ALS patients' muscle. Quantitative analysis by ELISA also indicated that TSP was increased in ALS patient's muscle. Since TSP is known to be released from platelet α-granules in response to thrombin stimulation its elevation implies involvement of the extravascular thrombolytic system in ALS. Other studies have indicated decreased circulating protease inhibitors and increased plasminogen activators in this disorder.

137.18 MUSCLE PLASMINOGEN ACTIVATORS (PAS) INCREASE ON NERVE CRUSH AND RECEDE ON REINNERVATION. D. Hantai*, J.S. Rao*, C.B. Kahler* and B.W. Festoff (SPON: A. Dick). Dept. of Neurology, UKMC, Kansas City, KS. and Neurobiology Research Laboratory at VAMC, Kansas City, MO 64128.

Our previous studies (J.Cell Biol. 103:1415-1421, 1986) showed 8-10 fold activation of 1st urokinase (uPA) and then tissue (tPA) PAs in muscle after denervation. In addition, specific components of the muscle fiber basement membrane (BM) are susceptible to locally-generated plasmin produced by PA activation of plasminogen (Exp. Neurol. 95:44-55, 1987). These studies suggest neural regulation of extracellular matrix of muscle in attmepted regeneration after injury. The present studies sought to further explore the neural regulation of PA activities in muscle. The nerve crush paradigm was used and both muscle contraction on nerve stimulation and return of choline acetyltransferase (CAT) activity was used to monitor re-innervation. uPA began to rise 24 hours after sciatic nerve crush in sciatic-innervated muscles. This was noted 1st in cytosol prior to a rise in membrane-bound activity. By 7 days, maximal membrane-bound uPA, approximately 7-8 fold above control levels, was detected using the S-2251 assay. tPA followed, both in soluble and membrane fractions, but uPA was last to return to baseline by 40 days. Coincident with return of nerve-evoked muscle contraction and CAT activity at 21 days, both PA activities showed their greatest drop from previous high levels. These results show tight regulation of PA levels in muscle by some neural influence. The mechanism of this influence is currently under study.

Supported by INSERM, the AMF, MDA, the ALS Association and the Medical Research Service of the Veterans Administration.

137.19 NEONATAL HERPES SIMPLEX VIRUS INFECTION OF MICE: AVOIDANCE LEARNING AND VIRUS CHARACTERISTICS. L. S. Crnic and L. I. Pizer* (SPON: J. Nolte) Depts. Pediatr., Psychiat., Microbiol., Univ. Colo. Sch. Med., Denver, CO 80262.

We have previously reported that neonatal infection with a mutant herpes simplex type 1 (HSV-1) virus produces transient CNS infection, interferes with granule cell migration in the cerebellum, and produces hyperactivity and deficits in passive avoidance but not in radial maze learning. We now report further behavioral effects and characterize the mutant virus.

Wild-type HSV-1 (14-120) was mutated and virions selected that grew in primate, but not mouse cells in vitro. BALB/c mice were injected subcutaneously in the shoulder on the second day of life with 2.5×10^6 plaque forming units of the mutant virus. The infection was mild, producing no deficits in body weight. Mice selected for high activity (> 95 squares crossed in a 3 min. open field test) were compared to control mice that had been injected with a killed virus preparation. Mice were trained in a shuttle box avoidance task signalled with 5 seconds of light and buzzer preceding 200 μa shock. Intertrial intervals were 30 sec. and 30 trials were run per day. There was no difference between infected and control groups (mean trials to criterion 18 ± 5 for infected mice, 20 ± 7 for control mice). While we have previously shown neonatally infected mice to be poor at passive avoidance learning, the present results show that they learn active avoidance normally, and thus likely have a deficit in inhibition of behavior rather than any difficulty with shock avoidance.

Several studies were undertaken to characterize the differences between wild-type virus, which kills neonates, and mutant virus, which produces mild infections. DNA was extracted from both wild-type and mutant virus and another strain of HSV-1, KOS. Viral DNA was cut with restriction enzymes (Bgl I, Eco R1, Hind III, Sal I) and run on a polyacrylamide gel. There were no differences between wild-type and mutant on major bands and few minor band differences. In contrast, both wild-type and mutant differed from KOS in several major bands. Thus, the nature of the mutations must not involve major rearrangement of or deletions from the genome.

The ability of the virus to make thymidine kinase (TK) determines neurovirulence in HSV-1. Virus infected cells were exposed to ^{14}C labeled thymidine, washed and then exposed to film. Wild-type but not mutant virus demonstrated TK activity. 3 of 10 lines retrieved after passage of mutant virus through mouse brain showed normal TK activity. Thus, the virus can revert to the wild-type TK phenotype in vivo. We postulate that a minor mutation in the TK gene is responsible for the reduced virulence of the mutant. Supported by NIH HD18378.

137.20 EXPERIMENTAL HERPES SIMPLEX (TYPE 1) ENCEPHALITIS IN RAT: DISTRIBUTION OF INFECTED NEURONS DEMONSTRATED BY IN SITU HYBRIDIZATION. J.R. O'Kusky, D. Walker*, J.B. Hudson* and P.L. McGeer. Division of Medical Microbiology, Department of Pathology and the Kinsmen Laboratory of Neurological Research, Department of Psychiatry, University of British Columbia, Vancouver, B.C., Canada, V6T 1W5.

Herpes simplex virus (HSV) is a major cause of human viral encephalitis. Autopsy findings frequently indicate a selective involvement of temporal and orbital neocortex, hippocampus and amygdala. This anatomical specificity has led to speculation that HSV may reach the central nervous system via the olfactory pathway and its connections with the limbic system. The distribution of infected neurons in the brains of adult rats following intraventricular inoculation of HSV (type 1) was examined using in situ hybridization with cloned HSV-1 DNA probes.

Herpes simplex type 1 virus (strain F) was suspended in Eagle's minimal essential medium and inoculated into anesthetized Sprague-Dawley rats. Stereotaxic injections (5 μl of virus suspension containing 50, 500 or 2500 pfu) were made into the dorsal aspect of the left lateral ventricle at the level of the decussation of the anterior commissure. Control animals received similar injections of Eagle's medium. Infected animals were moribund by 7-9 days after inoculation, at which time they were perfused with 4% paraformaldehyde in 0.1 M phosphate buffer. The brains were embedded in paraffin and serial sections were cut in the frontal plane at 7 μm. These sections were processed for in situ hybridization using a modification of the procedure of Brigati et al. (Virology, 126: 32, 1983). One cloned HSV-1 fragment from HSV-1 strain F (Eco R1 fragment G) was used as probe. The cloned HSV-1 DNA was labeled by random priming with ^{35}S dCTP to a specific activity of approximately 10^9 cpm/μg. Slides were coated in liquid film emulsion and exposed for 1-2 weeks.

Infected neurons were found to be concentrated bilaterally throughout the olfactory tubercle and the adjacent pyriform cortex. Smaller patches of infected neurons were detected in the caudate-putamen and basal forebrain. In the neocortex scattered neurons were seen most frequently in the cerebral hemisphere ipsilateral to the site of injection. The preferential distribution of infected neurons in the olfactory tubercle and pyriform cortex appears to be independent of an olfactory route of entry. Other factors which determine the neurotropism and localization of HSV infection within the brain are likely to include the distribution of HSV receptors. (Supported by the Medical Research Council of Canada)

138.1 A COMPARISON OF TWO N-METHYL-D-ASPARTATE ANTAGONISTS, CPP AND CGS 19755, IN THE GERBIL FOREBRAIN ISCHEMIA MODEL. C.A. Boast, S.C. Gerhardt*, G. Pastor*, J.C. Lehmann, P.E. Etienne and J.M. Liebman. Research Dept, Pharma Division, CIBA-GEIGY Corp., Summit, NJ 07901.

Previous reports have indicated that N-methyl-D-aspartate (NMDA) antagonists, administered intracerebrally, can have protective effects against brain damage following ischemia (Simon et al, 1984) or hypoglycemia (Wieloch, 1985). Systemic administration of 2-amino-7-phosphonoheptanoic acid (AP7) (Boast et al, 1987) or ((+)3-(-2-carboxypiperazin-4-yl)propyl-1-phosphonic acid (CPP) (Gerhardt & Boast, 1986) to gerbils can also limit ischemic brain damage. We now report a detailed comparison of CPP and a novel NMDA antagonist, cis 4-(phosphonomethyl)-2-piperidine-carboxylic acid (CGS 19755) (Lehmann et al, in preparation) in the gerbil ischemia model.

Bilateral carotid occlusion (20 min) of female Mongolian gerbils (TUM:[Mon], Tumblebrook Farms, West Brookfield, MA, 50 - 70 g) was conducted under methoxyflurane anesthesia. The drugs were administered at various doses intraperitoneally (i.p.) four times 2 hr apart, beginning at various times relative to the initiation of ischemia. Motor activity was measured, using Omnitech Digiscan chambers, 1 and 4 days later. Brains were removed, and sections were evaluated for evidence of hippocampal damage using a 5 point rating scale.

Both drugs showed statistically significant effects on ischemia-induced hypermotility and hippocampal damage. When drug administration began 15 min prior to the carotid occlusion, CPP was effective at 30 mg/kg, while CGS 19755 was effective at both 10 and 30 mg/kg. When 30 mg/kg of either drug was administered beginning some time after the initiation of carotid occlusion, CGS 19755 retained protective effects even with a delay of 4 hr, while CPP was not effective when a 1 hr delay was used. After a 24 hr delay between ischemia and drug treatment, neither drug showed positive effects.

These data support the growing body of evidence that NMDA antagonists may be useful in treating human brain ischemia which results from stroke or cardiac arrest. In particular, CGS 19755 appears to be a potent compound with protective effects that persist despite treatment delays of several hours.

138.2 THE NON-SEDATING BENZODIAZEPINE PARTIAL AGONIST CGS 9896 REDUCES ISCHEMIC HIPPOCAMPAL DAMAGE IN GERBILS. S. C. Gerhardt*, G. Pastor* and C. A. Boast. (SPON: R. Katz) Neuroscience Research, Pharma Division, CIBA-GEIGY Corp., Summit, NJ 07901

Degeneration of hippocampal neurons following ischemia in gerbils may be reduced by drug treatments acting through various mechanisms. Several drug classes (barbiturates, excitatory amino acid antagonists, benzodiazepines) that have been effective against ischemic damage also have sedative properties. It is not known whether the sedative properties of any of these compounds are essential for the observed protective effects. Non-sedating anxiolytics, such as CGS 9896 (Bennett and Petrack, 1984), which acts via benzodiazepine modulation, have now been described. We used the gerbil ischemia model to assess the effects of CGS 9896 and the sedating benzodiazepine, diazepam.

Female Mongolian gerbils (TUM:[Mon], Tumblebrook Farms, West Brookfield, MA) weighing 50-70 g were anesthetized with methoxyflurane and subjected to 20 min of bilateral carotid occlusion. Drug-treated animals received two injections (30 mg/kg i.p.) 4 hr apart, beginning either 15 min prior to carotid occlusion or immediately after occlusion. Ischemic controls received no injections.

Motor activity was recorded for 30 min in Omnitech Digiscan (Columbus, Ohio) chambers on the first and fourth day after the occlusion. Following the final motor activity assessment, brains were removed, sectioned, stained and evaluated for hippocampal damage using a 5-point rating scale.

Ischemia-induced motor activation, which has been shown to be correlated with the degree of hippocampal neuronal damage (Gerhardt and Boast, 1987), was reduced by pretreatment with CGS 9896 or diazepam. Post-treatment with diazepam was also effective. Hippocampal damage was decreased by both drugs, whether given before or after occlusion.

These results might be explained by a number of possible mechanisms, some of which may be related to the anticonvulsant properties of these drugs. Direct mechanisms include inhibition of abnormally high firing rates of hippocampal neurons, GABA facilitation, or alterations in postsynaptic potentials and resultant changes in Cl^- and Ca^{++} ion flux. It is also possible that there is an indirect mechanism by which the drugs would have effects on neurons other than those that are destroyed after ischemic insult. Regardless of the mechanism of action, it is now clear that sedation per se is not required in order for drugs acting via the benzodiazepine receptor complex to protect hippocampal neurons from ischemic damage.

138.3 GERBIL FOREBRAIN ISCHEMIA INCREASES ACETYLCHOLINE TURNOVER IN THE HIPPOCAMPUS BUT NOT IN STRIATUM. L.L. Peoples*, C. Cosi*, S.C. Gerhardt*, P.L. Wood and C.A. Boast. (SPON: R. Infurna) Psychol. Dept., Rutgers Univ., New Brunswick, NJ 08903 and Neuroscience/ Cardiovascular Research, Pharma Div., CIBA-GEIGY Corp., Summit, NJ 07901.

Reversible forebrain ischemia has been shown to produce selective hippocampal damage in rodents. Cognitive impairments associated with hippocampal damage have also been demonstrated in ischemic animals. Alterations in acetylcholine (ACh) function have been implicated in a variety of cognitive impairments in animals and humans. This study investigated the changes in ACh turnover (Tr) in hippocampus and striatum of gerbils which had been subjected to forebrain ischemia.

Under methoxyflurane anesthesia jugular catheters and loose carotid ligatures (Chandler et al, 1985) were externalized in female Mongolian gerbils (TUM: [Mon], Tumblebrook Farms, West Brookfield, MA). The gerbils were allowed to recover for 24 to 48 hr and then the carotid ligatures were tightened in an experimental group, thus occluding blood flow for 5 min. Twenty four hr later motor activity was measured in both experimental and control animals using Omnitech Digiscan apparatus (Columbus, OH). Increased motor activity at that time has been shown to be correlated with the degree of resulting hippocampal damage (Gerhardt & Boast, 1987). Five or six days after carotid occlusion phosphoryl-D9-choline dissolved in saline was infused via the jugular catheter at a rate of 15 umol/kg/min in a volume of 0.1 cc/min for 9 min. Gerbils were killed by focused microwave irradiation, brains were removed and bilateral samples of dissected hippocampus and striatum were frozen separately. The tissue samples were later prepared for gas chromatography - mass spectrometry (GC-MS) analysis of choline and ACh content (Hanin, 1974). The percentage of deuterium incorporated into regional brain choline or acetylcholine was monitored by GC-MS using the positive ionization mode (Wood & Peloquin, 1981). ACh Tr rates were calculated using the single infusion time method (Racagni et al, 1974).

Initial studies on non-ischemic gerbils were conducted to determine the necessary rate constants related to the time course of choline uptake and incorporation into ACh. These rate constants were found to be similar to those previously determined for the rat (Racagni et al, 1974). In ischemic gerbils ACh turnover in the hippocampus was significantly increased (average > 100%), but ACh turnover was not significantly affected in the striatum (average < 25%).

These data indicate that forebrain ischemia in the gerbil can result in selective increases in ACh Tr in the hippocampus. Since selective neuronal damage is also seen in this brain region, it is reasonable to postulate that the neurons that are damaged by ischemia usually participate in a negative feedback loop onto the cells of origin for ACh. Removal of this feedback could then result in increased ACh Tr. The possible implications for cognitive function are not clear at this time.

138.4 A NOVEL N-METHYL-D-ASPARTATE ANTAGONIST, CGS 19755, PREVENTS ISCHEMIA-INDUCED REDUCTIONS IN ADENOSINE A-1 RECEPTORS IN GERBIL BRAIN: A QUANTITATIVE AUTORADIOGRAPHIC STUDY. Michael F. Jarvis, Deborah E. Murphy, Michael Williams, Susan C. Gerhardt and Carl A. Boast. Drug Discovery Division, Research Department, Pharmaceuticals Division, CIBA-GEIGY Corporation, Summit, NJ 07901.

The CA-1 region of the hippocampus contains the greatest density of adenosine A-1 receptors in the mammalian brain and transient brain ischemia results in the destruction of the pyramidal cell layer within this region. Brain damage following an ischemic insult appears to result from the release of toxic quantities of endogenous excitatory amino acids (EAA; Hagberg et al.,1985). This mechanism is further supported by demonstrations that EAA receptor antagonists can block ischemic brain damage (Simon et al., 1984; Boast et al., 1987). In the present study, quantitative autoradiography of adenosine A-1 receptors was used to evaluate the protective effects of a new N-methyl-D-aspartate (NMDA) antagonist, CGS 19755 (Lehmann et al., this meeting). Under methoxyflurane anesthesia, female Mongolian gerbils (TUM:[MON]) had both common carotid arteries occluded for 20 min with microaneurysm clips. Drug-treated gerbils received four injections of CGS 19755 (30 mg/kg i.p.) 1, 3, 5 and 7 hours after the ischemic episode. Ischemic and normal controls received no injections. Four days following the ischemic episode, animals were sacrificed and [^{3}H]CHA (Cyclohexyladenosine) used to label adenosine A-1 receptors in 20 µ coronal brain sections. Tissue sections were incubated in Tris-HCl buffer (pH, 7.4) for 2 h using 4 nM [^{3}H]CHA. Non-specific binding was measured in the presence of 20 µM-2-CADO. Following washing and drying, sections were opposed to tritium-sensitive film for a month. Resulting autoradiograms were analysed using video densitometry.

[^{3}H]CHA binding sites were heterogenously distributed in gerbil brain with the greatest density of A-1 receptors in the stratum radiatum of the hippocampus followed by stratum oriens > cerebral cortex > thalamus. The 20 min ischemic episode caused a 35% reduction in [^{3}H]CHA binding in hippocampus and cortex but not thalamus. Post ischemic treatment with CGS 19755 resulted in a significant protection of the ischemia-induced reduction in A-1 receptor binding in both hippocampus and cortex. These results indicate that A-1 receptors in the CA-1 region of the hippocampus may be associated with pyramidal cells in agreement with other reports (Lee and Kreutzberg, 1987). Additionally, the selective NMDA-antagonist, CGS 19755, is effective post episode in reducing ischemia-induced alterations in adenosine A-1 receptors in the hippocampus and cortex.

138.5 FURTHER PROBING THE BRAIN LIPID CHANGES IN POST-DECAPITATIVE ISCHEMIA. R. Chandrasekhar* and G.Y. Sun (SPON: D. O'Brien). Biochemistry Dept. and Sinclair Comparative Medicine Research Farm, University of Missouri, Columbia, MO 65203.

Previous studies in our laboratory with rats injected ^{32}Pi (i.p.), ^{32}P-ATP and ^{3}H-inositol (intracerebrally) have indicated rapid decline of poly-phosphoinositides (Poly-PI) with time of post-decapitative ischemia. Concomitantly, there is an increase in the levels of diacylglycerols (DG) and free fatty acids (FFA). With poly-PI labeled with ^{3}H-inositol, the decrease in poly-PI is also marked by an increased turnover of inositol-phosphates which can be followed with time. Although the increase in DG can be largely accounted for by the decrease in poly-PI, the 3-5 fold increase in FFA remains unexplained. The present studies are directed towards probing the effects of post-decapitative ischemia on brain phospholipids that are prelabeled with ^{14}C-acetate. Three to four week-old Sprague Dawley rats were injected intracerebrally with 25 uCi of 1-^{14}C-acetic acid two hours prior to decapitative ischemic treatment (5 min). Under this condition, labeling of brain phospholipids due to acetate was attributed mainly to the de novo synthesis of fatty acids and subsequent phospholipid biosynthesis. Approximately 45% of the label was found in phosphatidylcholines although all other phospholipids, neutral glycerides, and cholesterol were also labeled. Ischemic treatment (5 min) resulted in no observable decrease in the major phospholipids except for a decrease in labeled phosphatidic acid and an increase in labeled DG. There was no obvious increase in the labeled FFA. These results suggest that the phospholipid pool represented by de novo biosynthesis did not participate in the FFA release due to post-decapitative ischemic treatment. Studies using another lipid precursor (e.g. ^{14}C-arachidonic acid) are presently in progress to further elucidate the mechanism of FFA release due to the ischemic insult. (Supported in part by AA 06661 from NIAAA).

138.6 ELECTROPHYSIOLOGICAL CORRELATES OF ISCHEMICALLY INDUCED NEURONAL DAMAGE IN THE RAT HIPPOCAMPAL FORMATION. J.J. Miller, J.M. Klancnik and L.A. Mudrick. Dept. of Physiology, University of British Columbia, Vancouver, B.C., Canada, V6T 1W5.

The mechanisms involved in the selective neuronal degeneration of hippocampal CA1 neurons, following cerebral ischemia, are poorly understood. It has been hypothesized that changes in calcium gradients may initiate a cascade of cellular events that cause delayed cell death. Utilizing an in vivo preparation we have followed the effects of ischemia on evoked population responses in the CA1 and dentate gyrus (DG), in order to to elucidate the events occurring during and after ischemia.

Male Wistar rats (350-500g) were anesthetized with urethane, the femoral artery cannulated and baseline mean arterial pressure (MAP) was recorded. Electrodes were implanted in the perforant path (PP) and ipsilateral DG to stimulate and record population responses in the DG, and in area CA3 and contralateral area CA1 to stimulate and record responses in the CA1. Paired pulse stimuli were applied from both PP and CA3 electrodes with 20 msec intervals between the first and second pulse of each pair. Responses were evoked and recorded before, during and for 24 hrs after an ischemic episode induced by haemorrhaging the animal until MAP reached 30 mmHg followed by bilateral carotid occlusion for 20 mins. Following release of the carotids, blood from the reservoir was reinfused. This model of ischemia produces consistent, highly selective damage to 93% of area CA1.

During ischemia all responses in both DG and CA1 rapidly disappeared. Recovery of population responses in the DG began within 1/2 hr following reinfusion. DG population spike amplitude rapidly increased to 200-300% of baseline value, without a corresponding increase in population EPSP slope, and maintained this increased amplitude for the duration of the experiment. The paired pulse responses indicated a loss of recurrent inhibition both at the onset of ischemia and during the early phase of post-ischemia recovery. CA1 population responses did not usually start to recover until about four hours after reinfusion. These responses recovered at most to baseline values, then attenuated and usually disappeared within 24 hrs. No changes in recurrent inhibition were found in the CA1. In addition, after ischemia, population spike latencies in both regions increased by up to 4 msec for the entire duration of the experiment.

These data indicate that functional damage to the CA1 pyramidal cells occurs within 24 hrs of ischemic insult. In contrast, the dentate granule cells demonstrate greatly potentiated responses. It is possible that this potentiation may be contributing to the pathophysiological processes occurring in CA1. (Supported by a Canadian MRC Program Grant to J.J.M.)

138.7 DETECTION OF 60k, A PUTATIVE PROTEIN KINASE C SUBSTRATE, IN THE CSF OF PATIENTS WITH PARANEOPLASTIC CEREBELLAR DEGENERATION. S. Gandy, J. A. Grebb, N. Rosen, K. Albert*, N. Anderson*, J. Cedarbaum, G. Sedvall*, J. B. Posner and P. Greengard. The Karolinska Institute, Stockholm, Sweden and Memorial Sloan-Kettering Cancer Center, The New York Hospital-Cornell Medical Center and The Rockefeller University, New York, NY 10021.

A variety of protein kinase substrate proteins, possibly neuron-specific, have been detected in human cerebrospinal fluid (CSF) by radioactive phosphorylation using 32P-ATP and protein kinases, followed by imaging with PAGE/autoradiography (Gandy et al, Neurology 37(Suppl 1): 193, 1987). Among the proteins which contribute to the CSF, those which participate in phosphorylation systems are likely to be neuron-specific because of the relative abundance of protein kinases and their substrate proteins within neurons. A systematic survey of phosphoprotein patterns in CSF from normal individuals and from patients with various neurologic and psychiatric diseases is in progress. One such illness, termed paraneoplastic cerebellar degeneration (PCD), is associated with rapid selective necrosis of Purkinje cells in the setting of active systemic cancer. Circulating anti-Purkinje-cell-antibodies (APCAs) may also be present. Using the CSF phosphoprotein pattern assay, we have detected the presence of a putative protein kinase C substrate of apparent Mr 60kd in 6 of 12 patients with PCD. This 60kd phosphorylatable protein was not seen in CSF from over 150 other patients, including normals and non-PCD ataxic disease controls such as olivopontocerebellar atrophy. Stratification by tumor type and presence of serum APCA disclosed that 60k was detectable in the CSF of 2/5 lung cancer patients (all APCA negative), 2/2 Hodgkin's disease patients (both APCA negative), 1/2 ovarian cancer patients (both APCA positive) and 1/2 patients with adenocarcinoma, primary unknown (both APCA positive). Neither serum APCA nor CSF 60k was present in a patient with breast cancer and PCD. The detection of this presumed Purkinje-cell-specific 60kd protein in PCD but not in other ataxias may be due to the more rapid course of PCD, leading to the relatively rapid accumulation of previously intracellular proteins in the CSF. The identification of neuron-specific phosphoproteins in human CSF may advance our understanding of the biochemical composition of at-risk neurons in various clinical situations. Further, disease-associated CSF phosphoprotein patterns may aid in antemortem diagnosis, differential diagnosis, nosology of neurologic and psychiatric diseases, and objective assessments of disease "activity" and response to therapy. [Supported by the Dystonia Medical Research Foundation, Huntington's Disease Foundation and The New York Academy of Medicine]

138.8 INCREASED 3-HYDROXYANTHRANILIC ACID OXIDASE AND DECREASED PICOLINIC CARBOXYLASE ACTIVITIES IN C6-GLIOBLASTOMA CELLS, FOLLOWING SERUM DEPRIVATION OR HERPES VIRUS INFECTION. E.G. Shaskan. Dept. of Medicine, Univ. of Connecticut Health Ctr., VA Medical Ctr., Newington, CT 06111.

Intermediary metabolism of tryptophan (kynurenine pathway) has long been associated with infectious diseases in man and recently has been linked to pathogenesis of human neurodegenerative disorders. The branch-point around 3-hydroxyanthranilic acid (3-HA) is theoretically important, since the products formed are potential intracellular chelators of Fe^{3+} (picolinic acid = PA) and Fe^{2+} (quinolinic acid = QUIN) and, thus, may play roles in iron-withholding as host defenses against intracellular microbes. Additionally, QUIN may be an endogenous neurotoxin (excitotoxin).

3-Hydroxyanthranilic acid oxidase (HAO) catalyzes the conversion of 3-HA to α-amino-β-carboxymuconic semialdehyde which then can be a substrate for picolinic carboxylase (PC) or spontaneously rearrange to form QUIN. Since HAO has been localized to astroglial cells in situ by immunohistochemistry, its activity was assessed in rat C6-glioblastoma cells which, in my laboratory, are also studied for their unique ability to naturally establish persistent infections by herpes simplex virus type 1 (HSV1). Although no measurable HAO activity could be demonstrated in C6 cells under standard serum conditions at cellular confluence, following serum deprivation for 1 hour more than three-times boiled-blank values of ^{14}C-QUIN were isolated from supernatants fractionated by standardized Dowex 50W cation exchange columns (method of Foster, et al., J. Neurochem. 47, 23, 1986), corresponding to values of approximately 100 pmol QUIN formed per mg protein per hour. Measured as $^{14}CO_2$ evolved from the same high speed supernatants, PC activity fell from stable baseline values of approximately 35 pmol per mg protein per hour under standard serum conditions to unmeasurable levels following 1 hour serum deprivation. This and related inverse relationships between HAO and PC activity, in direct temporal response to serum alterations, was also observed in VERO cells (transformed monkey kidney) and in primary cultures of human fibroblasts (HFFs). Independent of serum conditions, acute HSV1 infection increases HAO activity and decrease PC activity by an early mechanism associated with internalization of the virus, as determined from temperature studies. Absolute magnitudes for these host-cell enzyme responses to HSV1 infection seem to be more accentuated in permissive cells (VEROs and HFFs) than in restrictive cells (C6), although it remains speculative that modulation of this host cell response bears causal relationship to establishment of persistent HSV1 infection of C6 cells. Although precise mechanisms for alternate activation and inhibition of these branch-point enzymes requires further investigation, preliminary evidence suggests a role for ferrous iron. (Supported by The U.S. Veterans Administration and by the Univ. of Connecticut Research Foundation.)

138.9 SCHWANN CELL REMYELINATION RESTORES SECURE CONDUCTION TO CENTRAL DEMYELINATED NERVE FIBERS. P.A. Felts and K.J. Smith (Spon. G.E. Goode), Department of Anatomy and Cell Biology, Eastern Virginia Medical School, Norfolk, VA 23501 USA

Demyelinated central nerve fibers can be remyelinated by Schwann cells, but the conduction properties of the remyelinated fibers are not known. These properties are of interest since it is now possible to remyelinate persistently demyelinated central axons by the artificial introduction of Schwann cells into the lesion (Blakemore, Neuropath. Appl. Neurobiol. 8:365-375, 1982), and this finding has been advanced as of potential importance with respect to diseases such as multiple sclerosis.

Five rats were implanted with pairs of stimulating electrodes positioned extradurally over the dorsal columns at T_{12} and L_1. Recording electrodes were also implanted adjacent to each sciatic nerve at the ischium, so that recordings could be made (from anesthetized and paralyzed animals) every 1-2 weeks, for several months. It was therefore possible to obtain serial records of activity conducted through the lesion site, both before the lesion was induced, and during the periods of demyelination and remyelination.

After a control recording period of four weeks, the rats were again anesthetized, and ethidium bromide (1.0 µl of 0.5 mg/ml; Blakemore and Crang, J. Neurol. Sci., 70:207-223, 1985) was injected via a micropipette into the left dorsal column at T_{13}, to produce a unilateral demyelinating lesion in which all the affected fibers later underwent repair by remyelination. Records taken one hour after injection were normal, but during the period of demyelination (examined between 7-21 days) conduction in the affected fibers was blocked. Conduction was progressively restored during the period of remyelination, such that the compound action potential regained 60% of its normal amplitude by 10 weeks. The conducting fibers initially had prolonged refractory periods of transmission, but this parameter returned to within normal limits by 10 weeks. The number of conducting fibers could initially (between three and six weeks) be increased by reducing the body temperature, but this temperature sensitivity eventually disappeared. All records obtained omitting the lesion from the conduction pathway remained normal throughout the recording period.

Histological examination revealed the presence of a large (up to 80% of the ipsilateral dorsal column) lesion of Schwann cell remyelinated fibers, bordered by a thin band of fibers (2-15 wide) remyelinated by oligodendrocytes. The results show that Schwann cell remyelination of rat dorsal column axons is effective in restoring secure conduction.

138.10 **IMPROVEMENT OF THE CNS PATHOLOGY IN THE TWITCHER MOUSE FOLLOWING BONE MARROW TRANSPLANTATION.** **K.Suzuki, P. Hoogerbrugge*,B. Poorthuis* and K. Suzuki. University of North Carolina at Chapel Hill, N.C.; TNO Radiobiological Institute, Rijswijk, University of Leiden, Leiden, The Netherlands.**

The twitcher is an authentic murine model of globoid cell leukodystrophy (GLD), caused by a genetic deficiency of a lysosomal enzyme, galactosylceramidase. Its neuropathological hallmark is severe demyelination of the CNS white matter associated with degeneration of oligodendrocytes, gliosis and infiltration of macrophages. On the ultrastructural level, typical tubular and/or crystalloid inclusions are found in the cytoplasm of oligodendrocytes as well as in these macrophages. Various degrees of demyelination involve the PNS as well. The twitcher develops neurological symptoms around the day 20 postnatal and usually dies around the day 40. Following isogenic bone marrow transplantation (BMT), specific activity of galactosylceramidase increased and reached to the donner level in the bone marrow and spleen at day 14 after BMT. In the brain the enzyme activity increased slowly but steadily and reached 14-16% of control value at day 80-100 after BMT. Light and electronmicroscopic studies were carried out on these twitcher mice at 44, 102, 106 and 109 days after BMT. At 44 days, CNS pathology does not differ significantly from untreated twitcher mouse. Degeneration of myelin was extensive and macrophages containing typical inclusions of GLD were numerous in particular in the white matter of the cerebellum, brainstem and spinal cord. Vesiculation of myelin lamellae and myelin stripping by macrophages were observed. In addition to the typical macrophages of GLD, however, some lipid-laden macrophages were also found in the white matter. On some occasions macrophages contained both typical GLD inclusions and foamy lipid inclusions. In the CNS of the twitcher more than 100 days after BMT, many lipid-laden macrophages were observed but typical macrophages of GLD were either not observed or extremely rare. Degeneration of myelin lamellae was rare, and instead many thinly myelinated nerve fibers suggestive of remyelination were observed. GLD inclusions were, however, found in the cytoplasm of apparently remyelinating oligodendrocytes. Remyelination was evident in the PNS as well, and remyelinating Schwann cells also contained GLD inclusions. These findings suggest that following BMT, donner macrophages infiltrate into the Twitcher CNS and contributed to an improvement of the CNS pathology by supplying deficient enzyme, galactosylceramidase.

138.11 **CONTRAST ENHANCEMENT (POINT PROCESS) AND EDGE DETECTION TECHNIQUES IN COMPUTER TOMOGRAPHY AND NUCLEAR MAGNETIC RESONANCE BRAIN IMAGING.** T. Goldberg,* M.F. Casanova,* R. Suddath,* D. Daniel*, D. Weinberger. Clinical Brain Disorders Branch, St. Elizabeth's Hospital (NIMH, Washington, D.C. 20032

Computer Tomography (CT) and Magnetic Resonance Imaging (MRI) have revolutionized the practice of neurology by allowing accurate diagnosis of structural abnormalities in a non-invasive manner. While these techniques produce "scans" that are usually interpreted in a qualitative fashion, they generate quantitative information. Unfortunately, the quantitative interpretation of resultant images is limited by artifacts, partial volume effects, the physical properties of the structure visualized and physiological biases in image perception by the human eye. The use of a computer image analysis system (LOATS) makes interpretation easier by enhancing both contrast and edges. Images are digitized from X-ray films placed over a light box. Resolution is maximized by lowering the camera until the image of interest covers the whole field of view. Software routines allow calibration of background elimination. Contrast is enhanced by limiting the gray scale used to the transmission values of interest and selectively stretching its dark, midportion or bright regions. In those cases where the gray and white matter of the brain are studied, transmission values of cerebrospinal fluid and bone are noise clipped. Since the human eye can distinguish different colors better than shades of gray, optical density values are assigned to a fixed color scale. We have found gray scale reversal to be of use for cases where saturation is present at the dark end of the spectrum. Cinematographic sequencing of gray scale reversal, different coloration schemes and either dark or bright region stretching provides detailed information about image contours. Edge enhancement is implemented by Laplace transformation or Nomarski pseudo-optics. Both methods create high spatial frequencies of points which are emphasized by the human eye and give an idea as to the roughness of a section. Smoothing provides a linear weighting of adjacent pixels that deteriorates contrast and edges but is useful for correcting film artifacts. Enhancing contrast and edges of CT scan and NMR films maximizes their signal to noise ratio and emphasizes features which would otherwise be lost by cursory visual examination.

138.12 FURTHER STUDIES OF THE EXCITABLE PROPERTIES OF TE-671 CELLS. E. K. Stauffer and R. J. Ziegler. Depts. Physiol. & Microbiol. Univ. Minnesota-Duluth, Sch. of Medicine, Duluth, MN 55812.

We have reported (Ziegler & Stauffer, 1986. Soc. Neurosci. Absts. 12:87) that the presence of mumps virus changes the distribution of stimulus-evoked action potentials (SEAPs) of persistently-infected (PI) TE-671 cells from one composed primarily of normal, rapidly-rising, all-or-none SEAPS to one dominated by abnormal, slowly-rising, graded responses or by no responses at all. Short-term (48 hrs) treatment with rabbit anti-mumps antibody (RAA) did not reverse the effect.

The present data are from control studies which were designed to more fully describe the electrical characteristics of the TE-671 cell line, and from test studies designed to extend our previous observations by examining for certain membrane-associated phenomena which might be associated with the viral effect. Long-term (240 hrs) exposure to RAA was also investigated.

SEAPs were recorded intracellularly (single electrode current- and/or voltage-clamp) from cell cultures (mock-infected [MI] and PI) in response to anode-break stimulation. Standard ionic channel blockers (tetrodotoxin [TTX], tetraethylammonium ion [TEA], and cobalt ion [Co^{++}]) and/or ion substitutes were used to differentiate and identify specific voltage-gated ionic currents. Membrane electrical properties (resistance [R], time constant [τ], and capacitance [C]) were measured and/or calculated.

There were no significant differences of R, τ, or C between MI and PI cells. Long-term RAA treatment did not reverse the distribution of PI SEAPS to that found for the MI cells. Initial control studies from MI cells have shown rapid, inward currents to be associated with the rising depolarization phase of SEAPs, but there were no outward currents during the falling repolarization phase. TEA had no observable effect on the SEAPs. Instead, τ of the falling phase was similar to τ of electrotonic potentials recorded from the same cell. TTX greatly reduced the magnitude and rate of rise of SEAPs; Co^{++} eliminated the residual SEAP. Conductances calculated for SEAP repolarizations were not different from those of the resting state. These data are consistent with other results of virus-induced alterations of voltage-gated Na^+ channels (Fukuda et al. 1983. Brain Res. 262:79-89).

Supported in part by a grant from the Minnesota Medical Foundation.

138.13 ASTROCYTOSIS IN CAPRINE β-MANNOSIDOSIS. K. L. Lovell. Dept. of Pathology, Michigan State University, E. Lansing, MI 48824

Caprine β-mannosidosis, a genetic dysmyelinating disorder, is associated with a deficiency of β-mannosidase activity and tissue accumulation of oligosaccharides. Cytoplasmic vacuolation occurs in many cell types in the viscera, and, to various extents, in neurons and glia in the central nervous system. Clinical symptoms present at birth in goats include inability to stand and intention tremor. Morphological changes previously reported in fetal and postnatal goats with β -mannosidosis include severe myelin paucity in the brain and very mild deficits in the spinal cord. Consistent regional variation in the extent of myelin deficiency is an important feature of the brain pathology. Gliosis in some regions has been reported, but the astrocyte involvement has not been extensively investigated. In the present study, immunocytochemistry to localize glial fibrillary acidic protein (GFAP), a marker for astrocytes, was performed on paraffin-embedded and Epon-embedded sections from various regions in fetal (124/150 days gestation) and postnatal affected and control goats. The density and distribution of GFAP reactivity was analyzed in these sections. In some regions, changes in the distribution of glial processes were determined by electron microscopy and compared to immunocytochemical results.

In cerebellar white matter, both paraffin-embedded and Epon-embedded sections showed considerably more GFAP reactivity in the affected postnatal animals than in the control animals. However, the patterns of GFAP staining in the internal granular layer and the molecular layer were not substantially different between affected and control animals. In the optic nerve, increased numbers of astrocytic processes were present as early as 124 days gestation; previous studies demonstrated a substantial deficit in the number of myelinated axons at this relatively early stage of myelination. Regions of the cerebral white matter in postnatal affected goats showed more numerous astrocytic processes stained for GFAP than in control goats. These results indicate that early, as well as late, astrocytosis occurs as a prominent component of the pathological changes in β-mannosidosis. Further analysis of the development of the astrocyte and oligodendrocyte changes in this disorder will help define the pathogenesis of the dysmyelinogenesis and the gliosis.

138.14 DETECTION OF SOMATOSTATIN mRNA BY IN SITU HYBRIDIZATION CYTOCHEMISTRY IN NEURONS OF THE CAUDATE NUCLEUS OF THE HUMAN. W.A. Stoutenger[1,2], and M.-F. Chesselet[2]. Depts. of Neurosurgery[1], Pharmacology and Anatomy[2], Med. Col. of Pa., Philadelphia, PA 19129.

Neurons expressing somatostatin-like immunoreactivity have been described in the caudate nucleus of the rat, cat, monkey, and human. These somatostatin-positive neurons have been described morphologically as medium aspiny neurons and also contain NADPH-diaphorase activity.

In this study we sought to determine whether the mRNA for pre-pro-somatostatin (the precursor of somatostatin) could also be detected in post-mortem human striatum. An ^{35}S UTP labelled RNA probe complimentary to the mRNA for pre-pro-somatostatin was transcribed from a cDNA inserted in the SP65 vector (obtained from R. Goodman-Tufts Univ.). Human post-mortem tissue was obtained at autopsy; caudate nucleus was quickly frozen on dry ice, sectioned at 10 um, and kept at -70 C° until the morning of the experiment. Sections were quickly defrosted, fixed in paraformaldehyde, acetylated, dehydrated in graded ethanol, and hybridized for 3 1/2 hours at 50 C°. Following hybridization stringent rinses were applied to remove excess probe and RNAse treatment was performed to hydrolyse probe remaining as single strand non-hybridized RNA. Autoradiography was performed with Kodak NTB3 emulsion[1]. Some sections were stained for NADPH-diaphorase activity prior to in-situ hybridization.

Heavily labelled neurons of medium size were found scattered throughout the caudate and in tissue stained for NADPH-diaphorase activity these neurons were found to also be NADPH-diaphorase positive.

These results show that the mRNA for pre-pro-somatostatin can be detected by in situ hybridization cytochemistry in somatostatinergic neurons of the human caudate nucleus in autopsy material. Because neurons expressing somatostatin immunoreactivity have been shown to be preferentially preserved in the caudate nucleus of patients who died with Huntington's Disease we are now using the same approach to analyze levels of pre-pro-somatostatin mRNA in single cells in post mortem Huntington's Disease brain.

138.15 LYME BORRELIOSIS PATIENTS' SERA INHIBIT SYNAPTIC TRANSMISSION IN HIPPOCAMPAL SLICES. N. T. Carnevale, J. Monckton, J. J. Halperin Dept. of Neurology, SUNY, Stony Brook NY 11794

We have previously reported that many patients with chronic infection with Borrelia Burgdorferi have significant, reversible intellectual impairment, including memory dysfunction and fatigue. Clinical anatomic (CT and MRI scanning) and physiologic (EEG and evoked potentials) tests have failed to demonstrate a pathophysiologic basis for this disorder. Since there is physiologic and immunocytochemical evidence that serum factors may impair the functioning of CNS neurons in other diseases (eg multiple sclerosis, Sydenham's chorea, lupus erythematosis) we studied the effects of sera from patients with Lyme borreliosis (L.b.) on synpatic transmission in hippocampal slices in vitro.

Sera were obtained from normal volunteers, from L.b. patients with CNS symptoms, and from L.b. patients without CNS dysfunction. Samples were dialyzed (mw cutoff 3500) against hippocampal Ringer solution, and then diluted 1:4 in Ringer's. Rat hippocampal slices were prepared and maintained using standard techniques. Extracellular recordings were obtained from the CA1 region in response to stimulation of the Schaffer collaterals. Measurements were performed before and during exposure to test solutions, and after return to normal Ringer.

Control sera had no effect, but sera from many patients depressed the amplitude of the field EPSP and population spike (on average by approximately 20%). We conclude that sera from L.b. patients contains factors that affect neuronal function. This effect may be related to the CNS symptoms experienced by these patients. Work is in progress to identify these factors and the cellular mechanism(s) responsible for their effects.

This work was supported, in part, by a Veterans' Administration merit review grant (NTC).

138.16 THE DEVELOPMENT OF FUNCTIONAL ISLET CELL ADENOMAS IN SV40 TRANSGENIC MICE WITH PERIPHERAL NEUROPATHY. K. Dyer* and A. Messing. School of Veterinary Medicine, University of Wisconsin, Madison, WI 53706.

The expression of oncogenes in transgenic mice has become a useful means for creating animal models of disease processes, including those involving systemic influences on the nervous system. One group of transgenic mice carrying the structural genes for the simian virus 40 (SV40) small and large T antigens, attached in an inverted orientation to a metallothionein-growth hormone fusion gene (gene construction #202), develops hepatocellular tumors, islet cell adenomas of the pancreas, and generalized peripheral neuropathies in which axonal degeneration may be a prominent feature. We are interested in whether the peripheral neuropathy might be secondary to SV40 gene expression and neoplasia in a remote tissue. We have investigated the tissue-specificity and developmental onset of SV40 gene expression, using immunohistochemical methods, and have identified abnormalities in serum glucose and insulin levels which correlate with the onset of SV40 gene expression in the endocrine pancreas.

Mice with the #202 gene construction (described above) invariably develop generalized weakness and die at a mean age of 130 days, when all have multiple hepatocellular carcinomas, pancreatic β-cell tumors and generalized peripheral neuropathy. Immunocytochemical localization of SV40 T antigens, using a modified avidin-biotin peroxidase procedure, showed positive cells only in hepatic and pancreatic tumors, with occasional reactivity in the exocrine pancreas. T antigen expression was not detected in the central or peripheral nervous system of mice with obvious neuropathy. In a developmental study, evaluating mice at two week intervals from 14 days post-conception through 140 days post-natally, large T was first detected in pancreatic islet cells between 70 and 84 days of age. Pancreatic tumors became grossly evident by 98 days. The earliest age that positive immunoreactivity was detected in hepatocytes was in a 98 day-old mouse. Most animals did not begin expressing the SV40 genes in the liver until 112-126 days, and liver tumors were not grossly evident until after 126 days of age. Hypoglycemia and hyperinsulinemia were found in 126 day-old animals.

Expression of SV40 large and small T antigens does not appear to take place in either the central or peripheral nervous system of #202 transgenic mice. However, abnormalities in serum insulin and glucose levels resulting from functional islet cell adenomas of the pancreas and/or liver dysfunction may contribute to the degenerative changes seen in peripheral nerve.

138.17 LESIONS PRODUCED BY INTRACEREBROVENTRICULAR INJECTIONS OF MONOCLONAL ANTI-CONJUGATED DOPAMINE ANTIBODY IN THE MOUSE. C. Messier, N. Mons*, M. Meunier*, M. Geffard and C. Destrade. Labo. de Psychophysiologie, UA CNRS n°339, Institut de Biologie Animale, Avenue des Facultés, 33405 Talence and Labo. de Neuroimmunologie, Institut de Biologie Cellulaire et de Neurochimie du CNRS, 33077 Bordeaux, France.

This study examined the long-term effects of repeated intracerebroventricular injections of a monoclonal anti-conjugated dopamine antibody in the Balb/c mouse. This monoclonal antibody was raised after immunization with dopamine-glutaraldehyde-bovine serum albumin and produced by fused spleen cells with SP20 myeloma cells (Chagnaud et al., 1987). One of the selected hybridomas gave antibodies with a good affinity (IC50= 10^{-9} M) and was used for subsequent injection. Control animals received immunoglobulins from non-immune Balb/c mice. One month before the start of the experiment, 5 to 7 months old mice were implanted with a chronic cannula in the lateral ventricule and given 3 to 4 weeks to recover. The mice received a0.2µl injection (over 10 min) of the appropriate substance. This injection was repeated twice a week for five consecutive weeks. Weights of the animals were recorded before each injection and behavioral observations were made during the five-week period. Four to five months after the last injection, the animals were sacrificed and perfused through the aorta with glutaraldehyde for dopamine immunocytochemistry or classical histology. Some of the brain sections in each animal were processed for serotonin immunocytochemistry. In all the animals that received the monoclonal anti-conjugated dopamine antibody, we observed an enlargement of the ipsilateral ventricule and a moderate to complete destruction of the lateral and basal amygdala nuclei. In some animals, these lesions were observed bilaterally. In other animals, large portions of the ipsilateral cortex were necrotic. However, in most of these animals, the nigro-striatal pathway and the paraventricular dopamine cell groups were spared. A few animals showed a moderate to severe loss of dopamine immunoreactivity in the ventral tegmental area, the substantia nigra pars compacta and the caudate nucleus.The lack of a decrease of serotonin immunoreactivity in these animals suggest that the loss of dopamine immunoreactivity was a consequence of the repeated injections of the dopamine antibody. No lesions were observed in the mice that received the immunoglobulins from non-immune mice. These results show that an immune response directed against dopamine components can produce extensive damage to dopamine neuronal systems when this response takes place inside the blood brain barrier. The results may also provide some insights into the causes of diseases that affect the dopamine systems.

138.18 GENETIC LINKAGE OF VON RECKLINGHAUSEN'S NEUROFIBROMATOSIS TO THE NERVE GROWTH FACTOR RECEPTOR GENE

B.R.Seizinger*1,G.Rouleau*1,A.H.Lane*1,L.J.Ozelius*1,A.G.Farniarz*1,J.Ianazzi*1,W.Hobbs*1,J.C.Roy*1,B.Falcone*1,R.E.Tanzi*1,S.Huson*2,M.Upadhyaha*2,P.Harper*2,F.Collins*3,B.R.Korf*4,A.E.Goldstein*4,D.L.Hoover*4,M.Pericac-Vance*5,D.M.Parry*6,J.L.Bader*6,J.Mulvihill*6,M.A.Spence*7,M.Chao*8,R.L.Martuza*9,J.F.Gusella*1 (SPON:L.B.Jacoby). 1)Neurogenetics Laboratory, Massachusetts General Hospital, and Harvard Medical School,Boston, MA 02114; 2)Univ. of Wales College of Medicine, Cardiff,U.K.; 3)Univ. of Michigan,MI; 4) Children'sHospital and Harvard Medical School; 5)Duke Univ. Med. Ctr.,Durham,N.C., 6)National Cancer Institute, Bethesda,MD; 7)UCLA Scool of Medicine; 8)Cornell Univ. Med. College,New York,N.Y.; 9) Neurosurg.Service,Massachusetts General Hospital,and Harvard Medical School, Boston,MA.

Von Recklinghausen's neurofibromatosis(VRNF) is one of the most frequent and important genetic disorders affecting the human nervous system, with an incidence of 1 in 3000. VRNF has numerous clinical manifestations including mental retardation, learning disabilities, macrocephaly, bone abnormalities,etc., as well as the formation of multiple tumors affecting various organ systems. While different cell types can be affected,the most common abnormalities are in cells of neural crest origin. The primary defect underlying VRNF is not yet known, but may relate to fundamental mechanisms controlling growth and differentiation during development of the nervous system.

We have used a molecular genetic approach with polymorphic DNA markers for genetic linkage analysis in families displaying VRNF. We find that the VRNF gene is genetically linked to the locus encoding the receptor for the nerve growth factor, on the long arm of chromosome 17 in the region 17q12-17q22. The detection of recombination events separating the two loci suggests however that the nerve growth factor receptor gene is not the site of the primary defect in this disorder,but represents a genetic marker linked to the VRNF gene. The generation of additional DNA markers for this region on chromosome 17 containing the VRNF gene should allow prenatal and presymptomatic diagnosis, and will eventually lead to cloning and characterization of the defect, based on its chromosomal localization. This might open the doors for the development of an effective therapy in this serious neurological disorder, and could provide new insights into fundamental control mechanisms of proliferation and differentiation of the nervous system.

ALCOHOL AND BARBITURATES II

139.1 SEROTONIN NEURONAL SYSTEM INVOLVEMENT IN THE DIFFERENTIAL SENSITIVITY OF LONG-SLEEP (LS) AND SHORT-SLEEP (SS) MICE TO ETHANOL-INDUCED HYPOTHERMIA AND SLEEP TIME. T.A. French* and N. Weiner. Dept. of Pharmacology, University of Colo. Sch. of Med., Denver, CO 80262.

LS and SS mice selectively bred for differences in CNS sensitivity to ethanol (ETOH) exhibit markedly different sleep times following ETOH administration (4.2 g/kg, i.p.: LS-230 min, SS-0-5 min). We have previously determined that the greater sensitivity of LS mice to the hypothermic effects of ETOH may be partially explained by ETOH's greater depressant effect on serotonin (5HT) neurons in the hypothalamus (HYP) and dorsal raphe (DR), as indicated by a greater decrease in the in vivo tryptophan hydroxylase (TPH) activity in these brain regions of LS mice. The present investigation further examines the nature of the role of the 5HT neuronal system in the ETOH sensitivity differences between LS and SS mice.

ETOH administration (LS-3.0 g/kg, SS-5.2g/kg) 60 or 120 min prior to sacrifice was found to have no effect on in vitro TPH activity from the HYP or DR in either LS or SS mice. To examine the possibility that ETOH may decrease TPH activity in vivo by affecting the availability of the substrate tryptophan (TRP), TRP (100 mg/kg, ip.) was administered prior to ETOH. This dose of TRP in control mice will result in increases in 5HT neuronal function as indicated by 2-3 fold increases in in vivo TPH activity and 5-HIAA levels and 25-40% increases in 5HT levels with a maximum effect at about 50 min. When TRP is administered 30 min prior to ETOH (3.0, 3.5 or 4.2 g/kg) to LS mice the sleep times are reduced by 25-41% and waking blood ethanol levels are 30-35% higher than control LS mice. TRP pretreatment in LS mice not only prevents the 25% decrease in in vivo TPH activity at 20 min seen with ETOH alone, but results in a 2-fold increase in TPH activity in the HYP and DR relative to untreated mice. The ethanol-induced (E-I) hypothermia in TRP-treated LS mice is attenuated by 0.8-1.3°C between 15-180 min after ETOH. TRP pretreatment in SS mice results in a 3-fold increase in in vivo TPH activity at 20 min relative to ETOH alone. However, this increase in TPH activity has no apparent effect on either E-I sleep time or hypothermia in SS mice.

The present results demonstrate that the enhanced sensitivity of LS mice with respect to E-I sleep time and hypothermia can be attenuated by raising the level of activity in the 5HT neurons prior to ETOH treatment. This is consistent with our earlier observation that the increased sensitivity to ethanol inhibition of LS 5HT neurons in the HYP and DR may contribute to the greater E-I hypothermia and now suggests that these 5HT neurons may also contribute to the greater sleep time of LS mice.
Supported by USPHS grant AA03527.

139.2 DEPLETION OF BRAINSTEM 5-HYDROXYTRYPTAMINE (5HT) SUPPRESSES THE EXCITATORY EFFECT OF SYSTEMIC ETHANOL ON INFERIOR OLIVARY NEURONS (ION). S.G. Madamba*, G.R. Siggins, E.L. Battenberg and F.E. Bloom. Division of Preclinical Neuroscience, Research Institute of Scripps Clinic, La Jolla, CA 92037.

Previous studies in our laboratory show that systemic ethanol increases the discharge frequency of IONs in rats immobilized with halothane (1). These excitatory ethanol effects might be mediated by 5HT or a 5HT metabolite, because: 1) there is an abundant 5HT innervation of IONs; 2) 5HT can condense with acetaldehyde to form beta carbolines; 3) the beta carboline harmaline increases ION firing; 4) evidence exists for interactions between 5HT and ethanol (refs in 1). Therefore, we pretreated rats i.c.v. or intracisternally with 5,7 dihydroxytryptamine (5,7DHT; 75-150 µg in 20-50 µl) or with vehicle, after desipramine (25 mg/kg) to reduce depletion of catecholamines. After 7-10 days, animals were prepared for recording of IONs under 1% halothane anesthesia (1). Neuronal discharge rates were quantified every 10-15 min by computer before and 30-90 min after i.p. injection of ethanol 2 gm/kg. Neuronal locations were then marked with pontamine sky blue and the animals perfused with 4% paraformaldehyde. Brains were removed and prepared for routine immunohistochemistry. Serotonin immunoreactive structures (5HT-irs) were surveyed by light microscopy to classify the extent of terminal and perikaryal depletion and disruption by 5,7DHT. In separate unrecorded animals the 5,7DHT treatment was surveyed by electron microscopy to assess the probable functional status of the residual 5HT-irs. Light microscopy showed that the normal 5-HT innervation pattern of ION was greatly disrupted by 5,7DHT, with the normal moderate-to-rich innervation by fine varicose fibers severely diminished; remaining 5HT-irs were dilated and terminated bluntly. Ultrastructurally, at least 1/2 of control 5HT-irs are dendritic extensions of neurons located around or within the Olive. 5-HT reactive terminals make symmetrical synapses on the dendrites of unreactive IONs. In 5,7DHT treated animals, the remaining 5HT-irs were mainly vesicle-engorged dilated dendrites and axons. No convincing 5-HT reactive presynaptic structures were identified in samples from 5 treated rats. Firing rates in 6 neurons from 5,7DHT treated animals averaged a 12% increase after ethanol injection, compared to a 50% increase in artificial CSF-treated controls and a 68% increase in untreated controls (1). Only one neuron from 5,7DHT treated animals showed a marked increase in rate (to 170%) with ethanol, whereas one showed a marked rate reduction (to 59%). Our results suggest that ethanol-induced increases in olivary discharge rate previously reported (1) may involve intermediation by 5HT or a 5HT metabolite. Supported by NIAAA (AA-06420).

139.3 CYCLIC-AMP BLOCKS ETHANOL SUPPRESSANT EFFECT ON HIPPOCAMPAL NEURONAL FIRING. D.M. Benson, R.D. Blitzer and E.M. Landau. Depts. of Psychiatry, Mt. Sinai School of Medicine and Bronx VA Medical Center, New York, N.Y. 10029.

Ethanol causes a number of CNS effects, on biochemical, physiological and behavioral levels. The aim of the present study was to investigate the effects of ethanol on hippocampal pyramidal neurons in vitro , and to explore possible mechanisms underlying these effects. Hippocampal slices were prepared from adult male guinea pigs, and superfused with oxygenated artificial cerebrospinal fluid in a submerged tissue bath at room temperature. CA1 pyramidal neurons were impaled with either 3M KCl or 2M $KMeSO_4$ - filled glass microelectrodes. For voltage-clamp experiments, a single-electrode clamping amplifier was used (Axoclamp-2, switching frequency: 2 kHz).

50-100 mM ethanol produced a number of effects on the pyramidal cells. Slight membrane hyperpolarization and a small decrease in membrane resistance was typically observed. Spike threshold was increased and spike duration was shortened in most cells. Ethanol also produced an increase in the after-hyperpolarization current (I_{AHP}). The number of spikes elicited in response to a 30 second depolarizing current pulse was markedly decreased by ethanol, to 63.7 $\pm$ 15.1 % (n=22) of the control value. Ethanol also decreased the excitability produced by 1 uM carbachol. The suppressant effect of ethanol on spike rate was blocked by cyclic 3',5'-adenosine monophosphate (cAMP), when present in the recording electrode (0.1M, n=3) or applied in the bath as the 8-bromo analogue (0.5mM, n=3). Since cAMP decreases I_{AHP} , it is proposed that the AHP increase is the mechanism by which ethanol suppresses pyramidal cell firing.

139.4 ETHANOL REDUCES SINGLE UNIT ACTIVITY AND DISRUPTS THE RHYTHMICALLY BURSTING PATTERN OF NEURONS IN THE RAT MEDIAL SEPTUM/DIAGONAL BAND. B.S. Givens and G.R. Breese. Biol. Sci. Res. Ctr. Univ. of North Carolina Chapel Hill, N.C. 27514.

Ethanol alters the activity of the septohippocampal pathway as measured by acetylcholine release and high affinity choline uptake in the hippocampus. Ethanol also reduces the occurrence of theta rhythm recorded from the hippocampus. The region of the medial septum and the vertical limb of nucleus of the diagonal band (MS/DB) contains both the cholinergic septohippocampal neurons as well as the rhythmically bursting neurons which underlie hippocampal theta rhythm. Previous work in this laboratory has implicated the medial septum in the behavioral depressant effects of ethanol. The present study was performed to test the hypothesis that systemic administration of ethanol alters neuronal activity of MS/DB bursting neurons.

Extracellular single unit activity was recorded from rhythmically bursting MS/DB neurons in urethane anesthetized Sprague-Dawley rats. Intraperitoneal administration of 10% ethanol at doses of 0.75, 1.5 and 3.0 g/kg produced a dose related inhibition (29%, 42% and 50% below control levels) of the firing rate in approximately 80% of the cells at each dose. Equal volume injections of saline did not alter neuronal activity. The decrease in unit activity by ethanol began within 5 minutes, lasted for 30-60 minutes and was usually associated with a disruption of the rhythmically bursting pattern of firing. Blood ethanol levels, determined by gas chromatography, increased exponentially during the initial 40 minutes following ethanol administration after which they remain at a constant elevated level throughout the remainder of the experiment (3 hours). While the depression of MS/DB neuronal activity lasts an average of 45 minutes, the ethanol remains elevated long after the neurons return to a normal rate and pattern of firing.

One of the controlling influences on MS/DB activity is a GABAergic input from the lateral septum. Since several reports have indicated that ethanol can potentiate the effects of GABA, we iontophoresed GABA onto MS/DB neurons before and after the administration of 0.75 or 1.5 g/kg ethanol. Ethanol administration at both doses resulted in an approximately 20% enhancement of the inhibition due to GABA in a majority of MS/DB cells. While this effect did not reach significance, there was a significant correlation between the magnitude of the enhancement and the degree of inhibition of the spontaneous firing rate due to systemic ethanol. Thus, those MS/DB neurons which were most sensitive to ethanol were the cells most likely to demonstrate a potentiated response to GABA. Supported by a fellowship from the North Carolina Alcoholism Research Authority.

139.5 EFFECTS OF ACUTE ETHANOL ADMINISTRATION ON UNIT ACTIVITY AND POPULATION RESPONSES OF THE DENTATE GYRUS OF THE HIPPOCAMPUS. J.B. Wiesner and S.J. Henriksen. Div. Preclin. Neuroscience and Endocrinology, Res. Inst. at Scripps Clinic, La Jolla, CA 92024.

In order to determine the effects of acute ethanol administration on physiological processes of the hippocampal dentate gyrus, a structure associated with memory function, evoked field potentials and single unit activity were monitored in conjunction with administration of ethanol in halothane-anesthetized rats. Blood samples were obtained at intervals after injection of ethanol (16% w/v in saline) for determination of blood alcohol concentration (BAC).

'Population spikes' (PSs) of field potentials were evoked by electrical stimulation of the perforant path, and recurrent inhibition of the PS was measured by a paired-stimulation paradigm. Following intraperitoneal (i.p.) injection of ethanol (1-2.5 g/kg) but not saline, recurrent inhibition was enhanced in a dose-dependent fashion. At a dose of 2 g/kg (resulting in mean BAC of 196 mg%), recurrent inhibition was enhanced by 336% within 5 min of the injection and recovered with decreasing BAC by 4.5 hrs. In contrast, singly-evoked PSs (quantified by input-output analysis) or conditioning PSs (of the paired-stimulation analyses) were unaffected by doses of up to 2 g/kg, although they were depressed at the highest dose used (2.5 g/kg). Thus, recurrent inhibition of granule cell population responses is selectively sensitive to ethanol and appears to be independent of the depressant effect of higher doses of ethanol.

Spontaneous granule cell unit activity was suppressed by either i.p. (0.5-2 g/kg) or intravenous (0.25 g/kg) injection of ethanol, but not by control injection of saline. The effect of a 2 g/kg i.p. injection often consisted of two phases: (1) near total (92-100%) depression of unit activity beginning during the injection and lasting 4 to 15 min; (2) a rapid increase to a level of 40% of the baseline rate, increasing gradually over 3.5 hrs back to baseline level. The depression during the first phase did not appear to vary closely with the instantaneous BAC, suggesting to us that the early phase may be related to either (a) the rising limb of ethanol absorption, or (b) peripheral effects of ethanol. However, local electrophoretic application of ethanol (50-150 nA) also depressed spontaneous activity, indicating that depressant effects of ethanol on cell firing could be mediated centrally.

In conclusion, intoxicating levels of ethanol exert independent effects on different physiological processes of the dentate gyrus. We are currently investigating the possibility that certain of these effects, such as the enhancement of recurrent inhibition, may be mediated by an enhancement of the inhibitory action of GABA or somatostatin. (Supported by NIAAA 06420 and NIDA 03665.)

139.6 THE EFFECT OF ACUTE ETHANOL ON THE EXCITATORY AMINO ACID RESPONSES OF PURKINJE NEURONS IN CULTURE. C.L. Franklin* and D.L. Gruol (SPON: H. Neville), Div. Preclin. Neurosci. and Endocrin. and the Alcohol Research Center, Scripps Clinic and Res. Foundation, La Jolla, CA 92037.

Cerebellar Purkinje neurons (PNs) in culture are excited by the putative transmitter glutamate (Glu) and the Glu analogues Quisqualate (Quis) and Kainic Acid (KA) which activate specific receptor subtypes (Franklin and Gruol, Neurosci. Absts. 12, 1986). The excitatory responses produced by these agonists in the PN consist of an increase in simple spike firing and a period of bursting. However, the bursting component of the KA response is attenuated relative to the Glu and Quis responses. Quis is the most potent agonist. Acute ethanol (EtOH) significantly reduces the bursting component of the Glu response (Franklin and Gruol, Brain Res., 1987). In the present study, the action of EtOH on responses evoked by Quis and KA were examined and compared to that observed for Glu, to determine if the sensitivity to EtOH is localized to a particular receptor subtype. Extracellular recording techniques and exogenous application of Quis (1 μM), KA (50 μM) and Glu (50 μM) by micropressure application were used. Response characteristics were quantitated by computer. Recordings were made from PNs maintained in culture for >12 days. The cultures were prepared from the cortical region of fetal rat cerebella as previously described (Gruol, Brain Res 263, 1983). As was observed for the Glu response, acute exposure to EtOH at pharmacologically relevant doses (200 mg%) dramatically reduced the bursting component of the Quis response. Mean values for the % bursts during the Quis response were 29$\pm$5 ($\pm$SEM; N= 19, n= 9; N= number of trails, n= number of cells) under control conditions and 14$\pm$3, (N= 10, n= 4) during EtOH exposure. Mean values for % bursting during the Glu response were 39$\pm$11 (N= 13, n= 9) for control and 16$\pm$7 (N=13, n= 9) during EtOH exposure. In contrast, the bursting component of the KA response was not reduced by EtOH. Mean values for % bursting during the KA response were 10$\pm$2 for control (N= 19, n=9) and 10$\pm$5 during EtOH exposure (N= 9, n=5). Mean firing rates during the agonists responses (averaged over the duration of the response), which represent net excitation during the response, were not significantly altered by EtOH. Mean values were 12$\pm$1 Hz (N= 11), 11$\pm$1 Hz (N= 20) and 16$\pm$2 (N= 13) for Quis, KA and Glu responses under control conditions and 12$\pm$2 Hz (N=10), 11$\pm$2 Hz (N= 9) and 17$\pm$2 (N= 17) for Quis, KA and Glu responses during EtOH exposure. These data suggest that the sensitivity of the Glu response to acute EtOH may reside at the Quis receptor site or secondary sites that mediate the bursting component of the response. (Supported by NIAAA Grants AA06665 and AA06420).

139.7 ANTAGONISM OF ETHANOL-INDUCED DEPRESSIONS OF CEREBELLAR PURKINJE NEURONS IN RATS WITH THE BENZODIAZEPINE DERIVATIVE, Ro15-4513. Elizabeth A. Moore* and Michael R. Palmer. Department of Pharmacology, University of Colorado Health Sciences Center, Denver, Colorado 80262

Ro15-4513 is a benzodiazepine derivative which has been reported to antagonize the ataxic behavioral effects of ethanol (Suzdak et al., 1987). Local applications of ethanol by pressure ejection from multibarrel micropipettes cause dose-dependent and reversible depressions of cerebellar Purkinje neuron firing rates. These depressions could be antagonized by local applications of Ro15-4513 from another barrel of the same multibarrel pipette. In contrast, Ro15-4513 did not antagonize GABA-induced depressions of the firing rates of these same neurons. Although ethanol effects consistently recovered after short-duration applications of Ro15-4513, it was very difficult to demonstrate recovery of ethanol effects even one hour after longer local applications or repeated short applications of this putative ethanol antagonist. The lack of recovery may be due to a long half-life of Ro15-4513 in the tissue caused by the lipophilicity of this compound. To date, we have been unable to prevent or reverse the antagonism by Ro15-4513 of ethanol-induced depressions with local applications of Ro15-1788, a benzodiazepine antagonist which has been reported to prevent the effects of Ro15-4513 on ethanol-induced behavior (Suzdak et al., 1987). We conclude that Ro15-4513 can antagonize ethanol-induced depressions of cerebellar neuronal activity. However, the mechanism of this antagonism might not involve a classical benzodiazepine receptor. This work was supported by AA05915 and AA03527.

139.8 Intoxicating doses of ethanol block the development of long-term potentiation (LTP) in the dentate gyrus. M.F. Yeckel* and S.J. Henriksen, Research Institute of Scripps Clinic, La Jolla, CA. 92037.

Growing experimental evidence implicates the mammalian hippocampus in information processing, most notably, its ability to demonstrate short and long-term synaptic "plasticity" in response to repetitive stimulation. These synaptic events are hypothesized to be a potential substrate for associative learning. The hippocampus is also a brain structure uniquely sensitive to ethanol (E). An association may exist between the cognitive deficits well documented in human alcohol abusers and hippocampal sensitivity to E. Although some electrophysiological events have been shown to be selectively altered by chronic E, the effects of acute E on measures of hippoocampal plasticity remain to be adequately investigated. Accordingly, we have studied the effects of acute E on the ability to evoke long-term potentiation (LTP) in the rat dentate gyrus, both in halothane anesthetized and freely-moving, unanesthetized rats. LTP was induced in halothane-anesthetized control subjects (N=11) using a standard paradigm (8 trains of 20 ms pulses at 400 Hz, 1 train/10 sec). Stimuli were delivered to the angular bundle of the perforant path. Evoked synaptic events were recorded from the granule cell layer of the dentate gyrus using glass microelectrodes. Input/output and paired-pulse curves were determined both before and following tetanic stimulation. The tetanic stimulation induced a mean increase of 190% in the half-maximal primary evoked population spike compared to baseline, as assessed 30-60 min post-tetanus. E administered intraperitoneally (2 g/kg) to anesthetized rats (N=14) 10-25 min prior to tetanic stimulation blocked the development of LTP (defined as < 50% increase in the pre-ethanol population spike). E administered intravenously (0.5 g/kg) 1-2 min prior to tetanic stimulation also blocked the development of LTP (N=5). The mean blood alcohol concentration (BAL) in each case was 130-170 mg% at the time of stimulation. However, when tetanic stimulation was presented in these same rats after BAL returned to baseline (approx. 4 hrs post i.p. and 60 min post i.v. injections), LTP was induced. In unanesthetized, freely-moving rats (N=5) E (2.5 gm/kg i.p.) exerted similar electrophysiological effects. In other control studies, when E was given after induction of LTP potentiation was not altered. These data suggest that development of synaptic plasticity in the dentate gyrus can be effected by low intoxicating doses of E. (Supported by NIAAA 06420)

139.9 RO 15-4513 AND FG 7142 ANTAGONIZE THE EEG EFFECTS OF ETHANOL BUT ALSO PRODUCE LIMBIC SEIZURE ACTIVITY. C.L. Ehlers*, R. Ian Chaplin*, G.F. Koob (SPON: D.J. Kupfer) Research Institute of Scripps Clinic, La Jolla, CA 92037

The anxiolytic actions of ethanol have been suggested to be mediated through the benzodiazepine/GABA receptor ionophore complex. The data which support this hypothesis are based on biochemical and pharmacological studies demonstrating a facilitation of GABA function by ethanol and experiments utilizing various antagonists and inverse agonists. Recent studies have reported that the imidazodiazepine RO 15-4513 can selectively block several of the actions of ethanol in rats at doses which do not produce behavioral actions when administered alone. In the present study the selectivity of the electrophysiological effects of RO 15-4513 and the β-carboline FG 7142 administered alone and in combination with ethanol was investigated. 21 Wistar rats were implanted with chronic electrodes in anterior cortical sites and in the dorsal hippocampus. Following a 7-day recovery period rats were administered one of 3 doses of RO 15-4513 (1.5, 3, 6 mg/kg IP) or RO (6 mg/kg) plus 1 g/kg IP ethanol, or one of 2 doses of FG 7142 (2.5, 5 mg/kg IP) or FG (5 mg/kg) plus 1 g/kg IP ethanol. Ten minutes following the injections EEG was monitored on paper and magnetic tape for periods of 1-1/2 hours. EEG tapes were analyzed for spectral characteristics by computer and paper records recorded in parallel were hand scored for abnormal activity. Following high dose RO 15-4513 all rats tested (n=7) demonstrated abnormal EEG activity in the form of slow sharp waves, and also displayed episodic high amplitude recurrent hippocampal seizures. These ictal episodes were 5-10 seconds in length and were not associated with behavioral convulsions. Lower doses of RO also produced seizures in 8 of the 14 rats tested. Co-administration of ethanol with RO 15-4513 significantly reduced the mean number of seizures observed to one half those seen following RO alone. FG 7142 also produced ictal episodes in all animals at both doses tested, whereas co-administration of ethanol with FG caused a complete disappearance of seizure activity in all 7 rats tested. These studies suggest that these drugs produce potent electrophysiological actions of their own, and that FG 7142 may be more selective in its interaction with ethanol (Supported by AA 06059, AA06420, and AA 00098.)

139.10 ALCOHOL AND THE AUDITORY BRAINSTEM RESPONSE, BRAIN TEMPERATURE, AND BLOOD ETHANOL CONCENTRATION: A PARADOX EXPLAINED J. A. Lee[1@], E. P. Schoener[2@], D. W. Nielsen[4], and R. F. Berman[3@]. [1]Department of Obstetrics-Gynecology, [2]Pharmacology, [3]Psychology, [@]Wayne State University, Detroit, MI, 48201 and [4]House Ear Institute, Los Angeles, CA 90057.

Squires et al. (1978) found temperature-independent effects of alcohol upon the auditory brainstem response (ABR), and Jones et al. (1980) found temperature-dependent effects. This study addressed those apparently contradictory results with an integration of results for alcohol's dose- and time-related effects upon three measures: the ABR, brain temperature, and blood ethanol concentration (BEC). In studies previously reported by this group (Lee et al., 1983, 1985), the ABR and brain temperature were measured in unrestrained, Long-Evans rats throughout the 30 min before and 2 1/2 hrs after three alcohol doses (0.5, 2.5, and 5.0 g/kg), which were administered at least one week apart. The auditory stimulus, a 0.1-msec, constant-intensity click with repetition rates of 11, 33, and 66/sec, was delivered through a miniature transducer mounted on the rat's head. Brain temperature was measured with a thermocouple implanted in the forebrain. In a separate study (Lee et al., 1984), BEC was measured at nine time points following the same three alcohol doses. Blood samples were obtained from an indwelling aortic catheter. It was concluded that alcohol has both temperature-dependent and -independent effects, which vary according to alcohol dose and BEC-curve phase. Temperature-independent effects are more likely soon after alcohol administration when BEC is rising, or when BEC is fairly high and steady following a moderate dose. Temperature-dependent effects are more likely when BEC has fallen precipitously and is comparatively low following a high alcohol dose, particularly when behavioral thermoregulation is less likely. The Squires et al. (1978) and Jones et al. (1980) studies each used a combination of procedures likely to produce the respective ABR-alcohol-temperature results. Thus, not surprisingly, the paradoxical research results were due to differing experimental procedures. Based upon statistical analyses, it was concluded that alcohol-ABR effects are primarily central, since (1) alcohol had no statistically significant effect upon ABR wave I, and (2) alcohol-ABR effects did not differ significantly as a function of stimulus repetition rate. (The research was carried out in the Otology Research Laboratories, Henry Ford Hospital, Detroit, MI 48202.)

139.11 TEMPERATURE DEPENDENCE OF LETHALITY FROM ETHANOL GIVEN ALONE OR IN COMBINATION WITH PENTOBARBITAL. R.L. Alkana, M. Bejanian, B. Jones*, P.J. Syapin(1) and D.A. Finn*. Alcohol and Brain Research Laboratory, Institute for Toxicology, School of Pharmacy and (1) School of Medicine, University of Southern California, Los Angeles, CA 90033.

The relationship between ambient temperature, rectal temperature and ethanol sensitivity has been investigated in mice and rats following sub-hypnotic, hypnotic and lethal doses. In general, sensitivity to ethanol was found to increase as intoxicated body temperature increased. Ethanol dose response studies in the lethal range found a shift to the left in the 8 and 24 hour log dose-percent mortality curves and a significant decrease in the LD50 as ambient temperature was increased from 20 to 35°C. The present study extended the above findings to include the effects of body temperature manipulation on lethality from ethanol given in combination with pentobarbital. C57 male mice were injected with 7.8 g/kg ethanol, or with a combination of 7.8 g/kg ethanol plus 20 mg/kg pentobarbital, and were individually housed within chambers at 20, 25, 30 or 35°C for 24 hours following injection. Mortality was determined at 1, 2, 4, 8 and 24 hours post-injection. Rectal temperatures were measured in the surviving animals. The results indicate that ambient temperature significantly affected lethality at all time points after injection in both the ethanol and ethanol/pentobarbital groups. Chi square analysis indicated that survival was significantly greater in both groups of animals exposed to 20 and 25°C when compared to the animals exposed to 30 and 35°C at 2, 4 and 8 hours post-injection and when compared to the 35°C exposed animals at 1 hour post-injection ($p < 0.01$). At the 24 hour measurement survival was significantly greater in the 25°C animals when compared to all other temperature groups. There were statistically significant, ambient temperature-related differences in rectal temperatures in both the ethanol and ethanol/pentobarbital groups. The 35°C exposed animals became slightly hyperthermic, while the animals exposed to 30, 25 and 20°C became hypothermic. Rectal temperatures in the 35, 30 and 25°C exposed animals remained constant across time, but body temperatures in the 20°C exposed animals continued to drop throughout the exposure period. The increase in mortality from the 8 to 24 hour measurement in the 20°C exposed animals may have been due to prolonged extreme hypothermia. The relationship between body temperature and lethality can be explained by membrane perturbation theories of anesthesia and suggests that body temperature manipulation may represent an effective means of reducing lethality from ethanol or ethanol/combination overdoses. (Supported by USPHS grant R01 AA05234 from the National Institute on Alcohol Abuse and Alcoholism).

139.12 SELECTION OF LINES OF MICE FOR ACUTE SENSITIVITY TO THE HYPOTHERMIC EFFECTS OF ETHANOL. D.J. Feller, E. Young*, B. Tam*, C. Deutsch*, and J.C. Crabbe. Veterans Administration Medical Center, Portland, OR 97201.

The mechanism by which ethanol produces its behavioral effects and the way genotypic factors modulates the response of animals to ethanol is poorly understood. One approach to studying these questions is the selective breeding of mouse lines which differ in specific behavioral responses to ethanol. Thermoregulation, which is altered by ethanol, is an interesting system for examining sensitivity and the development of tolerance to ethanol. Mouse lines sensitive (COLD) to the acute hypothermic effect of ethanol and resistant (HOT) to this effect are being produced by the method of within family selection. The selection of replicate HOT and COLD line is now into the 8th generation. The response of the lines has gradually diverged. After 7 generations the difference in maximal temperature response between HOT1 and COLD1 was 2.3°C and 2.4°C for HOT2 vs COLD2. The average realized heritability for the diverging response in both replicates at generation 5 was $h^2=0.17$. No difference has been found in ethanol metabolism, which suggests that the lines differ in neurosensitivity. Second litter males and females of the 7th generation have been tested for their sensitivity to other alcohols and to the effect of hydralazine, a drug which induces hypothermia by a peripheral mechanism of action. Mice were tested for their hypothermic response to four doses of each alcohol, including ethanol, propanol, n-butanol, t-butanol and pentanol. The dose response curves were shifted to the left as the chain length increased. COLD2 mice exhibited a greater difference in hypothermic response than HOT2 mice to the 5 alcohols. At a dose of 3 g/kg ethanol, the HOT2 and COLD2 lines differed by 2°C. Comparable changes were observed with each of the other alcohols. The effects in the HOT1 vs COLD1 lines were not as great, but may increase in later generations of the selection process. The lines were identical in their hypothermic response to hydralazine, suggesting that the divergence in response to ethanol for the lines is not mediated through peripheral vasodilation. In conclusion, the HOT and COLD mice should be useful for elucidating ethanol's mechanism of action and the biological factors regulating sensitivity to its effects. These experiments are supported by PHS-NIAAA grants AA05828, AA06243, AA06498 and by a grant from the Veterans Administration.

139.13 EFFECTS OF PENTOBARBITAL ANESTHESIA ON RAT GASTROINTESTINAL FUNCTION. John J. Stewart, Cheryl D. Curd-Sneed* and Thomas W. Woods*, Department of Pharmacology, L.S.U. Med. Ctr., Shreveport, LA 71130.

This study examined the effects of sodium pentobarbital on gastric emptying, small intestinal transit and intestinal myoelectric activity. Gastric emptying and small intestinal transit were determined simultaneously in fasted, male rats given sodium pentobarbital (40 mg/kg). Drug was administered intragastrically by means of a stomach tube in 1, 2 or 3 ml dosing volumes. Each administered solution additionally contained a small quantity of nonabsorbed radioactive marker (0.5 μCi, $Na_2{}^{51}CrO_4$). Control animals received 2 ml of water containing marker only. Animals were sacrificed at 5, 15, 30, 45, 60 and 90 mins after drug administration and the stomach and small intestine were removed. Gastric emptying was calculated from the percentage of radioactivity remaining in the stomach versus time using a curve stripping program. Small intestinal transit was determined by calculating the geometric center of distribution for radioactive chromium along the bowel. Nine animals were chronically implanted with four bipolar, extracellular electrodes placed at 10 cm intervals beginning at the gastroduodenal junction. Five days after surgical preparation, intestinal myoelectric activity was monitored for a 1 hr period before, and a 3 hr period after intragastric sodium pentobarbital (40 mg/kg). All animals lost the righting reflex within 7 mins after drug administration. Gastric emptying was biphasic, consisting of a brief rapid phase, followed by a prolonged slow phase. Time to half emptying was 47 mins for water and 122, 156 and 128 mins for sodium pentobarbital given in 1, 2 and 3 ml, respectively. In contrast, small intestinal transit was not different for animals given sodium pentobarbital and water. The migrating myoelectric complex was present in fasted animals anesthetized with sodium pentobarbital, but there was a significant decrease in slow wave frequency and increase in the duration of regular spike activity at the sites monitored. Migrating myoelectric complex cycled every 12.8 ± 1.3 mins (mean ± SEM) during the control period and every 21.8 ± 1.2 mins ($P < 0.01$) after sodium pentobarbital. The results suggest that gastric emptying is inhibited during sodium pentobarbital anesthesia, while small intestinal transit and fasted patterns of intestinal myoelectric activity are relatively normal. (Supported by a grant from the Edward R. Stiles Trust Fund.)

139.14 SODIUM PENTOBARBITAL DECREASES FACILITATION AT THE CRAYFISH NEUROMUSCULAR SYNAPSE. B.D. Winegar, S.W. Leslie, and G.D. Bittner. Department of Zoology, University of Texas, Austin, TX 78712.

Synaptic plastic events such as facilitation are of interest in accounting for plastic changes in behavior which occur as a result of experience. Since the synapse is thought to be the primary site of action of many barbiturates, it is likely that many of the behavioral plasticities (e.g., sedation, tolerance) associated with barbiturate use and abuse are due to the effects of these drugs on synaptic plasticity.

Crayfish (Procambarus clarkii) were weighed and injected at the ventrocaudal aspect of the abdomen with various concentrations of sodium pentobarbital (PB) in order to determine at what dosage PB produces behavioral plasticities. Sedation and tolerance to PB were quantified by measuring eyestalk retractions from light tactile stimuli on the carapace dorsal to the compound eye. The animals showed significantly decreased eyestalk retractions ($F=5.35$; $df=24$; $p<0.05$) up to 30 min after injection of 109 mg/kg PB (0.6 mM). Significant tolerance to PB was observed following daily injections of 90.5 mg/kg PB (0.5mM) on day two ($F=16.30$; $p<0.0005$; $df=57$), with almost complete recovery on day three.

In order to determine whether PB produces changes in various measures of synaptic plasticity that might begin to account for behavioral plasticity, PB was tested for effects on facilitation and other measures of synaptic plasticity at opener-excitor neuromuscular synapses in the crayfish claw (cheliped). This preparation was exposed to various concentrations of PB dissolved in Van Harreveld's solution (pH=7.6) for 2 min while the excitor axon was stimulated at 5 Hz with 10 V twin pulses (0.02 msec duration; 5.0 msec delay). Facilitation was calculated from averaged (N=100) excitatory postsynaptic potentials (EPSP's) produced by the first and second stimuli in the twin pulse train. PB increased EPSP time constants while producing dose-dependent decreases in facilitation and EPSP amplitudes. Facilitation was significantly reduced at a concentration of 0.1 mM PB ($F=5.59$; $p<0.05$; $df=16$). Additionally, preliminary data suggest that 0.2 mM PB produces defacilitation, which is accompanied by severe suppression of EPSP amplitudes.

The decreases in facilitation suggest a presynaptic action of PB on synaptic plasticity. Since PB decreases synaptic calcium currents in a variety of preparations, it may reduce presynaptic residual calcium at the crayfish neuromuscular synapse to decrease facilitation. Observed increases in EPSP time constants by PB suggest that the drug also increases postsynaptic membrane resistance.

139.15 THE DIFFERENTIAL EFFECTS OF LIPOPHILIC AND HYDROPHILIC ANESTHETIC AGENTS ON THE SURFACE AND INTERIOR MEMBRANE ORDER OF DIMYRISTYLPHOSPHATIDYLCHOLINE MULTILAMELLAR LIPOSOMES. R.J. Hitzemann and A. Skolnakorn*. Department of Psychiatry and Behavioral Science, S.U.N.Y. at Stony Brook, Stony brook, NY 11794, and Psychiatry Service, VA Medical Center, Northport, NY 11768.

We have recently reported that as determined by 1H-NMR, ethanol disorders the interior of synaptic plasma membranes but orders the membrane surface (Hitzemann et al., BBA 852:159, 1986). The ratio of ordering/disordering activities increases with increasing temperature due to the preferential partitioning of ethanol to the membrane surface. It has also been noted that the genetic selectivity of anesthetic response [e.g., long sleep vs short sleep mice] decreases with increasing lipid solubility of the anesthetic agent (Howerton et al., Psychophamacol. 79:313, 1983 and J. Pharmacol. Exp. Ther. 227:389, 1983 and Marley et al, personal communication). We now report that anesthetics which demonstrate genetic discrimination, and some related anesthetics share with ethanol the ability to order the membrane surface. Fluorescence polarization (FPZ) techniques were used to monitor membrane order with the probes DPH (interior) and TMA-DPH (surface) in DMPC multilamellar liposomes both above and below the main phase transition temperature. The following anesthetics were examined: ethanol (1), propanol (2), butanol (3), pentanol, (4) hexanol (5), 2-chloroethanol (6), 2,2-dichloroethanol (7), 2,2,2-trichloroethanol (8), urethane (9), ethylacetate (10), acetone (11), ether (12) and chloroform (13). With an order of potency paralleling their oil/water partition coefficients all of the compounds tested disordered the membrane interior. In contrast, compounds 1, 2, 6, 7, 9, 10 and 11 had an ordering effect on the membrane surface. Compounds 3, 4, 5, 8, 12 and 13 disordered the membrane surface, although the concentrations required were higher than those needed to disorder the membrane interior. We suggest that the membrane components associated with the regulation of the ordering of the lipid bilayer may be the same components involved in the genetic regulation of anesthesia at the membrane level. Supported in part by the Veterans Administration.

139.16 ETHANOL-INDUCED LIBERATION OF SIALIC ACID, *WITHOUT SIALIDASE ACTIVATION, IN RAT LIVER SLICES. Joy Mathew* and W. R. Klemm, Brain Research Laboratory, Department of Veterinary Anatomy, Texas A&M University, College Station, TX 77843.

Membrane-bound glycoconjugates (glycoproteins, gangliosides) that contain sialic acid appear to be vulnerable to the action of ethanol on the brain (J. Neurosci. Res. 3: 341; 4: 371). Because the liver is the principal site of ethanol metabolism, we hypothesized that a similar phenomenon could occur in liver and may be of greater consequence.

When liver homogenates were incubated with varying concentrations of ethanol, there was no change in endogenous or exogenous sialidase activity up to 1 M, but there was a steady and marked loss of activity above 1 M. To investigate this effect under more physiological conditions, rat liver slices were incubated with varying amounts of ethanol (0, 0.1, 1, and 3 M) in circulated, oxygenated Yamamotto solution for 5 hours. There was a 48% increase in free sialic acid at 0.1 M, but a decrease at the higher, toxic concentrations. Sialidase activity, however, was not significantly affected at 0.1 M, but was inhibited at 1 M and 3 M. Alcohol-induced inhibition of sialidase was not prevented by addition of 2 mM pyrazole, a well-known inhibitor of alcohol dehydrogenase. Total liver protein was progressively decreased to 60% of control levels by increasing ethanol concentrations, and pyrazole did prevent this effect of ethanol. When ethanol was replaced by sorbitol, which mimics ethanol in shifting of the redox level, both sialidase activity and protein were decreased.

The results suggest that although sialidase may not be inhibited substantially by physiological levels of ethanol, toxic levels inactivate it in two ways: 1) direct ethanol effect, and 2) by shifting the redox level. The physiological effect of ethanol in increasing free sialic acid, even though enzyme activity seems unchanged, may indicate that the enzyme has greater accessibility to sialocompounds of intact cell membranes when the membrane is fluidized and destabilized by ethanol.

139.17 AN INTERACTION BETWEEN ETHANOL AND CYANAMIDE IN RAT BRAIN CATALASE ACTIVITY IN VIVO. C.M.G. Aragon*., L.M. Stotland* and Z. Amit. Center for Studies in Behavioral Neurobiology, Concordia Univ., Montreal, Quebec, Canada H3G 1M8.

The purpose of the present study was to further investigate the relationship between ethanol and brain catalase. Rats were pre-treated (i.p.) with different doses of ethanol (0.19 to 3 g/kg) or saline 30 minutes prior to administration of cyanamide (0.68 m mol/kg; i.p.) or saline. One hour later, under ether anesthesia, cardiac blood was collected and tissues were perfused in situ. Brain catalase activity was measured using the Clark electrode. Results confirm inhibition of brain catalase activity by cyanamide. Plasma ethanol levels were not altered by cyanamide. Ethanol protected catalase from cyanamide inactivation in a dose-related manner (maximum protection at 1.5 and 3 g/kg). In a second study the protected effect of ethanol (0, 0.37, 0.75 and 1.5 g/kg) was tested against several cyanamide concentrations. Results indicated that ethanol protection was progressively reversed by increasing concentrations of cyanamide. These data suggest a competition between ethanol and cyanamide for the catalase molecule, they confirm the presence of catalase and generation of H_2O_2 in the rat brain in vivo, and overall seem to support the notion that centrally formed acetaldehyde via brain catalase may be responsible for some of the psychopharmacological actions of ethanol.

139.18 MOTOR IMPAIRMENT PRODUCED BY ETHANOL, BARBITAL, OR LORAZEPAM IN RAT LINES SELECTED FOR DIFFERENTIAL SENSITIVITY TO ETHANOL: EFFECT OF GABAERGIC DRUGS. K. Kiianmaa* and K. Hellevuo*. (SPON: European Neuroscience Association). Research Laboratories of the Finnish State Alcohol Company (Alko Ltd), POB 350, SF-00101 Helsinki, Finland.

The AT (Alcohol Tolerant) and ANT (Alcohol Non-Tolerant) lines of rats have been selectively outbred for low and high sensitivity to motor impairment from ethanol, respectively. An acute dose of ethanol (1.25-2.75 g/kg, IP) impairs the motor performance on the tilting plane test of the ANT rats more than that of the AT rats at the same blood level. When tested over a wide range of doses, it was found that the ANT rats were also more sensitive than the AT rats to the motor impairment caused by barbital (80-160 mg/kg, IP) and lorazepam (1-7 mg/kg, IP). Since the primary target of these drugs is probably the GABA-benzodiazepine-receptor complex, we studied here the importance of GABAergic neurons in the differential sensitivity of the rat lines to ethanol. The rats were injected with the GABA receptor antagonist picrotoxin (2 mg/kg, IP), the GABA synthesis inhibitor isoniazid (250 mg/kg, IP) or the benzodiazepine antagonist Ro15-1788 (10 mg/kg, IP) followed by an injection of ethanol (2.75 g/kg, IP) or barbital (160 mg/kg, IP), doses, which caused marked motor impairment in both rat lines, or lorazepam 3 mg/kg, IP), which caused marked motor impairment only in the ANT rats. The tilting plane test was conducted 30 min later. Ro15-1788 antagonized only lorazepam-induced motor impairment. Isoniazid had no influence on the intoxication produced by any of the three drugs. Picrotoxin, however, antagonized the impairment of motor performance induced by ethanol, barbital, and lorazepam. Furthermore, there seemed to be some variability in this antagonism with the genotype: although the AT and ANT rat lines did not differ in the effect of picrotoxin on ethanol-induced intoxication, the ANT rats seemed to be more sensitive than the AT rats to the antagonism of barbital-induced motor impairment produced by picrotoxin. The results of these experiments encourage further studies on the involvement of GABA systems in the genetically-determined differences in ethanol sensitivity.

139.19 FAILURE OF A BENZODIAZEPINE PARTIAL INVERSE AGONIST Ro15-4513 TO ANTAGONIZE MOTOR IMPAIRMENT INDUCED BY ETHANOL. E.R. Korpi and K. Hellevuo*. Research Laboratories of the Finnish State Alcohol Company, Alko Ltd., POB 350, SF-00101 Helsinki, Finland.

Recently it has been reported that acute ethanol intoxication can be reversed by an imidazobenzodiazepine Ro15-4513 (1, 2, 3). We have found that the ANT and AT rat lines, selectively out-bred for high and low acute sensitivity to ethanol-induced motor impairment in the tilting plane test, respectively, also in the same way differ in motor impairment from the benzodiazepine agonist lorazepam (4). Therefore, it was very interesting to see whether Ro15-4513 would counteract the effects of ethanol in these rat lines.

Ro15-4513 was administered as a suspension in 5% (w/v) acaciae gummi (Ph.Eur.) in water, and ethanol as a 12 or 15% (w/v) solution in saline. The following experiments were conducted on the selected animal lines: 1) ANT and AT rats received ethanol (2.75 g/kg, i.p.) 15 min after Ro15-4513 (10 mg/kg, i.p.) or vehicle and were tested on the tilting plane 30 min after ethanol. 2) ANT and AT rats received ethanol (1.5 g/kg, i.p.), followed by Ro15-4513 (30 mg/kg, i.p.) or vehicle 5 min later, and were tested on the horizontal wire test at 10, 20, 30, 40, 50 and 60 min after ethanol. No differences were detected in the motor performances between the groups treated with Ro15-4513 or vehicle in either rat line.

In additional experiments, Han:Wistar rats were given ethanol (1.5 g/kg) intraperitoneally, and Ro15-4513 (2.5 to 100 mg/kg) either intraperitoneally or intragastrically at various times before and after ethanol administration, and the motor performance of the animals was measured on a Rotarod at various times after drug administrations. The effects of ethanol could not be counteracted by Ro15-4513 in these experiments, although the compound could penetrate into the brain as demonstrated by inhibition of [^{3}H]flunitrazepam binding in unwashed forebrain homogenates.

In summary, at present the benzodiazepine receptor inverse agonist Ro15-4513 in our hands has not proven to be an efficient antagonist of the motor impairment produced by moderate ethanol doses in rats.

139.20 GENETIC DIFFERENCES IN SUB-COLONIES OF LONG- AND SHORT-SLEEP MICE SELECTIVELY BRED FOR ETHANOL SENSITIVITY. D. Kim* and B.C. Dudek. Dept. of Psychology, SUNY at Albany, Albany, NY 12222.

Long- and Short-Sleep mouse lines (LS and SS) were bred for differences in sensitivity to the soporific effects of ethanol (ETOH). LS mice lose the righting reflex an order of magnitude longer than SS mice when given an IP dose of 3.8 g/kg. This difference has been shown to be the result of differences in nervous system sensitivity controlled by a polygenic system of at least nine genes. Two sub-colonies of these lines exist (Albany and Colorado) and have been separated for 26 generations. The Albany colony has been maintained by random mating within each line since generation 18. The original Colorado colony underwent some additional selection following generation 18 and the LS mice were tested with a lower dose of ETOH than SS mice in these generations. The present experiments directly compared the colonies on two dimensions. These were (1) the selection phenotype, loss of the righting reflex following hypnotic doses of ethanol (LRR duration) and (2) the biphasic shape of the sub-hypnotic ethanol dose response curve on locomotor activity, measured in a photocell apparatus.

Following IP administration of 3.8 g/kg ETOH, male LS mice of both colonies lost the righting reflex (LRR) for about 200 min. Female LS mice of both colonies had LRR durations of about 160 min. Albany colony LS mice regained the righting reflex at about 270 mg/sl blood ethanol levels (BEC) and Colorado colony LS mice at a surprisingly higher 305 mg/dl. A colony difference in LRR duration was seen for SS mice. Not all Colorado SS mice given 3.8 g/kg lost the righting reflex, but all Albany colony SS mice did, with a mean of about 27 min. At 4.2 g/kg ethanol, Colorado SS mice had significantly shorter LRR durations than Albany mice and BECs at waking were an average of 45 mg/dl higher in Colorado SS mice (500 mg/dl), as expected. Rectal temperatures at waking were lower in LS mice than SS mice, but this effect was similar for the two colonies. Locomotor activity effects of ethanol were biphasic in LS mice which showed activation at 1.5 g/kg but marked sedation at 2.5 g/kg. In SS mice, locomotor activity was increased by all doses up to 3.0 g/kg. No colony differences in activity dose response curves were detected. These studies thus demonstrate that added selection further increased resistance to ETOH sedation in Colorado SS mice, but did not increase sensitivity in LS Colorado mice. These changes did not extend to locomotor effects of sub-hypnotic doses, suggesting independence of activational effects of low ETOH doses and sedative effects of higher doses.

ALCOHOL AND BARBITURATES III

140.1 HYPERRESPONSIVENESS TO STRESS: DIFFERENTIAL EFFECTS OF PRENATAL ETHANOL ON MALES AND FEMALES. J. Weinberg. Department of Anatomy, The University of British Columbia, Vancouver, B.C., V6T 1W5, Canada.

Animals prenatally exposed to ethanol are hyperresponsive to stress in adulthood, and exhibit hyperactivity and deficits in behavioral response inhibition. In view of these findings, we hypothesized that behavioral or psychological variables which are effective in reducing arousal and thus dampening the pituitary-adrenal response to stress in controls may be less effective in ethanol exposed offspring.

Ethanol was administered to pregnant females in liquid diets and both pair-fed and ad libitum fed control groups were included. Following weaning (day 22), offspring were pair-housed by litter and by sex until testing at 60-80 days of age.

We first investigated whether opportunity to perform a consummatory response can reduce the adrenocortical response to novelty in fetal ethanol exposed animals. Animals were water deprived for 24 hr and tested in one of 3 conditions: 1) removed from home cage and blood sample obtained immediately; 2) placed in novel cage with water available; blood sample obtained 30 min later; 3) placed in novel cage with no water available; blood sample obtained 30 min later. All animals showed an increase in corticoids following 24 hr water deprivation, and placement in a novel cage produced a significant further increase in corticosterone. Availability of water in the novel cage markedly attenuated the corticoid response to novelty for all males. However, fetal ethanol-exposed females showed significantly less attenuation of their corticosterone response to novelty than both pair-fed and control females.

In a second experiment, we examined habituation to a stressful stimulus. Animals were restrained in Plexiglas tubes and blood samples were obtained following 30 or 60 min of restraint. All animals showed significant corticoid elevations at 30 min. Males showed no change in corticoids at 60 min, while both pair-fed and control females showed a significant corticoid decrease at 60 min. Once again, however, fetal ethanol-exposed females were more responsive to stress and still showed elevated corticoid levels at 60 min.

These data support the hypothesis that behavioral or psychological variables are less effective in inhibiting or attenuating the pituitary-adrenal response to stress in animals prenatally exposed to ethanol than in controls. Interestingly, females were more vulnerable to these effects of ethanol than males.

Supported by a grant from the Medical Research Council.

140.2 DOES THE PRENATAL EXPOSURE TO ETHANOL AFFECT AN ADULT'S TOLERANCE TO ALCOHOL? E. Reyes, K.D. Garcia, and J. Wolfe Dept. of Pharmacology, Univ. of New Mexico Sch. of Medicine Albuquerque, NM 87131

Fetal Alcohol Syndrome (FAS) is a condition that afflicts 2.2 out of every 1000 children born in North America. FAS is the leading cause of mental retardation with a known etiology.
Past studies in our laboratory have shown that rats exposed to ethanol in-utero have an increased preference for ethanol as adults. Corticosterol levels in response to stress have also shown to be altered by the in-utero exposure to ethanol.
The present study was undertaken to determine the effects of the maternal administration of alcohol on adult ethanol tolerance. Female wistar rats were fed lab chow, or were pair-fed nutritionally adequate liquid diets (Bioserv) containing either alcohol (6.7% w/v) or isocoloric carbohydrates starting on day 1 of gestation. The litters were culled to six and the pups were placed with non-alcohol treated surrogate mothers until they were weaned. At 45 days of age or older, animals were trained to walk on a wooden rod for a period of 5 minutes. Ethanol (2.5 gm/kg) was injected intraperitoneally (IP), and the animal was placed back on the rod, and timing was started. After the animal fell off of the rod 3 times (within 5 seconds) blood was collected and the time was recorded. The blood was assayed for alcohol content by the method of Lundquest (1959) which couples ETOH conversion to acetaldehyde to NADH generation. The in-utero exposure to ethanol has a significant effect on fall time between 6% and 0% pair-fed controls. The prenatal exposure to alcohol thus appears to increase an adult's tolerance to alcohol.

140.3 UNDERNUTRITION AND/OR PRENATAL ETHANOL EXPOSURE DIFFERENTIALLY INFLUENCE STEREOTYPIC AND LOCOMOTOR RESPONSES TO APOMORPHINE IN RATS. M. Horner*, J. H. Hannigan, J. W. Nalwalk*, B. A. Blanchard* and E. P. Riley. Center for Behavioral Teratology, SUNY-Albany, Albany, NY 12222.

We psychopharmacologically assessed the neural basis for behavioral dysfunction in rats exposed in utero to ethanol. Dose-dependent multiple behavioral responses to the dopamine agonist apomorphine were measured. Long-Evans rats were given a nutritionally-balanced liquid diet with 35% ethanol-derived calories (EDC) on days 6 through 20 of pregnancy. Controls were given either a liquid diet with sucrose substituted isocalorically for ethanol (0% EDC), or ad lib lab chow (LC). Pups were weaned at 21 days. At 27 days of age activity, locomotion, thigmotaxia and bouts of stereotypic behavior were scored in automated activity monitors for 15 min. On the next day male and female rats were injected with apomorphine-HCl (0.02, 0.1, 2.0 or 5.0 mg/kg/ml) or saline/ascorbate vehicle and behavior was assessed again for 60 min. Although analyses showed females were more active than males overall, there were no significant interactions with sex. There were no significant behavioral effects of prenatal ethanol exposure on day 27. Under the challenge of apomorphine administration, however, 35% EDC and 0% EDC animals displayed a dose-response shift to the right for stereotypy relative to LC rats. The 35% EDC animals also tended to show a dose-response shift to the left for locomotor activity relative to both the LC and 0% EDC groups. Taken together with our previous findings of altered responses to amphetamine by 0% EDC females and 35% EDC males at 28 days of age, the present results suggest that general undernutrition due to prenatal alcohol exposure (35% EDC) or resrtricted caloric intake (0% EDC) produces dysfunction in nigrostriatal dopamine systems, perhaps to be reflected in an increased synthesis and/or storage of dopamine without a concommittant change in utilization. Similarly, prenatal ethanol exposure per se may produce a more specific disruption of activation-mediating mesolimbic dopamine systems. The presumed pattern of neural dysfunction is being studied further with dopamine antagonists and in animals at different ages.

This work was funded by NIAAA grant #06721 to JHH.

140.4 OPEN-FIELD BEHAVIORS IN RATS TREATED WITH LOW OR HIGH DOSES OF ETHANOL ON POSTNATAL DAYS 1-7 OR 8-14. T.B. Sonderegger, D. Weimer*, J. Benz*, K. Mallon*, and B. Mesloh*, Dept. of Psychol., Univ. of Nebraska-Lincoln, Lincoln, NE 68588-0308.

This study examines the effects of low (L) (4g/kg) or high (H) (7g/kg) doses of ethanol administered during postnatal weeks 1 or 2 upon open field behaviors of female and male rats. Ethanol was administered twice daily on postnatal days (1-7), Week-1, or postnatal days (8-14) Week-2, in a 30% Sustagen (Mead Johnson) vehicle using an intragastric intubation procedure designed to counteract effects of underfeeding (Sonderegger et al., Neurobehavior. Tox. and Teratol. 4:477, 1982). Doses were tapered to reach the maximum dose in Wk-1 animals on day 4 and in Wk-2 animals on day 11. On postpartum day 1, pups from 14 litters of Charles Rivers CD albino rats (10 pups per litter) were used in a split-litter design. On postpartum day 1 pups were assigned to a treatment group: Week-1 (W-1), low dose (L) ethanol (E); L Sustagen (S); Pair Fed (PF); Week-2 (W-2) LE, W-2 HE, W-2 LS, and W-2, LE. S animals received comparable volumes of isocaloric (sucrose) vehicle. Body weights were comparable on day 21; animals were weaned at that time and housed in same-sex pairs with ad libitum food and water.

On days 70-90, blocks of same-sex animals were tested for four consecutive days in the open-field during the first part of the dark cycle. Two observers made microcomputer assisted observations (Sonderegger et al. Neurobehavior. Tox. and Teratol. 6:326, 1984) using programs for real-time observations. The programs permitted recorded of traditional activity measures, timing of event onsets, frequency records of specific behaviors, records of episode sequences, and summation of event times, etc., a total of 19 variables. Data were summed over the four days and submitted to a principal component factor analysis with a varimax rotation. Four factors, accounting for 63% of the variance, were identified as: Exploratory Activity, Nonexploratory Behavior, Grooming Behavior, and Atypical Head movements. As expected, females were more active than males, and W2H E animals differed most from the controls on several variables. Manova's performed on these data and their implications will be discussed. Univ. NE-Lin Research Council, Biomedical Support Grant RR 07055.

140.5 IMPAIRED SPATIAL NAVIGATION IN ADULT FEMALE BUT NOT ADULT MALE RATS EXPOSED TO ALCOHOL DURING THE BRAIN GROWTH SPURT. S.J. Kelly, C.R Goodlett, S.A. Hulsether and J.R. West. Alcohol and Brain Research Laboratory, Department of Anatomy, College of Medicine, University of Iowa, Iowa City, IA 52242, U.S.A.

Locating a submerged platform in a white tank filled with milky water using distal extramaze cues, a task referred to as the Morris water maze, can be used to assess hippocampal function (Morris, Garrud, Rawlings and O'Keefe, Nature 1982 297:681). Alcohol exposure during the brain growth spurt has been shown to alter the hippocampus and we have recently reported that rats aged 19 to 30 days of both sexes exposed to high blood alcohol concentrations (BACs) had impaired Morris maze performance (Goodlett, Kelly and West, Psychobiology, 1987, in press). In order to distinguish between a permanent effect and a developmental delay, we now report the effects of the same patterns of alcohol exposure that we used previously on the performance of adult rats in the Morris water maze.

Two groups were given 6.6 g/kg/day of ethanol via an artificial rearing technique (feedings every 2 h) on postnatal days 4 to 10. One group received the alcohol condensed into 8 h of each day which caused cyclic BACs with peaks at 307 mg/dl whereas the other group received the alcohol uniformly over 24 h which caused stable BACs of 60 mg/dl. Two control groups consisted of rats artificially reared on milk solution alone and rats reared normally by a dam. All rats were raised to day 90 and then tested in the Morris water maze. The rats were given eight trials per day until they met a strict performance criterion. Then the platform was moved to another position and the rats were tested until criterion was met again. In order to determine whether the effects found were the result of impaired ability to use distal extramaze cues, additional groups were tested using an elevated visible platform.

In adult male rats, neither alcohol exposure nor artificial rearing had an effect on Morris maze performance. In contrast, in adult female rats, condensed alcohol exposure but not uniform alcohol exposure was detrimental to the initial learning of the Morris water maze. Female rats given condensed alcohol exposure or artificially reared on milk solution alone did not differ in their ability to locate a visible platform.

In summary, exposure to high BACs during the brain growth spurt impairs Morris maze performance in adult female rats but not adult male rats even though both sexes were equally impaired during the juvenile period. This finding suggests that alcohol alters Morris water maze performance via disruption of a still developing sexually dimorphic substrate(s). (Supported by NIAAA grant AA05523 to J.R.W.).

140.6 ACUTE AND CHRONIC ETHANOL TREATMENTS ALTER GABA RECEPTOR-OPERATED CHLORIDE CHANNELS. Andrea M. Allan and R. Adron Harris. Department of Pharmacology and Alcohol Research Center, University of Colorado Health Sciences Center, Denver, CO 80262.

The molecular mechanisms underlying the development of ethanol tolerance and dependence are still unknown. There is considerable evidence that ethanol enhances the opening of $GABA_A$ receptor-operated chloride channels. Our laboratory has previously demonstrated that in vitro additions of low concentrations(10-45mM) of ethanol increases GABA agonist mediated chloride ($^{36}Cl^-$) uptake into brain membrane vesicles (microsacs) (Allan and Harris, Pharmacologist 27:125, 1985; Allan and Harris, Life Sci. 39:2005, 1986). Here we report the effects of acute and chronic ethanol administration on muscimol- and ethanol augmentation of muscimol-stimulated $^{36}Cl^-$ flux into microsacs prepared from mouse cerebellum

DBA/2J mice (25-30g) were chronically fed ethanol (5% v/v) in a liquid diet for 7 days. Control mice were fed an isocaloric diet with sucrose subsituted for ethanol. Animals were sacrificed the morning of the 8^{th} day and cerebellar microsacs were prepared for muscimol- and ethanol potentiation of muscimol-stimulated $^{36}Cl^-$ uptake as previously described (Harris and Allan, Science 228:1108, 1985). Exposure to physiologically relevant concentrations of ethanol (10-45mM) in vitro potentiated muscimol-stimulation of $^{36}Cl^-$ flux in control (pair-fed), but had no effect on cerebellar microsacs prepared from ethanol tolerant/dependent mice. Muscimol-stimulation of $^{36}Cl^-$ flux was not different for pair-fed and ethanol treated mice.

Other mice were acutely treated with a single i.p. injection of 4 g/kg ethanol and sacrificed at either 5 min, 60 min, 24 hr post-injection and microsacs were prepared from cerebellum. Augmentation of muscimol-stimulated $^{36}Cl^-$ by in vitro ethanol was abolished by a single 4 g/kg injection of ethanol. This "rapid tolerance" occurred within 5 min and disappeared within 24hr after ethanol treatment. The reduced sensitivity of ethanol treated (acute and chronic) mice to ethanol potentiation of muscimol-stimulated $^{36}Cl^-$ uptake offers a biochemical correlate to the phenomenon of ethanol tolerance. Moreover, these findings suggest that this tolerance develops rapidly following a single hypnotic dose of ethanol. Supported by funds from the Veterans Admin. and USPHS grants AA05233, AA06399 and AA03527.

140.7 REGIONAL DIFFERENCES IN CA1 POPULATION EVOKED RESPONSES IN HIPPOCAMPAL SLICES OF CHRONIC ETHANOL-TREATED RATS.
R. A. Palovcik, B. E. Hunter, and D.W. Walker. Dept. of Neuroscience, Univ. of Fla., Coll. of Med. and V. A. Med. Ctr., Gainesville, FL 32610.

Among the long term effects of chronic ethanol treatment (CET) are changes in excitability of hippocampal CA1 pyramidal neurons to stimulation of the stratum radiatum (SR) fiber pathways. Increases in the amplitude of extracellular evoked population spikes have been demonstrated for dorsal hippocampus in vivo and in vitro with paired pulse stimulation (Abraham et al., 1981 and Rogers and Hunter, 1985). No differences between CET and controls have been found with single pulse stimulation in dorsal hippocampus. It was therefore of interest to determine whether regional differences exist in the magnitude of field potentials between dorsal and ventral hippocampus in CET and control populations. CET rats were fed a nutritionally complete liquid diet containing ethanol for 20 weeks followed by an 8 week withdrawal period. Control rats were pair fed the same diet without ethanol but with isocalorically substituted sucrose. Population evoked responses from CA1 to SR stimulation were evaluated for areas of dorsal, central, and ventral hippocampal slices by systematically varying stimulus current magnitude (input/output functions).

Control animals exhibited significantly smaller population spike amplitudes in ventral hippocampus than dorsal or central hippocampus to SR stimulation. CET animals exhibited no regional differences for SR evoked population spikes. Therefore, CET produced a significant increase in population spike amplitude in ventral hippocampal slices relative to control. No significant differences were found for EPSP amplitudes recorded from stratum pyramidale (SP) or SR between CET and control rats. However, EPSP slopes in ventral hippocampus of control rats were significantly decreased compared to CET rats and dorsal and central hippocampal areas in control rats. There were no significant differences in latency to onset of EPSP in stratum pyramidale, negative EPSP in SR or any population spikes. No significant differences in threshold were detected for elicitation of population spikes between CET and control rats.

Our results indicate a decreased population spike size in ventral hippocampus of normal rats with no concomitant changes in negative EPSP amplitude recorded in SR or positive EPSP amplitude recorded in SP. This suggests that increased population spike amplitude for CET rats in ventral hippocampus is due to decreased inhibition, consistent with previous results. Decreased inhibition may also be reflected in the increased slope of the SP extracellular EPSPs of CET rats. Population spike amplitude for central and dorsal CET hippocampus were also greater than for control hippocampus. Although these were not significant, they may reflect reduced CET effects on dorsal and central hippocampus which can only be detected with paired pulse techniques. Changes in hippocampal excitability due to CET exhibit regional specificity and appear to be greatest for ventral hippocampus.

Supported by the Veterans Administration, Grants NIAAA AA00200 and RCDA AA00065 (BEH).

140.8 ETHANOL TREATMENT ALTERS CNS PLASMA MEMBRANE COMPONENTS IN MICE. B. L. Hungund*, M. J. Modak* and S. P. Mahadik. (Spon. M. Rapport) Dept. of Analyt. Psychopharm. & Div. of Neurosci., N. Y. State Psych. Institute, & Dept. of Biochem. & Mole. Biophys., Coll. of Physicians & Surgeons of Columbia Univ., New York, NY 10032 and Dept. of Biochem. Univ. of UMDNJ, Newark, NJ 07103.

It is now accepted that ethanol exerts its pharmacological effects by altering the physicochemical properties of biological membranes. Some evidence is based on the changes in the lipids and fluidity associated with the development of tolerance to ethanol. We report here the results of the effects of chronic ethanol treatment on a) levels of fatty acid ethyl esters (FAEEs), indicators of structural change in plasma membranes; b) Na,K-ATPase, one of the major markers for plasma membrane function and c) GTP-binding proteins (G-Ps), presumed to be involved in signal (neurotransmitter or hormonal receptor-mediated) transduction across plasma membranes, in membrane fractions from whole brain and subcellular fractions of mouse. Male Swiss-Webster mice were treated with ethanol by an inhalation procedure. The animals were sacrificed by decapitation after 3 and 6 days of exposure to ethanol and the membrane fractions were prepared. The FAEEs were quantitated by gas chromatographic procedure. FAEEs (oleic, C18:1 and linoleic, C18:2 acids) were increased in whole brain membranes as well as in synaptic plasma membranes after 3 days of exposure. Na,K-ATPase activity of whole brain membranes was increased (15%) upto 3 days of treatment and then showed slight decrease after 6 days of treatment. The G-Ps were first labeled by photoaffinity using α-P32-GTP and then labeled proteins were analysed by SDS-slab gel electrophoresis followed by autoradiography (Basu & Modak J. Biol. Chem. 262:2369, 1987). A total of 18 labeled polypeptides were identified in both control as well as alcohol treated membranes. However, differences were noted in the amounts of individual G-Ps. These differences were of two types: 1. the contents of some G-Ps (70 kDa, 59 kDa & 44 kDa) were increased substantially after 3 days of treatment and then decreased after 6 days of treatment, 2. the extractibility of G-Ps with Triton X100 was reduced in alcohol treated membranes compared with controls. It is possible that after alcohol administration, the turnover of these proteins is altered either by their increased synthesis (which is unlikely since overall protein synthesis is shown to be decreased) or by their decreased loss from membrane. Alternately, the level of GTP incorporation is altered as a result of alteration of membrane structure. It is suggested that the chronic alcohol treatment leads to a significant changes in FAEEs which probably contribute to changes in activities of membrane proteins.

140.9 EFFECTS OF ETHANOL ON ARRAYS OF SINGLE NEURONS RECORDED OVER SEVERAL DAYS IN THE RAT CORTEX Chapin, J.K. and Patel, I.M.* Hahnemann University, Philadelphia, PA 19102

Traditional methods of using single unit recording to assess drug effects on the brain are often limited by: 1- the presence of anesthetics, 2- the inability to hold the units long enough to observe a recovery, or long term effects, and 3- the high degree of variance associated with single unit discharge. To alleviate these problems we have implemented the technique of recording many units simultaneously through chronically implanted microwire electrodes (stainless steel, .001", teflon coated). Well isolated cortical neurons may be continuously recorded through such electrodes for periods of up to 21 days in awake, behaving animals. This is advantageous in drug studies because it allows: 1- units to be recorded to full recovery, 2- chronic effects of drugs to be observed, 3- an increased data yield per experiment, 4- internal controls for several different types of experimental variation, and 5- a view of drug effects on the "ensemble" properties of neural networks.

In each of several animals we have implanted bundles of up to eight microwires in either the somatosensory or motor cortex of rats. In experiments, ethanol was administered intraperitoneally 3-4 times over a three-week period. Experimental monitoring of the units' activity was typically done every day whether or not drugs were being administered. Each day the spike waveforms, discharge characteristics, and sensorimotor response properties of each unit were thoroughly scrutinized to determine whether they were the same cells as were recorded the previous day. These units were recorded for one or several hours while the rat alternately ran and rested on a computer controlled treadmill (5 sec ON, 5 sec OFF cycle). A precise record of this motor behavior was obtained by video taping the experiments. Each video frame was automatically labelled with the time in 10 msec increments, allowing post-hoc frame-by-frame analysis for correlation of behavior with the activity of all recorded units.

Use of these techniques allowed the following observations: 1- cortical neurons exhibit a high degree of variability in their response to ethanol. Some cells were virtually unaffected while others recorded simultaneously in the same animal virtually ceased their activity for more than an hour, finally recovering to normal only after up to 8 hours. 2- Tolerance of these single cells to ethanol developed after a single injection. Supported by AA-06965 and AA-00089.

140.10 EFFECT OF CHRONIC ETHANOL TREATMENT ON DOPAMINE RECEPTOR SUBTYPES IN RAT STRIATUM. L. Lucchi*, S. Govoni, M.R. Moresco*, S. Bergamaschi* and M. Trabucchi^. (SPON: N. Brunello) Istitute of Pharmacological Sciences, University of Milan and ^Chair of Toxicology, 2nd University of Rome, Italy.

The chronic treatment with ethanol modifies the postsynaptic transducing mechanisms linked to dopamine receptors. In particular, the adenylate cyclase displays an increased basal activity and a reduced responsiveness to dopamine.

The recent progress in the understanding of adenylate cyclase regulation at striatal level indicates the existence of subclasses of dopaminergic receptors which have an opposite action on cyclic AMP formation (D1 stimulatory and D2 inhibitory).

Along this line, we have revised the effect of chronic ethanol administration (6% in the drinking water for 21 days) on adenylate cyclase activity by measuring the dopamine promoted cyclic AMP formation and the ability of selective D2 agonists to inhibit adenylate cyclase. In addition, the effect of chronic ethanol treatment on dopamine recognition sites was assessed by means of the measurement of the binding of specific ligands. SCH 23390 was used as selective D1 dopamine receptor probe. Dopamine D2 recognition sites were measured using tritiated spiperone as ligand and sulpiride as displacer. This technique labels D2 sites functionally correlated with the dopamine-inhibited adenylate cyclase (Govoni et al., Brain Res. 381:138,1986).

Ethanol treatment affected both the dopamine stimulated and the dopamine inhibited cyclases. The ability of dopamine to stimulate cyclic AMP was less than half in homogenates prepared from treated animals (80% in controls, 30% in ethanol treated). Bromocriptine inhibited cyclic AMP formation by 37% in homogenates prepared from control striata and by 14% in treated animals.

In striatal synaptic membranes prepared from ethanol treated rats the sulpiride displaceable tritiated spiperone binding was reduced by 27% and tritiated SCH 23390 by 25%.

The data show that striatal adenylate cyclase is less stimulated by dopamine and less inhibited by bromocriptine in homogenates prepared from rats chronically treated with ethanol. The binding results indicate that both dopamine-receptor types are reduced by the chronic ethanol treatment paralleling the functional results on cyclase activity.

140.11 CHRONIC ETHANOL TREATMENT REDUCES CHOLERA TOXIN MEDIATED [^{32}P]ADP-RIBOSYLATION OF 46 KILODALTON PROTEIN IN CEREBRAL CORTICAL MEMBRANES OF C57BL MICE. P. T. Nhamburo, P. L. Hoffman and B. Tabakoff. (SPON: C. Rabe). Lab. of Physiologic and Pharmacologic Studies, NIAAA, Bethesda, MD 20892

Receptor regulated adenylate cyclase (AC) system consists of three components; receptor, catalytic unit and guanine nucleotide binding proteins (G). The alpha subunits of the inhibitory (α_i) (Mol. Wt. ranging 39-41 Kd) and stimulatory (α_s) (Mol. Wt. ranging 42-52 Kd) G-proteins contain a site which is ADP-ribosylated by pertussis (islet-activating protein) and cholera toxins, respectively. Chronic administration of ethanol to mice in vivo in a paradigm that produced tolerance to and physical dependence on ethanol has been reported to cause significant decreases in the Gpp(NH)p-dependent AC activity and in the apparent coupling of β-adrenoceptors to G_s. To elucidate the mechanism of these changes, we have therefore, measured [^{32}P]ADP-ribosylation catalysed by either cholera or pertussis toxin in ethanol-treated animals. Male mice (C57BL/6) were fed a liquid diet containing either 7% (v/v) ethanol or an equicaloric amount of sucrose (controls) for 7 days. Cerebral cortical membranes from naive (chow-fed), control and ethanol-treated mice were incubated with 100 μM [α-32P]NAD for 60 minutes at 30°C, in the presence or absence of either preactivated toxin. [^{32}P]ADP-labelled proteins were then separated by SDS-polyacrylamide gel electrophoresis, and ^{32}P estimated by autoradiography. Although several protein bands were [^{32}P]ADP-ribosylated by cholera toxin, only the 46Kd band was signficantly decreased (30-50%) following ethanol treatments in vivo compared to those from either controls or naive mice. There was no significant change in [^{32}P]ADP-ribosylation of pertussis toxin substrate (40 Kd band). The decrease in ADP-ribosylation of the 46 Kd protein which shares the same molecular weight as that reported for G_s, could indicate a reduced amount of this protein, or structural changes or defects in this protein so that it is altered as a substrate for ADP-ribosylation by cholera toxin.

140.12 DO GLUCOCORTICOIDS PLAY A ROLE IN HIPPOCAMPAL CELL LOSS DURING CHRONIC ETHANOL TREATMENT? G. Rachamin*, W.G. Luttge, B.E. Hunter and D.W. Walker. Department of Neuroscience, College of Medicine, University of Florida, and VA Medical Center, Gainesville, Fl 32610.

Both chronic exposure to ethanol and aging result in loss of hippocampal pyramidal neurons. Recent reports indicate that corticosterone (CORT) receptors and CORT-concentrating cells are depleted in the hippocampus of aged rats, due to cumulative exposure to glucocorticoids over the life span. We have investigated the hypothesis that glucocorticoids play a similar role in the production of hippocampal cell damage during chronic ethanol treatment (CET), thus leading to selective losses of glucocorticoid receptors and glucocorticoid-concentrating cells.

Liquid diet containing ethanol (36% of total calories as ethanol) was administered to male Long-Evans rats for 20-24wks (starting at 3mo of age), a period of CET previously found in our laboratory to produce hippocampal neuronal cell loss. Control rats were pair-fed with identical diets, except for isocaloric substitution of sucrose for ethanol. Morning blood ethanol concentrations in the ethanol-fed rats averaged 149±20mg%. At the end of CET animals were adrenalectomized, and 24hrs later specific binding to cytosolic glucocorticoid receptors in the hippocampus was determined. Specific binding of [^{3}H]dexamethasone to Type II receptors was not significantly different between the two groups (Ethanol=236±10 and Sucrose=285±48 fmoles/mg protein). Similarly, no significant differences in [^{3}H]aldosterone specific binding to Type I receptors (in the presence of RU26988 to block binding to Type II receptors) were observed between ethanol and control animals (53±8 and 71±12 fmoles/mg protein, respectively). Basal morning plasma CORT concentrations in the ethanol rats were within the normal physiological range, while those in control rats were significantly elevated (5.61±2.19 versus 59.41±12.15ng/ml, $p<0.001$). Since our CET studies were conducted in Long-Evans rats we also measured adrenocorticosteroid binding in young (3-5mo) and old (24-26mo) male Long Evans rats. There was no significant influence of age on binding to Type II (Young=237±32 and Old=245±13 fmoles/mg protein) nor to type I (Young=70±8 and Old=60±6 fmoles/mg protein) receptors in these animals. In conclusion, the data do not appear to support the idea that glucorticoids play a role in the production of hippocampal neuronal damage during CET or aging in the Long Evans strain of rats. However, the possibility that alcohol may have a differential effect on glucocorticoid receptors in the left and right hippocampus or in different regions within it can bot be excluded.

140.13 EFFECTS OF CHRONIC ETHANOL CONSUMPTION ON [^{3}H] INOSITOL TRISPHOSPHATE SPECIFIC BINDING IN MOUSE CEREBELLUM. T.L. Smith and S. Battiste-Milton. Veterans Administration Medical Center, Tucson, AZ 85723 and Dept of Pharmacology, University of Arizona Health Sciences Center, Tucson, AZ 85724.

Inositol 1,4,5 trisphosphate (IP_3), a product of receptor-mediated phosphoinositide hydrolysis, has been identified as a second messenger which mobilizes intracellular Ca^{2+}. Specific saturable binding of radiolabeled IP_3 has been demonstrated in adrenal cortex, hepatocytes, neutrophils, and more recently in rat brain. Since ethanol is known to affect neuronal Ca^{2+} disposition, it was of interest to determine 1.) whether specific binding sites can also be observed in mouse brain and 2.) to determine what effects ethanol added in vivo and in vitro may have on this system. Membrane fragments from discrete brain regions of C57/BL mice were suspended in 20 mM TRIS (pH 7.7) containing NaCl, 20 mM; KCl, 100 mM; EDTA, 1 mM. Tissue samples (250-600 ug protein) were incubated for 10 mins at 0° in the presence of 2.5-80 nM [^{3}H]IP_3 (3.5 Ci/mmol) in a final volume of 0.5 ml. The reaction was stopped by rapid vacuum filtration and the filters rinsed with three 3 ml aliquots of ice-cold 50 mM TRIS (pH 7.7). Differences between measurements in the absence and presence of 10uM IP_3 were used to define specific binding. The rank order of [^{3}H]IP_3 specific binding capacity was: cerebellum > hippocampus > cortex > midbrain. Scatchard analyses of the binding data for cerebellum yielded K_D and Bmax control values of 62 nM and 3.86 pmoles/mg protein, respectively. Ethanol, at or above 100 mM, enhanced [^{3}H]IP_3 binding by c.a. 15% in control mice. In contrast, chronic consumption of an ethanol-containing liquid diet (7%, v/v) for 8 days resulted in a significant decrease ($P < 0.05$) in specific binding: 2.42 ± 0.60 pmoles/mg protein vs 3.89 ± 0.77 pmoles/mg protein for pair-fed controls in the presence of 50 nM [^{3}H]IP_3. It is concluded that IP_3 binding varies greatly in different brain regions and that ethanol given in physiological concentrations has a modest effect on this system. (supported by a Vet. Admin. Medical Research grant.)

140.14 CHANGES IN THE DENTATE FASCIA FOLLOWING CHRONIC ETHANOL EXPOSURE IN LS AND SS MICE. A. J. Scheetz, J. A. Markham and E. Fifkova. Dept. of Psychology, Univ. of Colorado, Boulder, CO 80309.

Short-Sleep (SS) and Long-Sleep (LS) mice differ in the duration of acute ethanol induced narcosis. The SS mice are relatively unaffected by acute doses of ethanol that are sufficient to induce several hours of sleep in the LS mice. We have previously shown that chronic ethanol exposure results in a decrease in the frequency of basket cells subjacent to the granule cell layer of the dentate fascia in the ethanol sensitive LS mice but not in the ethanol insensitive SS mice (Scheetz et al., Brain Res., 403:151-154, 1987). The present report details information regarding the specificity and time course of this effect. Mice were grouped into one of three conditions: Ethanol, nonethanol liquid diet and standard lab chow receiving groups. At the end of the 3 months of ethanol exposure animals were perfused with glutaraldehyde and embedded in epon. Five 1 μm sections, 60 μm apart, were obtained from each tissue block. The sections were mounted and stained with toluidine blue. We exposed another group of SS and LS mice to 20 days of ethanol with the concentration of ethanol gradually increased from 11.5% ethanol derived calories (EDC) to 23% EDC to 35% EDC over a period of 2, 7, and 11 days respectively. The perfusion and tissue preparation was the same as in the preceding experiment. Basket cells were identified according to the criteria of Ribak and Anderson (J Comp. Neurol., 192:903-916, 1980). The frequency of basket cells was defined as the number of basket cells per unit length of the granule cell layer. The density of granule cells was computed by dividing the total number of granule cells by the total area of the granule cell layer. In these two experiments there was no significant difference in the density of granule cells between LS control and LS ethanol animals. Likewise, no differences in density of granule cells were found between SS control and ethanol mice. In the short-term exposure experiment there was a clear, but insignificant, trend in the LS groups for the ethanol treated animals to have a lower frequency of basket cells. Because glial proliferation is known to precede neuronal degeneration, we counted the density of glial cells in these slides. It was found that the density of glial cells in the LS ethanol animals was significantly higher than in the LS control group. The density of glial cells in the two SS groups was not significantly different. No such glial proliferation was observed in the tissue from the 3 month exposure experiment, indicating that a majority of the cell loss has occurred before 3 months. The fact that we found the glial proliferation after only 20 days of ethanol exposure indicates that the effect of ethanol on the loss of basket cells may be occurring during the first month of chronic ethanol exposure. None of these effects is accompanied by the loss of the principal neurons in this region. Supported by NIAAA grant AA06196.

140.15 THE EFFECT OF ETHANOL WITHDRAWAL ON GABA FUNCTION IN THE IN VITRO HIPPOCAMPUS. T.J. Chesnut. Wadsworth Center for Laboratories and Research, New York State Department of Health, Albany, NY, 12201.

Changes in gamma-aminobutyric acid (GABA) mediated systems in the central nervous system have been suggested to be involved in ethanol withdrawal induced hyperexcitability. The in vitro brain slice preparation of rat hippocampus was used to determine the effects of ethanol withdrawal on the GABA-mediated recurrent inhibitory pathway of area CA1. Wistar rats were rendered ethanol dependent by feeding them ethanol in a liquid diet (Bio-Serve, Inc.) at a concentration supplying 35% of the total calories in the diet. Rats treated thusly for 9 days became highly ethanol dependent as documented by the behavioral criteria of Majchrowicz (Psychopharmacol., 43:245-254). Blood alcohol levels (BALs) were measured in these animals and indicated that the BALs at 9 days averaged 50 mM. This information was used to develop an "in-chamber" withdrawal technique by assuming that the cerebrospinal fluid ethanol concentration was also 50 mM (Newlin et al, Brain Res., 209:113-128).

Transverse slices 375 um thick were cut from hippocampi obtained from animals rendered ethanol dependent as indicated. All slices were incubated at 32-33°C in oxygenated artificial cerebrospinal fluid (ACSF) constantly perfused through the experimental chamber. The moment of ethanol withdrawal was controlled by preparing and incubating the slices in ACSF containing 50 mM ethanol. Withdrawal could then be initiated when desired by changing the perfusate to ethanol-free ACSF. Comparison of measurements obtained both before and after such "in-chamber" withdrawal can therefore indicate changes at the moment of withdrawal under conditions that can be directly related to behavioral dependence.

Surprisingly, intracellular measurements obtained from 13 pyramidal cells indicated no withdrawal-induced hyperexcitability except for one cell that displayed spontaneous depolarizing potentials lasting up to 10 seconds in length upon which were superimposed action potentials. Changes in the post-synaptic potential (PSP) recorded due to activation of the GABA-mediated recurrent inhibitory pathway were measured by obtaining current-voltage curves, both in the presence and in the absence of the GABA-mediated response. No withdrawal-induced changes in the resting input conductance of the cell or in the reversal potential of the PSP were observed. The effects of withdrawal on the conductance due to the PSP have not yet been determined due to the small number of cells. The studies do indicate, however, that the described method of "in-chamber" withdrawal permits detailed investigation of the effects of ethanol withdrawal on GABA function under conditions directly related to behaviorally-induced ethanol dependence.

140.16 **INTENSITY OF PENTYLENETETRAZOL-LIKE DISCRIMINATIVE STIMULUS PRODUCED BY ETHANOL WITHDRAWAL DEPENDS ON DOSE AND DURATION OF ETHANOL GIVEN IN NUTRITIONALLY BALANCED DIET.** D. Benjamin*, C.M. Harris, S. Bhadra, M.W. Emmett-Oglesby, and H. Lal. (SPON: L.J. Achor) Dept of Pharmacology, Texas College of Osteopathic Medicine, Ft. Worth TX 76107.

Ethanol withdrawal produces anxiety which may motivate continued ethanol abuse. We have developed the pentylenetetrazol (PTZ) discrimination paradigm (Lal and Emmett-Oglesby, Neuropharmacology 22:1423, 1983) as a bioassay (Lal and Fielding, Drug Dev. Res., 4:3-21, 1984) to investigate anxiogenic treatments, including ethanol withdrawal. PTZ is anxiogenic in humans and produces an interoceptive discriminative stimulus (IDS) in rats that is mimicked by anxiogenic drugs and antagonized by anxiolytic drugs. Rats trained to discriminate PTZ and given ethanol by gavage exhibit a PTZ-like IDS during withdrawal (Lal et al., Fed. Proc. 46:1301, 1987); however, the only source of nutrition in the previous experiments was the ethanol or sucrose solution. To test if the PTZ-like withdrawal stimulus could be demonstrated when rats are adequately nourished during ethanol treatment, a nutritionally complete diet was used as the vehicle (Benjamin et al., Fed. Proc. 46:712, 1987) for ethanol. The rats were given the ethanol-diet mixture for 4 days, followed by a terminal dose (3 g/kg) of ethanol given by gavage, and tested for blood ethanol concentrations or lever-selection. Blood ethanol peaked at 3 mg/ml, at 3 h after gavage, and declined to 0.6 mg/ml by 12 h after the final dose, at which time 90% of ethanol-treated rats selected the PTZ-appropriate lever. The percent of rats selecting the PTZ-lever declined to baseline values within 72 h. This withdrawal IDS was dose-dependently antagonized by ethanol or diazepam. When the duration or dose of the ethanol treatment was varied, the percent of rats selecting the PTZ-appropriate lever during withdrawal varied accordingly. The intensity of the PTZ-like IDS was maximal after a daily ethanol dose of 12.5 g/kg, given for 3 days. These results suggest that withdrawal from ethanol given in a nutritionally complete diet produces a discriminative stimulus comparable to the stimulus produced by anxiogenic drugs. In addition, the intensity of the withdrawal stimulus varies directly with the dose and duration of ethanol treatment. (Supported by NIAAA grant #R01-AA06890)

140.17 EFFECT OF CHRONIC ETHANOL WITHDRAWAL ON SEIZURE RESPONSES TO INFERIOR COLLICULUS MICROINJECTIONS OF BICUCULLINE METHYLIODIDE, PICROTOXININ AND KAINIC ACID. Gerald D. Frye. Dept. of Medical Pharmacology, Texas A&M University College of Medicine, College Station, TX 77843.

Susceptibility to sound-induced wild running, clonic-tonic seizures is a well documented characteristic of physical dependence on ethanol in rats undergoing withdrawal. This susceptibility to seizures can be blocked by microinjection of gamma-aminobutyric acid (GABA) agonists into the inferior colliculus. An adaptive reduction in GABAergic inhibition in the inferior colliculus may be responsible for sound seizure susceptibility since similar wild running, clonic-tonic seizures can also be induced in ethanol-naive rats by microinjections of GABA antagonists, bicuculline methiodide (BMI) and picrotoxin into the inferior colliculus (Frye, G.D., J. Pharmacol. Exp. Ther. 237:478, 1986). The present experiments compared the sensitivity of inferior colliculi in ethanol-dependent and ethanol-naive rats to bilateral microinjections of BMI, picrotoxinin (PIC) and the excitatory amino acid agonist, kainic acid (KA; infusion rate = 0.5ul over 5min). The ED_{50}s for wild running seizures in ethanol-naive rats were approximately, BMI (10-pmol), PIC (11.0pmol), KA (17.0pmol). ED_{50} estimates for wild running seizures in withdrawing ethanol-dependent rats were not different from those of ethanol-naive animals for any of the agents. However, when more severe clonic seizure responses were considered, ED_{50}s in withdrawing ethanol-dependent rats were significantly lower than those for ethanol-naive animals for all three convulsants. These results suggest that ethanol dependence increases susceptibility to clonic seizures that may be due to enhanced rostral seizure spread from the inferior colliculus, while susceptibility to wild running responses that originate more directly from the inferior colliculus are unaltered. However, ethanol dependence does not appear to evoke significant changes in the relative sensitivity of the inferior colliculus to seizures caused by GABA antagonists when compared to excitatory amino acid agonists, as might be expected if GABAergic adaptation had occurred. This work was supported in part by Public Health Service Grant AA06322.

140.18 ETHANOL WITHDRAWAL IN WSP AND WSR SELECTIVELY BRED MICE: MEASURES ACROSS GENERATIONS. A. Kosobud, E. Young*, B. Tam*, C. Deutsch*, and J.C. Crabbe. Departments of Medical Psychology and Pharmacology, Oregon Health Sciences University and Veterans Administration Medical Center, Portland, OR, 97201.

Withdrawal Seizure Prone (WSP) and Withdrawal Seizure Resistant (WSR) lines of mice have been selectively bred for differences in withdrawal following chronic inhalation of ethanol (EtOH) vapor. Mice are selected on the basis of severity of handling-induced convulsions (HIC) during withdrawal. In the experiments presented here, withdrawal was assessed in WSP, WSR and WSC (a non-selected control) lines of mice between the 10th (S_{10}) and 17th (S_{17}) selected generation, and following three generations of relaxed selection (S_{24}). Blood ethanol concentrations (BEC) were measured during induction of physical dependence and during withdrawal. During withdrawal, HIC and body temperature were recorded, and mice were observed for other signs of withdrawal including tremor, straub tail and backward walking. Comparisons of earlier selected generations (Kosobud and Crabbe, J. Pharmacol. Exp. Ther., 238:170-177, 1986) showed that WSP and WSR mice reached similar BEC during intoxication, and eliminated EtOH at a similar rate. During withdrawal, WSP mice consistently showed more severe HIC and tremor, and tended to show more straub tail than WSR mice. In the present experiments, WSP mice showed more severe HIC, tremor and straub tail during withdrawal than WSR mice, while WSC mice were intermediate. In S_{17}, the amount of hypothermia seen during withdrawal was similar in WSP and WSR mice, but in S_{24}, hypothermia was greater in WSP than WSR mice. BEC were similar in WSP, WSC and WSR mice in the early generations, but in later generations WSP mice reached higher BEC during intoxication, and appeared to eliminate ethanol more slowly, than WSR mice. In summary, WSP and WSR mice also differ in severity of signs of EtOH withdrawal other than HIC, confirming that the selection has altered some general properties of EtOH withdrawal. Three generations of relaxed selection did not result in a large reduction in selection response, suggesting that many of the genes responsible for the withdrawal difference in these lines are fixed. A small difference in EtOH metabolism is present in the most recent generations of these lines, and is probably making some contribution to the difference in withdrawal severity seen in WSP and WSR mice. These experiments are supported by PHS-NIAAA grants AA05828, AA06243, AA06498 and by the Veterans Administration.

140.19 GABA MODULATION OF ELECTRICAL SEIZURE DISCHARGE DURING ETHANOL WITHDRAWAL L.P. Gonzalez and J.F. Czachura* . Univ. of Oklahoma Health Sciences Center, Oklahoma City, OK 73190.

Previous reports from this laboratory have suggested that GABAergic neurons of the substantia nigra may be regulators of ethanol (EtOH) withdrawal seizures and related symptomatology. In those studies, we observed a significant suppression of induced motor convulsions following intranigral administration of the GABA agonist muscimol or of the benzodiazepine flurazepam. In order to further evaluate the role of GABA-receptive neurons in the EtOH withdrawal syndrome, we examined the effects of local injections of muscimol on EEG spikes and paroxysmal activity observed in cortical and subcortical sites during withdrawal. Sprague-Dawley rats received chronic bilateral implants of guide cannulae placed just above the substantia nigra zona reticulata (SNR). Monopolar, semi-microelectrodes were implanted within the amygdala, hippocampus, inferior colliculus (IC), and SNR, and bilateral electrodes over visual cortex. One week after surgery the animals received chronic EtOH exposure in EtOH-vapor inhalation chambers. Following sixteen days of chronic exposure, the animals were removed from the chambers and were observed for evidence of withdrawal hyperexcitability. Eight hrs. after removal from the chamber, 30 min. of EEG activity was recorded from the implanted electrodes. Animals then received bilateral injections (0.5 ul) into SNR of either muscimol (15, 30, or 60.0 ng per side) or vehicle. Twenty min. after injection, EEG activity was again observed and recorded for an additional 30 min. Four to six hrs. after injection, the animals were tested for susceptibility to audiogenic seizures. Control subjects received the same handling and treatment, but no exposure to EtOH.

EtOH withdrawal was accompanied by the occurrence of EEG spikes at all of the sites observed, but most consistently in SNR and in IC. Intranigral muscimol injection resulted in a significant decrease in spike activity in both SNR and in IC, but had no effect on cortical spikes; effects at other subcortical sites were inconsistent. Although several interpretations of these results are possible, they suggest that nigral GABA regulation of EtOH withdrawal seizure activity may be due to effects on IC, which has been implicated in the mediation of audiogenic seizures, and perhaps also on influences of SNR on descending motor pathways. Further, it appears that nigral GABA neurons may not be involved in regulation of forebrain seizure activity during EtOH withdrawal.

TRANSPLANTATION III

141.1 PHYSIOLOGICAL COMPARISON OF NORMALLY DEVELOPING STRIATAL NEURONS AND TRANSPLANTED STRIATAL NEURONS IN RATS. J.P. Walsh, F.C. Zhou, C.D. Hull, R.S. Fisher, M.S. Levine and N.A. Buchwald. Mental Retardation Research Center. University of California, Los Angeles. 760 Westwood Plaza, Los Angeles, CA 90024.

Intracellular techniques were used in brain slices to study transplanted striatal neurons (TSNs), neonatal striatal neurons and adult striatal neurons. To produce TSNs, fetal striatal tissue (E14) was implanted as a dissociated cellular suspension into the striatum of adult rats. Intracellular records were obtained 2-6 weeks after transplantation. The graft was easily identifiable in each brain slice study as a separate nonmyelinated structure within the host striatum. Differences in biophysical, synaptic and morphological properties were found between TSNs and adult striatal neurons. These dissimilarities appeared to be related principally to the lower developmental age of the TSNs versus the host striatal neurons. To test this possibility, striatal neurons from rat pups, age-matched with the TSNs, were also examined. The results indicated a general agreement in neuronal properties between the TSNs and rat pup neurons.

Responses of neurons to hyperpolarizing current pulses were used to determine input resistance. The input resistance of TSNs (20 to 27 days after transplantation) was 30.7±1.13 mΩ (n=6), while age matched pups (10-16 days postnatal) had an input resistance of 26.5±4.8 mΩ (n=7). By contrast, the input resistance for adult striatal neurons was 14.5±1.5mΩ (n=11).

Stimulation of adjacent host striatum elicited both excitatory and inhibitory postsynaptic potentials (PSPs) in TSNs (20-38 days post transplant). Similarly, striatal neurons of age matched pups displayed combined excitatory and inhibitory PSPs in response to local stimulation. In adult striatal neurons, by contrast, only excitatory PSPs were evoked.

The morphology of individual neurons was examined following intracellular injection of the fluorescent dye, lucifer yellow. TSNs characteristically had varicose swellings along dendritic shafts and a relatively sparse distribution of spines. These finding were similar to those in striatal neurons of neonatal rats. Medium-sized spiny neurons of the adult striatum, however, lacked dendritic varicosities, had a very dense distribution of dendritic spines and tended to have more complex dendritic fields. Each of the properties examined in this study suggests that TSNs follow the usual developmental pattern expected for maturing medium-sized spiny neurons of the striatum. Supported by HD-07032.

141.2 LONG TERM SURVIVING EMBRYONIC GRAFTS OF STRIATAL TISSUE IN RAI BRAINS. F.C. Zhou, N.A. Buchwald, C.D. Hull, R.S. Fisher and M.S. Levine. Mental Retardation Research Center, UCLA School of Medicine, 760 Westwood Plaza, Los Angeles, CA 90024.

Embryonic brain tissue has been grafted into host brains in many species of animals. In almost all cases the graft survived for a relatively short period of time as compared to the life span of the species involved. The short period of graft survival leads to two as yet, unanswered questions. First, will brain grafts survive long enough to be considered as "permanent" constituents of the recipients brain? Second, if a humoral and/or connective interaction occurs between the graft and the host brain, is this interaction "durable" as compared to the life-span of the species involved. We investigated these questions by grafting neo-striatal tissue into brains of 2-month old Sprague-Dawley rats and allowing the recipients to survive for 17 months (the average life-span of rats is 2-3 years and they are considered to be aged at 17-18 months).

Dissociated striatal cells from 14 day embryonic rats were grafted into striatum (n=7) and substantia nigra (n=3) of the 2 month old recipients. Eight animals survived for seventeen months. Of these, 6 had sizeable (dia. >0.7mm) transplants (TP) [striatum, n=4; nigra, n=2]. Immunocytochemical staining showed that a large population of neurons staining positive for gamma aminobutyric and existed in the TPs. Acetylcholinesterase (AcHE) staining showed that AcHE-positive cells were scattered throughout the TPs.

In general, neurons in the TP seemed to be normal at least in terms of nuclear position. Staining with an antiserum to the catecholaminergic enzyme, tyrosine hydroxylase (TH), showed that TH-positive fibers from the host had penetrated into the grafts and formed dense terminal boutons. These TH-positive terminal boutons existed in a patchy pattern similar to that which occurs at 6-7 weeks of graft survival. In the long term survivals however, the bouton density of TH fibers appeared greater than in the 6-7 week grafts. These results indicate that grafted neurons can survive through the adult life-span of the recipient species, and that host TH-positive fiber ingrowth to the TP is not a transitory phenomenon. Supported by USPHS Grant HD05958.

141.3 **EFFECTS OF A UNILATERAL ASPIRATIVE LESION OF THE FIMBRIA-FORNIX ON HIPPOCAMPAL ELECTROENCEPHALOGRAPHIC AND GLUCOSE METABOLIC ACTIVITY.** R.W.Jonnson*, R.D.Vingan*, D.L. Dow-Edwards, T.H. Milhorat, and J.L. Rubie. Laboratory of Cerebral Metabolism, Department of Neurosurgery and Department of Anatomy and Cell Biology, SUNY Health Science Center at Brooklyn, Brooklyn, N.Y. 11203

Adult female Long-Evans rats were implanted with unilateral hippocampal chronic recording electrodes. Baseline hippocampal theta activity generated within Ammon's horn and dentate gyrus was obtained for each rat. Animals were then divided into two groups: (1) unilateral fimbria-fornix lesion and, (2) sham operation. The lesion consisted of aspiration of the fimbria-fornix and overlying neocortical tissue ipsilateral to the recording electrode. Sham operated rats underwent identical operative exposure of neocortex without lesioning of the intracranial contents.

At 1 week intervals following surgical intervention, theta wave activity was recorded during treadmill walking and in the anesthetized state (using ethyl ether).

After 3 months, each rat was prepared for measurement of cerebral glucose metabolic activity according to the [^{14}C] 2-deoxyglucose protocol of Sokoloff. Under halothane anesthesia each rat (375-425g) received a femoral arterial and a venous catheter which were threaded subcutaneously and externalized at the dorsum of the neck. The rats were allowed to awaken for a minimum of 2 hours. [^{14}C] 2-deoxyglucose was administered as an intravenous pulse (125 uCi/kg). Each animal was freely moving on a treadmill apparatus and timed arterial samples were then taken for determination of the time course of the arterial plasma concentrations of [^{14}C] deoxyglucose and glucose. At 45 minutes the animals were sacrificed with sodium pentobarbital. The brains were removed, frozen and later sectioned for autoradiography. Sections were also taken for acetylcholinesterase staining and thionin staining. Autoradiographs were analyzed densitometrically to determine the local concentrations of ^{14}C in the tissues. From the local tissue ^{14}C concentrations and the time courses of the plasma [^{14}C] deoxyglucose and glucose concentrations, local rates of glucose incorporation were calculated by the operational equation of the method.

Results demonstrate that complete unilateral fimbria-fornix lesions lead to sustained loss of ipsilateral hippocampal theta activity as well as loss of acetylcholineserase staining. Glucose metabolic activity is also diminished in several regions of the ipsilateral hippocampus.

141.4 **RESTORATION OF HIPPOCAMPAL THETA RHYTHM AND GLUCOSE METABOLISM BY EMBRYONIC SEPTAL CELL SUSPENSION GRAFTS FOLLOWING UNILATERAL FIMBRIA-FORNIX LESION.** R.D. Vingan*, D.L. Dow-Edwards, T.H. Milhorat, L.A. Freed* and S.E. Fox. Laboratory of Cerebral Metabolism, Department of Neurosurgery and Department of Physiology, SUNY Health Science Center @ Brooklyn, Brooklyn, N.Y. 11203

Electroencephalographic patterns, glucose metabolic activity and cholinergic neurochemical anatomy were analyzed as indices of hippocampal activity in adult female Long-Evans rats following unilateral fimbria-fornix lesions and subsequent transplantation of embryonic septal cell suspensions.

Each rat received a unilateral hippocampal chronic recording electrode for determination of baseline theta wave activity in the walking and anesthetized states. Animals were divided into 2 groups: (1) unilateral fimbria-fornix lesion only (control), and (2) lesion with embryonic day 15-16 septal cell suspension transplants (experimental). The lesion consisted of aspiration of the fimbria-fornix and overlying neocortex ipsilateral to the recording electrode. Septal transplant tissue (5 ul) was injected over a 1 minute period into the lesion cavity of the experimental group immediately after the lesion was completed.

At 1 week intervals following surgical intervention, hippocampal theta activity was recorded during treadmill walking and in the anesthetized state (using ethyl ether).

After 3 months, each rat was prepared for measurement of cerebral glucose metabolic activity according to the quantitative [^{14}C] 2-deoxyglucose protocol of Sokoloff. Under halothane anesthesia each rat (375-425g) received a femoral arterial and a venous catheter which were threaded subcutaneously and externalized at the dorsum of the neck. The rats were allowed to awaken for a minimum of 2 hours. Each animal was freely moving on a treadmill apparatus and timed arterial samples were then taken. At 45 minutes the animals were sacrificed with sodium pentobarbital. The brains were removed, frozen and later sectioned for autoradiography. Sections were also taken for acetylcholinesterase staining and thionin staining.

Results indicate that embryonic day 15-16 septal cell suspension implants restore activity to the denervated hippocampus with normalization of EEG patterns, glucose metabolism and cholinergic neurochemistry. Work on the cholinergic relationship to glucose metabolism and EEG activity is currently being analyzed with the use of eserine (i.p. 0.1-0.15 mg/kg).

141.5 PROTECTION OF CHOLINE ACETYLTRANSFERASE- AND NERVE GROWTH FACTOR RECEPTOR- IMMUNOREACTIVE NEURONS IN NUCLEUS BASALIS MAGNOCELLULARIS BY EMBRYONIC CORTICAL TRANSPLANTS INTO DEVASCULARIZED RAT NEOCORTEX.
E.P. Pioro* and A.C. Cuello (SPON: B.E. Jones). Dept. of Pharmacology and Therapeutics, McGill University, Montreal, PQ, H3G 1Y6, Canada.

Choline acetyltransferase (ChAT) immunoreactive neurons in the rat nucleus basalis magnocellularis (NBM) project to the cortex (Rye, et al., Neuroscience, 13: 627, 1984) and also display nerve growth factor receptor (NGFr) immunoreactivity (Taniuchi, et al., PNAS, 83: 1950, 1986). We have previously shown that protection from retrograde degeneration of these neurons in response to a devascularizing neocortical lesion can be achieved with pharmacological means, such as gangliosides (Cuello, et al., Brain Res, 376: 373, 1986). A morphological study was undertaken to determine if embryonic cortical cells implanted into devascularized rat neocortex could similarly prevent retrograde neuronal degeneration in this nucleus as has been shown with kainic acid-induced cortical lesions (Sofroniew, et al., Brain Res, 378: 409, 1986).

Cell suspension preparations of cortex obtained from rat embryos were injected into previously devascularized neocortex of 3 month old rats. After a 6 month post-transplantation survival, rats were perfusion-fixed and brains were processed for peroxidase immunocytochemistry using monoclonal antibodies against ChAT (provided by F. Eckenstein and H. Thoenen) and rat NGFr (provided by E. Johnson). The lesioned cortical area which formed a cavity in untreated rats was replaced in some rats receiving cortical implants by proliferated neural tissue. Retrograde neuronal degeneration as revealed by ChAT and NGFr immunostaining was noted in the NBM ipsilateral to lesioned neocortex in untreated animals. However, in rats receiving implants, these neurons showed less degenerative changes which will be discussed. In addition, the NBM neurons ipsilateral to the transplant demonstrated an abundant plexus of NGFr immunopositive neurites.

The findings demonstrate survival of embryonic cortical cells implanted into previously devascularized rat neocortex and at least a partial protection from retrograde degeneration of ChAT and NGFr immunoreactive neurons in the NBM.

141.6 TRANSPLANTS OF CELL SUSPENSIONS FROM FETAL TECTUM INTO ADULT RAT.
M. C. Zrull* and J. R. Coleman (SPON: J. J. Freeman) Departments of Psychology and Physiology, University of South Carolina, Columbia, South Carolina 29208.

Embryonic tectal tissue was implanted into normal adult hosts as a step in establishing a model for neural transplantation. The study had two related objectives: to determine the viability of transplanted embryonic tectal cells, and to evaluate the efficacy of True Blue, a flourescent dye, in labeling transplanted cells.

Developing tecta were dissected from Sprague-Dawley (S-D) rat fetuses at 16 days of gestation (E16). The tissue was processed into a cell suspension with a modification of standard procedure (cf. Bjorklund et al., 1983, Acta Physiol. Scand. Supp., 522: 1-10). At the incubation phase E16 tecta were suspended in 2% (w/v) True Blue (Sigma) in a .1% trypsin in .6% D-glucose medium. After one hour exposure to True Blue the tissue was rinsed, resuspended in D-glucose solution, and injected into S-D adult male rats. Host animals received bilateral 10 µl injections of the tissue suspension. Implants to the cerebellum were placed stereotaxically just caudal to the inferior colliculi. Adult control rats received bilateral 10 µl injections of 2% True Blue in D-glucose solution at similar sites. After four weeks survival animals were sacrificed and perfused with saline and buffered formalin. Every fourth section was saved for Nissl processing and stained with thionin.

In Nissl material host animal transplant sites were highly vascularized, densely packed, heterogeneous cellular areas in the folia white matter. Small, darkly stained, disc shaped and slightly larger spherical cells predominated; the former possibly small collicular stellate cells and the latter cerebellar granule cells. Normal cerebellar medium size, violet, fusiform Golgi cells and large, opaque violet Purkinje cells were also seen. Atypical to cerebellum were green-blue stained, rectangulated, polygonal cells similar in size to the medium multipolar cells of dorsal cortex and central nucleus of inferior colliclus. Observations of Nissl sections in controls revealed less densely packed and vascularized injection regions predominated by green-blue stained cerebellar Golgi, Purkinje, and molecular layer spheroidal cells. In controls green-blue stained cells were found throughout a greater region of cerebellum than in hosts. Control granule cells were darkly stained but less opaque than putative small tectal stellate cells found in host cerebellum. In host animals trails of flourescent cells were observed along cannula tracts in the cerebellum with prominent clusters of cells seen at the top and bottom of injection sites. In contrast, flourescent cells in controls followed Purkinje cell layers through much of the cerebellum. While flourescence sections did show retrograde labeled brain stem cells in all animals, it was apparent that transplanted tectal cells were present in host brains.

141.7 CROSS-SPECIES TRANSPLANTS OF FLOW CYTOMETRY SORTED VENTRAL MESENCEPHALIC BOVINE CELLS. J.J. Lopez-Lozano. Dept. of Neurology and Dept. of Experimental Surgery. Clinica Puerta de Hierro. Universidad Autonoma. 28035-Madrid. Spain.

Our research group is interested in analyzing and isolating specific populations of CNS cells to be used for in vitro (i.e: cell culture) or in vivo (i.e: cell transplant) studies. Laser flow cytometry has been found to be an appropriate tool for the analysis and isolation of large numbers of cells and specifically for discrimination and separation among heterogeneous cell populations. Since we reported that relatively pure Tyrosine hydroxylase (TH)-containing neurons from neonatal ventral mesencephalon could be obtained by flow cytometry and cell sorting techniques (FCACS) (Lopez-Lozano et al., Soc. for Neuroscience, 1985) and that FCACS-cells from the anterior hypothalamus survive, migrate and express vasopressin after being implanted into neurohypophysectomyzed adult rats (Lopez-Lozano et al., Anat. Rec. 214:75,1986), we continue studying the short-term effects that the laser and hydrodynamic sheer forces used in cell sorting procedures may have on a population of fetal ventral mesencephalic bovine cells. The purpose of the present communication is to examine the morphological and immunocytochemical behavior of TH-containing ventral mesencephalic FCACS neurons from bovine embryos after being implanted into unilaterally denervated striatum of adult Sprague-Dawley rats (200 gr.). Ventral mesencephalon (containing substantia nigra) from 3-4 month-pc old bovine animals were quickly dissected and cells were dispersed by an enzymatic-mechanical procedure (0.1% trypsin) (Notter et al., Brain Res. Bull, 12: 307, 1984). Viability was better than 92%. The suspension of ventral mesencephalic cells was then analyzed separately in an EPICS C (Coulter Electronics, Madrid, España) multiparameter flow cytometer system and relatively enriched by flow cytometry and cell sorting techniques. Later, the recovered suspension of sorted ventral mesencephalic cells was implanted into the dorsal striatum of 6-OHDA lesioned rats. In order to describe the migration and differentiation of the transplanted cells, the recovered suspension was previously labelled with 0.03% fast blue. At time periods of 4 days to 4 weeks, animals were intracardially perfused with appropriate fixative. Implanted cells were studied by Fluorescence and phase contrast microscopy, catecholamine-containing histofluorescence and TH-immunocytochemistry. The data demonstrate that FC-sorted fetal ventral mesencephalic cells can survive and develop after being cross-species implanted into adult host striatum and are similar to the results obtained with unsorted dissociated cells. Also, the results of this study indicate that neurons maintain their phenotype and express TH. This study provides further evidence that flow cytometry and cell sorting techniques can be used to provide a source of donor tissue for transplantation. 141.8 THALAMIC STIMULATION EVOKES SINGLE-UNIT ACTIVITY IN FETAL NEOCORTICAL TISSUE GRAFTED INTO THE CEREBRAL HEMISPHERE OF NEWBORN RATS. E.J. Neafsey, J.C. Sørensen*, N. Tønder* and A.J. Castro. Dept. of Anatomy, Loyola Univ. Stritch Sch. of Med., Maywood, IL 60153 and Instit. of Anat. B., Univ. of Aarhus, Denmark.

Several studies involving fetal neocortical transplants placed within the newborn cerebral hemisphere have demonstrated extensive host-transplant interconnections. In light of data demonstrating host thalamic inputs to these grafts, the present study was initiated to examine thalamo-transplant connections electrophysiologically. Accordingly, unilateral neocortical lesions were made by aspiration just rostral to the coronal suture in 0-1 day old, hypothermic-anesthetized black-hooded rats. Immediately after lesion placement, blocks of fetal (E15-16) neocortex were placed into the lesion cavity. The grafts were held in place by a bone flap. At 4-5 months of age, host animals were re-anesthetized with ketamine (100 mg/kg) and secured in a stereotaxic instrument. A large craniotomy was made and a stimulating electrode was inserted into the ventral thalamus ipsilateral to the transplant. A glass-insulated tungsten recording microelectrode was used to sample single unit activity within the graft while electrically stimulating the thalamus with 0.1-0.2 msec negative single pulses of 300-500 uamps. In several animals, the stimulation evoked single or multiple orthrodromic spikes at a latency of 5-6 msec; this activity was usually followed by a long lasting (200 msec) cessation in the cell's activity. In one instance the single unit appeared to be driven antidromically by the stimulation since the cell responded at a constant 2 msec latency. At selected points along each electrode tract, small electrolytic (10 uamps DC for 10 sec) marking lesions were made and their locations within the transplant and ventral thalamus were subsequently verified histologically. The patterns of the observed responses resembled electrophysiological findings in normal animals. These results provide electrophysiological confirmation of transplant afferents arising from the host thalamus. (Supported by NIH Grant NS 13230 and funds from the Danish MRC.)

141.9 CONNECTIONS OF NEOCORTEX XENOGRAFTS IN THE RAT BRAINSTEM. D. W. Marion,* and R. D. Lund° (SPON: R. G. Selker), Dept. of Neurological Surgery and °Dept. of Neurobiology, Anatomy and Cell Science, Univ. of Pittsburgh, Sch. of Med., Pittsburgh, PA 15261

Previous studies have shown that retinal ganglion cell grafts placed in the rat midbrain send projections only to appropriate subcortical visual centers. To determine if this specificity is unique to retinal transplants or if it occurs with other types of CNS grafts, we studied the projections of mouse sensorimotor (SM) and occipital (Occ) cortex, transplanted into neonatal rat brainstem. Neocortex was dissected from E13 CD-1 mice and placed into various brainstem regions of one-day-old Sprague-Dawley rats. At 3-5 weeks of age horseradish peroxidase (HRP) was injected into the cervical spinal cord. Thirty-six hours later the animals were perfused with 4% paraformaldehyde. Serial coronal brainstem sections 30μm thick were stained for cell morphology, fibers, or HRP reaction product. Graft projections were also demonstrated with a monoclonal antibody to a mouse neuronal cell-surface antigen.

Transplants within the aqueduct or substance of the dorsal midbrain sent projections to the superior colliculus with specific fields of termination: Occ cortex to the superficial layers, and SM cortex to the intermediate gray. Grafts in the ventral midbrain projected to the substantia nigra, grafts in the dorsal pons projected to the periaqueductal gray and the region of the dorsal raphe nucleus, and surface grafts along the ventral lateral pons projected into the spinal cord. Projections to the substantia nigra, periaqueductal gray, region of the dorsal raphe nucleus and spinal cord were found from SM and Occ cortex grafts. HRP reaction product was found only in cells of ventral lateral pontine grafts. Thus, while SM and Occ cortex grafts placed near the superior colliculus projected to specific and appropriate targets, grafts placed in the ventral midbrain and pons projected to nuclei not considered normal targets for neocortical projections.

We conclude that specificity of projections of neocortex xenografts is influenced by the region of rat brainstem into which the graft is placed. Cortical grafts respond to both specific and non-specific cues which may be target derived, and regional location is an important factor in determining graft innervation patterns. Supported by NIH grant EY05283.

141.10 DEVELOPMENT OF GABA NEURONS IN CULTURES AND GRAFTS IN THE ADULT RAT HIPPOCAMPUS.

G. Barbin, O. Robain*, F. Rozenberg*, A. Prochiantz° and Y. Ben-Ari.
INSERM U.029. Hôpital de Port-Royal. 123 Bd de Port-Royal. 75014 Paris. France.
°INSERM U.114, Collège de France. 11 place Marcelin Berthelot. 75231 Paris Cédex 05. France.

The intrahippocampal GABAergic system mediates a particularly powerful inhibition which plays a central role in preventing paroxysmal discharges. Using antibodies directed as GABA, we have examined the development of GABA labeled neurons in cultures and in intrahippocampal grafts.

The hippocampus taken form E19 rat embryos was dissociated into a cell suspension and grafted into the hippocampus of adult rats. Animals were examined at various time intervals (up to 3 months) following transplantation. The grafts were localized either in the stratum radiatum of CA1 or the molecular layer of the fascia dentata. The implanted tissue was capable of survival and growth without exhibiting a laminar organization. Golgi silver staining allowed the visualization of various morphological neuronal types : large spiny, small aspiny pyramidal neurons and bipolar cells. Granule neurons were rarely encountered. Conventionnals electron-microscopy revealed various types of symmetric and asymmetric synapse in the grafts. With an antibody directed againts GABA, there was a substantial proportion (around 20 %) of GABA immunoreactive neurons within the graft, this proportion is higher than that found in the host. Moreover a dense labelling of the neuropil was observed, this allowed a clear distinction between the grafted area and the host.

A substantial proportion of labeled neurons (both with the GABA antibodies and with 3H GABA uptake) was also found in cultures of the cell suspensions. The morphological patterns were similar to those seen in the grafts with a majority of pyramidal shaped GABA neurons.

In conclusion dissociated hippocampal neurons taken from embryos survive in the adult rat hippocampus and express a high potential for growth and sprouting in vitro and in vivo. This is particularly conspicuous for GABA immunoreactive neurons.

141.11 FETAL HIPPOCAMPAL CELLS TRANSPLANTED INTO THE ISCHEMICALLY DAMAGED CA1 REGION DEMONSTRATE NORMAL CHARACTERISTICS OF ADULT CA1 CELLS. L.A. Mudrick, K.G. Baimbridge and J.J. Miller. Dept. of Physiology, U. of British Columbia, Vancouver, B.C., V6T 1W5

Previously we have demonstrated that transplanted fetal hippocampal cells can survive and mature in brain regions irreversibly damaged by cerebral ischemia. We have now examined the properties of these transplanted cells and observe that there is some degree of selectivity for the survival of CA1-like neurons. This may have resulted from the judicious selection of fetal hippocampi at an appropriate developmental stage.

Consistent, highly selective damage was produced in the dorsal CA1 region of the hippocampus by combining haemorrhagic hypotension to a MAP of 30mmHg with bilateral carotid occlusion for 20 minutes. In an attempt to reconstruct the necrotic area, one week following ischemia, the region was repopulated with five rostro-caudal injections of dispersed E18 hippocampal neurons. In one series of experiments the cells were labelled with ^{3}H-Thymidine to confirm the presence of transplanted cells. After one to eight months the brain tissue was fixed, 20µm serial sections were made and the following anatomical techniques were undertaken on groups of adjacent sections. One set of sections was stained with thionin for quantification and morphological analysis. A second set of sections was histochemically processed to visualize AChE-containing axons in order to assess the integration of the transplanted cells into the host tissue. Lastly, immunohistochemical techniques were used to localize calbindin D_{28K} (a protein specific for CA1 hippocampal pyramidal cells, parvalbumin (a protein localized in GABA containing neurons, and ChAT to characterize the intrinsic properties of the transplanted cells.

Histological examination revealed that the grafted cells were morphologically similar in size and appearance to adult CA1 hippocampal pyramidal cells. A network of AChE-containing fibres were seen throughout the grafts possibly representing neurite extensions of the original medial septal-diagonal band afferents and formation of new synaptic contacts. Calbindin and parvalbumin were detected within subpopulations of the grafted neurons. No ChAT positive cells were observed. The immunoreactivity also revealed that the transplanted cells had formed extensive neurite networks.

The results indicate that CA1 hippocampal cells, taken from 18-day old fetuses, may be at a developmental stage which permits their selective survival after dissociation and transplantation. When placed in a suitable environment, they integrate into the host tissue, appear morphologically similar and express the same neuron specific markers as the adult cells they have replaced.
(Supported by a Canadian MRC Program Grant to J.J.M. and K.G.B.)

141.12 EFFECTS OF TOLUENE EXPOSURE ON DEVELOPING PURKINJE NEURONS: EVIDENCE FROM INTRAOCULAR CEREBELLAR TRANSPLANTS USING BIOCHEMICAL AND ELECTROPHYSIOLOGICAL TECHNIQUES. A-Ch. Granholm, G. A. Gerhardt, M. Eriksdotter-Nilsson*, A-C. Hansson*, A. Henschen*, G. Hoglund*, P. Nylen*, M. Palmer, L. Olson* and B. Hoffer, Depts. Pharmacol. and Psychiat., U. of Colo. Hlth. Sci. Ctr., Denver, CO 80262, Depts. Histol. and Physiol., Karolinska Institute, Box 60400, 10401 Stockholm, Sweden and Dept. Occupat. Neuromedicine, Natl. Board Occupat. Safety Hlth, Res. Dept., 17184 Solna, Sweden.

The purpose of this study was to investigate the temporal and regional effects of the solvent toluene in the CNS. Isolated cerebellar transplants in oculo were studied using electrophysiological and biochemical techniques. Fetal rat cerebellar anlage (E 13-14) were grafted to adult hosts which were then exposed to a dose of 1000 ppm gaseous toluene 21 hrs per day for 9 weeks. Controls were cerebellar anlage from the same litter transplanted to recipients which were exposed to room air during the same interval. Growth of cerebellar grafts, monitored by repeated stereomicroscopic observations through the cornea, was moderately reduced in the toluene-treated animals. Extracellular recordings of the spontaneous activity of Purkinje neurons in the cerebellar grafts were performed within 10 days after the last exposure in both groups. Purkinje neurons in the toluene-treated recipients showed a slightly decreased spontaneous discharge rate as compared to the controls (mean discharge rates were 22 $\pm$ 1.5 Hz (n=27) vs. 29 $\pm$ 1.2 Hz (n=6), $p<0.05$). Postsynaptic sensitivity of the intraocular Purkinje neurons to norepinephrine (NE) was evaluated by superfusions with known concentrations. NE elicited a dose-dependent slowing of the discharge rate in both groups, however, the toluene-exposed Purkinje neurons were significantly supersensitive to NE as compared to the control group (EC50 0.35 uM, 95 % confidence limit 0.31-0.39 uM (n=19) vs. EC50 15.9 uM, 95 % confidence limit 2.4-100 uM (n=27)). Hill plots demonstrated that the dose-response relationships in both groups were linear and parallel to one another. The tissue levels of NE in the toluene-treated grafts were approximately 2-fold greater than in the control transplants. Moreover, the ratios of NE to free (3-methoxy-4-hydroxyphenyl)ethylene glycol (MHPG) were significantly reduced in both transplant and host cerebellum after toluene exposure. These data indicate that toluene treatment during development causes decreased spontaneous activity of isolated Purkinje neurons as well as a marked alteration in pre- and postsynaptic NE mechanisms. (Supported by USPHS grants ES02011 and AA05915).

141.13 EFFECTS OF FETAL SUBSTANTIA NIGRA TRANSPLANTS ON LESION-INDUCED DEFICITS IN TRAINED CIRCLING BEHAVIOR. J.B. Richards and C.R. Freed., Depts. of Med. and Pharm., Univ. of Colo. Health Sci. Ctr., Denver, CO 80262.

Rats with unilateral lesions of the nigrostriatal dopamine (DA) system will circle in a direction ipsilateral (ipsi) to the lesioned side when injected with amphetamine (AMPH). Unilateral transplantation of fetal substantia nigra DA neurons into the DA deficient striatum reduces or even reverses the direction of AMPH circling because of release of DA from the transplant and receptor supersensitivity on the same side. Unilateral DA lesions also cause performance deficits in rats trained to circle for reward (Dunnett and Bjorklund, Neurosci. Letters 41: 173, 1983). We have found these rats have great difficulty in turning contralateral (contra) to the lesioned side and show moderate deficits in turning ipsi to the lesioned side. We have studied whether unilateral transplantation of fetal substantia nigra neurons can restore trained circling behavior in rats with unilateral nigrostriatal lesions. Male Sprague-Dawley rats 300-400 gm were trained to circle both to the left and to the right for a water reward. After performance stabilized, rats were lesioned with unilateral injections of 6-hydroxydopamine (8 µg in 4 ul of 0.2 mg/ml ascorbate-saline) in the medial forebrain bundle (AP. 4.4 caudal to bregma; L. 0.9 from midline; V. 7.5 below dura; nose bar 2.3 below interaural line). Three to four weeks after lesioning, animals were tested for AMPH-induced circling with a dose of 1.5 mg/kg i.p. Rats which failed to reach a criterion of 150 net turns ipsi to the lesion during a 2 hr period were eliminated from the study. Their ability to circle for a water reward contra and ipsi to the side of the lesion was also measured. Rats were divided into a tranplant group and a control group. The transplant group was injected with a minced suspension containing DA cells from the ventral mesencephalon of 14-16 day old rat embryos. Injections of 3 µl were made along 5 tracks in the nucleus accumbens and striatum (Site 1: AP +3.4, L 2.0; Site 2: AP +2.4, L 2.0; Site 3: AP +2.4, L 3.5; Site 4: AP +1.4, L 3.5; Site 5: AP +0.2, L 4.0; nose bar set at 5.0 above the interaural line). Control rats received saline. After transplantation the rats were assessed for AMPH-induced circling and trained circling at 4 week intervals. Following behavioral experiments, animals were sacrificed and transplant survival verified by immunohistochemical staining for tyrosine hydroxylase. Preliminary results have shown that rats transplanted with fetal cells (n=6) reversed their circling direction after AMPH (439 net ipsi turns/2 hr to 220 net contra turns/2 hr) but showed only slight and not significant improvement in the trained circling task.

141.14 TRANSPLANTATION OF FETAL CORTEX INTO ADULT RAT BRAINS WITH MIDDLE CEREBRAL ARTERY INFARCTIONS. M. F. Gonzalez, T. J. Mampalam*, J. E. Loken*, A. Poncelet* and F. R. Sharp. Departments of Neurology and Neurological Surgery, V.A. Medical Center and University of California, San Francisco, CA 94121.

Recently it has been demonstrated that transplantation of fetal neural tissue can be used to treat the symptoms and signs of degenerative or inherited brain disorders. The present study extends the uses of transplantation by showing that parietal fetal cortex transplants survive in infarcted regions of adult rat brains produced by middle cerebral artery (MCA) occlusions.

Adult (250-300 g) Sprague-Dawley rats were anesthetized and their MCA occluded using the technique of Zea Longa et al. (Stroke, in press). Briefly, a 4-0 monofilament nylon suture was threaded up the common carotid and internal carotid arteries into the MCA until resistance was felt. Following occlusion of the MCA for 3 hours the suture was withdrawn. One to two weeks later 12 surviving subjects were reanesthetized and received transplants of neocortex from 16-17 days old embryos. A month later these subjects were perfused. Coronal sections throughout the infarcted area and surviving transplants were Nissl stained and reacted for NADPH-d and acetylcholinesterase (AChE) histochemistry.

Fetal cortex transplants survived in infarcted or ischemic areas of the brains of 9 of 12 subjects. The size of the surviving transplants varied considerably, and they filled infarcted cavities, formed bridges between surviving host cortex, or displaced non-infarcted but ischemic host cortex. Nissl stain confirmed the presence of transplants and the demarcation of the transplant/host border. The number of neurons in transplants was similar to or greater than in surrounding host cortex, but cells were not arranged in laminae. Normal NADPH-d stained neurons were found in transplants as previously reported in frontal cortex transplants (Gonzalez and Sharp, J. Neurosci., in press). All surviving transplants also contained normal appearing AChE positive neurons which were either similar to or greater in number than in surrounding host cortex. AChE positive fibers were also found in all transplants but their density was usually less than that of normal host cortex. Both, NADPH-d and AChE positive fibers crossed host/transplant interfaces. These results demonstrate that it is possible to successfully transplant fetal tissue into ischemic and infarcted areas of adult mammalian brain.

141.15 INTRODUCTION OF NEW GENES INTO ADULT RAT BRAIN VIA GRAFTED CELLS. M.B. Rosenberg[1*], J.A. Wolff[1*], J.-K. Yee[1*], Li Xu[1*], C. Shultz[2], T. Friedmann[1*] and F.H. Gage[2]. Departments of [1]Pediatrics and [2]Neurosciences, School of Medicine, Univ. Calif. San Diego, La Jolla, CA 92093.

We are developing methods for introducing new functions into the mammalian CNS by implantation into the brain of cells that have been genetically modified in vitro to express foreign genes (transgenes). Continuous rat fibroblast lines, primary cultures of rat skin fibroblasts and glia from neonatal rat neocortex were infected with replication-incompetent, helper-free retrovirus vectors expressing either the human hypoxanthine phosphoribosyltransferase (HPRT) gene alone or the bacterial neomycin resistance gene together with either the firefly luciferase gene or the E. coli beta-galactosidase gene. The cultures were grown in media containing hypoxanthine/aminopterin/thymidine (HAT) or the neomycin analog G418 to select for $HPRT^+$ or neomycin-resistant infected cells, respectively, and the resulting selected cells were then injected intracerebrally into rats. The grafted cells survived for at least three months, as indicated by immunohistochemical detection of the fibroblast and astrocyte marker proteins fibronectin and glial fibrillary acidic protein. Furthermore, the transgenes continued to be expressed, as determined by measurement of HPRT and luciferase enzyme activities in extracts prepared from dissected tissue or by histochemical detection of beta-galactosidase activity in situ. These experiments indicate that genetically modified cells survive and express new functions after implantation into rat brain and suggest a new approach to the therapy of some CNS disorders.

141.16 NORADRENERGIC NEURON TRANSPLANTS: ELECTROPHYSIOLOGICAL UNIT ACTIVITY OF INTRASTRIATAL LOCUS COERULEUS GRAFTS IN FREELY MOVING CATS. M.E. Trulson. Dept. Anat., Coll. Med., Texas A&M University, College Station, TX 77843.

A great deal of attention has been devoted recently to transplanting fetal brain donor tissue into adult host brain. Much of this work has been done with monoamine-containing neurons. We have previously studied transplanted serotonergic (Brain Res. Bull. 17, 1986, 461) and dopaminergic (Life Sci., in press) neurons. In the present study we examined the electrophysiological activity of individual noradrenergic (NE) neurons transplanted from cat fetal brain tissue to adult host cat brain. Forty-day old cat fetus served as the source of immature NE-neurons. Pregnant females were anesthetized by intravenous sodium pentobarbital (dose as needed to maintain surgical anesthesia) and prepared for caesarian section. The embryos were surgically removed from the uterus under sterile conditions and their brains removed and the dorsal medulla containing the LC was dissected free. The grafting procedures were essentially those described by Bjorklund and his colleagues (Acta Physiol. Scand. Suppl. 522, 1983, 1). The female host cats were anesthetized with ketamine (10 mg/kg) and xylocine (0.4 mg/kg) and placed in a stereotaxic instrument. Injections were made through a small burr hole with a sterile 100 µl Hamilton syringe with a 23 gauge needle. The 5 µl suspensions were deposited at the rate of 1 µl/min and 5 min were allowed for diffusion prior to removing the needle. Macroelectrodes for recording the electroencephalogram (EEG) electromyogram (EMG) and eye movement potentials (EOG) were implanted according to standard procedures. Following recovery from surgery electrophysiological recordings were made using procedures previously described (Brain Res. Bull. 17, 1986, 461). Transplanted LC neurons displayed the slow (2-3 spikes/sec) and regular spontaneous activity during periods of quiet waking, as previously described by Rasmussen et al. (Brain Res. 371, 1986, 324). However, in contrast to the profound decrease in LC unit activity that occurs in intact cats during sleep, transplanted neurons maintained the same discharge pattern and rate across sleep stages. Furthermore, transplanted LC neurons were unresponsive to simple auditory and visual stimuli in contrast to their sensitivity to such stimuli in intact, freely moving cats (Rasmussen, et al., Brain Res. 371, 1986, 324). Transplanted LC neurons were inhibited by clonidine; however, the dose required to inhibit the neurons was significantly higher than that in intact animals. These data suggest that NE neurons can be transplanted into a host brain and display spontaneous electrophysiological activity. However, the electrophysiological and pharmacological properties are very different from those in intact animals.

141.17 FETAL HIPPOCAMPAL GRAFTS REDUCE INCREASED OPEN FIELD ACTIVITY PRODUCED BY ADMINISTRATION OF TRIMETHYLTIN TO ADULT RATS. M. L. Woodruff, R. H. Baisden, D. L. Whittington,* and S. Wray# Department of Anatomy, East Tennessee State University, Quillen-Dishner College of Medicine, Johnson City, TN 37614, and #NIH, NINCDS, Bethesda, MD 20892.

Exposure to trimethyltin (TMT) is known to produce behavioral changes related to TMT's effect on the hippocampus (e.g. Dyer et al., Neurobehav. Tox. Teratol., 4, 1982). The purpose of the present experiment was to determine whether grafts of normal fetal hippocampal tissue could ameliorate one of the behavioral changes associated with exposure to TMT. Thirty nine adult male Long-Evans rats were included in the experiment. Twenty three rats were gavaged with an aqueous solution containing 7 mg/kg (expressed as the free base) of TMT. Seven rats (Group TMT) received no further treatment. Forty five days after gavage eight rats were given bilateral lesions of the hippocampus (Group THL) and eight received bilateral lesions of the hippocampus followed immediately by implantation of fetal brain tissue (Group TTR) into the lesion cavity. Of the remaining rats eight served as normal control subjects (Group N), and eight were given bilateral lesions of the hippocampus (Group HL). All surgery was performed while the rats were anesthetized with sodium pentobarbital. Counts of line crossings in an open field during three consecutive daily 10 min sessions was used to assess activity begining eighty days after surgery. A two-factor ANOVA with a repeated measure on the within (days) factor was used to evaluate the data. Significant groups ($F(4,34) = 10.16$, $p < .01$) and days effects ($F(2,68) = 4.10$, $p < .05$) were found. The interaction was not significant. Post hoc Newman-Keuls tests indicated that Group TTR did not differ from Group N on any of the days, but did cross significantly fewer lines than Groups TMT, THL, and HL. Histological evaluation using Nissl, Bodian, or immunocytochemical procedures was conducted following behavioral testing. The transplants were found to occupy fifty percent or more of the lesion cavity. Nerve fibers were seen to cross between the host and the transplant. Choline acetyltransferase- and vasoactive intestinal polypeptide-positive cells and fibers and substance P- and tyrosine hydroxylase (TH)-positive fibers were seen within all transplants. Some of the transplants also contained a few TH positive cells. These data indicate that fetal brain grafts can develop in TMT-damaged host brains, obtain innervation from the host and reduce at least one toxicant-induced behavioral deficit. (Supported by USPHS Grant # ES04070 to MLW.)

142.1 THE EFFECT OF DEXAMETHASONE ON THE BINDING OF ^{125}I-NERVE GROWTH FACTOR TO PC12 CELLS. M. D. Tocco,* M. L. Contreras, and G. Guroff. Section on Growth Factors, National Institute of Child Health and Human Development, Bethesda, MD 20892

PC12 is a cell line developed from a rat pheochromocytoma that exhibits sympathetic neuron-like properties in response to nerve growth factor (NGF) and some chromaffin cell-like properties when treated with corticosteroids. The responses of the cells to nerve growth factor have been explored in some detail; the responses to corticosteroids not so thoroughly. Corticosteroids prevent the neurite outgrowth produced by nerve growth factor in normal chromaffin cells from neonatal animals. Although no such inhibition of neurite outgrowth has been seen in PC12 cells, it seemed reasonable to explore the possibility that NGF and corticosteroids display some type of competitive interaction in this model. Accordingly, we have studied the effects of dexamethasone on the binding of ^{125}I-NGF to PC12 cells.

PC12 cells were grown as monolayers in Dulbecco's modified Eagle's medium with 6% CO_2 and 15% serum. The cells were treated for various times with 10^{-6} to 10^{-11} M dexamethasone. After the treatment the cells were washed and exposed to ^{125}I-NGF. After 60 minutes the cells were washed thoroughly and dissolved in 0.5 M NaOH. Binding was evaluated by counting a portion of the NaOH and assaying another portion for protein. Specific binding was calculated by comparing the binding with tracer alone with that in the presence of 2.5 µg/ml of unlabeled NGF.

Our results indicate that dexamethasone causes a time- and concentration-dependent decrease in the binding of ^{125}I-NGF to the cells. This decrease begins after 1 day of treatment and is maximal after 5 days. The maximal decrease is frequently as much as 70%. A maximal decrease can be seen at concentrations of dexamethasone as low as 10^{-8} M. The decrease appears to involve primarily the low affinity sites. Since chronic treatment of PC12 cells with NGF has been shown to induce a long-term, several-fold increase in the binding of ^{125}I-NGF, we examined the effect of dexamethasone treatment on this apparent up-regulation of the NGF receptor. Our data indicate that simultaneous treatment of PC12 cells with NGF and dexamethasone completely prevents this up-regulation.

The mechanisms by which dexamethasone decreases the binding of ^{125}I-NGF are unknown. We are inspecting the suggestion that dexamethasone selects for a receptor-low population of PC12 cells. Alternatively, we are pursuing the possibility that dexamethasone alters the rate of biosynthesis of the NGF receptor. These studies may shed light on the interactions of nerve growth factor and corticosteroids in the phenotypic determination of normal chromaffin cells and sympathetic neurons.

142.2 **VARIANT PC12 CELLS WHICH FAIL TO RESPOND TO NERVE GROWTH FACTOR POSSESS HIGH AFFINITY NGF RECEPTORS** D.D. Eveleth* and R.A. Bradshaw. Dept. of Biol. Chem., College of Medicine, Univ. of California, Irvine, CA 92717.

The rat pheochromocytoma cell line PC12 is a widely used in vitro model for the nerve growth factor (NGF) induced differentiation of neural crest derivatives into mature sympathetic neurons. PC12 cells as well as other NGF responsive cells express two classes of NGF receptors that are distinguished primarily by their affinity for NGF. More recently, Green et al. (Green, S.H., Rydel, R.E., Connolly, J.L. and Greene, L.A., J. Cell Biol., 102:830,1987) isolated variant lines of PC12, designated nnr, which fail to respond to NGF, apparently lack the high affinity receptors for NGF and do not internalize NGF in the usual fashion. To determine whether the two classes of receptors are encoded by different genes and to clarify their roles in the NGF induced response, we have reexamined the variant, PC12nnr5, (kindly provided by L. Greene) and found that it expresses high affinity NGF receptors. These receptors sequester NGF bound to the cell surface and are depleted as a result. In PC12 cells, internalized NGF is degraded into amino acids; the PC12nnr5 cells do not degrade the sequestered NGF, indicating that the defect preventing the PC12nnr5 cells from responding to NGF is not a lack of appropriate receptors but an inability to properly process the bound NGF (and their receptors) once sequestered. These results suggest internalization is a required part of the signalling mechanism that leads to the differentiated state. The PC12nnr5 cell line also fails to respond to basic fibroblast growth factor (bFGF), which elicits a response very similar to NGF in PC12 cells. Since the PC12nnr5 cell line is competent to extend neurites in response to other stimuli, the defect in PC12nnr5 cells lies in a pathway common to the NGF and bFGF signaling systems. Supported by the American Cancer Society (BC273) and the USPHS (NS19964).

142.3 DETECTION OF A NERVE GROWTH FACTOR RECEPTOR ON FETAL HUMAN SCHWANN CELLS. J.G. Assouline and N.J. Pantazis. Dept. of Anatomy, Univ. of Iowa Medical College, Iowa City, IA 52242.

Several types of neural crest-derived cells, including Schwann cells, possess nerve growth factor (NGF) receptors. The possibility that fetal human Schwann cells in culture have an NGF receptor was examined in this study. Primary Schwann cell cultures were established from peripheral nerves (both thoracic and sciatic) obtained from 16-21 week human fetuses. After dissociation of nerve tissue in a trypsin-collagenase mixture, Schwann cell cultures were established by two different procedures. In one procedure, cells were seeded in a feeding medium (FM) consisting of Ham's F12/Dulbecco's modified minimal essential medium (DMEM), with 10% fetal calf serum and ascorbic acid for 48 hrs. The cells were then treated (24 hrs) with FM supplemented with cytosine arabinoside, followed by incubation in FM containing cholera toxin and pituitary extract. In an alternative procedure, the dissociated cells were seeded in a medium containing DMEM with insulin, transferrin, hydrocortisone, biotin, sodium selenite, ascorbic acid as well as cholera toxin and pituitary extract (48 hrs). Cells were then switched to a similar medium which lacked the cholera toxin and pituitary extract.

Cell identity was established by morphological and immunological criteria. Schwann cells were spindle shaped and contained laminin as indicated by immunofluorescence studies; whereas fibroblasts were flat, polygonal and contained fibronectin. Furthermore, monoclonal anti-leu 7 (HNK-1) antibody which binds to myelin associated glycoprotein in neuroectodermal tissues also labelled the Schwann cells.

The NGF receptor was detected by several techniques including light microscopic autoradiography (ARG), immunofluorescence, and transmission electron microscopy (TEM). For ARG, cells were incubated with ^{125}I-NGF and covered with photographic emulsion. The silver grains were localized predominantly to the Schwann cells. Immunofluorescence (IF) was performed in two ways. In one method the cells were incubated with unlabeled NGF followed by anti-NGF primary antibody and visualized with a fluorescent second antibody. In another method a monoclonal antibody to the human NGF receptor (gift of M. Bothwell) was used. With both IF methods, an NGF receptor was seen on the Schwann cells. The anti-NGF receptor antibody was also used in TEM and in these studies, the NGF receptor was localized to the plasma membrane of the Schwann cells.

In conclusion, various techniques have established that Schwann cells from human fetuses ranging from 16 to 21 weeks expressed an NGF receptor in culture. The NGF receptor is a useful marker for Schwann cells. Future study will examine whether human Schwann cells in vivo have an NGF receptor. (Supported by an NIH grant, GM28644, to NJP).

142.4 BIOCHEMICAL CHARACTERIZATION OF THE NERVE GROWTH FACTOR RECEPTOR ON FETAL HUMAN SCHWANN CELLS. N.J. Pantazis and J.G. Assouline. Dept. of Anatomy, Univ. of Iowa Medical College, Iowa City, IA 52242.

Fetal human Schwann cells in culture have a nerve growth factor (NGF) receptor (Assouline and Pantazis, abstract this meeting). In this study the molecular weights (M_r) of the NGF receptor proteins were determined by immunoprecipitation of the receptor and examination of the receptor proteins on sodium dodecyl sulfate (SDS) polyacrylamide gels.

Experimentally, primary cultures of fetal human Schwann cells were established from peripheral nerves from 16-21 week fetuses (Assouline and Pantazis, abstract this meeting). The Schwann cells were incubated with ^{125}I-NGF (2 nM) which was crosslinked to the NGF receptor with 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDAC). The crosslinked ^{125}I-NGF-receptor complex was solubilized with η-octyl glucoside and was immunoprecipitated using a primary monoclonal anti-human NGF receptor antibody (gift of M. Bothwell) followed by a second antibody which is directed against the primary antibody. The precipitated receptor was solubilized in SDS sample buffer, run on an SDS gel and the positions of the NGF receptor proteins were determined with X-ray film.

Two protein bands with M_r of 190 and 90 kDa were seen on the gel. Possibly the 90 kDa protein is a fragment of the 190 kDa protein or alternatively the 190 kDa protein may be an aggregate of the 90 kDa protein. Both possibilities are under investigation.

Several observations suggest that these proteins are the NGF receptor proteins. First, monoclonal antibody was used for immunoprecipitation. Second several control experiments indicate that these are the NGF receptor proteins. For example, neither protein was seen on the gel when the antibody was omitted from the procedure. In another control experiment, a monoclonal antibody to rat NGF receptor which does not crossreact with human NGF receptor was used, and again neither protein was evident. When the immunoprecipitation procedure was performed on human melanoma cells which possess an NGF receptor, the 190 and 90 kDa proteins were observed. Third, proteins of similar M_r were observed by other investigators who have examined the NGF receptor on SDS gels.

In conclusion, an NGF receptor was detected on fetal human Schwann cells in culture and the M_r of the receptor proteins were 190 and 90 kDa. This immunoprecipitation procedure is being used to determine whether freshly dissected nerve which has not been placed in culture contains an NGF receptor. Both low and high affinity NGF receptors have been described and whether human Schwann cells have one or both receptor types is being investigated. Although the significance of an NGF receptor on Schwann cells is unexplained, it may play an important role in neuronal development. (Supported by an NIH grant, GM28644, to NJP).

142.5 CULTURED NEURAL CREST CELLS EXPRESSING A NON-NEURONAL ANTIGENIC DETERMINANT RECOGNIZED BY A MONOCLONAL ANTIBODY, G1N1, POSSESS RECEPTORS FOR NERVE GROWTH FACTOR (NGF). P. Bernd. Department of Anatomy, Mount Sinai School of Medicine of the City University of New York, New York, NY 10029.

This laboratory has previously demonstrated that a subpopulation of long-term cultured neural crest cells (1 to 2 weeks past explantation) have receptors for Nerve Growth Factor (NGF) and exhibit specific binding of iodinated NGF (^{125}I-NGF). These cells are likely to be targets of NGF during the early stages of embryonic development. Further co-localization studies revealed that neuron-like cells possessing tyrosine hydroxylase-like, serotonin-like, or vasoactive intestinal polypeptide-like immunoreactivity did not have receptors for NGF. Cultures were prepared from the trunk region of 48 hr quail embryos, and maintained in complete medium containing 5% chick embryo extract (CEE) and 15% fetal bovine serum.

It has been previously shown (Barbu et al., J. Neurosci., 6:2215, 1986) that 25% of migrating neural crest cells carry an antigenic determinant recognized by a monoclonal antibody, G1N1. This determinant was also demonstrated to be present in virtually all satellite cells of peripheral ganglia, all Schwann cells of peripheral nerves, and in subpopulations of sensory and autonomic neurons. Non-neuronal precursor cells, recognized by G1N1, were identified immunocytochemically in our neural crest culture system using an avidin-biotin-peroxidase technique (G1N1 antibody, courtesy of Dr. N.M. Le Douarin, used at a dilution of 1:100 or 1:500). We also observed that a subpopulation of cells was G1N1 positive. These cells were either spindle-shaped or flattened in appearance.

To determine whether the G1N1 positive cells have NGF receptors, co-localization studies were performed. Cultured neural crest cells were rinsed with CEE-free tissue culture medium (2 hr; 37°C), incubated with ^{125}I-NGF (5 ng/ml, 100 cpm/pg; 1 hr; 37°C), rapidly rinsed six times with ice-cold phosphate buffered saline, fixed (4% paraformaldehyde in 0.1M sodium phosphate buffer), and processed for immunocytochemistry. The cultures were subsequently embedded in epon and sectioned (1 μm). Examination of light microscopic radioautographs revealed that the majority of G1N1 positive cells specifically bound ^{125}I-NGF. It is likely, therefore, that the non-neuronal precursor cells, present in neural crest cultures, are responsive to NGF. The nature of this response remains to be determined. Unstained neural crest cells, labelled by ^{125}I-NGF, were also observed, indicating that additional cell types are NGF targets and need to be identified. Supported by grants from the NSF (#BNS-8600256), March of Dimes (#1-1011), and the Dysautonomia Foundation.

142.6 LOCALIZATION OF NGF RECEPTOR IMMUNOREACTIVITY ON SPECIFIC EPITHELIAL CELL POPULATIONS. S.L. Patterson*, G.C. Schatteman*, S.J. Thompson*, and M. Bothwell (SPON: M. Liebowitz). Dept. of Physiology and Biophysics, Univ. of Washington, Seattle, WA 98195.

We have employed monoclonal antibodies to human NGF receptor (Marano et al., J. Neurochem. 48: 225-232 1987) and to rat NGF receptor (Chandler et al., J. Biol. Chem. 259: 6882-6889 1984) to immunocytochemically localize NGF receptors in human, monkey, and rat tissues. In addition to the expected immunostaining of elements of the sensory and sympathetic nervous system, we were suprised to detect immunoreactivity on certain epithelial cells.

Most epithelia, including epidermis of finger tip and of hairy skin and epithelia of the GI tract, were devoid of NGF receptor immunoreactivity except for that on nerve fibers. However NGF receptor immunoreactivity was detected on basal epithelial cells of some hair follicles, of some papillae of dorsal tongue, of some regions of lip, and of the junctional epithelium of gingiva. In addition, myoepithelial cells of a variety of exocrine organs, including mammary gland, salivary gland and sweat gland were specifically immunostained.

The basal epithelial cell populations which bear NGF receptor immunoreactivity typically are in regions which receive unusually abundant sensory innervation. In addition, myoepithelial cells, with the exception of those of mammary gland, receive sympathetic innervation. However the immunoreactivity we detect associated with epithelial cells is apparently intrinsic to the cells since it is too extensive to represent merely closely associated nerve fibers.

We have not yet confirmed by independent means that the immunoreactivity observed corresponds to authentic NGF receptors. However, if these are functional NGF receptors, their functional role is obscure. As most of these epithelial cell populations are targets of sensory or sympathetic innervation, they presumably produce NGF. In this sense, they may be likened to Schwann cells which may express both NGF and NGF receptors, for reasons which are not yet understood.

142.7 LOCALIZATION OF NGF RECEPTOR mRNA AND PROTEIN INPRIMATE SENSORY NEURONS. J.G. Heuer*, G.C. Schatteman* and M. Bothwell. Dept. of Physiology and Biophysics, Univ. of Washington, Seattle, WA 98195.

Mammalian dorsal root ganglionic (DRG) neurons require NGF for survival during embryonic development and retain some responsiveness in adults. While the mechanism of action of NGF remains obscure, cell surface receptors for NGF have been extensively characterized. This laboratory and its collaborators have isolated monoclonal antibodies against the human NGF receptor, and cDNA clones encoding the human NGF receptor. Using these tools, we have been characterizing the distribution of receptor expression in developing and adult primates. Immunostaining with monoclonal antibody NGFR5, using an avidin-biotin horseradish peroxidase system, has been employed to localize sites of NGF receptor expression in monkey and human dorsal root ganglia. In both adult and embryonic DRG, NGF receptor immunoreactivity was heterogeneously distributed among sensory neuronal cell bodies. Some cell bodies stain strongly, while staining of others was barely greater than in controls with irrelevant antibodies. There was no apparent correlation of level of receptor immunoreactivity with size of cell bodies or position within the ganglia. Immunocytochemical results were confirmed by localization of NGF receptor mRNA utilizing in situ hybridization histochemistry with an NGF receptor cDNA probe. In DRG of adult monkey, we detected extensive hybridization to some neuronal cell bodies, while hybridization to other cell bodies was only slightly above background. These results are consistent with the results of Richardson et al., (J. Neurosci. 6: 2312-2321) showing that a subpopulation of rat DRG neurons bind NGF with high affinity. We find that immunostaining of NGF receptors in central projections of DRG neurons to spinal cord is predominantly restricted to Rexed lamina 1 and the dorsal margin of lamina 2 where small unmyelinated (C) fibers predominate. Peripheral projections of sensory neurons to cutaneous tissue also show NGF receptor immunoreactivity restricted predominantly to small unmyelinated axons. These results are consistent with the observed preverential loss of small unmyelinated axons in sciatic nerve in fetal guinea pigs immunochemically deprived of NGF (Johnson et al., Neurosci. 8: 631-642 1983).

142.8 AN IMMUNOHISTOCHEMICAL STUDY OF THE NERVE GROWTH FACTOR (NGF) RECEPTOR IN DEVELOPING RATS. Qiao Yan and E.M. Johnson, Jr. Department of Pharmacology, Washington University School of Medicine, St. Louis, MO 63110.

NGF receptor expression was studied in rats between embryonic day 11 (E11) to postnatal day 10 (PND-10) by using a monoclonal antibody, 192-IgG, which specifically recognizes rat NGF receptor.

Sympathetic ganglia were positive for NGF receptor immunoactivity (NGFRI) at all ages. The staining was dense and uniform. As early as E11, NGFRI was found in the trigeminal ganglia, rostral dorsal root ganglia (DRG), and potential caudal DRG region, which suggests that the migrating neural crest cells may already be NGFRI positive. In DRG, NGFRI was relatively low at E13, had increased by E18 and decreased thereafter. Scattered cells, apparently neuroblasts, were NGFRI positive in E13 gut, but were not seen at other times. All embryonic peripheral nerves were very densely stained which dramatically decreased postnatally.

In spinal cord, NGFRI first appeared in the rostral portion of ventral, but not in the caudal, spinal cord as early as E11. By E13 NGFRI staining in ventral spinal cord was very dense; the caudal portion of E13 spinal cord showed an NGFRI staining pattern similar to rostral E11 spinal cord, indicating there is a rostral to caudal gradient of expression of NGFRI. At E15 the staining was much reduced in ventral spinal cord, both in terms of density and area. Between E18 and PND-0, some motoneurons in the lateral motor column appeared NGFRI positive. In dorsal spinal cord, NGFRI expression began at the dorsal root entry zone of E13, became very prominent in the whole dorsal horn at E18, and continued through postnatal stages. Area in brain stem innervated by the trigeminal ganglia central processes was NGFRI positive as early as E11 and persisted into the postnatal period. Large cell bodies in the basal forebrain region were NGFRI positive starting at about E15 and remained so postnatally. The cell surface of cerebellar Purkinje's cells including dendrites, were NGFRI positive starting at about PND-6 and very prominent at PND-10. Staining was also present on external granular cells. NGFRI disappeared in cerebellum around PND-15.

NGFRI staining in pia matter was very dense. Dental papilla also showed very distinctive staining. Both of these structures are known to originate from neural crest. Muscle components, limb buds and somites, were NGFRI positive starting at E11; the staining on myotubes became very dense at E15 and E18 and largely disappeared after E20.

The changes in NGFRI staining seen in this study suggest that NGF may have broader effects during development than previously thought.

142.9 DISTRIBUTION OF NGF-RECEPTOR-LIKE IMMUNOREACTIVITY IN THE POSTNATAL RAT BRAIN. F.P. Eckenstein, Dept. of Neurology and VIABR, Oregon Health Sciences University, Portland, OR 97201

Soluble neurotrophic factors that promote survival and differentiation of specific neuronal cell types are likely to be involved in the regulation of development in various neuronal systems. The so far best studied example is Nerve Growth Factor (NGF) and its action on sympathetic and sensory neurons. More recently, evidence has accumulated showing that NGF is also appears to be important for the development of cholinergic neurons in the mammalian basal forebrain (BFB). NGF has been shown to act on responsive cells through binding to a specific receptor. Monoclonal antibodies recognizing the receptor have now become available, and it is possible to use these antibodies to identify potential sites of NGF-action in central nervous system (CNS).

This report describes a survey of the spatial and temporal pattern of expression of NGF-receptor-like immunoreactivity (NGFR-LI) in the postnatal rat CNS. Immunohistochemical techniques (both PAP and immunofluorescence) using the monoclonal NGFR-antibody produced by Chandler et al. (J. Biol. Chem. 259: 6882-6889, 1984; a gift of Dr. E. Johnson, St. Louis) were employed for the study.

Intense, specific staining was observed in fibers in the olfactory bulb (OB); neuronal cell bodies in the BFB; non-neuronal cells in the median eminence (ME); fibers in the thalamus (THAL); fibers and possibly cell bodies in the cerebellum (CERB); fibers in the spinal cord (SC). The following table indicates the subjectively scored staining intensity for the NGFR in these areas at specific postnatal developmental stages:

	day 1	day 5	day 12	adult
OB	nd	nd	nd	+++
BFB	+	+++	++	++
ME	-	-	+	++
THAL	+	+++	+	-
CERB	nd	+++	+++	-
SC	+++	+++	+++	+++

Using double-staining techniques for the localization of the NGFR and the cholinergic marker choline acetyltransferase in the same section it was found that the markers label identical cells in the septal area and the nucleus basalis. In the caudate only very few neurons stained faintly for the NGFR. The number of stained neurons was considerably smaller than that of ChAT-positive neurons in that area, and the faint NGFR-staining did not allow unambiguous double-staining.

Interestingly, NGFR-LI was found to be transiently expressed in structures for which there is no demonstrated biological effect of NGF: the thalamus and the cerebellum. This might suggest that NGF has a specific developmental function in these areas, but the value of such a suggestion clearly depends on demonstrating that the staining observed represents true NGF-receptors and not immunologically similar material. It will also be important to identify the neuronal cell type expressing NGFR-LI in these areas. Experiments addressing these questions are in progress.

142.10 DISTRIBUTION OF NGF RECEPTORS IN THE RAT BASAL FOREBRAIN: AN IN VITRO AUTORADIOGRAPHIC STUDY. Henry. K. Yip, Dept. of Anatomy, University of Utah, School of Medicine, Salt Lake City, Utah 84132.

We have used a monoclonal antibody 192-IgG to localize the NGF receptor in the basal forebrain of the rat by in vitro autogradiographic technique. Brain tissues were fixed in 0.1% formaldehyde and frozen sections of forebrain were incubated with (0.02 -2 nM) ^{125}I-192 -IgG or ^{125} I-NGF. Alternate serial sections were also incubated in the same media, with the addition of 1000-fold excess of unlabelled 192-IgG or NGF, or with equimolar of ^{125}I-cytochrome C, to produce autoradiograms representing nonspecific binding. Autoradiograms were generated by apposition of the labelled tissue sections to either emulsion - coated coverslip or LKB ultrofilm in X-ray cassettes. After 2- to 4- day exposure period, the coverslips and the films were developed.

The distribution of NGF receptors in the rat basal forebrain exhibits marked regional heterogenity. The binding pattern of ^{125}I-192-IgG and ^{125}I-NGF was similar but they differ in binding density. High concentrations of NGF receptors were found in the cortex, with the highest concentration in lamina VI and parts of lamina IV. The cingulate, entorhinal and primary olfactory cortices contain, in general, higher concentration of NGF receptors than did the other cortices. Very high density of NGF receptors were also seen in ventral and ventroposterior thalamus, olfactory tubercle and habenular nucleus. Moderate amount of NGF receptors were observed in association with the medial septal nuclei, diagonal band of Broca, hippocampus. lateral preoptic area, caudate-putamen nucleus, ventral pallidum. Low concentration of NGF receptors were found in amygdala and globus pallidus.

This finding indicates that in vitro receptor autoradiography of ^{125}I-192-IgG or ^{125}I-NGF binding to rat brain sections provides a sensitive method for the localization of NGF receptor in well-defined, highly circumscribed areas. These results have demonstrated that in addition to the localization of NGF receptors on the cholinergic neurons, NGF receptors can also be found on the other types of neurons in the rat basal forebrain.

TROPHIC AGENTS: NERVE GROWTH FACTOR III

143.1 CO-TREATMENT OF RAT PC12 CELLS WITH NGF AND BASIC FGF RESULTS IN COOPERATIVITY OF NEUROTROPHIC RESPONSES. R.E. Rydel and L.A. Greene, Department of Pharmacology, New York University School of Medicine, New York, N.Y. 10016

Fibroblast growth factors are well-characterized peptides that have potent angiogenic activity and which are mitogenic for many cell types. We have previously demonstrated that PC12 cells respond to FGFs by conversion to a neuronal phenotype in an almost identical fashion as that promoted by NGF (R.E. Rydel and L.A. Greene, *Soc. Neurosci. Abst.* 11:935, 1985). In the present study, we have extended these findings to determine the effects of simultaneous treatment of PC12 cells with both NGF and basic FGF (bFGF). The responses we analyzed were long-term, transcription-dependent responses of PC12 cells which are associated with their conversion to a neuronal phenotype, and which are highly specific for NGF and FGFs. These include neurite initiation, induction of phosphorylated, high molecular weight microtubule-associated protein 1.2 (MAP1.2), and elevation of AChE activity.

While both NGF and bFGF promote neurite initiation from PC12 cells, the rate of initial process outgrowth in serum-containing medium is always greater in the presence of NGF. Moreover, co-treatment with both factors results in a rate of neurite initiation of greater magnitude than that generated by either factor alone. In one experiment, after 6 days of treatment 53% of the cells possessed processes greater that 3 cell diameters in length with NGF, while neuritic processes were evident on only 24% of the cells in the presence of bFGF. However, simultaneous treatment of PC12 cell cultures with both NGF and bFGF resulted in 94% of the cells extending neurites. NGF or bFGF treatment also brings about an elevation of AChE activity. After 3 days of treatment, optimal doses of either factor will produce an approximately 2-fold increase in AChE activity. At sub-optimal doses, simultaneous treatment of PC12 cells with NGF and bFGF enhance AChE activity in an additive fashion. At optimal doses of both factors, the elevation of AChE activity was greater than that produced by either factor alone, but was less than additive. With regard to induction of phosphorylated MAP1.2, NGF and bFGF individually induce an approximately 15-fold increase when added to cultures for 13 days. Similar treatment with optimal doses of both factors added together results in an approximately 30-fold increase.

This work indicates that exposure of PC12 cells to an additional neurotrophic factor can enhance the maximal response to a single neurotrophic factor. Thus, co-expression of neurotrophic pathways during development can permit supra-maximal responses. Thus, in the presence of either sub-optimal or optimal levels of a given neurotrophic factor, further modulation of responses is still possible. Supported in part by NIH Research Grant NS-16036. R. 143.2 NERVE GROWTH FACTOR MODULATION OF NEUROPEPTIDE LEVELS IN ADULT SENSORY NEURONS IN CULTURE. R.M. Lindsay, C. Lockett and J. Winter Cell Biology, Sandoz Institute for Medical Research, London, U.K. (SPON: M. Gaze)

In contrast to the essential survival factor role of nerve growth factor (NGF) during sensory neuron ontogeny, the requirement of adult sensory neurons for NGF has not been well defined, although we have recently shown that adult rat dorsal root ganglion (DRG) sensory neurons can survive idefinitely *in vitro* in the absence of NGF (Neurosci. Soc Abs. 12, 299.13, 1986). Using immunofluorescence and radioimmunoassay, we have now examined the influence of NGF on the expression of certain neuropeptides in adult rat DRG neurons in culture. When pooled ganglia from lumbar, thoracic and cervical levels were cultured the percentage of CGRP (20-25%), substance P (12-20%) and somatostatin (<10%) containing neurons was found by immunofluorescence labelling to be essentially the same after 2 - 12 days in culture in the presence of NGF, and within the range of reported values for these ganglia *in vivo*. For a more detailed comparison between *'in vivo'* and *'in vitro'*, lumbar ganglia L3-L5 from the left side of one animal were sectioned, stained with anti CGRP and substance P, while the corresponding right-side ganglia were cultured and similarly stained after 2 and 7 days in culture. Similar percentages of CGRP (30-40%) and substance P (15-25%) positive cells were found in each case, indicating that the ratio of sub-types of DRG neurons which survive in culture is representative of the *in vivo* population and that the expression of neuropeptides by DRG neurons is probably restricted to a defined sub-population. Although NGF did not influence the number of DRG neurons which expressed specific neuropeptides, the level of substance P in adult DRG neuron cultures was found to be greatly increased (6 - 10-fold, cf. controls) when NGF was continuously present for 10 - 14 days. This marked elevation of substance P levels could be obtained even when the addition of NGF to cultures was delayed for 6 or more days. We conclude that NGF is not required for survival of peptidergic adult DRG neurons but does regulate the level of neuropeptide within these cells.

143.3 EFFECTS OF NGF AND INSULIN ON TUBULIN mRNA LEVELS IN SYMPATHETIC NEURONS. P. Fernyhough and D.N. Ishii (SPON: J.F. Masken) Physiology Department, Colorado State University, Fort Collins, CO 80523.

Like nerve growth factor (NGF), insulin and IGFs can induce neurite outgrowth and support survival of sympathetic neurons (Recio-Pinto et al., J. Neurosci. 6: 1211, 1986). These factors may provoke the increased assembly of tubulin into microtubules, which are important structural elements of neurites. Tubulin mRNA levels are elevated by NGF in pheochromocytoma PC12 cells (Fernyhough and Ishii, Neurochem. Res. in press, 1987) and by insulin and IGF-II in human neuroblastoma SH-SY5Y cells (Mill et al., 1985). The elevation of tubulin mRNA may be a common prelude to neurite formation under the direction of neuritogenic polypeptides. A critical test of this hypothesis requires that NGF and insulin can modulate tubulin mRNA levels in normal neurons. Purified RNA was analyzed by the Northern and dot blot methods using as probes for alpha- and beta-tubulin mRNAs the cDNA clones pKα1 (contains all of the coding region) and pDβ1 (contains all of the coding region except 21 bases from the 5' end), respectively. Equivalent amounts of RNA were analyzed in each experiment. NGF (4 μg) or vehicle were administered s.c. daily for 1 week to neonatal rats. Relative α-tubulin mRNA levels were increased 49 and 27% in RNA from sympathetic chain ganglia (two experiments). To determine whether these were direct effects on neurons, we continued the study in cultured 13-day-old embryonic chick sympathetic neurons under conditions in which the non-neurons were essentially eliminated (Recio-Pinto et al., 1986) on Primaria (Falcon) dishes. NGF and insulin increased both α- and β-tubulin mRNA levels within 2-4 hr. The maximum response (2-3 fold increase) was reached in about 8 hr with NGF and about 24 hrs with insulin. The response to NGF was transient, as previously observed for NGF in PC12, and insulin in SH-SY5Y, cells. It was not determined whether insulin's response in sympathetic neurons was also transient. The half-maximally effective concentration was about 10 pM for NGF, which is consistent with activity being mediated through the high affinity Slow NGF receptors. Insulin was active at concentrations below 1 nM, indicating it was acting through insulin receptors, rather than Type I IGF receptors. The mechanism for the elevation of tubulin transcripts may involve stabilization, as shown for NGF in PC12 cells (Ferynhough and Ishii, 1987). These results show NGF and insulin can elevate tubulin transcripts in sympathetic neurons, and provide critical support for the hypothesis. (Supported in part by NIH grant RO1 NSDK 24327 and an award from the Diabetes Research and Education Foundation).

143.4 NERVE GROWTH FACTOR DEPRIVATION RESULTS IN THE REACTIVATION OF LATENT HERPES SIMPLEX VIRUS IN SYMPATHETIC NEURONS IN VITRO. C.L. Wilcox* and E.M. Johnson, Jr. (SPON. D.B. McDougal, Jr.) Department of Pharmacology, Washington University School of Medicine., St. Louis, MO 63110.

Little is known about the mechanisms involved in the establishment and reactivation of latent herpes simplex virus (HSV). Neurons of neural crest-derived sensory ganglia and sympathetic ganglia are the predominant sites of latent HSV. These are nerve growth factor (NGF)-dependent neuronal cell types. We have determined that NGF is important in the maintenance of the latent state of HSV in sympathetic neurons in vitro.

Dissociated sympathetic neuronal cultures were prepared from fetal rat superior cervical ganglia. For 10 days after plating, the cultures were treated with 20 μM fluorodeoyuridine which reduced the non-neuronal cell population to less than 5%. Inoculation with 1 plaque-forming unit of HSV-1 per cell in the presence of either 10μM aphidicolin or 50 μM acyclovir resulted in 100% survival of the cultures. The drug was removed 7 days after inoculation with HSV. We detected no evidence of productive HSV infection, determined by assaying either cell lysates or culture media for infectious virus. Using immunohistochemistry, there were no detectable HSV antigens. Cultures have been maintained for up to 5 weeks postinoculation without any evidence of productive viral infection. When the cultures were deprived of NGF by treatment with antibodies to NGF, 100% of the cultures produced infectious HSV. The first cells that developed positive immunohistochemical staining for HSV antigens were neurons, indicating that the neuron was the site of latency. Latent cultures treated with nonimmune serum did not result in the reactivation of HSV. In addition, we have determined that 5 μg/ml 6-hydroxydopamine and 0.1 mM colchicine resulted in reactivation of latent HSV.

In summary, we have established an in vitro model of HSV latency which duplicates accurately viral latency in vivo. NGF deprivation resulted in the reactivation of latent HSV. These data suggest a physiologically important role of NGF in the maintenance of HSV latency. The data also indicate that the replication of HSV DNA was not necessary for the establishment of latency, as latency was achieved in the presence of drugs which block viral DNA replication.

143.5 NERVE GROWTH FACTOR PREVENTS VINBLASTINE-INDUCED SYMPATHECTOMY IN A DOSE-DEPENDENT FASHION IN NEWBORN RATS: EFFECT OF GM1 GANGLIOSIDE. G. Vantini, M. Fusco*, N. Schiavo*, D. Benvegnù* and A. Leon. Fidia Research Laboratories, 35031 Abano Terme (PD), Italy.

We have utilized the model of vinblastine (VNB)-induced sympathectomy to quantitatively assess in vivo: 1) the activity of nerve growth factor (NGF; from male mouse submaxillary glands), and 2) the capability of GM1 ganglioside to modulate NGF effects. GM1 has been reported to facilitate NGF effects in cultured PC12 pheochromocytoma cells and neurons obtained from chicken embryo sensory and sympathetic ganglia.

The degree of sympathectomy induced by a single injection of VNB (0.15 mg/Kg, subcutaneously) given on postnatal day 3 was evaluated by measuring the noradrenaline (NA) content in sympathetically innervated organs (e.g. heart, spleen) of 6-day-old animals. Rat pups were treated s.c. on postnatal days 3, 4 and 5 with different doses of NGF, ranging from 0.01 to 0.5 mg/kg and/or GM1 (30 mg/kg). NGF was able to antagonize the NA decrease in a dose-dependent manner. The NGF dose-response curve obtained for the heart exhibited a different profile as compared to that for the spleen, thereby reflecting a different sensitivity of the corresponding sympathetic innervation to VNB and/or NGF treatments. Furthermore, GM1, but not asialo GM1, was able to potentiate the NGF effects in preventing the VNB-induced neurotoxicity. Thus, this model of VNB-induced sympathectomy appears to be suitable for evaluation of the activity not only of NGF(s) or NGF-like substances obtained from different sources, but also of agents capable of modulating NGF effects.

143.6 STUDIES OF GRAFTED ADRENAL MEDULLARY CELLS, EFFECTS OF NGF. I. Strömberg*, T. Ebendal*[1] and A. Hultgård*[2] (SPON: A. Seiger). Dept. of Histology and [2]Medical Cell Genetics, Karolinska Institute, 104 01 Stockholm, Sweden, and [1]Dept. of Zoology, Uppsala University, 751 22 Uppsala, Sweden.

Adrenal medullary tissue pieces, transplanted to the anterior chamber of the eye, can reinnervate a sympathetically denervated iris. In order to see which cell type(s) in the adrenal medulla that can produce processes, cell suspensions were injected into the anterior eye chamber. Using fibronectin, many single cells attached to the surface of the iris. In iris whole-mounts of such irides, a change was suggested from adrenaline-producing cells to noradrenaline-producing cells using antibodies raised against adrenaline (A) and dopamine β hydroxylase (DBH). Six days postgrafting, almost all cells showed A-like immunoreactivity and were negative with DBH, while after 1 month all cells were DBH-positive. One to three months postgrafting some single cells were elongated and had thick, short processes. When occasionally a network of nerve fibers was seen, it originated either from a cluster of cells, rather than from single chromaffin cells, or from single sympathetic ganglion-type cells. The reinnervated area was very small compared to the area that adrenal medullary tissue pieces can innervate in the same length of time. One factor that influences the outgrowth from these grafts is nerve growth factor (NGF). Although a sympathetically denervated iris has increased endogenous levels of NGF, this amount of NGF does not seem to be enough for single cells to produce nerve terminals, except for the few ganglion cells that produced large and varicose nerve plexuses resembling normal sympathetic nerves. When increasing the levels of NGF further by weekly injections into the anterior eye chamber for 3 weeks, there was a clear increase in number of cells that produced processes. The innervated areas were much larger, and the nerve plexuses had a more normal appearance as opposed to the short and thick processes that elongated chromaffin cells produced without added NGF. The number of ganglion cells had increased remarkably, and a transitional cell type with a cell body as large as a ganglion cell but with a chromaffin-like strong fluorescence intensity was also found. We conclude that large numbers of sympathetic neuron-type cells result when adult adrenal medullary cell suspensions are treated with NGF in oculo.

143.7 NGF AS A NEUROTROPHIC FACTOR IN THE BASAL FOREBRAIN: EVIDENCE FROM TISSUE TRANSPLANTED IN OCULO. S. Skirboll*, M. Eriksdotter-Nilsson*, T. Ebendal*[1], L. Hersh[2], J. Massoulié*[3], L. Olson*. (SPON: L. Skirboll). Dept. of Histology, Karolinska Institute, Stockholm, Sweden; [1]Dept. of Zoology, Uppsala Univ., Uppsala, Sweden; [2]Univ. of Texas Health Science Ctr., Dallas, TX; [3]Lab. de Neurobiologie, ENS, Paris, France.

In the present study, in order to further discern the role of NGF in the central nervous system, we have attempted to employ a unique in vivo model. Fetal (E17) rat basal forebrain tissue was transplanted to the anterior chamber of the eye, utilizing a treatment protocol of pre-grafting incubation and weekly 5 ul intraocular injections of either NGF (10,000 BU/ml) or saline. In vivo measurements of the transplants reveled a significant ($p < 0.05$) increase in the size of the NGF-treated grafts. Following pretreatment with diisopropylfluorophosphate (DFP), the transplants were processed for acetyl cholinesterase (AChE) histochemistry, and choline acetyltransferase (CAT) and recently developed AChE immunocytochemistry. The NGF-treated transplants demonstrated an increase in the number of specifically stained neurons in all three histological analyses, of which the most pronounced effect was seen with AChE immunocytochemistry ($p < 0.05$). The number of cholinergic neurons per unit volume of transplant, however, was not significantly increased with NGF treatment. The density of nerve fiber outgrowth, as visualized by AChE immunocytochemistry (unaffected by prior DFP) was only slightly enhanced. In addition, preliminary results from transplants treated instead with polyclonal antibodies to NGF have proved inconclusive, which may reflect the rapid turnover of such antibodies in the anterior chamber of the eye.

Thus, we have demonstrated that in oculo transplantation of basal forebrain tissue is a useful model for examining the in vivo effects of NGF on central cholinergic function. Basal forebrain tissue can be influenced to survive and mature at different rates in oculo, and our results suggest that NGF may act as a neurotrophic factor for noncholinergic as well as cholinergic neurons of the basal forebrain. Additional studies are in progress to determine the turnover of NGF in oculo, optimal dosage and treatment schedules, and to identify which noncholinergic cell populations may be the most susceptible to the effects of NGF.

143.8 NERVE GROWTH FACTOR (NGF) IS PRESENT IN HYPOTHALAMIC OLIGODENDROCYTES: IMMUNOCYTOCHEMICAL EVIDENCE FROM PRIMARY CULTURES IN SERUM-FREE MEDIUM. D. Gonzalez*, W.L. Dees* and S.R. Ojeda. Neuroscience Division, Oregon Regional Primate Research Center, Beaverton, OR 97006 and Department of Veterinary Anatomy, Texas A & M University, College Station, TX 77843.

Although the presence of NGF in brain is well documented little attention has been given to its presence in the hypothalamus or to the cell type that contains NGF. The present investigation was undertaken to examine this issue. Hypothalamic cells from 19-day-old rat fetuses were mechanically dispersed and seeded in 35 mm culture dishes at 0.8×10^6 cells/plate onto coverslips precoated with 10% fetal bovine serum (FBS). The cells were cultured for 4 days in F12: Dulbecco's medium (1:1) containing 0.7% FBS, 5 µg/ml insulin, 100 µM putrescine, 30 nM sodium selenite, and 100 µg/ml transferrin. At the end of this period the FBS-containing medium was removed and the cells were cultured two more days in serum-free medium. They were then fixed in Zamboni's fixative (2 h) or 3.7% formaldehyde (10 min) and processed for immunohistofluorescence analysis. All primary antibodies were prepared in rabbits and were kindly supplied to us by Dr. J. deVellis, J. Bottestein and E. Tiffany-Castiglioni; an antirabbit IgG coupled to fluorescein isothiocynate was used as the secondary antibody. Cells containing immunoreactive NGF were scattered over a layer of other cells which had attached to the coverslip surface. Both the body and processes of the positive cells displayed strong NGF immunoreactivity. Absorption of the antiserum with NGF (20 µg/ml) completely eliminated the immunoreactivity. Astrocytes, identified by the presence of glial fibrillary acidic protein (GFAP) had a morphological aspect completely different from that of NGF-containing cells and did not display NGF immunoreactivity following elution of the GFAP antibody. In contrast, cells identified as oligodendrocytes (because they express the membrane galactosphingolipid galactocerebroside and the cytosolic enzyme glycerol 3'-phosphate dehydrogenase) had a morphological aspect identical to NGF-containing cells. Upon their mechanical removal from the coverslip, the NGF immunoreactivity disappeared indicating the NGF is contained in oligodendrocytes. The results suggest that the hypothalamus has the capability of expressing the NGF gene and that this capacity is limited to cells of the oligodendroglial cell lineage. Supported by NIH grants HD-09988, Project IV and NIAA07216.

143.9 NERVE GROWTH FACTOR-LIKE IMMUNOREACTIVITY IN THE DEVELOPING RAT COCHLEA. Gerard Despres* and Raymond Romand. Université de Clermont II. Laboratoire de Neurobiologie, Ensemble Scientifique des Cezeaux, B.P. 45, 63170, AUBIERE (France)

The presence of nerve growth factor-like protein have been investigated on cryostat sections from Sprague Dawley rat cochleae of various stages(0,2,6,7,8,10,15,30 days old and adults) by indirect immunofluorescence technique. Sheep polyclonal anti serum against 2.5S NGF (a gift of H. Thoenen) has been tested for specificity to NGF firstly on sections of mouse submaxilary glands. Secondly, absence of fluorescent staining was observed when anti-NGF antiserum was omitted or when normal sheep serum was used instead of anti-NGF or when anti-NGF antiserum was previously immunoabsorbed with pure 2.5S NGF. NGF-like immunoreactivity was clearly present in the organ of Corti from birth to postnatal day 6 and localised in the hair-cells. A gradient of staining was visible between basal and apical turns at birth and at 2 days where the basal was most intensely labeled. From postnatal day 7 the gradient of staining was inverted, the basal turn becoming less reactive. Immunostaining completely disappeared around postnatal days 9-10 and was also non-existant in 15 days, 1 month old and adults rats. The immunofluorescence is essentially localised at the highest third part of the hair-cells and seem to coincide with the Golgi complex network. No immunostaining could be registered in the spiral ganglion cells. Control experiments allow to postulate that immunostaining in the hair-cells probably results from the interaction of NGF-antibodies with an endogenous NGF-like material. Synaptogenesis being not completed at birth in the rat, it is possible that this substance is, up to postnatal days 7-8, one of the trophic factors suspected in the rat cochlea. Spiral ganglion cells may require other neurotrophic factor during development.

143.10 NGF IN TESTIS AND EPIDIDYMIS: LOCALIZATION OF MESSAGE AND PROTEIN AND MEASUREMENT OF BIOLOGICAL ACTIVITY. L. Olson*, G. Ayer-LeLievre*, H. Persson*[1], T. Ebendal*[2] (SPON: G. Kindr[3]) Dept. of Histology, Karolinska Institute, 104 01 Stockholm, Sweden; [1]Dept. of Medical Genetics, [2]Dept. of Zoology, Uppsala University, 751 22 Uppsala, Sweden, and [3]Dept. of Neurosurgery, Univ. of Colo. Med. Ctr., Denver, CO 80262.

The presence of high levels of nerve growth factor (NGF) in the male mouse submandibular glands remains enigmatic, although it may represent one example in which NGF's primary function is not associated directly with the nervous system. Several observations in the literature suggest that another such instance may be the presence of NGF in the male reproductive system. However, there have been no direct studies of the rodent testis and epididymis to address this question. Using affinity-purified antibodies raised against mouse salivary gland β-NGF, we found immunoreactivity in rat and mouse testis. All cells of the germ cell line except spermatogonia were strongly immunoreactive in both species. Immunoreactivity was also seen in residual bodies in testis and epididymis. Using antibodies directed against specific peptide sequences within NGF and pro-NGF, the pattern of NGF-like immunoreactivities could be further subdivided; immunoreactivity with a high degree of regional specificity was localized to defined portions of the epithelium of ductus epididymidis throughout the various portions of caput and in corpus and cauda. Presence of NGF protein was also shown by a two-site enzyme immunoassay indicating about 10 and 70 ng NGF per gram tissue in mouse testis and epididymis, respectively. Extracts from these organs stimulated fiber outgrowth in cultured sympathetic ganglia, an effect which was blocked by anti-NGF antibody. Blot analysis of RNA prepared from testis and epididymis demonstrated the presence of 1.3 kB and 1.5 kB NGF message except in one case, the rat testis, where only the 1.5 kB message was found. In situ hybridization also localized the NGF message to the germ cell line excluding the spermatogonia, late spermatides and spermatozoa in the seminiferous tubules, and to the epithelium of ductus epididymidis. Leydig and Sertoli cells appeared negative using both immunohistochemistry and in situ hybridization techniques. We conclude that five types of analysis -- blot and in situ hybridization, enzyme immunoassay, immunohistochemistry and bioassay -- all strongly indicate production of NGF in the male rodent reproductive system, and suggest a non-neuronal role for NGF possibly relating to sperm maturation and/or motility.

143.11 IMMUNOCHEMICAL AND BIOLOGICAL CHARACTERIZATION OF IMMUNOAFFINITY PURIFIED FAB FRAGMENTS AGAINST MOUSE NERVE GROWTH FACTOR. L. Callegaro*, A. De Martino*, S.D. Skaper, D. Benvegnù*, G. Vantini, C. Triban*, G. Toffano and A. Leon. (SPON: S. Mazzari). Fidia Research Laboratories, 35031 Abano Terme (PD), Italy.

Intracerebral injections of antibodies to nerve growth factor (NGF) provide one experimental mode to verify whether endogenously occurring NGF exerts an influence on the cholinergic neurons of the basal forebrain in vivo. Since whole antibodies, due to their size, may not penetrate well the neonatal and/or adult brain, we have purified and characterized anti-NGF Fab fragments.

Polyclonal antibodies against male mouse submaxillary gland ß-NGF were raised in rabbits. The specific antibody fraction was isolated from rabbit antiserum utilizing immunoaffinity chromatography and proteolyzed by papain digestion. The resulting Fab fragments were then purified on a Protein A-Sepharose column and subsequently isolated by immunoaffinity chromatography using ß-NGF linked to Sepharose 4B. Elution of the immunoreactive fraction was accomplished by high salt concentration.

Chemically, the purity of the isolated IgG and its Fab fraction was evaluated by SDS-gel electrophoresis and fast protein liquid chromatography; specificity was assessed utilizing Western blots. In addition, the biological activity of both the purified IgG and its Fab fragment was tested by the ability of these fractions to block the survival-promoting activity of NGF for embryonic (E8) chick dissociated dorsal root ganglionic neurons. Both fractions displayed a high activity, with 5 ng/ml of ß-NGF being fully blocked by 0.5 ug/ml or less of the specific Fab fragments. Fab fragments prepared from preimmune serum IgG were inactive up to 80 ug/ml. Experiments are currently in progress to assess the ability of these Fab fragments to function in vivo by inducing immunosympathectomy.

SPINAL CORD I

144.1 **A SIMPLE METHOD OF COMBINING AUTORADIOGRAPHY AND HRP-TMB HISTOCHEMISTRY ON THE SAME TISSUE SECTION.** K.N. Nandi*, J.A. Beal and D.S. Knight* (SPON: J.E. Penny). Department of Anatomy, Louisiana State University Medical Center, Shreveport, LA 71130.

In order to determine the sequence of development of various types of spinal neurons defined by their projection we have developed a method for combining tritiated thymidine autoradiography for birthdate determination with the demonstration of retrogradely transported horseradish peroxidase (HRP). Because of its greater sensitivity, TMB is the chromogen of choice for the demonstration of HRP. However, the HRP-TMB reaction product is unstable and lost when the tissue is processed for autoradiography. By reversing the process, i.e. developing the tissue for autoradiography and then reacting with TMB, we were able to preserve some HRP-TMB reaction product but results were inconsistent. However, the use of osmium as a postreaction stabilizing agent (1% osmium tetroxide in 0.1M phosphate buffer, pH 6.0 at 45°C for 15-30 minutes) preserves the HRP-TMB reaction product in the form of a brownblack precipitate which is not destroyed when the tissue is subsequently processed for autoradiography. Although some reaction product appeared to fade from secondary and tertiary dendrites, no detectable loss was noted in the nerve cell bodies. As an additional advantage we found that background levels of the autoradiographs stabilized with the osmium procedure are extremely low.

In conclusion, osmication of HRP-TMB reaction product results in a stable compound which is not destroyed by autoradiographic processing and enables us to demonstrate tritiated thymidine autoradiography and HRP-TMB reaction product on the same tissue sections.

144.2 **DETERMINATION OF THE SEQUENCE OF PROLIFERATION OF MARGINAL (LAMINA I) NEURONS IN THE SPINAL CORD OF THE RAT.** J.A. Beal, D.S. Knight* and K.N. Nandi* Department of Anatomy, Louisiana State University Medical Center, Shreveport, LA 71130.

The present study is an attempt to determine if different types of neurons within lamina I proliferate in a specific pattern or sequence. Separate groups of marginal neurons were defined on the basis of size and dendritic architecture using the Golgi technique. This method was combined with tritiated thymidine autoradiography to determine each neuron's time of origin or "birthdate". Pregnant rats of the Wistar strain were injected (i.p.) with tritiated thymidine (5.0µCi/g body wgt., spec. act. 6.7 Ci/m mole) on one of embryonic (E) days E13 through E18. Pups were delivered and later sacrificed on postnatal day P30. Tissue from the lumbar enlargement was processed via the Golgi technique and impregnated neurons were drawn with the aid of a Leitz microscope with drawing tube attachment. Sections were then remounted in JB-4 plastic, sectioned at 3.5 microns, and processed for autoradiography. Nuclei of impregnated neurons were then examined for radioactive label. In animals treated on day E13 all neurons of the marginal layer are labelled with tritiated thymidine. In animals treated on E14, most marginal cells are still labelled, but all of the large and some of the small to medium size pyramidal and multipolar shaped neurons are now unlabelled. In animals treated on E15 approximately half the neuronal population of the marginal zone is unlabelled. Most of these unlabelled neurons are pyramidal, multipolar or flattened shaped cells which display a variety of dendritic patterns. On the other hand most labelled cells at E15 are round or fusiform shaped. Some of these labelled neurons have longitudinal arbors restricted to lamina I, while others have delicate ventral dendrites which arborize in laminae II and III. A few of these neurons are labelled in animals treated as late as day E17 and are amongst the last neurons of the spinal cord to complete cell division. In conclusion, the results show that marginal neurons proliferate in a definite sequence, but there is overlap between the proliferative periods of the various cell types.

144.3 **MET-ENKEPHALIN IMMUNOREACTIVITY IN THE LAMINA X REGION OF PRIMATE SPINAL CORD.** C.M. Kocol*, and C.C. LaMotte, Sec. of Neurosurgery, Yale Univ. Sch. of Med., New Haven, CT 06510.

We determined met-ENK like immunoreactivity (MELI) in the lamina X region of the primate (Macaca fascicularis) spinal cord (segments C6-7) using the PAP method. Heavy concentrations of this peptide were found in terminal fields dorsolateral to the central canal. Lesser amounts of MELI were distributed in the dorsal grey and the ventral grey commissures, as well as the pericanal area. Labelled met-ENK neurons were identified lateral to the central canal.

With electron microscopy several MELI terminal types were found throughout lamina X. The most prevalent type contained both granular and agranular vesicles; however there were also some MELI terminals containing only clear, round vesicles. In most cases, these terminals formed either asymmetrical or symmetrical synaptic junctions with various sizes of unlabelled dendrites. These dendrites, in turn, were commonly also postsynaptic to unlabelled R-terminals. MELI terminals also were found to synapse with unlabelled somata in the lateral regions of lamina X. Axo-axonic junctions were observed between MELI and unlabelled R terminals, in which the MELI terminal was presynaptic. Occasionally MELI terminals were observed to be postsynaptic to an unlabelled glomerular terminal in the most lateral region of lamina X. Lateral to the canal, MELI neurons and their dendrites received input from both MELI and unlabelled R terminals; a recent report has shown some spinoreticular neurons in X to contain ENK (Nahin and Micevych, Neurosci. Lett. 65:271).

When compared with our past studies of the ultrastructure of MELI in the monkey dorsal horn, some differences are evident; for example, terminals contacting spines were common in the dorsal horn but rarely observed in lamina X. Also, it appears that MELI terminals containing large granular vesicles are more frequent in lamina X, whereas R type MELI terminals were more common in laminae I and II. Since local ENK neurons are considered to be the major source of ENK terminals in both areas, the differences in terminal types may reflect differences in the character or function of those cells in each region, or possibly differences in colocalization of other neurochemicals. **(Supported by NIH grant NS13335)**

144.4 ENKEPHALINERGIC TRIGEMINAL AND SPINAL NEURONS PROJECTING TO THE RAT THALAMUS. J.A. Coffield* and V. Miletic, (SPON: P. Bach-Y-Rita), Dept. of Comparative Biosciences, School of Veterinary Medicine, University of Wisconsin, Madison, WI 53706.

Although much is known about the anatomy, physiology and pharmacology of trigeminothalamic (TTT) and spinothalamic tract (STT) cells, little information is available regarding their putative neurotransmitter content. In order to determine whether any TTT and STT cells exhibit enkephalin immunoreactivity (ENK), we have combined the techniques of retrograde labeling and immunocytochemistry.

Unilateral injections (50-100nl) of the retrograde tracer Fluoro-Gold (FG, 4%) were made stereotaxically into the medial thalamus (MT) of 12 rats and lateral thalamus (LT) of 7 rats. After 3-8 days, the animals were deeply anesthetized and perfused with 4% buffered paraformaldehyde. In some rats, colchicine (10μg/ml) was injected intrathecally over the lumbar spinal cord eight hours before sacrifice. Vibratome sections of the thalamus (100μm), and of the brainstem and spinal cord (30μm) were examined with a fluorescent microscope. The trigeminal and spinal sections were then processed for ENK with rhodamine immunofluorescence.

MT injection sites (anteromedial, central medial, mediodorsal, reuniens, rhomboid, and submedius nuclei) were exclusive of LT injection sites (the lateral dorsal, lateral posterior, ventroposteromedial, and ventroposterolateral nuclei, and the posterior nuclear group). FG-labeled neurons were distributed throughout the trigeminal and spinal tissue, although MT injections labeled mostly cells in laminae VI and VII, and LT injections neurons in laminae I and V.

After immunocytochemical processing, single-labeled ENK neurons paralleled the distribution of the retrogradely-labeled cells. However, only 10% of the MT-projecting, and 14% of the LT-projecting trigeminal and spinal neurons were enkephalinergic. The MT-projecting ENK neurons originated from laminae VI and VII. The LT-projecting neurons were located in the white matter just dorsal to lamina I and in lamina V.

These data indicate that, in the rat, a small number of TTT and STT neurons are enkephalinergic. These data also suggest that the MT and LT-projecting ENK neurons have differential laminar origins, and distinct roles in thalamic sensory processes.

144.5 ORIGIN OF SPINAL NERVE TERMINALS CONTAINING A NOVEL NERVE TERMINAL PROTEIN: CONTRIBUTION OF DESCENDING PATHWAYS. S.S. Kanekar, T.C. Ritchie and J.D. Coulter. Neuroscience Program and Dept. of Anatomy, The Univ. of Iowa, Iowa City, IA 52242.

The monoclonal antibody S-7B8 recognizes an integral membrane protein in selected populations of nerve terminals in the central nervous system. The S-7B8 antigen appears to be associated with synaptic vesicle membranes. In rat spinal cord, S-7B8 immunoreactive nerve terminals are concentrated in the superficial dorsal horn (laminae I and IIi). Less dense staining extends ventrally through laminae V, and the ventral horn contains some sparse staining. Primary afferent neurons give rise to most of the stained terminals in laminae I and II, and a portion of those in the deeper laminae of the dorsal horn. Current efforts are focused on localizing the cells of origin of the remaining S-7B8 positive nerve terminals in the spinal cord.

In the developing nervous system, the S-7B8 antigen is contained in certain fiber tracts, but becomes concentrated in nerve terminals during and after synaptogenesis. Since the antibody densely stains the developing corticospinal tract, this system is a possible source of S-7B8 positive nerve terminals in the adult spinal cord. Double-label studies were carried out using HRP injections into the lumbosacral spinal cord to retrogradely label corticospinal neurons, followed 3 days later by topical application of colchicine to the sensory/motor cortex to allow immunocytochemical localization of cell bodies containing the S-7B8 antigen. Numerous double-labelled pyramidal cells were evident in layer V of the cerebral cortex, indicating that in adult, as well as developing rats, corticospinal neurons do contain the S-7B8 antigen. S-7B8 immunoreactive cell bodies have also been observed in certain brainstem nuclei following application of colchicine, suggesting that additional descending pathways to the spinal cord may contain the S-7B8 antigen. Using the double-labelling method described above, cells giving rise to the lateral vestibulospinal tract have been shown to contain the S-7B8 antigen and are a likely source of the S-7B8 positive nerve terminals present in the spinal ventral horn.

These results indicate that the corticospinal tract, and possibly other descending systems, contribute to the distinctive, highly localized pattern of S-7B8 immunoreactivity in the spinal cord. From these studies, it appears that the S-7B8 antibody will be a useful probe for examining the synaptic connections and development of descending spinal pathways.

144.6 Occurrence of substance P-like immunoreactivity in synaptic glomeruli of the spinal cord and trigeminal nucleus caudalis of the rat. A. Ribeiro-da-Silva*, P. Tagari* and A.C. Cuello. Department of Pharmacology and Therapeutics, McGill University, 3655 Drummond Street, Montreal, P.Q. H3G 1Y6, Canada.

The present study provides a characterization of the substance P-like immunoreactive central boutons of synaptic glomeruli in the superficial dorsal horn of the spinal cord and trigeminal nucleus caudalis of the rat.

A comparative study of the light microscopic and ultrastructural distribution of substance P-like immunoreactivity in laminae I-II of the spinal cord and trigeminal nucleus caudalis was carried out using a bispecific anti-substance P/anti-HRP monoclonal antibody (P4C1) (Suresh, M.R. et al., Proc. Natl. Acad. Sci. USA, 83:7989, 1986). Ultrathin sections of laminae I-II of the spinal cord and trigeminal nucleus caudalis were obtained from five blocks per animal. The immunoreactive axonal boutons and all synaptic glomeruli were counted on the electron microscope screen. The features of immunoreactive and non-immunoreactive glomeruli were analyzed with an automated image analysis system (Quantimet 920).

In lamina II, of the spinal cord, a significant number of the labelled varicostities were central boutons (C_I) of type I synaptic glomeruli. They could be recognized as such by the scalloped contour, types and number of peripheral profiles, reduced density of mitochondria and localization in the dorsal horn. However, these immunoreactive glomerular C_I boutons (about 10% of the total number of C_I) differed from the prevailing population of type I glomeruli because they established less synapses, only rarely had peripheral axonal boutons and contained more than three dense-core vesicles per profile.

In the trigeminal laminae I and II, the substance P fibres and varicosities had a plexiform orientation, at the light microscopic level, that contrasted with the mainly rostro-caudal orientation of the plexus of the spinal cord. By electron microscopy, the number of immunoreactive profiles was lower, but the main ultrastructural findings were rather similar, in spite of the different orientation of the neuropil. However, many immunoreactive varicostities were confluent and axosomatic contacts were more frequent than in the spinal cord.

In contrast with current thinking, this demonstrates that substance P immunoreactivity occurs in a considerable number of type I synaptic glomeruli, morphologically distinct from those that have fluoride-resistant acid phosphatase activity. It also reinforces the concept that the gelatinosa of the spinal cord and the trigeminal nucleus are homologous structures.

(Dr. A. Ribeiro-da-Silva acknowledges a grant from the Gulbenkian Foundation, Lisbon).

145.1 FUNCTIONALLY IDENTIFIED LOCAL CIRCUIT NEURONS IN RAT TRIGEMINAL SUBNUCLEUS INTERPOLARIS. M.F. Jacquin, M. Barcia*, J. Golden* & R.W. Rhoades. Dept. Neurosci., NY Coll. of Osteo. Med., Old Westbury, NY 11568 & Dept. Anat., NJ School of Osteo. Med., Piscataway, NJ 08854.

Intracellular recording, electrical stimulation, receptive field (RF) mapping, and HRP injection techniques were used to determine the morphology, response properties, and collateral projections of 18 local circuit (LC) neurons in trigeminal (V) subnucleus interpolaris (SpVi). None were antidromically activated from thalamus, tectum, or cerebellum, and their axons could be seen terminating locally. All exhibited narrow, biphasic action potentials following gentle displacement of 1, and only 1, facial whisker. More forceful deflection of adjacent whiskers often activated LC cells, though this reflected artifactual displacement of the 1 whisker RF. They responded within 1.34±0.28ms (mean±S.D.) of ipsilateral V ganglion shocks, and 16 gave a phasic discharge to whisker deflection without directional sensitivity or spontaneous activity. The other 2 cells were tonically activated and 1 of these exhibited spontaneous discharges which could be inhibited by deflection of adjacent whiskers. The morphology and topography of these 18 cells were remarkably consistent. Small round to ovoid shaped multipolar somata (area: 183±78 um^2) were located 0.4-1.6mm rostral to the SpVi-caudalis border, each within the confines of the longitudinal column made by the arbors of primary afferent axons with the same 1 whisker RF. Axons of LC neurons (diameter:1.69±0.66 um) had a transverse trajectory, giving off 2.7±1.3 recurrent collaterals which arborized extensively in the region of the soma with both terminal and en passant boutons. After proceding to an SpVi region remote from the soma, the parent axon always bifurcated. One branch traveled rostrally, within either a nuclear axon bundle or the V spinal tract, to end in subnucleus principalis, while the other branch traveled caudally to end in caudalis. Each branch gave off intermittent non-recurrent collaterals which arborized in topographically appropriate regions of each of the 4 V brainstem subnuclei. The total # of collaterals per subnucleus was variable (e.g. 4.5±1.8 in SpVi). These cells had 4.1±1.2 proximal dendrites which extended 440±140um rostrocaudally and occupied 2.0±1.3 of 4 transverse quadrants surrounding the soma. Thin sinuous dendrites branched extensively within a narrow area adjacent to, or overlapping with, the soma, and rarely gave rise to spines. Rather, they ended in multi-lobed, bulbous, grapelike swellings, connected by slender processes. The dendritic tree had a transverse perimeter of 459±226um and a form factor of .61±.15; neither differed from that of their presumed presynaptic primary afferent arbors (379±87um; .55±.11). An unusual feature of the SpVi LC cell is its extensive internuclear connections. Its somadendritic form, however, is similar to that of inhibitory LC cells in cat lateral geniculate (Hamos et al. Nature 317:618, 1985). SpVi LC cells may control the gating of V primary afferent inputs to projection cells in SpVi and other V subnuclei. Support: DE07662,DE07734,DE06528,BNS8517537, AOA.

145.2 MORPHOMETRIC COMPARISON OF FUNCTIONALLY IDENTIFIED TRIGEMINOTHALAMIC AND TRIGEMINOCEREBELLAR NEURONS IN TRIGEMINAL SUBNUCLEUS INTERPOLARIS. J. Golden*, M. Barcia*, R.W. Rhoades & M.F. Jacquin (SPON: H.P. Zeigler). Dept. Neurosci., NY Coll. of Osteo. Med., Old Westbury, NY 11568 & Dept. Anatomy, NJ Sch. of Osteo. Med., Piscataway, NJ 08854.

A prior study (Woolston et al., J. Neurophys. 48:160, 1982) in rat trigeminal (V) subnucleus interpolaris (SpVi) has shown that thalamic- (VB) projecting neurons have larger receptive fields (RF) than cerebellar- (CB) projecting cells, and that both groups have larger RF's than cells which do not project to either of these targets. In the present study, intracellular recording, electrical stimulation, RF mapping, and HRP injection procedures were used to determine if the structure of these cells differed. 21 VB-, 12 CB-projecting, and 32 local circuit neurons were studied. Most of these (18, 9, and 18, respectively) responded only to whisker deflection and these results are summarized below (Mean ± S.D.; see Jacquin et al., this volume, for data on local circuit neurons):

	Thalamic	Cerebellar
Latency to V ganglion shock	1.32 ± 0.22	1.54 ± 0.34 ms
Latency to antidromic activation	1.12 ± 0.75	0.61 ± 0.09 ms
# of whiskers comprising RF	11.6 ± 5.7	4.4 ± 4.9
Range of # of whiskers	3 - 25	1 - 15
Adaptation properties	all phasic	8 phasic, 1 tonic
mm rostral to caudal SpVi border	0.9 - 1.9	0.8 - 1.6
Soma transverse area	453 ± 198	351 ± 149 um^2
# of proximal dendrites	5.1 ± 1.8	5.0 ± 1.2
Modal dendritic ending	spines	spines
* Dendritic transverse perimeter	1363 ± 557	888 ± 273 um
* Dendritic transverse area	82,670 ± 46,930	48,210 ± 31,760 um^2
Dendritic shape: form factor	0.56 ± 0.20	0.70 ± 0.16
* Rostrocaudal dendritic extent	606 ± 189	412 ± 35 um
Parent axon diameter	2.80 ± 1.22	2.53 ± 1.17 um
* # of axon collaterals in SpVi	1.7 ± 1.9	0

(* - significant difference between groups, $p<.05$)

Transverse and rostrocaudal dendritic extent correlated significantly with RF size both within and between VB- and CB-projecting groups. Moreover, local circuit neurons each responded to only 1 whisker and they had significantly smaller dendritic trees than that of projection neurons. These data suggest that dendritic extent is a mechanism controlling RF size in whisker-sensitive SpVi neurons. The nature of the primary afferent convergence expressed in SpVi projection neurons merits further study. Such cells have multiple whisker RF's, yet they do not respond to deflection of intervening guard hairs or hairy skin, therein resulting in discontinuous RF's. Since these receptor types are innervated by axons which project to whisker regions of SpVi, a mechanism must exist to account for such selectivity in primary afferent convergence.

145.3 RECEPTIVE FIELD SYNTHESIS IN TRIGEMINAL SUBNUCLEUS INTERPOLARIS. I. CORTICAL INPUTS. K.L. Rossner & M.F. Jacquin. Dept. of Neuroscience, New York College of Osteopathic Medicine, Old Westbury, NY 11568.

Rat trigeminal (V) subnucleus interpolaris (SpVi) receives inputs from both low and high threshold primary afferents, ipsilateral V subnucleus caudalis and amine containing nuclei, and contralateral somatosensory cortex. The resultant receptive field (RF) properties of SpVi cells can be summarized: local circuit neurons have small low threshold RF's, each reflecting input from 1 class of receptor organs (e.g. 1 whisker); thalamic- (VB) or cerebellar- (CB) projecting SpVi cells have larger low threshold RF's, yet convergence is restricted to 1 class of receptor organs (intramodality; e.g. multiple whiskers). RF size correlates with dendritic tree area, though it remains to be determined why nociceptive inputs are not widely reflected in SpVi RF's, and why multi-whisker-sensitive projection neurons do not respond to intervening guard hairs or skin. Since these receptor organs are innervated by axons which project to SpVi whisker regions, primary afferent segregation cannot account for these 'discontinuous', modality-specific RF's. To determine the role of cortical input in the synthesis of SpVi RF's, right somatosensory cortex was removed in 7 adult rats. 4-34 days later, single unit recording, electrical stimulation, and RF mapping techniques were used to study the responses and projections of 235 cells in left SpVi. In 13 cells, projection status was verified by intracellular HRP staining. Physiological data are summarized below, compared with that of 208 cells from 27 normal rats:

	Cortex Ablated	Normal
Mean latency (±SD) to V ganglion shk.	1.43 ± 0.41 ms	1.43 ± 0.57
Mean # of spikes/ganglion shk. at 2XT	1.93 ± 1.24	1.88 ± 1.20
% VB- vs CB-projecting vs local circ.	17.0,11.5,71.5	28.8,10.6,60.6
% best-responsive to noxious stimuli	2.5	2.4
% with intermodality convergence	7.7	0.0
% unresponsive to any stimulus	7.2	0.5
% whisker(s)-sensitive	55.7	63.5
Mean # of whiskers (VB-project)	7.12 ± 4.98	9.23 ± 5.41
Mean # of whiskers (CB-project)	2.56 ± 2.18	3.11 ± 2.45
Mean # of whiskers (local circuit)	1.83 ± 2.01	1.04 ± 0.27
% local circuit with > 1 whisker RF	27.5	2.9
% with spontaneous discharges	26.8	17.3
% phasic vs tonic evoked responses	77.9 vs 14.9	91.3 vs 8.2
% with directional sensitivity	12.3	5.3
% with inhibitory surround	5.1	3.4
% with split or cervical RF's	0.8, 0.4	0.0, 0.0

The RF's of 41 V primary afferents were normal, as was the topographic organization of SpVi. Qualitative effects include the incidence of multiple-whisker-sensitive local circuit, and intermodality convergent, cells. The relative #'s of nociceptors were unchanged. Thus, cortical inputs contribute to RF size and convergence in a small # of low threshold SpVi neurons. Other quantitative effects remain to be substantiated. Support: NIH (DE07662, DE07734), AOA.

145.4 RECEPTIVE FIELD SYNTHESIS IN TRIGEMINAL SUBNUCLEUS INTERPOLARIS. II. INPUTS FROM SUBNUCLEUS CAUDALIS. B.H. Hallas & M.F. Jacquin. Dept. of Neuroscience, N.Y. Coll. of Osteo. Med., Old Westbury, NY 11568.

In an accompanying abstract (Rossner & Jacquin, this volume), we described the effects of cortical ablation upon the receptive field (RF) properties of neurons in trigeminal (V) subnucleus interpolaris (SpVi). Cortical inputs were shown to contribute to RF size, and the type of afferent inputs expressed (modality convergence), in a small # of low threshold SpVi neurons. The relative # of nociceptors was unchanged. A similar experimental paradigm was used here to clarify the role of V inter-subnuclear connections in the synthesis of SpVi RF's in the barbiturate-anesthetized rat. Intra- and extracellular recording, electrical stimulation, and RF mapping were used to study the responses and projections of 403 SpVi cells in 11 rats, 39-113 days after surgical isolation of V subnucleus caudalis from SpVi. Transverse hemisections were made through the lateral half of the left medulla just caudal to the obex. Since this lesion severs V primary afferents caudal to SpVi, as well as postsynaptic inter-subnuclear axons traversing to and from SpVi, kainic acid was used to selectively remove caudalis inputs to SpVi. 5 rats received kainic acid injections into caudalis 4-21 days prior to providing similar data on 294 SpVi cells. Projection status was verified in each of 13 cells stained with HRP. Physiological data (mean ± SD; %) are summarized below and compared with that of 386 cells from 9 normal adult rats:

	Hemisect	Kainic Acid	Normal
Latency to V ganglion shock (ms)	1.52 ± 1.2	1.64 ± 1.3	1.46 ± 0.5
% VB-project vs interneurons	15.9, 84.1	16.7, 83.3	26.0, 74.0
% nociceptive-biased	3.72	4.76	3.15
% with intermodality convergence	4.96	12.58	0
% unresponsive to any stimulus	16.62	12.24	1.02
% whisker(s)-sensitive	36.97	37.75	35.12
# of whiskers in RF (VB-project)	6.4 ± 2.4	8.6 ± 2.9	5.1 ± 2.3
# of whiskers in RF (interneur.)	3.1 ± 1.4	2.8 ± 1.3	1.0 ± 0
% interneur. with > 1 whisker RF	33.89	34.09	0.0
% with spontaneous discharges	31.91	34.78	9.13
% phasic vs tonic evoked resp.	59.3, 24.1	59.2, 28.6	88.0, 11.0
% with directional sensitivity	8.91	6.13	4.27
% with split or cervical RF's	3.0, 2.2	5.4, 2.0	0.0, 0.0

V primary afferents rostral to hemisection had normal RF's (N=67) and collateral arbors (N=11). Cell topography was also normal. Kainic acid and hemisection produced significant #'s of local circuit neurons with multi-whisker RF's, as well as cells expressing intermodality convergence (e.g. whisker plus guard hair). Significant #'s of spontaneously active and unresponsive neurons were also recorded, while the nociceptor encounter rate was unchanged. Thus, caudalis inputs contribute to RF size, modality convergence, responsiveness, and baseline activity in a substantial # of SpVi cells. These effects are qualitatively similar to those observed following lesions of somatosensory cortex. Support: NIH (DE07662, DE07734), AOA.

145.5 PROJECTION PATTERNS FROM PRIMATE AND FELINE DENTAL STRUCTURES TO CENTRAL TRIGEMINAL NUCLEI. L. E. Westrum[1], L. R. Johnson*[2], M. A. Henry[3], and R. C. Canfield*[4]. (SPON: R. Haschke). Depts. of Neurosurg.[1,4], Biol. Structure[1], and Restorative Dentistry[4], Univ. of Wash., Seattle, WA 98195; Depts. of Surg. Dent., and Cell. and Struct. Biol.[2], Univ. of Colo., Denver, CO 80262, and Facial Pain Ctr.[3], Univ. of Florida, Gainesville, FL 32610.

The distribution of dental afferents to the brain stem trigeminal nuclear complex (TNC) is being studied and compared in cat and monkey using intrapulpal application of the toxic lectin ricin (Ricinus communis agglutinins; RCA 60) and subsequent light microscopic methods for staining degeneration. We have previously shown that these preparations in cat probably demonstrate a more accurate and complete picture of the central distributions of dental afferents than is seen with transganglionic degeneration after dental lesions only or transganglionic transport of HRP from tooth pulps. Adult healthy Macaca fascicularis under deep anesthesia received unilateral intrapulpal injections of ricin (2-8 µl, 0.1% ricin-RCA 60) in all the teeth in both maxillary and mandibular quadrants. The dental pulps were exposed by an occlusal access and injections made immediately with minimal manipulation and only into the superficial part of the pulp. The animals were sacrificed after 8 days. The ganglia were prepared for cell stains and the brain stems frozen sectioned in the transverse plane; then serial (1 in 8) sections were stained by the Fink-Heimer method. The degeneration in the brain stem is striking, as it is distributed throughout all TNC subnuclei ipsilaterally. The distribution often appears as columns, with a medio-lateral orientation at dorsal, middle and ventral levels. In contrast to cat, also after ricin application, the monkey shows more ventral terminations in the main sensory nucleus and less of a ventral projection in the spinal subnuclei caudally. The monkey also has terminations in deeper laminae, often in isolated clusters, in subnucleus caudalis and at the C-1 level. The findings show clear differences, but with some similarities between primate and feline dental projection patterns.

(Supported by NIH Grants DE04942 and NS20482. LEW is an affiliate of the CDMRC, University of Washington.)

145.6 NEUROTRANSMITTER LOCALIZATION IN THE FELINE TRIGEMINAL MAIN SENSORY NUCLEUS. L.R. Johnson*[1], L.E. Westrum[2], and M.A. Henry[3] (Spon: B.R. Fink) [1] Depts. of Surgical Dentistry and Cellular and Structural Biology, Univ. of Colo., Denver, CO 80262, [2] Depts. of Neurological Surgery and Biological Structure, Univ. of Wash., Seattle, WA 98195, [3] Facial Pain Center, Univ. of Florida, Gainesville, FL 32610.

Previous studies have examined the localization of neurotransmitters within the caudal subnuclei of the brain stem trigeminal nuclear complex but apparently none have examined the main sensory nucleus (MSN). The purpose of the present study is to describe the immunocytochemical localization of neurotransmitters in the MSN.

Normal cats with no oral or facial pathosis were anesthetized with Ketamine and maintained on a respirator (O_2-Halothane) and then transcardially perfused with either 4% PLP in a 0.1 M PO_4 buffer or 0.1 M PO_4 buffered solution containing 3% paraformaldehyde and 0.1% picric acid followed by washes of 10 and 30% sucrose in the same buffer. Following the perfusions the brain stems were removed from the cranial vault and stored in 30% sucrose in 0.1 M PO_4 buffer for 48 hrs. Frozen sections (35um) were taken and processed using the indirect PAP method of Sternberger. Sections from the brain stems perfused with 4% PLP were incubated with primary antibodies to somatostatin, substance P (graciously provided by Dr. R.H. Ho), met-enkephalin or cholecystokinin. Sections perfused with the picric acid solution were incubated with antibodies to choline acetyltransferase.

Small and medium size somatostatin positive neuronal profiles are present in both the dorsomedial (DM/MSN) and ventrolateral (VL/MSN) MSN. Terminal arbors and boutons en passant positive for substance P are also present in both subdivisions of MSN. Met-enkephalin positive small and medium size cell bodies and terminals are only present in VL/MSN just rostral to pars oralis. A modest number of cholecystokinin positive terminals appear to be randomly distributed throughout the entire MSN. Large, medium and small neuronal cell bodies positive for choline acetytransferase are seen in VL/MSN, with the greatest numbers of positive profiles in VL/MSN just rostral to pars oralis, within DM/MSN a few medium and small choline acetytransferase containing neurons are present.

In summary this study indicates that systems using substance P and possibly cholecystokinin send projections to MSN, while projecting or intrinsic neurons in the MSN use somatostatin, met-enkephalin or acetylcholine as neurotransmitters. Supported by NIH grants DE04942 and NS20482. L.E.W. is an affiliate of the CDMRC Univ. of Washington.

145.7 FINE STRUCTURAL CHARACTERISTICS AND SYNAPTIC CONNECTIONS OF TRIGEMINOCEREBELLAR PROJECTION NEURONS IN RAT TRIGEMINAL NUCLEUS ORALIS. W.M. Falls, B.J. Moore*, and M.T. Schneider*. Dept. of Anatomy, Michigan State Univ., East Lansing, MI 48824.

Retrograde horseradish peroxidase (HRP) studies in our laboratory (Falls, W.M. and M.M. Alban, Somatosensory Res., 4:1-12, 1986) have shown that the dorsal one-half of the border zone (BZ) of rat trigeminal nucleus oralis includes among its neuronal population a morphologically distinct type of trigeminocerebellar projection neuron (TCPN) that innervates the orofacial portions of one or more of the four major tactile areas of the ipsilateral cerebellar cortex (i.e., crura I and II, the paramedian lobule, and the uvula). The presynaptic elements contacting BZ TCPN's were classified following electron microscopical examination of serial sections made from two of these cells which were retrogradely labeled with HRP following injections into ipsilateral crura I and II of the cerebellar hemispheres. In one experiment, an ipsilateral trigeminal sensory root rhizotomy was also performed in order to determine if identified BZ TCPN's receive direct primary trigeminal afferent input. Three types of axon terminals contacting proximal as well as higher order labeled dendrites have been recognized. By far the most numerous endings (Type I) are filled with clear, spherical to oval synaptic vesicles and form at least one asymmetrical axodendritic contact. Synapsing less frequently on dendritic shafts are boutons (Type II) containing pleomorphic synaptic vesicles and forming symmetrical to intermediate synaptic junctions. The least frequently encountered synaptic terminal (Type III) contains flattened synaptic vesicles and makes a single symmetrical synaptic contact with a dendritic shaft. The cytological heterogeneity of these three terminal types suggests that the activity, and therefore the efferent output of BZ TCPN's is influenced by axons from multiple neuronal origins. In addition, the density and placement of Type I endings along the entire dendritic tree would suggest that the cells of origin of this terminal type play a major role in controlling the activity of BZ TCPN's. The rhizotomy portion of this study indicates that a number of Type I endings are derived from primary trigeminal neurons. Type I endings, displaying dark degeneration after a two day survival period, are positioned centrally in simple glomeruli where each forms an axodendritic synapse on a single higher order dendrite of an identified BZ TCPN. No degenerating endings synapsed on proximal dendrites. It is at these synapses that the possible transfer of orofacial tactile inputs to BZ TCPN's are made by Type I endings for direct relay to crura I and II. Transmitter release at the axodendritic synapses may be modified presynaptically within the glomeruli by axoaxonic synapses between a terminal containing flattened synaptic vesicles and the Type I ending. (Supported by NIGH Grant DE06725)

145.8 PROGRESSIVE ACTIVATION OF THE PARATRIGEMINAL NUCLEUS DURING ENTRANCE TO HIBERNATION. T. S. Kilduff, C.D. Radeke*, F. R. Sharp and H. C. Heller*. Depts. of Psychiatry and Biological Sciences, Stanford Univ., Stanford, CA 94305 and Dept. of Neurology, Veterans Admin. Med. Cntr., San Francisco, CA 94121.

The paratrigeminal nucleus (PTN) is a brainstem structure whose function is unknown and whose anatomical connections are poorly understood. Originally described by Ramon y Cajal, the PTN was virtually ignored until the morphological and immunohistochemical studies of Chan-Palay in 1978. We have previously reported that, in the squirrel, the PTN is the only one of 85 brain structures examined to undergo a significant increase in its relative 2-deoxyglucose (2DG) uptake during deep hibernation in comparison to euthermia. We now report that, during the transition from euthermia to deep hibernation, there is a progressive activation of the PTN that is reversed during arousal.

Citellus lateralis, maintained at 5°C and under an LD 12:12 photoperiod, were prepared with chronic jugular catheters and subcutaneous re-entrant tubes. Animals were injected in darkness with [^{14}C]2-deoxyglucose (150 uCi/kg) during seven phases of the hibernation cycle: euthermia (n=16), three body temperature (T_b) intervals during entrance to hibernation (T_b=30°-25°C, n=4; T_b=25°-20°C, n=4; and T_b=20°-15°C, n=6), deep hibernation (T_b<8°C, n=6), and both early (T_b < 8°-35°C, n=4) and late (T_b=25°-35°C, n=5) in arousal from hibernation. The 2DG was allowed to incubate for 45 min in the euthermic animals. Because of the influence of T_b on metabolism, the incubation period was longer in the other experiments and was inversely proportional to the animal's metabolic rate. Animals were terminated by a sodium pentobarbital overdose, the brains were removed, frozen, sectioned at 20u and exposed to x-ray film for 7 days.

The PTN was readily apparent on the resultant autoradiographs of animals injected during the latter two phases of entrance and deep hibernation but not obvious during euthermia, arousal or the early phase of entrance to hibernation. Optical density (O.D.) measurements were made from the autoradiographs of the PTN and 94 other neural structures using a densitometer. O.D. ratios were calculated for all 95 structures as the ratio of the O.D. of the structure to the mean O.D. of all 95 brain structures. Analysis of variance revealed a highly significant increase in the O.D. ratio of the PTN as T_b decreases ($p < 0.001$; $F = 105.5$, $df = 4, 31$). As T_b increases during arousal from hibernation, the O.D. ratio progressively declines ($p < 0.001$; $F = 109.3$; $df = 3,27$). All 95 neural structures were also ranked in order of O.D. ratio, from highest to lowest, across the seven phases of the hibernation cycle. Whereas the PTN ranked #90 of 95 structures during euthermia, it rose during entrance from #55 in the T_b range 30°-25°C, to #36 in T_b=25°-20°C to #5 in T_b=20°-15°C to #1 during deep hibernation. These changes in ordinal rank indicate that the PTN is progressively increasing its 2DG uptake during entrance to hibernation relative to all brain structures.

These observations implicate the PTN as playing a role in the entrance and maintenance of hibernation and support the hypothesis that the PTN is a thermoafferent relay whose activity is enhanced by decreased T_b (Supported by NSF BNS-8216918 to HCH).

146.1 AREA CA_1 OF THE HIPPOCAMPUS OF THE RAT PROJECTS TO THE CONTRALATERAL HIPPOCAMPAL FORMATION. Th. van Groen* and J.M. Wyss (SPON: E.E. Geisert). Department of Cell Biology and Anatomy, University of Alabama at Birmingham, Birmingham, AL 35294.

Extensive research into the commissural projections of the hippocampus in the rat has indicated that all commissural projections from the hippocampus proper originate in neurons within the CA_2, CA_3 and CA_4 regions. In contrast, the CA_1 pyramidal neurons were not considered the origin of any commissural projection but were thought to project only ipsilaterally to the subiculum, entorhinal cortex, lateral septal nuclei and perhaps to CA_1 itself. In order to further investigate the connections of area CA_1, anterograde and retrograde tracing studies were conducted. 5 - 20 nl injections of wheat germ agglutinin conjugated horseradish peroxidase (WGA-HRP) or [^{3}H] amino acids were made ipsilaterally into area CA_1. Following all injections into the septal third of CA_1 anterograde label could be seen in the contralateral subiculum (pyramidal layer) and somewhat lighter labeling was present in area CA_1 (stratum oriens and stratum radiatum). Also, labeling was present in layers I, III and V of the contralateral postsubiculum. To confirm the CA_1 origin of the projection, injections of retrogradely transported fluorescent dye tracers were made into the subicular complex and/or area CA_1. Following all injections into the septal portion of the postsubiculum, subiculum, and CA_1 fields, neurons in the pyramidal layer of the contralateral area CA_1 were labeled. This labeling occurred over a rather discrete region of area CA_1 that was similar in septo-temporal extent to the injection site. The CA_1 projection appears to be confined to the septal third of the field. Together these results demonstrate that the small pyramidal cells of area CA_1 do project to the contralateral hippocampal formation.

146.2 BRAINSTEM DISTRIBUTION OF HORSERADISH PEROXIDASE AFTER INJECTION OF THE NODOSE GANGLION IN MACAQUES. A.P. Knox, N.L. Strominger and D.O. Carpenter. Dept. of Anatomy, Albany Medical College, Albany, NY 12208.

Horseradish peroxidase conjugated to wheat germ agglutinin [10 µl, 1%] was injected unilaterally into the nodose ganglion in four monkeys, 'Macaca fascicularis'. After 24-36 hours, animals were anesthetized and perfused transcardially with saline followed by 4-8% gluteraldehyde. Brainstems, blocked either transversely or in the horizontal plane, and cervical spinal cords were sectioned at 50 µm and reacted with tetramethyl benzidine. Alternate sections were stained with neutral red.

Retrograde labeling of perikarya occurred ipsilaterally in the following brainstem nuclei: dorsal motor of the vagus, ambiguus, retroambiguus, and occasionally in the various subnuclei of the solitary complex. Many neurons were labeled in the ipsilateral retrofacial nucleus as well as a few on the contralateral side. Afferent fibers and terminal label was present in the throughout the region of the solitary nuclei, in the area postrema and in the pre-area postrema. Within the cervical spinal cord, the dorsomedial nucleus and spinal nucleus of the accessory nerve were labeled ipsilaterally.

The nucleus ambiguus in all cases consisted of two populations of labeled neurons, a cluster of larger cells tending to be diffuse and located in dorsal and medial parts of the nucleus, and a cluster of smaller more compactly arranged neurons tending to be in ventral and lateral parts of the nucleus. The latter appeared similar in size and configuration to cells of the dorsal motor nucleus of the vagus.

146.3 IDENTIFICATION OF NUCLEI IN THE HUMAN BRAINSTEM: A CHEMOARCHITECTONIC APPROACH USING ACETYLCHOLINESTERASE REACTIVITY G. Paxinos and I. Tork. School of Psychology and School of Anatomy, University of New South Wales, Sydney, Australia 2033

The present study attempts to establish the human homologues to nuclei identified in other animals by considering the chemoarchitectonic profile of nuclei. We report that nuclei known to have intense acetylcholinesterase (AChE) reactivity in the rat are similarly reactive in the human. Thus, in the lateral tegmentum, the parabigeminal nucleus shows intense reactivity in both species. The most intense AChE reactivity in the tegmentum is associated with the pedunculopontine tegmental nucleus (PPTg). This nucleus straddles the lateral aspects of the superior cerebellar peduncle. The lateral dorsal tegmental nucleus is also reactive in both species. Cell bodies reactive for AChE were observed in the locus coeruleus, PPTg, and compact part of the substantia nigra. Cajal identified in the kitten the rhabdoid nucleus as a parvocellular zone girthing the posteroventral aspects of the decussation of the superior cerebellar peduncle and connecting the interpeduncular nucleus with the dorsal tegmental nucleus. The Rhabdoid nucleus is AChE reactive in all mammalian species studied including the human. We conclude that while species variations in the content of neuroactive compounds of different nuclei occurs, the chemoarchitectonic profile of homologous nuclei is remarkably stable.

146.4 THE STRUCTURE OF NEURONS THAT CONTRIBUTE TO LAYER I DENDRITIC BUNDLES IN THE RAT RETROSPLENIAL CORTEX. J.M. Wyss and Th. van Groen.* Department of Cell Biology and Anatomy, University of Alabama at Birmingham, Birmingham, AL 35294.

Recently we have demonstrated that layer II neurons in retrosplenial cortex of the rat display a point to point commissural projection and that apical dendrites of these neurons form tight bundles in layer I. The region of the bundles receives thalamic input, while the area between the bundles receives cortical and little or no thalamic input. In the present study we employed the fixed slice preparation to identify the structure of the neurons that contribute dendrites to these dendritic bundles, and compared them to cells in layer III that do not appear to have dendrites in the bundles. In each of 10 rats, an initial injection (10-30 nl) of fluorogold (2%) was made into the right retrosplenial cortex and following a 4 day survival, the rats were perfused with 150 ml of 4% paraformaldehyde, the brain was removed from the skull, the retrosplenial cortex was blocked and 100-200 µm sections were cut on a vibratome and stored at 4^{0}C until used. Under fluorescent illumination, fluorogold labeled cells in layer II were impaled with a glass micro-pipette containing Lucifer Yellow (4%). When a layer II cell was penetrated, negative electrical current was passed through the pipette solution to force the dye into the cytoplasm. In other cases we have filled both commissural and noncommissural layer III cells. The results of these studies indicate that the layer II neurons of the retrosplenial granular cortex display long apical dendrites and only very short and thin basal dendrites. The apical dendrites invariably begin to arborize in layer Ib and reach their greatest extent of arborization in layer Ia. Many of the apical dendrites do not ascend perpendicular to the pial surface of the brain, but angle through layer Ic and then turn and ascend through layer Ib and Ia. Dendritic spines are primarily located on the distal portions of these dendrites. In contrast to layer II cells, layer III neurons display better developed basal dendrites, and apical dendrites that arborize extensively in layer Ib and Ic but have few branches in layer Ia. Further the layer III neurons have a larger and triangular shaped cell body while the somata of layer II neurons tend to be small and spindle shaped. These data clearly demonstrate that the layer II commissural neurons which form dendritic bundles in the retrosplenial cortex are morphologically different from layer III commissural and non-commissural neurons.

146.5 CORTICAL STRUCTURE IN FRONTAL REGIONS OF THE WEST INDIAN MANATEE (Trichechus manatus) R.L. Reep, J.I. Johnson, R.C. Switzer, W.I. Welker. Department of Neuroscience, University of Florida, Gainesville, FL 32610; Anatomy Department, Michigan State University, East Lansing, MI 48824; Department of Pathology, University of Tennessee, Knoxville, TN 37920; Department of Neurophysiology, University of Wisconsin, Madison, WI 53706.

Cortical architecture was examined in Nissl, myelin, AChE and cytochrome oxidase material from four brains. In general, the cortex exhibits a high degree of organization, with well defined laminae, robust cell densities, and a markedly striated layer VI.

In the pregenual region, the medial wall and ventromedial cortex are characterized by a prominent layer II that is compact and continuous, broad layer III, no granular layer IV, and large celled layer V with clear layer Vb. Proceeding from the midline onto the dorsolateral surface, layer II becomes progressively less distinct; layer V is thinner, contains smaller cells which are more sparsely distributed, and a less distinct Vb. There appears to be a granular layer IV which merges with the small pyramidal cells of layer III.

Ventrolaterally, the medial wall structure continues until the junction of the olfactory peduncle with the basal cortex. Dorsal to the shallow rhinal fissure, layer II becomes more irregular and a lamina dissecans is seen between poorly defined layers III and V. There is no visible claustrum or extreme capsule. Instead, distinct cell clusters (150-500um dia) become visible in layer VI, and extend dorsally into in an otherwise typical dorsolateral cortex. These clusters are spaced at fairly regular 500-1000um intervals. Likewise, a deeply situated AChE-positive band extends dorsally from the rhinal fissure, becoming fragmented and coextensive with the cell clusters seen in layer VI. Proceeding caudally, layer VI clusters are distributed continuously into progressively more dorsal cortical areas, until a prominent fissure is reached.

Dexler (1913, Gegenbaus morphol. Jahrbuch 45:97) first noted these cell clusters in the brains of the other extant Sirenian genus, Dugong, and termed them Rindenkern, or cortical nuclei. They may represent a fragmented claustrum or specializations peculiar to somatic sensory cortex.

146.6 **TELENCEPHALIC REGIONAL VOLUMETRIC ASYMMETRIES IN TARSIERS AND LORISES.** M-C de Lacoste, T. Adesanya*& D. J. Woodward. *Department of Cell Bio. & Anat. UTHSCD, Dallas, TX 75235.*

One of the goals in our laboratory is to detemine if cerebral asymmetry has been selected as a trait expressed during speciation within the primate order. In previous studies we have described telencephalic regional volumetric asymmetries in the family **Lemuridae** and in some species from superfamilies **Ceboidea, Cercopithecoidea & Hominoidea**. Outstanding prefrontal asymmetry appeared to be characteristic of ceboid cerebra, while most of the remaining primate brains exhibited striking retrocalcarine asymmetries [de Lacoste et al, 1986]. This study was undertaken to delineate hemispheric regional volumetric asymmetries in **Tarsiidae**[N=4], a family of Haplorhines, and in **Lorisidae** [N=12], a family of strepsirhines. There is a fairly wide range of brain morphology for the different species within family Lorisidae. The cerebrum of *Galago demidovii*, for example, is nearly lissencephalic, excepting a Sylvian fissure and calcarine complex. In contrast, the brain of *Nycticebus coucang* exhibits a number of sagitally oriented fissurets, some of which may serve as limiting sulci for cytoarchitectural zones [Sanides & Krishnamurti, 1966]. In family Tarsiidae, cerebral gyral and sulcal patterns are more uniform, albeit unique. The Sylvian or pseudosylvian fissure is actually a small groove, the corpus callosum is narrow and short, frontal cortex is relatively small, temporal cortex is poorly developed and cerebellar foliation is minimal. Striate and extrastriate areas, however, are very well developed and appear to comprise the largest part of the neocortex. We were, therefore, especially interested in determining if regional volumetric asymmetries in tarsiers are more pronounced in visual and visual-related areas.

Complete anterior to posterior series of coronal sections [cut at 10-20μ] were photographed and digitized. Sectional and regional volumes were integrated using the laboratory CARP system and SPSSx. Correction factors and a set of indices of asymmetry were calculated using algorithms developed for these purposes. Anatomical delimiters varied with the species but included the rectus, arcuate, central, intraparietal, lunate, para-, pre- and retro-calcarine sulci as well as the genu of the corpus callosum and lateral geniculate nucleus.

Results indicated that species within family Lorisidae manifest variant patterns of regional volumetric asymmetries. Some of the species [e.g., *Galago demidovii* and *Nycticebus coucang*] evidenced pronounced prefrontal but little striate and extrastriate regional volumetric asymmetries. Other species [e.g., *Galago senegalensis*] displayed significant retrocalcarine asymmetries similar to those described for other strepsirhines [de Lacoste et al, 1985]. In contrast, the tarsier cerebra consistently manifested a high percentage difference between left and right striate and extrastriate cortical volumes. We believe that the retrocalcarine asymmetry exhibited by the tarsiers demonstrates the significance of asymmetry in primate brain specialization.

146.7 **ORGANIZATION OF MOTONEURONS INNERVATING EPAXIAL AND HYPAXIAL MUSCULATURE IN THE FROG, RAT, AND MONKEY.** M. Kramer, T. Deacon, A. Sokoloff, and A. Filler. Biological Anthropology, Harvard University, Cambridge, MA 02138.

Recent tracer studies have demonstrated a segregation of motoneurons innervating epaxial versus hypaxial muscles in snakes and rats but not in fish and mudpuppies, suggesting possible differences in the organization of motoneurons innervating axial muscles in amniotes and anamniotes (Fetcho, J., J. Comp. Neurol., 249:521, 1986). To establish a broad comparative base for investigating the organization of motoneurons that innervate axial musculature, we have used WGA-HRP to trace the innervation of individual epaxial and hypaxial muscles in two species of mammals, the rat and cynomolgus monkey, and an anuran species, the grass frog. Individual muscles were injected with from 0.5-2.5 microliters of tracer. After 24-72 hours animals were sacrificed and perfused, then muscles and spinal cords were removed, sectioned and processed for peroxidase using the tetramethyl benzidine histochemical method.

In the rat and the monkey a single unilateral injection of WGA-HRP into either an erector spinae or transversospinalis muscle labels a multisegmental column of motoneurons occupying the extreme ventral tip of the ipsilateral ventral horn. An injection into the rectus abdominis muscle in either mammalian species labels a column of motoneurons that is centrally placed in the ventral horn and extends from its medial to its lateral edge. Unilateral injections into the rectus muscle result in both ipsilateral and contralateral cell labeling. In the grass frog unilateral injections into epaxial musculature label a column of motoneurons located in the ventral tip of the ipsilateral ventral horn although a few labeled neurons are located more dorsally. Injections into the frog rectus muscle label motoneurons that are located centrally in the ventral horn although a few labeled cells are located near the ventral tip of the ventral horn. Unilateral injections into the frog rectus muscle result in both ipsilateral and contralateral cell labeling.

These results demonstrate a discrete dorsoventral segregation of motoneuron columns innervating epaxial and hypaxial muscles in the rat and monkey. A similar though less discrete pattern is also evident in an anamniote, the frog. A pattern of ipsilateral epaxial versus bilateral hypaxial muscle innervation is observed in both mammalian and anuran species. The multisegmental labeling observed following extremely small single muscle injections indicates that a relatively large number of neurons innervate individual axial muscles and suggests the possibility that many of these neurons project to multiple muscles.

146.8 SURFACE FEATURES OF THE FOREBRAIN OF THE BOWHEAD WHALE, BALAENA MYSTICETUS. D. W. Duffield* (SPON: W. Flory). Dept. of Veterinary Anatomy, School of Veterinary Medicine, Louisiana State University, Baton Rouge, LA 70803.

Very little information is available on the brain of the bowhead whale, a large right whale that inhabits Arctic waters. Hunted almost to extinction in the last century by commercial whalers, it now may be threatened by oil and gas exploration and drilling within its range. It is now legally hunted only by Eskimos for their subsistence. Initial studies on the brain of this endangered species were done in conjunction with an environmental impact study.

Observations were made on 11 Eskimo-harvested bowhead whale brains that were removed via the extremely large foramen magnum. Tissues were fixed on site in 10% formalin. All were damaged in removal. Six had been sliced into 1 cm sections. The brain of the bowhead whale is similar to other cetacean brains and particularly to the brain of the Southern right whale. The hippocampus is relatively small, but does protrude into the lateral ventricle. An olfactory peduncle is present as in other baleen whales. An olfactory bulb has not been recovered, but is presumed to exist, because there are nerve fibers in the peduncle. The lateral part of the rostral rhinal sulcus is difficult to locate grossly. Semilunar and ambient gyri are visible on the rostromedial aspect of the temporal lobe. The olfactory tubercle is characteristically large, and the diagonal band is readily discernible. Clefts in the bowhead brain are similar to those described in other cetacean brains. The insula is modestly developed. The pineal body is present in the choroid plexus of the third ventricle ventral to the splenium corporis callosi. There is no interthalamic adhesion. The caudolateral thalamus is well developed, and the medial geniculate body is large. The lateral geniculate body is a definite raised structure on the caudolateral extremity of the thalamus.

The cooperation of the tissue collectors and whaling captains is gratefully acknowledged. Initial funding was by the University of Maryland from Bureau of Land Management funds and subsequent funding from the North Slope Borough, Barrow, AK.

146.9 DISTRIBUTION OF MONOAMINERGIC, CHOLINERGIC, GABAERGIC, AND PEPTIDERGIC MARKERS IN THE HUMAN CEREBRAL CORTEX. F. Javoy-Agid*, B. Scatton[a], P. Cervera*, M. Ruberg*, R. Raisman*, H. Taquet[b]*, J.J. Benoliel[b]*, A. Maubourgne[b]*, F. Cesselin[b]*, S. Jegou[c]*, H. Vaudry[c]*, Y. Agid* (SPON: A. Enjalbert). INSERM U 289 and b U 288 - CHU Pitié-Salpêtrière - 75013 Paris - a Synthélabo-LERS - 92220 Bagneux - c Groupe CNRS 650 - 76130 Rouen - FRANCE.

A detailed biochemical study of the distribution of various markers of neurotransmitter systems was investigated in the entirety of the cerebral cortex in human brain postmortem. The brains from two subjects with no known neurological or psychiatric disease were examined. The frozen hemispheres were cut in 9 mm frontal sections throughout the entire rostrocaudal extent. On each of the 23 sections -divided in 4 equal portions- the entire cortical gray matter (separated from the white matter) was dissected out. Biochemical assays were performed on an aliquot of the tissue of each different parts. The presence of classical neurotransmitters and neuropeptides in all cortical samples suggests a widespread distribution throughout the cerebral cortex. However, each biochemical marker distributed heterogeneously in a distinct pattern. The ascending monoaminergic and cholinergic systems project in a non uniform manner. The highest noradrenergic innervation was found in the fronto-parietal area, whereas the dopaminergic input seemed denser in the prefrontal cortex. The serotonin innervation predominated in the prefrontal and temporal regions. CAT activity, a marker for cholinergic systems, was high in prefrontal and temporal cortex. The distribution of GAD activity most likely corresponding to intrinsic GABAergic neurons appeared quite uniform. Low content in monoaminergic markers was found in the occipital region. In general, neuropeptides were concentrated in the prefrontal and rostral part of the temporal cortex (VIP, Substance-P, CCK-8), with an exception for opioid peptides (met and leu-enkephalin) which concentrated in the occipital region.

146.10 IMMUNOHISTOCHEMICAL MAPPING OF ADENOSINE DEAMINASE-CONTAINING NEURONS IN SEPTAL NUCLEI AND IN FIBER PROJECTIONS TO THE MEDIAL HABENULA. K.M. Dewar, T. Yamamoto, W.A. Staines, P.E. Daddona*, J.D. Geiger and J.I. Nagy. Department of Physiology, Faculty of Medicine, University of Manitoba, Winnipeg, Manitoba, R3E 0W3.

The localization of neurons containing adenosine deaminase (ADA) within various nuclei of the septum and the septal efferent projection to the medial habenula has been investigated. ADA-immunoreactive neurons were identified within the posterior septum, namely the septofimbrial and triangular septal nuclei, and within the dorsal and ventral regions of the lateral septal nuclei. Intense ADA-immunostaining was also seen in the densely packed neurons of the bed nucleus of the anterior commissure. Furthermore, numerous ADA-immunoreactive fibers were detected in the stria medullaris and these fibers appeared to give rise to an ADA-containing terminal field, which was of a fine punctate nature, in the medial habenula. The existence of this putative ADA-containing projection from the posterior septal nuclei to the medial habenula via fibers in the stria medullaris was further investigated by the use of retrograde tracing and lesion techniques. Microiontophoretic injection of Fluoro-gold into the medial habenula resulted in the retrograde labelling of a large number of ADA-positive neurons within the septofimbrial (95-97%) and triangular septal nuclei (95%), and in the majority of the neurons in the bed nucleus of the anterior commissure. In addition, unilateral transection of the stria medullaris effectively reduced immunostaining for ADA in the medial habenula posterior to the lesion with a concomitant reduction in ADA activity (40%) in the medial habenula ipsilateral to the side of the lesion.

In summary, the present study demonstrates ADA-immunostaining within subpopulations of neurons in septal nuclei. These findings are consistent with the highly restricted distribution of ADA-immunoreactivity elsewhere in the rat brain. Furthermore, a major projection of ADA-containing neurons from the posterior septal nuclei to the medial habenula has been documented. ADA may prove to be a useful marker to delineate septal subregions and to distinguish their anatomical relationships with other brain areas. Whether ADA-immunoreactivity in septal neurons and in neurons elsewhere in the rat CNS reflects their utilization of purines as transmitters and/or neuromodulators is still a matter of speculation.

146.11 EVOLUTION OF THE PRIMATE SUBICULUM. E. Armstrong and G. T. Frost*. Dept. of Anatomy, Louisiana State University Medical School, New Orleans, LA 70112.

Previous studies have shown that the sizes of structures in the limbic system are correlated both with brain size and phylogenetic position. A morphometric study on the subiculum, the major output zone of the hippocampal region in primates, allowed us to test several hypotheses regarding its size. The data were collected from 16 primate species, of which 6 were prosimians and 8 were nonhuman anthropoids. Data from human brains were collected as well. The subiculum was identified and the cell layer measured on Nissl stained serial sections. The border between the subiculum and CA1 of the hippocampus was identified by the loss of the stratum radiatum which is present in CA1. The lateral border of the subiculum, located deep to the presubicular granule cells, was identified by the presence of large pyramidal cells in the subiculum. The subiculum was measured by digitizing outlines of the subicular grey matter that had been magnified using flat-field optics, usually around 20X. Approximately 20 sections per brain were analyzed. Allometric or scaling studies on logarithmically transformed data were used to analyze the observed differences in size.

The results show that as the primate brain enlarges the subiculum does as well, but to a lesser degree than the total brain. This indicates that larger primate brains have disproportionately smaller subiculi. Prosimians and anthropoids, subordinal divisions of primates, differ in morphometric scaling: for a given brain weight prosimians have bigger subiculi than anthropoids. These results resemble the scaling seen in the connected limbic nuclei, the anterior thalamus (AP) and the medial mamillary body (MMB). Among prosimians the subiculum scales in a 1:1 fasion with AP and MMB, indicating that, among these species, size differences occur while maintaining the same proportions. On the other hand, the scaling among the nonhuman anthropoids, is somewhat less than 1, indicating that in anthropoids, the subiculum has expanded volumetrically more than AP or MMB. The human data do not fit the nonhuman anthropoid trend, however. The human subiculum is smaller than expected for an anthropoid on the basis of brain weight, AP or MB sizes, suggesting an altered morphometric relationship between the subiculum and the interconnected diencephalic nuclei occurred during human evolution.

146.12 AN ANATOMICAL STUDY OF THE INSULAR AND CINGULATE CORTEX OF THE WALLABY, MACROPUS EUGENII. L. Mayner. Dept. of Behavioural Biology, R.S.B.S. Australian National University, Canberra, Australia.

The few cursorily anatomical studies on the cortical features of Australian marsupial have neglected the description of both insular and cingulate cortical regions. The following description of the cingulate and insular cortical regions, is part of an extensive study of the cortical cytoarchitectonic features of the wallaby, a diprotodontid Australian marsupial mammal. The method of identification of the two regions was from homologies of placement with eutherian mammals, as well as results from horseradish peroxidase (HRP) tracing studies for further confirmation. Thionin was used for the Nissl stain and the Mesulam TMB method was used for visualising the HRP product. The insular region contains two areas, an agranular area lying rostral to the granular area, placed lateroventrally behind the frontal cortex and in front of the parietal cortex. In the agranular area layer II appears to merge with layer III and layer IV is missing. Layer V contains deeply staining elongated cells which resemble cells found in layer II of other regions. Layer VI also contains elongated cells among the pseudopyramidal cells. A cell sparse layer appears to be present between layers V and VI. The granular insular region contains six layers. Within these are two prominent layers of sparsely packed cells, one between layers IV and V, the other between layers V and VI. HRP injections into the insular region result in both retrograde and orthograde label in the oral subdivision of the ventromedial nucleus of the thalamus. The cingulate region is found mostly in the medial cortical wall. Layer IV was not found within this region. Layer I is very wide however, layer II is not very prominent and at times blends with layer III cells. Layer III is a rather wide layer, at the point where the cingulate region encroaches onto the dorsolateral ridge of the cortex, a division in the form of a cell sparse layer, appears between layers III and V. This division is prominent in the dorsal convexity and extends about half way down the medial cortical area. Just above this, layer III cells appear to form a narrow band of densely packed, deeply staining cells. In layer V there are medium and some large pyramidal cells mostly moderately staining, and a few large pyramidal cells are deeply staining. Layer VI contains pseudopyramidal cells. After HRP injections into the anterior nuclei of the thalamus retrograde label was found in the cingulate cortex. These results show that the metatherian mammalian cortical plan for these two regions follows that of the eutherian mammal and that the organisation of the cortical plan of the wallaby has many similarities with eutherian mammals such as the rat.

146.13 MEDULLARY PROJECTIONS TO THE PONS AND BASAL FOREBRAIN: POSSIBLE SUBSTRATES INVOLVED IN DRINKING BEHAVIOR: G. L. Edwards, J. T. Cunningham*, T. G. Beltz*, and A. K. Johnson. Departments of Psychology and Pharmacology and The Cardiovascular Center, The University of Iowa, Iowa City, IA, 52242.

Numerous studies have implicated the basal forebrain in the control of drinking behavior. Notably, the tissue in the region of the anteroventral third ventricle (AV3V) has been implicated in these controls, particularly angiotensin II (ANG II)-induced drinking. Recent studies suggest the median preoptic nucleus (MnPO) may be the critical tissue in the AV3V region for the control of drinking (Neuroendo. 37: 73-77, 1983). Additionally, the lateral parabrachial nucleus (LPBN) in the pons is reported to be important in the control of ANG II-induced drinking (Am. J. Physiol. 251: R504-509, 1986).

Since the LPBN and MnPO both receive input from similar areas of the medulla it is of interest to determine if these inputs overlap or possibly neurons within the medulla project to both the MnPO and the LPBN. In order to investigate these possibilites, microinjections of either rhodamine labelled latex beads or Fluoro-Gold were made into the LPBN and MnPO. After a 4-5 day recovery period the animals were sacrificed and perfused. Serial sections of the medulla were mounted on slides and viewed with a fluorescence microscope. Neurons labeled from injections into the LPBN were observed primarily in the nucleus of the solitary tract (NTS), area postrema (AP), and the ventrolateral medulla in the region of the A1 catecholamine cell group. Neurons labeled by injections into the MnPO were observed primarily in the ventrolateral medulla in the region of the A1 cell group. Although retrograde label from injections into the MnPO was primarily observed in different cells than retrograde label from LPBN injections, there appear to be cells in the ventral medulla containing both Fluoro-Gold and rhodamine labeled beads. This observation suggests that a subpopulation of neurons in the medulla may project to both the LPBN and MnPO and subsequently affect information processed by these nuclei possibly relevant to drinking behavior. Ongoing studies are aimed at determining the chemical nature of these projections and their possible role in drinking behavior.

This research is supported by NIH grant HL14388.

146.14 THE TERMINAL NERVE OF DOLPHINS: GENERAL ANATOMY AND LHRH-IMMUNOCYTOCHEMISTRY.
L.S. Demski, M. Schwanzel-Fukuda and S.H. Ridgway*. School of Biological Sciences, Univ. of Kentucky, Lexington, KY 40506; Rockefeller Univ., New York, NY 10021; and Naval Ocean System Center, San Diego, CA 92152.

The gross morphology and general histology of the terminal nerve (TN) was studied in several specimens each of the common dolphin (Delphinus delphis) and the Pacific bottlenosed dolphin (Tursiops gilli). Brains for routine observation had been fixed in 10% formalin for some time. Nerve strands and ganglia were initially identified by treatment with 1% osmium. In Tursiops two nerves were fixed in Bouin's for LHRH immunocytochemistry (antisera to synthetic LHRH) and another one was immersed in 2-3% gluteraldehyde (in cacodylate buffer) for EM. In both cases the tissue was obtained within several hours after death. The latter was post-fixed in osmium. The TN is composed of many parallel strands runnning in the pia on the ventromedial surface of the frontal lobe. Its fibers enter the cranium from paired medial foramina located just above the frontal poles. TN bundles enter the brain in the anterior perforated substance or run along the optic chiasma or branches of the cerebral arteries. Ganglia are distributed along the TN with the largest situated at the point of cranial entry. The latter contains many (ca. 2,000-4,000) round cells (ca. 30 um) which have a capsule of satellite cells and are pear-shaped in some sections, suggesting a unipolar appearance. The nucleus is oval to irregular in shape with a prominent nucleolus. The cytoplasm contains round mitochondria, rough ER, lipofucsin granules and other inclusions. Synapses on the cells have not been observed; however, our observations are limited. A few scattered LHRH-immunoreactive (ir) cells, round or fusiform in shape with clear nuclei, are also present in the main ganglion. LHRH-ir fibers, single or in small fascicles, were also seen in the ganglion or along the bundle of the main nerve trunk. Occasionally LHRH fibers encircle or form a network around a single large non-ir cell. EM observations of LHRH-ir cells have not yet been made. Nerve strands contain many myelinated fibers (2-8 um), a feature seemingly unique to the TN of odontocetes. In at least Tursiops, some unmyelinated fibers are also present. Functional roles in sensory and/or autonomic control of nasal sacs and reproduction are suggested for the components of the dolphin TN.

146.15 THALAMIC PROJECTIONS TO VENTROLATERAL AND DORSOMEDIAL SUBSECTORS OF THE PREFRONTAL CORTEX IN THE RHESUS MONKEY. T. H. Henion* and H. Barbas. Dept. Health Sci. and Anatomy, Boston Univ. and Sch. of Med., Boston, MA 02215.

The thalamic input to ventrolateral (areas 11 and caudal 46) and dorsomedial (areas 32, 14 and 8a) subsectors of the prefrontal cortex was studied with the use of the retrograde transport of horseradish peroxidase (HRP) in rhesus monkeys. These areas constitute parts of a ventral and a dorsal trend of a gradual laminar differentiation observed within the prefrontal cortex (Barbas, H. and Pandya D.N., Neurosci. Abstr., 8:933, 1982). The orbitofrontal and medial prefrontal areas studied are architectonically less differentiated regions within each of the two trends than ventral area 46 and area 8a.

Most labeled thalamic neurons in each brain were found in the medial dorsal nucleus (MD). These neurons occupied predominantly the dorsal half of MD after HRP injection in dorsomedial prefrontal regions, and the central portion of MD after HRP injection in ventrolateral regions. In addition, dorsomedial prefrontal sites seemed to receive a greater proportion of their thalamic input from the intralaminar nuclei than did ventrolateral sites.

There were striking differences in the origin of thalamic projections to areas 8a and 46 when compared with the projections directed to the less architectonically differentiated areas 32, 14 and 11. Area 8a and ventral area 46 received most of their thalamic projections from the parvocellular (>60%), and a smaller proportion from the multiform (<10%) division of MD. Medial areas 32 and 14 and orbital area 11, however, received most of their MD projections from the magnocellular division. Moreover, a significant number of neurons from midline and anterior nuclei projected to medial prefrontal and orbitofrontal (>10% of the total number of labeled cells), but few, if any, projected to areas 8a or 46. The less architectonically differentiated areas 32, 14 and 11 had more widespread thalamic connections, whereas the more differentiated areas 8a and 46 had more focal thalamic connections.

The results suggest that the pattern of thalamic projections to the prefrontal cortex is correlated with the degree of architectonic differentiation of the prefrontal regions studied, and to some extent with the relative dorsomedial or ventrolateral location of each prefrontal target region.

146.16 HIGH RESOLUTION BRAIN MAPPING. D.E. Hillman, M. Canaday*, G. Mahoney* and R. Crank*. Department of Physiol. and Biophys., New York Univ. Med. Ctr., 550 First Ave., New York, NY 10016.

A major difficulty in mapping immunolabels, receptor binding, functional labels and other details of the nervous system has been the restriction of low resolution frames of digital imaging techniques. Large digital images, however, contain so much data that they are difficult to analyze and virtually impossible to store. Solutions are found in applying combinations of technology in a comprehensive recording and analysis approach for digital mapping of the rat brain. High resolution mapping is done in two ways: (1) by interactive recording of structural boundaries using a moving stage, or (2) by digitizing 4000 x 4000 pixel frames. The single large frames (16 megabytes) are captured on a real-time, digital, video-disk of an image processor from a line scan camera. The approach allows automated image processing for edge enhancement, edge detection and selective processing of density defined structure through a cascade of operations generating images from which boundaries can be obtained as the structural maps. The advantage of multiple frame approach is that lenses having higher resolving power can be used and local visual analysis provides means to survey the entire section at the highest resolutions of the light microscope. The software, in both cases, is designed for mapping boundaries of structures within localized areas of the brain. Each object can be labeled and interactively amended as necessary to represent the original data. Digital brain atlases allow superimposition of structural boundaries over chemically defined structure at the cellular and the synaptic level for graphical display in the same coordinate system. Furthermore, three-dimensional representations by wireframe and rendered surfaces are useful for demonstrating relationships between objects in various perspectives. (NS13742 from NINCDS.]

146.17 DIGITAL RAT BRAIN: A COMPUTERIZED STEREOTAXIC ATLAS
A.W. TOGA, M. SAMALE*, T.L. ARNICAR-SULZE*, and J.W. STUDT*,
Laboratory of Neuro Imaging, Department of Neurology
UCLA School of Medicine, Los Angeles, CA. 90024

Mapping the central nervous system in accurate three space has historically taken the form of stereotaxic atlases. These maps of neuroanatomy not only help localize structures deep to the surface of the brain but also help us understand the relationships between those structures. Computerized digital imaging technologies (both 2D and 3D) have already proven extremely useful in the study of neurophysiology (Toga, et al., 1985,1986,1987; Hibbard & Hawkins, 1984; Smith, Schlusselberg & Culter, 1984). This paper describes an application of 3D neuroimaging to a stereotaxic rat brain atlas.

We have developed a system which maintains a 3 dimensional database of a neuroanatomic atlas. This database is derived from the drawings contained in a published atlas (with publishers permission). Software algorithms were developed which provided automatic contour extraction for the surface and outlines of certain neuroanatomic structures. The system automatically searches adjacent plates iteratively and extracts successive contours. Because the plates are separated by some distance (which can vary), we interpolated data between the contours. An interactive display package was developed whereby the user can synthesize images using the following utilities; wireframe modelling, solid modelling with surface rendering, shading, transparency, cut-away views, color indexing of neuroanatomic structures, perspective and rotation about all 3 axes.

The images which are produced can be labelled and functional data manually inserted by the user. Although the database is not comprehensive, it is constantly being expanded. Those structures most easily circumscribed have been completed. Examples include the corpus callosum, ventricular system, hippocampus, caudate and others.

146.18 A COMPUTER METHOD FOR VOLUME DETERMINATION OF STRIATE AND EXTRASTRIATE CORTEX IN PRIMATE BRAIN.
W.K. Smith, M.C. de Lacoste, S.A. Azizi, D.S. Schlusselberg, and D.J. Woodward. *Dept. of Cell Biology and Anatomy, Univ. of Texas Hlth. Sci. Ctr. at Dallas, Texas 75235.*

Previous work in our laboratory, using the **CARP** system (Computer Aided Reconstruction Package) for data compilation, has suggested that striate and extrastriate cortices are highly asymmetrical in primate brain [de Lacoste *et al*, 1986]. These studies, however, were limited in quantitative assessment in that telencephalic regions were defined using gross anatomical landmarks. This study was undertaken to develop methods for evaluating striate and extrastriate primate brain asymmetries using a video image analysis subsystem of **CARP** originally developed for 2-deoxyglucose autoradiography research. The aim was to develop more accurate methods for assessing volumes of cortical gray matter from histological preparations.

Formalin-fixed rhesus brains (N=4) obtained from Brooks Air Force Base were coronally sectioned (50 microns) with a freezing microtome and stained with Cresyl violet. Care was taken to assure uniformity of the staining procedure. The stained sections were mounted on glass slides and placed on a light box beneath a video camera. Video images were captured in a digital frame buffer and analyzed in an IKONAS color raster graphics system using the **CARP** software running on a Data General MV/8000 II host computer. Image processing routines were used to perform video averaging, to eliminate intensity gradients originating in the light source, and to correct geometrical anisotropy in the video digitizer.

The CSCAN utility of **CARP** was used first to isolate the cortex from the white matter in the sections and then to automatically detect and store the external and internal borders of the cortical gray matter in a computer database. The use of pseudocolor enhancement of the video digitized cortical cytoarchitecture was successful in determining the boundaries between striate and extrastriate cortex and between extrastriate cortex and surrounding areas. The line editing features of **CARP** allowed the construction of graphical line segments representing the cortical regions. Areas could be computed for these delineated regions of cortex on the left and right sides of each brain.

Areas in consecutive series can be reconstructed into a volume and quantitated using **CARP** utilities. These strategies provide a basic framework for determining regional volumes within cortical areas. Our long term goal is to include refined image analysis techniques to obtain quantitative information about details of cortical cytoarchitecture.

146.19 **Whole-Brain Mapping: Strategies for the Construction of "Nested" Computerized Atlases.** C.A. Lemere*, C. Wurtz and R.B. Livingston. Brain Mapping Project, Dept. of Neurosciences S-001, UCSD, La Jolla, CA. 92093.

The anatomy of the brain has been studied at varying levels of magnification and resolution for centuries. However while micrographs, functional diagrams, and "wire frame" atlases have been produced, a complete brain map, corrected against preparation artifacts, has never been created. With the recent progress in digital image processing and computer databasing such an atlas is feasible for the first time. Ideally this atlas would contain a bit-map of all structures down to the limits of optical microscopy. In practice this creates an impossible amount of data...hundreds of terabytes to map at 20 μm resolution. Our strategy avoids this problem by retaining only the data needed to assign each cell soma an xyz address and a cytoarchitectural identifier (e.g. "pyramidal cell") These data are acquired by automated microscopy, by precessing a 10 μm thick section, stained for a specific cell type, under a CCD line camera. The CCD, along with the automated stage and host computer, assigns the address and size parameter and determines the cell type (based on the spectral response of the stained cell). Thus each cell requires only 10 bytes to define it for the map. Since we take one section every 100 μm, we are addressing approx. 10% of the cells in the brain, thus our human atlas will contain about 50 GBytes of neuronal data. To ensure 3-D accuracy and fidelity to the in vivo state we employ a sequential registration control process (hence the term "nested") utilizing the outer and ventricular surfaces and the pre-capillary vasculature as biological fiducials. We apply CT scans to correct for fixation, dissection, and freezing effects, and digital images of the blockface (acquired as the specimen is sectioned) to control for compression and shrinkage during histological processing. Finally we apply 2-D warping algorithms such that our map addresses accurately reflect the in vivo position of the given cell. We are currently acquiring data from the rat, the cynomologous monkey, and the human, for which we will construct complete maps. These atlases are ultimately more than a collection of precise spatial coordinates for the neuronal somata, glial cells and fiber tracts. They will be the framework for a computer-manipulatable neurobiological database, capable of containing physiological, neurochemical, and functional information.

146.20 CAPSAICIN-INDUCED DAMAGE TO SUBDIAPHRAGMATIC VAGAL FIBERS AND CENTRAL AFFERENT TERMINALS FROM THE STOMACH. S.S. Bernier*, E.H. South, and R.C. Ritter. (SPON: D. Fragaszy). Dept. of VCAPP, College of Veterinary Medicine, Washington State University, Pullman, WA 99164-6520 and WOI Regional Program in Veterinary Medicine, University of Idaho, Moscow, ID 83843

The neurotoxin capsaicin destroys small unmyelinated primary sensory neurons in a variety of peripheral nerves. Recently, we reported behavioral data which indicate that capsaicin pretreatment attenuates suppression of food intake by stimuli thought to act via vagal afferents. To assess capsaicin-induced vagal damage, we performed transmission electron microscopy on the subdiaphragmatic vagi of adult rats treated with 175 mg/kg capsaicin (dosage series: 25, 50, 50, and 50 mg/kg). We also examined labeling of cell bodies and terminals in the dorsal hindbrain following injection of wheat germ agglutinin conjugated horseradish peroxidase (WGA/HRP) into the stomach wall of intact and capsaicin-treated rats. Twenty-four hours after capsaicin treatment, unmyelinated fibers in the vagi exhibited marked vacuolation and swollen mitochondria. By 72 h post-capsaicin a profound disruption of the integrity of unmyelinated fibers was observed. One week after capsaicin injection the disruption was less evident and by 23 days post-capsaicin the vagal fiber structure was overtly no different from controls. No damage to myelinated vagal fibers was observed at any time. Light microscopic evaluation of dorsal hindbrain sections of rats receiving stomach wall injections of WGA/HRP revealed terminal labeling in the subnuclei of the nucleus of the solitary tract (NST) and the dorsal motor nucleus (DVM) associated with gastric projections of the vagus (Shapiro and Miselis, 1985). The DVM also exhibited marked retrograde filling of the motor neuron cell bodies. In contrast to controls, capsaicin-treated rats exhibited dramatic reductions of terminal labeling in the NST. Loss of labeling was apparent at 24 h post-capsaicin onward and was still evident at least 23 d post-capsaicin. There was no apparent loss of filling of the DVM cell bodies.

Capsaicin-induced vagal damage results in reduced labeling of sensory projections of the gastric vagus in the dorsal hindbrain. These findings are consistent with the silver impregnation studies of Dinh and S. Ritter (1985) as well as our behavioral and electrophysiological findings (Ritter and Ladenheim, 1985; South and Ritter, 1986; Yox and Ritter, 1986; Ritter et al., 1987) indicating that capsaicin destroys a subpopulation of vagal afferent fibers which carry information from the gastrointestinal tract. Supported by NIH grants R01 NS20561 and R01 NS21805.

147.1 FOUR POLYPEPTIDES PURIFIED FROM GREEN MAMBA VENOM, WHICH BLOCK K CHANNELS, LABEL SPECIFIC RECEPTORS ON RAT BRAIN SYNAPTIC MEMBRANES. R.G. Sorensen and M.P. Blaustein. Dept. of Physiology, Univ. of Maryland Med. School, Baltimore, MD 21201.

Four polypeptides, (designated α-, β-, γ- and δ-DaTx), purified from the venom of the green mamba, Dendroaspis angusticeps, have been recently shown to block ^{86}Rb efflux from rat brain synaptosomes, [Benishin et. al., Fed. Proc. 46:504, 1987.] Two of the polypeptides, α- and δ-DaTx, preferentially block a component of ^{86}Rb efflux corresponding to a voltage-gated, rapidly-inactivating K channel. The other two, β- and γ-DaTx, preferentially block a component of ^{86}Rb efflux corresponding to a voltage-gated, non-inactivating K channel. Here, we characterize the binding of these four venom polypeptides to synaptic membranes prepared from rat brain.

The four polypeptides were radioiodinated. Their binding was determined from competitive displacement assays in which the ability of increasing amounts of an unlabelled polypeptide to displace the binding of a radiolabelled polypeptide was measured. Each polypeptide labelled a specific receptor on rat brain synaptic membranes. Maximal binding was observed in physiological salt solutions. Preliminary data indicate that [^{125}I] α-DaTx and [^{125}I] δ-DaTx both bind with a $K_D \simeq 1$ nM and $B_{max} \simeq 1.5$ pmol ligand bound / mg protein. [^{125}] β-DaTx and [^{125}I] γ-DaTx have about 10-fold lower affinity, $K_D \simeq 10$-15 nM, but a similar number of binding sites, $B_{max} \simeq 2.5$ pmol / mg protein. Radioiodinated α and γDaTx were crosslinked to synaptic membranes to identify the receptor polypeptides. The radioiodinated toxin was equilibrated with synaptic membranes for 30 min at 37°. Crosslinking of the toxins to membrane polypeptides was initiated by the addition of 0.05 to 1 mg/ml dimethyl suberimidate for 2-4 hr. The membrane polypeptides were subsequently separated by SDS-polyacrylamide gel electrophoresis and autoradiograms were prepared to determine attachment of the labelled ligand. Preliminary results indicate that α-DaTx and γ-DaTx bind to different receptors, as each polypeptide appears to be covalently crosslinked to a distinct polypeptide. [^{125}I] α-DaTx specifically labels a single polypeptide with apparent M_R = 80 kDa. [^{125}I] γ-DaTx specifically labels two polypeptides with M_R = 35 and 80 kDa. The different labelling patterns for the two toxins seems consistent with their observed abilities to block different K channels in rat brain. These venom components may be useful as potential ligands for the isolation and purification of mammalian voltage-gated K channels. [Supported by NIH grant NS-16106].

147.2 SINGLE-CHANNEL POTASSIUM CURRENTS IN MEMBRANE VESICLES DERIVED FROM NORMAL AND MUTANT *DROSOPHILA* LARVAL MUSCLES. A. Komatsu and C.-F. Wu. Dept. of Biology, Univ. of Iowa, Iowa City, IA 52242.

Single-channel analysis of *Drosophila* mutants with altered membrane currents may provide insights into the molecular mechanisms of ion channel function. We have developed a sarcolemmal vesicle preparation suitable for patch-clamp recordings. Single-channel recordings using this preparation can be compared with macroscopic current data previously obtained from conventional voltage-clamp experiments in both larval and adult muscles.

Spherical membrane vesicles were prepared by exposing 3rd instar larval musculature to a high KCl solution containing collagenase (1 mg/ml). The experiments were conducted in the "cell"-attached configuration using vesicles bathed in 130 mM K^+ solution to maintain a resting potential near zero. One-third of the patches in which a gigaohm seal was formed contained complex channel activity which may consist of multiple channels. These patches exhibited only outward currents when pipette contained 2.5 mM K^+. When pipettes contained 130 mM K^+, these currents were reversed around 0 mV and became inward at hyperpolarizing potentials.

Other patches showed distinct single-channel activities that can be classified into at least two types: a voltage-dependent channel (type I) and a non-voltage-dependent channel with sustained activity (type II). Type I channels had a unit conductance of 10 pS and an extrapolated reversal potential of -100 mV when pipette contained 2.5 mM K^+. When pipette contained 130 mM K^+, this type of channel had a unit conductance of 40 pS and a reversal potential of 0 mV. The probability of channel opening peaked at 20-30 msec following steps of membrane depolarization and slowly declined over hundreds of msec.

Type II channels had a unit conductance of 50 pS at 0 mV and a reversal potential lower than -60 mV when pipette contained 2.5 mM K^+. When pipette contained 130 mM K^+, this type of channel had a unit conductance of 90 pS and a reversal potential of 0 mV. The I-V relations for this type of channel can be described by the Goldman-Hodgkin-Katz constant field equation and the kinetics resemble those of Ca^{++}-dependent K^+ channels in other preparations. Preliminary experiments with inside-out patches suggest that this channel is Ca^{++}-dependent and that 10 mM TEA causes a 20% reduction in unit conductance.

Comparisons of single-channel currents were made between normal and *slowpoke (slo)* mutant larvae, which lack a macroscopic Ca^{++}-dependent K^+ current (Elkins *et al, PNAS*, 83:8415, 1986). In normal larvae, 23% of the active patches (n=57) contained type II channel activity. This is in contrast to *slo* mutants in which no patches (in a total of n=58) contained type II channel activity. However, the proportion of patches showing complex channel activity were similar: 35.1% in normal and 43.1 % in *slo* mutant larvae. These results suggest that the *slo* mutant lacks a functional Ca^{++}-dependent K^+ channel. Further pharmacological experiments in inside-out patches are under way to determine whether the defect resides in the channel itself or in its activation mechanism.

147.3 CONCOMITANT ALTERATION OF POTASSIUM CHANNEL GATING AND PHARMACOLOGY IN A SHAKER MUTANT OF DROSOPHILA. F.N. Haugland and C.-F. Wu, Dept. of Biology and Dept. of Physiology and Biophysics, Univ. of Iowa, Iowa City, IA. 52242.

Electrophysiological analysis of mutations affecting ion channels allows the various functional properties of channels to be correlated with specific structural domains altered by individual mutations. In Drosophila, mutations of the Shaker (Sh) locus affect a transient potassium current, I_A, in larval muscle fibers (Wu and Haugland, J. Neurosci. 5:2626, 1985). Analysis of defective I_A in Sh mutants can reveal the functional roles of the affected structural domains within the I_A channel as determined by molecular genetic techniques.

Membrane currents in larval muscle fibers of the Sh^5 mutant were compared with normal using two-microelectrode voltage clamp. The current-voltage (I-V) relation was shifted to more positive potentials and steepened. Step depolarizations from -80 mV to potentials between -20 and +20 mV elicited an I_A whose amplitude was markedly reduced while steps to more positive potentials induced an I_A of nearly normal amplitude. The time course of I_A in the mutant was only slightly slower than normal. In a paradoxical fashion, I_A tail currents following repolarizations from +40 to 0 mV or more negative potentials had a normal amplitude but with abnormally rapid kinetics of decay. A mathematical model demonstrated that this seeming contradiction can result from a simple alteration in a kinetic scheme of I_A channel gating. Further voltage-clamp experiments revealed altered pharmacological properties. Sh^5 channels were much more sensitive to blockade by 4-aminopyridine (4-AP). At a concentration of 5 μM 4-AP, Sh^5 I_A was blocked by more than 90% while normal I_A was blocked by less than 65%. Since the Sh^5 mutation was induced by ethyl-methane-sulfonate, a mutagen which often results in single amino acid replacements, our data raise the possibility that the gating and 4-AP binding functions reside within the same structural domain of the I_A channel. Alternatively, these two functions may be governed by separate regions that may be influenced by the Sh^5 mutation site. This work was supported by NIH grants NS00675 and NS18500 to CFW.

147.4 PROPERTIES OF THE A-CURRENT IN MATURE, DISSOCIATED AMPHIBIAN SPINAL NEURONS IN CULTURE. A. Hernandez-Cruz.* (SPON: Paul R. Adams) Lab. of Neurobiology, The Rockefeller University, 1230 York Ave, New York, N.Y. 10021

Acutely dissociated neurons from the adult salamander spinal cord exhibit fast Na-dependent action potentials which repolarize very rapidly by the activation of K^+ currents. In a previous communication, evidence was presented for the presence of two sustained K^+ currents: The Ca-dependent K^+ current and the delayed rectifier (Hernandez-Cruz & MacLeish, Soc. Neurosci. Abst. Part 2 , pp 1348, 1986). In this report, the properties of a third component, similar to the A-current (I_A), are examined. Enzymatically dissociated cells were plated on plastic petri dishes and recorded (after 1 to 5 days in culture) with patch electrodes containing (in mM) 90 KAsp, 20 Sucrose, 10 NaH_2PO_4 , 4 $MgCl_2$, 1 ATP and 0.5 K_2EGTA (pH 7.3). Step depolarizations elicited a transient outward current when cells were held at rest (-70 mV) and bathed in a solution containing (in mM): 20 TEA, 0 NaCl, 0.2 $CaCl_2$, and 10 $MgCl_2$. This current peaked within 8-10 ms and inactivated exponentially with a time constant between 30 and 45 ms (19-22 °C). It was eliminated by 1.5 mM 4-AP or by holding potentials positive to about -30 mV. Half-activation of this current was observed at about -10 mV and half-inactivation at about -40 mV, with a small overlap near -30 mV. Both size and steady-state inactivation of I_A varied widely among different neurons from the same cultures, being absent in some of them. In general, inactivation curves were displaced 10 -15 mV in the positive direction, as compared to most neuronal systems, suggesting that a significant fraction of A channels could be available for activation during repetitive firing and not only at potentials near rest. Cadmium (0.5 mM) increased the I_A amplitude and shifted the inactivation curve even more into the positive region without affecting the inactivation time constant. This effect could not be attributed to screening effects or to blockade of Ca^{2+} channels. In current clamp experiments, Cd^{2+} and 4-AP were used to examine the possible role of I_A in the cell electrical behavior. When 4-AP was added to normal Ringer solution, the spike elicited by short pulses increased in size and broadened. On the other hand, Cd^{2+} reduced spike amplitude and shortened its duration slightly. In the last case, an effect due to Ca-current blockade by Cd^{2+} could not be completely ruled out, although similar changes in spike morphology were not observed when $[Ca^{2+}]_o$ was reduced from 2 to 0.2 mM. A decrease in firing frequency and a faster adaptation was observed in the presence of 4-AP. This was interpreted as a result of a more extensive activation of the delayed rectifier and Ca-activated K^+ currents secondary to spike broadening.

Present address: Dept. of Neurobiology & Behavior, SUNY at Stony Brook, NY 11794. (Supported by the Klingenstein Fund and Fogarty International Center, NIH)

147.5 CHARACTERIZATION OF A TRANSIENT K^+-CURRENT IN TRIGEMINAL ROOT GANGLION SENSORY NEURONS. I. Spigelman* and E. Puil (SPON: D. M. J. Quastel). Department of Pharmacology Therapeutics, Faculty of Medicine, The University of British Columbia, Vancouver, B. C., V6T 1W5, Canada.

Sensory neurons in the trigeminal root ganglion (TRG) of the guinea-pig share certain properties with other craniospinal neurons of mammals. For example, they both exhibit action potentials that are followed by brief afterhyperpolarizations (AHPs) lasting 1-20 ms. The AHPs are sensitive to blockade by external application of tetraethylammonium (TEA; 10 mM), which also prolongs the spike duration and decreases repetitive spike discharge (Puil and Spigelman, Neuroscience, in press). In preliminary studies using conventional intracellular recording techniques, we have found that bath administration of 4-aminopyridine (4-AP; 1 mM) also prolonged spike duration but, unlike TEA, 4-AP did not appreciably reduce the amplitude of AHPs and enhanced repetitive firing.

To investigate the effects of K^+-channel blockers more extensively, and to characterize an ionic current which may give rise to the AHP, we have performed pharmacological analyses of neuronal properties in slices of the TRG using single electrode voltage clamp techniques. In TRG neurons which were clamped at holding potentials of ~-40 mV, a transient outward current was evident at termination of hyperpolarizing voltage command steps (5-40 mV). This fast current had an onset of <5 ms and its deactivation was complete by ~40 ms. Similar currents could be evoked during application of tetrodotoxin (1 μM) using depolarizing voltage commands when the holding potential was near -65 mV. In addition, the transient outward current (holding potential -40 mV) could be reduced by increasing the extracellular K^+-concentration from 5 mM to 20-40 mM. These currents were blocked by bath application of TEA (1-10 mM). Similar applications of 4-AP (1-5 mM) did not significantly reduce the transient outward current. However, administration of either K^+-channel blocker elicited a decrease in leak conductance. These results suggest that the transient outward current in TRG neurons is mediated by K^+ ions. The characteristics of this current indicate its participation in the genesis of the short-lasting AHPs following spikes and presumably would be important in the regulation of repetitive spike discharge in TRG sensory neurons.

Supported by the Medical Research Council of Canada and by a Research Traineeship of the Canadian Heart Foundation.

147.6 MEMBRANE RESONANCE IN TRIGEMINAL ROOT GANGLION NEURONS: INVOLVEMENT OF K^+-CONDUCTANCES. E. Puil, B. Gimbarzevsky* and I. Spigelman*. Department of Pharmacology & Therapeutics, Faculty of Medicine, The University of British Columbia, Vancouver, B.C., V6T 1W5, Canada.

An outstanding feature of the plasma membrane in the trigeminal root ganglion (TRG) neuron and in other excitable cells is that during a small perturbation by a stimulus, there is a natural frequency of oscillation or resonance. The impedance of such a system has a maximal value at the resonant frequency, and like a low bandpass filter, falls rapidly at frequencies on either side of the peak resonant frequency. The characteristics of this TRG neuronal filter are based on the values of capacitive, as well as on the resistive and inductive components in the membrane. Since the resistive and inductive components are attributable to various time- and voltage-dependent conductances, we have investigated the effects of ionic channel blockers on the genesis of membrane resonance. The complex impedances and impedance magnitude functions of neurons were determined in in vitro slices of the TRG of guinea pigs using frequency-domain analyses of intracellularly recorded voltage responses to specified oscillatory input currents. At their initial resting membrane potentials, all neurons exhibited resonance in the range of 30 to 200 Hz in their impedance magnitude functions. Bath applications of the selective Na^+-channel blocker, tetrodotoxin (10^{-6} M) produced only minor changes, whereas tetraethylammonium (TEA: 10^{-2}) markedly increased the impedance magnitude and also suppressed the resonant behavior in a reversible manner. Such applications of 4-aminopyridine (4-AP; 10^{-3} M) decreased the peak resonant frequency in a manner similar to TEA application. Unlike TEA, however, 4-AP usually increased the sharpness of the resonant hump, in addition to the impedance magnitude in many neurons. For quantification, the complex impedance data were fitted with a neuronal model derived from linearized Hodgkin-Huxley-like equations. This yielded estimates for membrane electrical properties. Although input capacitance was unchanged by drug administration, both K^+-channel blockers decreased the time-invariant resting conductance that includes a lumped leak conductance component. The time- and voltage-dependent conductance was decreased by TEA, and increased by 4-AP. The time constant which is associated with this conductance as well as with the inductive property of the membrane also was decreased by TEA, and increased by 4-AP. These data suggest a primary involvement of two K^+-conductance systems in membrane resonance, or separate sites of action of TEA and 4-AP in the blockade of the K^+-channels.

Supported by the Medical Research Council of Canada and the Canadian Heart Foundation.

147.7 DIFFERENTIATION OF NEUROBLASTOMA CELLS INDUCES EXPRESSION OF K CHANNELS. C.J. Smith-Maxwell*, R.A. Eatock and T. Begenisich*. Dept. Physiol., University of Rochester, Rochester, NY 14642.

We have examined whole-cell currents in two closely related mouse neuroblastoma cell lines: Neuro-2a and Neuro-2a-AB-1 ("AB-1"). The AB-1 line was derived from the Neuro-2a line in J. Olmsted's laboratory. Depolarizing voltage steps elicit both Na^+ and K^+ currents in Neuro-2a cells but only Na^+ currents in AB-1 cells raised in standard culture conditions. We were interested in whether the AB-1's had lost K-channel genes or simply the ability to express those genes in standard conditions. Our approach was to see whether the cells would express K^+ currents if induced to differentiate. We applied agents that have been shown to differentiate AB-1's (Notter and Leary, Dev. Brain Res. 26:59-68, 1985) or other neuroblastoma cells, as assayed by changes in cell division and morphological changes (extension of neurites, hypertrophy, expression of cell surface markers).

AB-1 cells were grown at 37°C in humid 5% CO_2/95% air in one of the following media: *a) control medium:* Ham's F12 plus 10% fetal calf serum (FCS); *b) DMSO:* 7-13 days in F12 containing 1.3% dimethylsulfoxide and 0.3% FCS (Smith, J. Physiol. 382:191P, 1987); *c) mitomycin/Brdu:* 5 days in F12 containing 10% FCS, 500 ng/ml mitomycin C and 10 μM bromodeoxyuridine (the Brdu was added 6 hrs. after the mitomycin). All media contained 50 μg/ml gentaminicin and 2.5 μg/ml fungizone. In both treatments (b-c), cells were larger than controls and cell division was slowed or stopped. DMSO-treated cells were round with no processes or with thick bud-like processes. Mitomycin/Brdu promoted neurite extension.

Membrane currents were studied using the whole-cell gigohm-seal technique to clamp membrane voltage at depolarized levels. The bath contained a high-Na^+ solution while the pipette contained KCl or K-aspartate, 11 mM EGTA, and 3 mM K_2-ATP. Both DMSO and mitomycin/Brdu induced K^+ currents; Na^+ currents, present in both control and treated cells, appeared relatively unaffected. The induced K^+ currents were smaller than K^+ currents in the Neuro-2a cells. They were largely blocked by adding 10 mM tetraethylammonium to the bath. Given the high EGTA in the pipette and the low bath concentration of Ca^{2+} (2 mM), it seems likely that the induced K^+ currents were not primarily Ca^{2+}-activated.

We conclude that AB-1 cells possess K-channel genes whose expression is negligible in standard conditions and greatly enhanced by differentiating agents.

147.8 POTASSIUM CHANNELS IN ENCEPHALITOGENIC RAT LYMPHOCYTES: CHARACTERISTICS OF INACTIVATION AND ROLE IN CELL ACTIVATION S.I.V. Judge*, J.Z. Yeh*, M.D. Mannie* and P.Y. Paterson*(SPON: L.D. BROWN). Dept. of Pharmacol. and Dept. of Microbiol.-Immunol., Northwestern Univ. Med. Sch., Chicago, IL. 60611.

Myelin basic protein (MBP)-reactive, Lewis (Le) rat T lymphocytes mediate the transfer of experimental allergic encephalomyelitis (EAE) into normal Le rats following MBP stimulation of cell activation and proliferation. Using the gigohm-seal whole-cell variation of the patch clamp, we studied voltage-gated potassium (K) channels in both MBP-sensitized lymph node cells (LNC) and the MBP-reactive GP1 continuous cell line at rest and during MBP stimulated proliferation-activation. Characterization of K channel inactivation under conditions of prolonged depolarization revealed a shift in the voltage-dependence of steady-state (SS) inactivation, which correlated in a time-dependent manner with the extent of cell activation and proliferation. Over the 9-10 day cell cycle, SS inactivation was half-maximal (V1/2) at progressively more depolarized potentials during the first 6-7 days. The subsequent 2-3 days evidenced a rapid shift of V1/2 back to resting levels. V1/2 occurred around -50 mV (slope factor: SF=4.4) at rest, within 1-2 mV of the current activating potential -40 mV (SF between 4.8 and 5.2) during peak cellular activation, at progressively more depolarized potentials up to -28 mV (SF=4.0) during proliferation, and reversed over the course of one day to -40 mV (SF=4.0) as cells began returning to rest. For all T cells studied, the decay of outward current was fit by a single exponential. The time constants of inactivation showed a nonsystematic variability of 300-500 ms at all potential steps, which did not correlate with the resting or activated states of these cells. LNC showed an almost complete inactivation of current at all potentials during the 1.8 s depolarizing pulses, in contrast to the GP1 cells which showed a residual non-inactivating current that increased as the cells progressed through their activation phase.

The capacity of these cells to transfer EAE constitutes a measure of cell activation. Therefore, cellular activation assays were performed on MBP-sensitized LNC to simultaneously assess the involvement of K channels in cell activation and subsequent EAE induction. Cells were incubated with tetraethylammonium (TEA; 100mM), methoxyverapamil (D600; 200uM), 4-aminopyridine (4-AP; 10mM) or nifedipine (200uM) during activation cultures with MBP. These blockers did not inhibit or modify the induction of EAE into Le rats. Concurrent proliferation assays showed that, at doses above 100uM, both D600 and nifedipine inhibited proliferation as measured by [^{3}H] thymidine uptake, while TEA and 4-AP had no effect. SITS (4-acetamido-4'-isothiocyanostibene2,2'disulfonic acid), a modulator of neuronal K channels, strongly stimulated proliferation.

In summary, our results demonstrate a depolarizing-hyperpolarizing pattern of shifts in the voltage-sensitivity of K channel SS inactivation after MBP stimulation. The amount of non-inactivating current correlates with the level of cellular activation for the GP1 cells but not for LNC. We also show that K channel blockers do not prevent the activation of T cells and their ability to mediate the transfer of EAE.

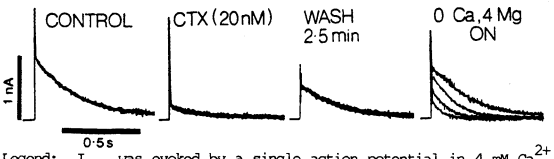
147.9 **EFFECTS OF CHARYBDOTOXIN AND EXTRACELLULAR CALCIUM ON THE TIME COURSE OF THE AFTERHYPERPOLARIZATION CURRENT (I_{AHP}) OF BULLFROG GANGLION NEURONS.**
P.S. Pennefather and J.W. Goh. Faculty of Pharmacy, University of Toronto, Toronto, ON M5S 1A1, Canada.

Charybdotoxin (CTX) is a basic protein isolated from the venom of the Israeli scorpion, Leirus quinquestriatus which has been shown to block the large voltage and calcium activated potassium channel found in many types of cells (Smith et al., J. Biol. Chem., 261:14607). We find that low concentrations of CTX (4-20 nM) reversibly prolongs the action potential recorded in neurons of the Bullfrog sympathetic ganglion. This result is consistent with the reported action of the toxin, since a large, voltage and calcium activated potassium channel (I_C) is known to be responsible for spike repolarization in these cells. However, we find that another calcium-activated potassium channel called I_{AHP}, is also blocked by similar concentrations of CTX. Superficially, the action on both currents resembled that produced by blocking calcium influx but, a more detailed analysis of the effect ruled out this possible mechanism. The exponential decay of I_{AHP} evoked by either a single action potential or a train of spikes is always longer following the train. Lowering extracellular calcium causes the decay rate of I_{AHP} to increase (see last panel of Figure). Between 4 and 1 mM calcium, the half decay time is reduced 1.4-fold per halving of calcium levels. Thus, the time course of I_{AHP} is a measure of the calcium load produced by action potentials. CTX reduced I_{AHP} amplitude without affecting time course (see Figure). It is thus, unlikely that CTX reduces calcium influx and we conclude that two channels with very different calcium, voltage and time dependencies share a common type of receptor for CTX.



Legend: I_{AHP} was evoked by a single action potential in 4 mM Ca^{2+} and was measured by switching to voltage clamp mode during the repolarization phase of the spike. 20 nM CTX caused an almost complete inhibition of I_{AHP}. Recovery had a half time of about 3 minutes. The last panel shows superimposed records taken at successive 30 second intervals after changing the bathing solution to one that contained 4 mM Mg^{2+} and no calcium.

147.10 CALCIUM-ACTIVATED POTASSIUM CHANNELS IN RAT CORTICAL NEURONS IN CELL CULTURE. C.Zona, G.Pirrone*, M.Deodati*, A.Brancati*. Chair of Human Physiology, Department of Experimental Medicine, University of Rome, Tor Vergata, Rome, Italy.

Ca-activated K channels from rat cortical neurons in cell culture were studied in detached inside-out membrane patches (Hamill et al., Pflügers Arch. 391: 85, 1981).The neurons were derived from 13-15 days rat embryos cortices and were dissociated with trypsin and plated on collagen-polylysine coated coverslips (Dichter, Brain Res. 149 : 279, 1978). In a physiological K gradient ($[K]_o$ = 3 mM and $[K]_i$ = 120 mM where $[K]_o$ is the K concentration in the pipette and $[K]_i$ is the concentration in the bathing solution), when the patches were depolarized, outward currents were recorded. The Ca-activated K channel was identified by its Ca and voltage sensitivity, and this was the channel most commonly observed under the conditions of these experiments. Other channels were, however, occasionally observed. The increased current noise when the channel was open was apparent and was useful for distinguishing between open and closed states. The channel was observed in 90% of all patches and even with small pipettes, multiple channels were obserbed. The channel was voltage gated. Both the frequency of channel opening and the duration of the open state increased as the patch was depolarized from 0 to 50 mV at a constant Ca concentration. The conductance of the channel in physiological K gradient over this range was of about 120 pS. The activity of this channel was regulated also by the Ca concentration on the cytoplasmic surface of the membrane. As the internal Ca concentration decreased both the probability of channel opening and the duration of the open state decreased. The effect of small ions on permeation through the channel and the mechanisms by which this current interact to determine cortical neuronal excitability will be discussed.

147.11 DOPAMINE INCREASES A K^+ CONDUCTANCE AND INHIBITS SPONTANEOUS ACTION POTENTIALS RECORDED FROM MELANOTROPIC CELLS OF RAT PITUITARY. J.Stack* A. Surprenant & R.G. Allen. (SPON:L. Bazier) Vollum Institute, Oregon Health Sciences University, Portland, OR. 97201.

Basal secretion of α-melanotropin (α-MSH) and other proopiomelanocortin (POMC)-derived peptides in the rat intermediate pituitary is calcium-dependent and this basal secretory activity is inhibited by activation of dopamine (D_2) receptors; however ionic mechanisms which may underlie these actions are not known. Therefore we have made intracellular recordings of membrane voltages and membrane currents (using single-electrode voltage clamp) from rat intermediate pituitary cells.

Neurointermediate lobes were enzymatically and mechanically dispersed in a collagenase Hanks Hepes solution at 37°C; cells were plated onto 12 mm coverslips that had been treated with poly-L-lysine. Intracellular recordings were made 4 hr - 3 days after dispersion, temperature was 35-37°C. Parallel release studies, using β-endorphin immunoassays, showed that basal secretion was approx. 0.1 pmoles/min/lobe equivalent; 1 μM bromocryptine abolished basal release and this inhibition was blocked by 1 μM haloperidol.

Spontaneous electrical activity was recorded from all cells whose input resistances were greater than 600 MΩ. Spontaneous TTX-sensitive action potentials (APs; 1-2 ms duration, 50 mV amplitude), occurred at 0.2 - 2 Hz in about 50% of spontaneously active cells; TTX-insensitive/cobalt-sensitive membrane oscillations (10 ms duration, 2-10 mV amplitude) occurred in all cells and spontaneous hyperpolarizations (50 ms duration, 5-20 mV amplitude) occurred in cells in which both sodium and calcium APs were present. The hyperpolarization was associated with an increased membrane conductance, was dependent on extracellular K^+ concentration and was blocked by cobalt. Bromocryptine (1 μM) and dopamine (5 μM) hyperpolarized the membrane, increased the membrane conductance and abolished spontaneous APs. The amplitude of the dopamine hyperpolarization decreased when the membrane was hyperpolarized and reversed polarity at the K^+ equilibrium potential.

These results indicate that activation of dopamine receptors on melanotropes increases a K^+ conductance in the membrane. The occurrence of spontaneous calcium-dependent depolarizations in cells shown to be functionally active (by immunoassay) provides a mechanism by which basal hormone secretion may be directly coupled to calcium influx.

147.12 POSSIBLE INVOLVEMENT OF GTP-BINDING PROTEINS IN COUPLING OF MUSCARINIC RECEPTORS TO M-CURRENT IN BULLFROG GANGLION CELLS. H.S. Lopez*, D. Brown and P.R. Adams. (SPON: P.K. Coyle). Department of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, NY 11794.

In bullfrog ganglion "B" cells application of muscarine or neuropeptides reduces a voltage-dependent K-current (Im) as well as producing some increase in leakage. We have investigated the possible involvement of G proteins in receptor/conductance coupling. Firstly, the effect of brief applications (30-40 sec) of 1 uM muscarine on control responses elicited by hyperpolarizing 20 mV voltage steps from -30 or -40 holding potentials were measured. This concentration of muscarine on average inhibited 55% of Im, and after 30-120 sec washing almost complete recovery was seen. However, the extent of inhibition in individual cells was quite variable (30-80%). A second pipette, containing GTP-gamma-S, was then inserted into the cell and negative current (-2 to -4 nA) applied for 2 minutes, and this electrode then removed. The effect of 1 uM muscarine was then retested. Inhibitions of Im ranging from 0 to 100% were observed. However, most of the cells did not recover following washout. In all cells showing greater than 30% inhibition of Im by muscarine after GTP-gamma-S injection, no recovery was seen. Several GTP-gamma-S injected cells showed no response to muscarine, although they did before GTP-gamma-S injection. The injected GTP-gamma-S appeared to reduce Im by itself although this effect might be due to the trauma of double impalement and iontophoretic injection. GTP-gamma-S injected cells also responded to muscarine with a larger inward current instantaneously appearing at -50 or -60 mV potentials than control cells, and this inward current (presumably reflecting increased leakage) also failed to recover. These data suggest that muscarinic receptors activation in "B" cells reduces M conductance via activation of a GTP-binding protein.

147.13 GTP-γ-S INHIBITS THE M-CURRENT OF DISSOCIATED BULLFROG SYMPATHETIC NEURONS. Stephen W. Jones. Dept. Physiology and Biophysics, Case Western Reserve University, Cleveland OH 44106.

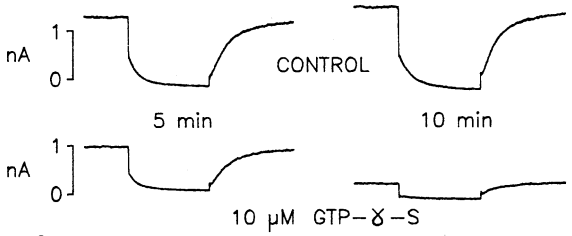
The M-current of bullfrog sympathetic neurons is a voltage-dependent potassium current that is inhibited by muscarinic agonists and certain neuropeptides. It has been supposed that the coupling between the receptors and the M-channel is indirect, but a second messenger has not been conclusively identified. Whole-cell patch clamp recording has been used to test the action of GTP-γ-S, a metabolically stable analog of GTP that produces prolonged activation of GTP-binding proteins.

Sympathetic ganglia were dissociated, and isolated neurons were clamped with 1-1.5 MΩ electrodes [filled with (mM) 100 KCl, 1 K_2EGTA, 5 Na_2ATP, 4 $MgCl_2$, and 2.5 NaHEPES, titrated to pH 7.2 with KOH, adding ~8 mM K]. The extracellular medium contained (mM) 115 NaCl, 1.5 KCl, 2 $CaCl_2$, and 2.5 NaHEPES, pH 7.2.

Without GTP-γ-S, the M-current increased in the first few minutes of whole-cell recording, but was relatively stable thereafter for approximately 1 hour. 10-100 μM GTP-γ-S in the pipet either prevented the initial increase in M-current, or decreased the M-current over a period of minutes (see Figure). The leakage conductance often increased with GTP-γ-S. The M-current (and/or leak increase) sometimes recovered partially over tens of minutes following the maximal effect.

This suggests that a GTP-binding protein might be involved in coupling of receptors to M-channels. Further experiments are necessary to test that hypothesis, and to establish whether the GTP-binding protein acts directly or via generation of cytoplasmic second messengers.

Supported by NIH grant NS 24471.



Currents are in response to 0.6 sec steps to -60 mV from the holding potential of -30 mV, in a cell with 10 μM GTP-γ-S in the pipet (below), or in a control cell (above).

147.14 EXCITATORY ACTIONS OF TETRAHYDRO-9-AMINO-ACRIDINE ON HIPPOCAMPAL PYRAMIDAL NEURONS. D. R. Stevens and C. W. Cotman . Dept. of Psychobiology, University of California, Irvine, Ca. 92717

We have examined the actions of tetrahydro-9-aminoacridine (THA) on guinea pig hippocampal pyramidal neurons in an *in vitro* brain slice preparation using intracellular recording techniques. THA (10-1000μM) depolarized CA_1 pyramidal neurons. This action of THA was accompanied by an increase in action potential frequency and a decrease in membrane conductance. Since THA is a potent anti-cholinesterase, we examined it's action in the presence of atropine. Neither atropine nor tetrodotoxin prevented THA's excitatory action. These results indicate that the excitatory action of THA is independent of the release of neurotransmitter.

Repolarization of membrane potential did not reverse the conductance decrease associated with the action of THA, demonstrating that this change is a direct action of THA. In twelve neurons the extrapolated reversal potential was -88 ± 5 mV, near the reversal potential of potassium ions in this preparation.

THA also excited CA_3 pyramidal neurons. In these neurons, THA caused increased action potential frequency and the appearance of bursts of action potentials followed by large afterhyperpolarizations. When the membrane potential was hyperpolarized to prevent bursts a decrease in conductance was observed. This result suggests that the mechanism of THA's excitatory action on CA_3 pyramidal neurons was a decrease in potassium conductance similar to that observed in CA_1 neurons. In addition, a broadening of the action potential was observed which could enhance the bursting behavior.

These experiments demonstrate that THA has excitatory actions on hippocampal pyramidal neurons which result from blockade of potassium conductance(s) and are independent of THA's anti-cholinesterase activity. The potassium blocking action of THA resembles the action of acetylcholine on "m" currents and appears to account for the excitatory action of THA in both CA_1 and CA_3 pyramidal neurons. The qualitative differences in the effects of THA on CA_1 and CA_3 pyramidal neurons may result from intrinsic properties of these two populations of neurons.

This potassium current blockade may contribute to the reported efficacy of THA in improving cognitive function of patients suffering from Alzheimer's disease.

147.15 CARBACHOL BLOCKS A K^+ LEAK CHANNEL IN HIPPOCAMPAL NEURONS. R.D. Blitzer, D.M. Benson, and E.M. Landau. Depts. of Psychiatry, Mt. Sinai School of Medicine and Bronx V.A. Medical Center, Bronx, NY 10468.

Carbachol (CCh) depolarizes hippocampal pyramidal cells while increasing their membrane resistance. It is known that CCh blocks two voltage-dependent K^+ channels, I_{AHP} and I_m. In addition, we have previously shown (Landau *et al*, *Soc. Neurosci. Abstr.*, 11:572, 1986) that CCh blocks an additional, voltage-insensitive K^+ current (a "leak" channel). We now provide further evidence for the K^+- dependence of the CCh effect, and investigate the pharmacology of the "leak" channel.

Slices of guinea pig hippocampus were maintained in a submerged tissue chamber at room temperature, and CA1 neurons were impaled with 3M KCl-filled electrodes. For voltage-clamp experiments, a single-electrode clamping amplifier was used (Axoclamp-2, switching freq. = 2-3 kHz). CCh effects on the I-V relationship of voltage-clamped cells were determined by measuring the instantaneous membrane currents resulting from 3-sec voltage steps. Changing the K^+ concentration in the bath predictably altered the reversal potential of the CCh effect. In 5 mM K^+, 10 μM CCh decreased membrane conductance, resulting in a crossover at -91 ± 9.4 mV (n=12). In 25 mM K^+, the crossover shifted to -49 ± 3.4 mV (n=6). These values were similar to those seen with 10 μM serotonin (-84 ± 8.4 mV (n=10), and -46 ± 2.7 mV (n=6), respectively). However, in some cells (n=3), CCh induced an inward current without an I-V crossover.

We studied the effects of various K^+ channel blockers on the depolarization or inward current produced by 10 μM CCh (ΔV = 9.7 ± 4.6 mV, n=18; ΔI = 90 ± 60 pA, n=12). 2M tetraethylammonium, in the electrode, blocked the depolarizing effect of CCh (ΔV = -2 ± 1.9 mV, n=9). Prolonged exposure to 4 mM Ba^{+2} (applied in the bath) also blocked the CCh effect (ΔV = 0 mV, n=1; ΔI = 2.5 ± 5 pA, n=4). Neither 4-aminopyridine (in the bath) nor cesium (in the electrode) had any effect on the depolarization induced by CCh. We conclude that CCh exerts its effects by blocking 3 different K^+ channels, including a voltage-insensitive "leak" channel (I_L) which is blocked by TEA and Ba^{+2}.

147.16 TIME-DEPENDENT INWARD RECTIFICATION IN RAT SUBSTANTIA NIGRA COMPACTA NEURONS: VOLTAGE-CLAMP ANALYSIS. M.G. Lacey,* and R.A. North. (SPON: R.A. Baird) Vollum Institute for Advanced Biomedical Research, Oregon Health Sciences University, Portland, OR 97201.

Intracellular recordings were made from neurons in the substantia nigra zona compacta in a rat brain slice maintained at 36°C. Cells fired spontaneous action potentials at rates of 1-5 Hz and were hyperpolarized by dopamine. Membrane currents were measured under voltage clamp at holding potentials of -50 to -60 mV during hyperpolarizing steps to between -60 and -120 mV.

Hyperpolarizing steps evoked a slowly developing inward current; its amplitude was larger for greater hyperpolarizations, reaching five times the value of the instantaneous or 'leak' current. This current took between 0.5 and 20 s to reach a steady-state value; the time course was faster at more negative potentials. Superfusion with Cs^{++} (1-10 mM) markedly reduced this current, rendering the steady-state membrane current similar to the instantaneous current. This current was unaffected by addition of Mg^{++} (10 mM), Co^{++} (1 mM), Cd^{++} (0.3 mM), Ni^{++} (0.3 mM), 4-aminopyridine (1 mM) or TTX (1 μM) to the superfusate.

A further membrane current was observed at the termination of hyperpolarizing commands to potentials more negative than -65 mV. This was an outward tail current which declined within about 20 s and was unaffected by extracellular Cs. This was probably a potassium current as it was reduced by TEA (30 mM) and was negligible during recordings with Cs-filled electrodes. This novel current was also insensitive to Mg^{++} (10 mM), Co^{++} (1 mM), Cd^{++} (0.3 mM), Ni^{++} (0.3 mM), 4-aminopyridine (1 mM) or TTX (1 μM).

The Cs-sensitive inward current activated by hyperpolarization from resting levels is similar to that variously called I_h, I_f/I_{Kz} or I_Q in other cells. An additional smaller outward current, probably carried by potassium ions, is inactivated by hyperpolarization and rapidly activated by repolarization, complicating the study of the Cs-sensitive inward current. The activation of the potassium current at the termination of a hyperpolarization produces a slowing of action potential discharge lasting several seconds.

Supported by DA03161 and MH40416.

147.17 ENHANCEMENT OF ANOMALOUS RECTIFICATION IN RAT LOCUS COERULEUS NEURONS BY ETHANOL. S. A. Shefner and S. S. Osmanovic. Department of Physiology and Biophysics, University of Illinois College of Medicine, Chicago, IL 60680.

Intracellular recordings were made from rat locus coeruleus (LC) neurons in a totally submerged brain slice preparation. Voltage-current (V/I) curves were constructed by plotting the amplitude of electrotonic potentials elicited by hyperpolarizing current pulses as a function of current amplitude. V/I curves determined in control artificial cerebrospinal fluid show anomalous rectification (AR) as indicated by a progressive decrease in slope resistance with membrane hyperpolarization. The V/I relation becomes linear at membrane potentials more negative than -105 to -115 mV (transitional zone), with a slope resistance much lower than that observed near the resting membrane potential. An anomalous rectification ratio (AR ratio) was obtained by dividing the slope resistance immediately below the resting potential by the slope resistance from the linear part of the V/I curve below the transitional zone. The AR ratio ranged from 1.5 to 6.6 with a mean of 3.2 $\pm$ 0.2 (S.E.M., n = 30 cells). Raising the external K^+ concentration shifted the V/I curves and transitional zone in the depolarizing direction by 58.5 $\pm$ 2 mV per ten-fold change in K^+ concentration (n = 6) as predicted by the Nernst equation. Both external Ba^{2+} (0.5 - 2 mM) and Cs^+ (0.5 - 3 mM) depressed AR making V/I relations almost linear throughout the whole potential range and increasing slope resistance. When K-acetate recording electrodes were used, AR was present immediately after impalement but completely disappeared by about 1 hour of recording (n = 25).

V/I curves were determined before, during and after washout of ethanol (30-100 mM) applied by superfusion in the bath. In 8 of 12 LC neurons tested, ethanol inhibited spontaneous firing and increased the AR ratio by 41 $\pm$ 9% (mean $\pm$ S.E.M.). These effects were dose-dependent and reversed with washout of ethanol. Percent inhibition of firing in response to ethanol was found to be correlated with the change in AR ratio (correlation coefficient = 0.84, df = 10, significant, $p < .01$).

On the basis of sensitivity to external Ba^{2+} and Cs^+ and its dependence on external K^+, anomalous rectification in LC neurons resembles the classical K^+-specific anomalous rectifier described in marine egg cells and skeletal muscle. Whether ethanol enhancement of AR in LC neurons is functionally related to other inhibitory effects of ethanol on these neurons remains to be determined.

147.18 LOCALIZATION OF POTASSIUM CHANNELS ON MYELINATED MAMMALIAN AXONS. T.R. Gordon, D.L. Eng*, J.D. Kocsis & S.G. Waxman. Depts. of Neurology, Yale Medical School and V.A. Medical Center, Palo Alto CA 94304.

Recent studies have indicated the presence of several pharmacologically distinct types of potassium conductances on mammalian myelinated axons of both the central and peripheral nervous systems. This study uses intracellular and sucrose gap recording techniques to examine the effects of the potassium channel blockers 4-aminopyridine (4-AP) and tetraethylammonium (TEA) on rat sciatic nerve. The resultsyy indicate that 4-AP- and TEA-sensitive channels are localized differently from each other on the axon.

Sciatic nerves from Wistar rats, aged 11 days to 23 weeks, were stimulated with a single supramaximal stimulus in a sucrose gap chamber. Young nerves demonstrated compound action potential broadening followed by a TEA-sensitive postspike positivity (PP) several hundred milliseconds in duration in the presence of 4-AP. These 4-AP effects attenuated markedly with age: there was minimal broadening and no measurable PP from mature nerves. However, a 200 Hz 100 ms duration stimulus train evoked a TEA-sensitive PP in Krebs' solution (NS) in all ages which was of similar waveform and relative amplitude to that of young nerves in the presence of 4-AP. TEA alone had no appreciable effect on action potential waveform after a single shock. Intracellular recordings in the presence of 4-AP showed a prolonged depolarization, from which bursts of action potentials could arise, followed by an afterhyperpolarization (AHP) with a time course similar to that of the PP. All fibers studied in NS alone exhibited the AHP following a stimulus train. In TEA alone a stimulus train lead to a brief AHP but not to the prolonged AHP. The brief AHP was sensitive to 4-AP.

These data confirm the presence of two pharmacologically distinct types of potassium channels on rat sciatic nerve, one sensitive to 4-AP and the other to TEA. The response to 4-AP greatly attenuates with maturation (myelination) suggesting that 4-AP-sensitive channels are primarily represented at internodal regions. The TEA-sensitive channels require a prolonged depolarization for activation and are blocked by TEA in both immature and mature nerves, suggesting that these channels have an appreciable nodal representation. Supported by the VA and the NIH.

147.19 4-AMINOPYRIDINE-SENSITIVE POTASSIUM CHANNELS IN THE NONMYELINATED AXONS OF THE TURTLE OLFACTORY NERVE. D.L. Eng* and J.D. Kocsis. Depts. of Neurology, Stanford and Yale Med. Sch.; and V.A. Med. Ctr. Palo Alto, CA 94303

Recent studies on amphibian and mammalian myelinated axons indicate that 4-aminopyridine-sensitive potassium channels may be important in action potential repolarization, and a tetraethylammonium-sensitive potassium channel, which has a longer time course, may be important in the regulation of repetitive firing. The purpose of this study is to determine the 4-AP and TEA-sensitivity of a different functional class of axons: the nonmyelinated axons of the turtle olfactory nerve (ON). The ON is an ideal experimental preparation for the study of nonmyelinated axons. Pseudemys scripta (carapace 7"-8") were decapitated, and the olfactory nerve dissected into several bundles. A sucrose gap recording method was used to examine the compound action potential and changes in membrane pot-ential of the fine calibre (0.1-0.2 µm) ON axons. Recordings were conducted at room temperature (24°C). A normal compound action potential recorded in the sucrose gap consisted of a monophasic negative wave followed by a negative tail having a duration up to several seconds. 4-AP broadened the compound action potential in a dose-dependent manner (25 µM-100 µM) Higher concentrations of 4-AP lead to conduction block. 4-AP did not lead to a change in membrane potential. TEA (1 mM-10 mM) did not change the compound action potential, the delayed negativity, or membrane potential. CsCl (25 µM to 5mM) also had no effect on the compound action potential or membrane potential. Capsaicin (100 µM) broadened the compound action potential and caused a membrane depolarization. 100 µM 4-AP and 5 mM TEA applied simultaneously, slightly broadened the compound action potential compared to 4-AP applied alone; repetitive stimulation (5-40 Hz for 1 sec.) elicited either a modest or no post-train posit-ivity. When 100 µM 4-AP, 5 mM TEA, and 5 mM CsCl were applied simultaneously, 5-20 Hz stimulation elicited a strophanthidin-sensitive post-train positivity.

These results indicate that 4-AP-sensitive potassium channels are important for action potential repolarization in the turtle olfactory nerve. The prominent TEA-sensitive afterhyperpolarization observed in mammalian myelinated axons is not observed in the turtle ON suggesting a difference in the organization of potassium channels in these axon types.

147.20 GABA-INDUCED DEPOLARIZATION OF MYELINATED RAT DORSAL ROOT AXONS; PHARMACOLOGY AND IONIC MECHANISMS. R.D. Fields, R.B. Bhisitkul* and J.D. Kocsis. Dept. of Neurology, Yale Med. Sch., and VA Med. Center, Palo Alto, CA 94304.

Many axon types in the peripheral nervous system of amphibians and mammals exhibit a depolarization in response to gamma-aminobutyric acid (GABA). Moreover, this response is seen in in vitro preparations of rat spinal roots where fibers are isolated from the cell body and synaptic terminals, thus suggesting the presence of receptors for GABA on the axonal membrane at asynaptic regions. Axonal GABA receptors are selectively localized on sensory fibers, as opposed to motor fibers, in rat spinal roots. In an effort to characterize this axonal GABA receptor and the ionic mechanisms of the depolarization, we have studied the effects of GABA agonists on rat dorsal roots in isolated preparations using a variety of extracellular recording methods including the sucrose gap technique, and intra-axonal recording and stimulation. Our results show a rapid depolarization of approximately 8 mV upon application of 400 µM GABA or 200 µM muscimol, which is accompanied by a reduction in input resistance of about 15%. Changes in membrane conductance were measured by intracellular current injection through the recording microelectrode equipped with a bridge circuit, and by extracellular measurements of rheobase and propagation of electrotonic potentials. The GABA-induced depolarization could be blocked by the $GABA_A$ receptor antagonist bicuculline methiodide (200 µM), but was not affected by the $GABA_B$ receptor agonist baclofen (200 µM). In addition, the GABA effects were potentiated by 200 µM diazepam, further suggesting that these peripheral axonal receptors resemble the $GABA_A$ receptor described in the central nervous system. Furosemide, a Cl^- pump inhibitor, or Zn^{2+}, which blocks Cl^- channels in some systems, both prevent the GABA-induced depolarization of dorsal roots, suggesting that the increased membrane conductance may result from the activation of Cl^- selective channels. This interpretation is supported by measurements showing a relationship to the chloride equilibrium potential and ionic substitution experiments which are being pursued currently.

These results suggest that $GABA_A$-like receptors are present on at least some mammalian myelinated sensory axons. The activation of these receptors leads to increased Cl^- conductance with an attendant depolarization if an outwardly directed Cl^- gradient is maintained by a furosemide-sensitive Cl^- pump.
Supported in part by the Medical Research Service of the VA and the NIH.

148.1 SUBTYPES OF MAMMALIAN DORSAL ROOT GANGLION NEURONS IN CELL CULTURE: ELECTROPHYSIOLOGICAL STUDIES USING INTRACELLULAR AND PATCH CLAMP TECHNIQUES. M.J. McLean and P.B. Bennett*, Dept. of Neurology and Cardiovasc. Res. Program, Vanderbilt Univ. Med. Ctr., Nashville,TN 37212

Subtypes of dorsal root ganglion neurons (DRGn) are identifiable in intact ganglia in situ by conduction velocity and action potential (AP) waveform. In this study, adult mouse and human ganglia were dissociated to single cells after incubation in enzyme containing solutions. Conventional intracellular electrophysiological recordings were made in phosphate buffer from DRGn plated in collagen-coated dishes and maintained in vitro for up to 5 months prior to experiments. Patch clamp experiments were performed on freshly dissociated neurons. As in intact ganglia, "A-like" neurons (ALN) in vitro fired brief (<1.5 msec duration) APs which were reversibly abolished by tetrodotoxin (TTX, 10^{-8}M) and fired only a few times during long intracellularly-applied current pulses. Whole-cell inward currents (K^+ replaced by Cs^+ in pipette solution) included a large rapidly-inactivating early component abolished by TTX and a small slowly-inactivating component resistant to TTX. Both currents varied with $[Na^+]_o$, but not $[Ca^{++}]_o$. "C-like" neurons had long-duration APs (2-8 msec) which fired in sustained repetitive fashion during long depolarizations and persisted in 30 μM TTX. I_{Na} consisted of a small TTX-sensitive early component and a large slowly-inactivating TTX-resistant component. Both ALN and CLN were quiescent at rest. CLN, but not ALN, depolarized and fired bursts of APs in response to capsaicin, histamine and bradykinin applied to somata by pressure ejection from blunt micropipettes positioned nearby. Similar findings were observed in both mouse and human DRGn. Thus, DRGn in monolayer dissociated cell culture maintain properties of subtypes of DRGn in intact ganglia and can be classified further in vitro by the proportion of two inward Na^+ currents generating the upstrokes of the APs. In addition, CLN in cell culture are sensitive to pain-producing substances which activate nociceptive DRGn in situ. Thus, the DRGn in cell culture provide a useful model for studying properties and effects of chemical substances at the cellular level for comparison with those on subtypes of neurons in animals and man.

148.2 VOLTAGE-DEPENDENT CURRENTS OF MYENTERIC NEURONS IN CELL CULTURE. J.L. FRANKLIN* & A.L. WILLARD. Dept. of Physiology 206H, University of North Carolina, Chapel Hill, NC 27514

Myenteric neurons have diverse electrophysiological properties and are very heterogeneous with respect to their neurotransmitter content and the types of synaptic potentials they cause, both in vivo (North, Neuroscience 7:315; Gershon, A. Rev. Neurosci. 4: 227) and in culture (Nishi & Willard, Neuroscience 16:187; Willard & Nishi, Neuroscience 16:201, 213). We are interested in how functions of enteric neurons are related to their electrophysiological properties and in how those properties can be altered by synaptic activity. As a first step toward that end, we have determined the voltage-dependent currents found in myenteric neurons.

Whole cell patch clamp recordings were made at 20 - 22° C from rat myenteric neurons grown in cell culture for 4-22 days. At least 5 different voltage-dependent currents were detected in all cells tested: 1. A fast TTX-sensitive Na current. 2. A fast "A" type K current. This current rapidly activates (t_{peak}<10 ms) and inactivates ($t_{0.5}$ 10 ms). Like other A currents, it is fully inactivated at holding potentials positive to -55 mV, blocked selectively by millimolar 4-aminopyridine and relatively insensitive to tetraethylammonium (TEA) up to 25 mM. In contrast to many A currents, it is blocked when Ba replaces Ca or when Ca currents are suppressed by Cd or Co. 3. A "delayed rectifier" K current. This current does not inactivate during 175 msec pulses, is sensitive to TEA (IC_{50} 5 mM) and shows no Ca-dependence. 4. A rapidly activating (5 msec) and inactivating ($t_{0.5}$ 12 msec) Ca current. 5. A slower (t_{peak} 15-20 ms) non-inactivating Ca current.

Although all 5 currents appear to be present in all cells, their relative amplitudes vary significantly among different cells. At present, we have no evidence that there are qualitative differences in the currents found in subsets of neurons. Experiments are in progress to determine how the relative amplitudes of the different currents can be altered by synaptic and electrical activity in these neurons. Supported by NIH grant NS24362 and by an Alfred P. Sloan Fellowship to ALW.

148.3 PUMILIOTOXIN-B INCREASES EXCITABILITY AND INDUCES REPETITIVE ACTION POTENTIAL DISCHARGES IN BULLFROG SYMPATHETIC NEURONS. Geoffrey G. Schofield Forrest F. Weight, and Stephen R. Ikeda. Section of Electrophysiology, Lab. of Physiologic and Pharmacologic Studies, National Institute on Alcohol Abuse and Alcoholism, Rockville, MD 20852.

The alkaloid pumiliotoxin-B (PTX-B), isolated from the skin of the Panamanian frog *Dendrobates pumilio*, has been shown to prolong and potentiate muscle twitches, cause repetitive EPP discharges in response to a single nerve shock, and cause repetitive action potential discharge superimposed on a depolarizing after-potential in response to a single brief depolarization (Rao, K.S. *et al*, Mol. Pharmacol. in press). To characterize the effects of PTX-B on nervous tissue we have investigated the effects of the toxin on bullfrog postganglionic sympathetic neurons using conventional intracellular microelectrode techniques.

Under control conditions, orthodromic or antidromic stimulation, or brief (10 msec) depolarizing current pulses injected into the soma via the recording pipette induced a single large overshooting somal action potential followed by an after-hyperpolarization (AHP). After superfusion with 2 μM PTX-B these stimuli induced either self-sustaining repetitive action potential discharges or bursting pacemaker activity. Prior to the initiation of spontaneous activity a post-AHP depolarization was observed. The amplitude of the post-AHP depolarization was dependent on the stimulation frequency, and appeared to be responsible for the spontaneous action potential discharge. When repetitive activity was induced by orthodromic stimulation it was often associated with bursts of EPSPs whereas antidromic stimulation or intracellular current injection resulted in repetitive activity free of these EPSP bursts.

PTX-B-induced repetitive action potential discharges were not dependent on external Ca^{2+} as they persisted in Ca^{2+}-free or Cd^{2+} (0.5 mM) containing solutions. However, superfusion with Na^+-free or TTX (3 μM) containing solutions resulted in a cessation of repetitive activity which returned on reapplication of Na^+ or washout of TTX.

We conclude that PTX-B induces a use-dependent increase in neuronal excitability. Voltage-clamp experiments are being conducted to elucidate the mechanism of action of PTX-B on sympathetic ganglion neurons.

We would like to thank Dr. E. X. Albuquerque for providing the toxin and for helpful discussions during the course of these experiments.

148.4 ELECTROPHYSIOLOGY OF ISOLATED NEURONS FROM BULLFROG INTRACARDIAC GANGLION. A. Tse*, R.B. Clark* and W. Giles*, (SPON: J. Remmers). Dept. of Physiology, Faculty of Medicine, University of Calgary, Calgary, Canada T2N 4N1.

Neuronal cell bodies from the parasympathetic ganglia of the interatrial septum of bullfrog (Rana catesbeiana) heart were isolated using an enzymatic digestion procedure. The vagus nerve trunk was separated from the septum, cut into 1 - 2 mm lengths, and incubated in Ca^{2+}-Ringer containing 0.2% Collagenase and 0.1% Elastase for 0.5 hr at 30°C. Cell bodies, released by triturating the segments of nerve trunk through a fire-polished Pasteur pipette, were maintained in tissue culture medium (50% L - 15) for 24 hrs before use.

Isolated cell bodies were spherical or slightly ellipsoidal, with diameters of 20 - 25 μm. Electrophysiological recordings were made at 20° C using the "gigaseal" method. Resting membrane potential (r.p.) was -49.5 mV (S.D., 4.9; n = 6). Injection of current pulses (1 ms, 2 - 3 nA) evoked action potentials with the following characteristics: threshold, -31.5 ± 3.5 mV; maximum overshoot, +40.6 ± 6.5 mV; maximum after-hyperpolarization, -74.1 ± 3.2 mV; duration (at 0 mV), 2.6 ± 0.3 ms; maximum rate-of-rise, 85 ± 26 V/sec. The after-hyperpolarization decayed with a time constant of 100 - 150 ms; this slow decay arose from the large input resistance (0.5 - 2 Gohms) of the neurons negative to r.p. Injection of hyperpolarizing current pulses (1 ms, 1 nA) produced electrotonic decays with a similar time course. Cell capacitance was 50 - 65 pFd.

Preliminary voltage clamp experiments identified a rapid TTX-sensitive inward current, a slower Cd^{2+}-sensitive inward current, and at least two components of outward current. The reversal potential of the outward currents, estimated from current tails was -75.0 ± 1.2 mV (n = 3) in 2.5 mM K^+ Ringers, not significantly different from the maximum after-hyperpolarization of the action potential. Outward current tails decayed rapidly in the membrane potential range -50 to -70 mV: in 3 cells the time constant was 5.6 ± 2.0 ms at -50 mV, 4.5 ± 1.7 ms at -60 mV, and 3.6 ± 2.2 ms at -70 mV. Cd^{2+}-containing (0.3 mM) Ringers abolished 50 - 90% of the outward current, implying that most of the outward current in these isolated neurons is generated by a Ca^{2+}-dependent K^+-conductance.

Supported by an A.H.F.M.R. grant to W. Giles.

148.5 DIRECT EFFECTS OF THE LINCOSAMIDE ANTIBIOTIC, CLINDAMYCIN, ON SYMPATHETIC GANGLION CELLS. L.M. Konopka* and R.L. Parsons. (SPON: S. Freedman). Department of Anatomy and Neurobiology, College of Medicine, The University of Vermont, Burlington, Vermont 05405.

The lincosamides are one of the most commonly used types of antibiotics. One side effect of these compounds is interference with cholinergic neurotransmission, especially well documented at the neuromuscular junction but also occurring at autonomic ganglia. However, only limited information is available concerning possible direct effects of these agents on the general properties of neurons. Therefore, the present study was undertaken to identify possible direct actions of one lincosamide, clindamycin, on the properties of sympathetic ganglion cells and to compare the concentration dependence of direct effects on ganglion cell properties to the development of ganglionic blockade. All experiments were done in vitro using sympathetic ganglion B cells of the bullfrog, Rana catesbeiana, maintained in a HEPES buffered solution at 20-23°C.

We found that clindamycin produced a number of concentration and time dependent alterations in the properties of individual ganglion cells. Many ganglion cells were depolarized during either bath application (1×10^{-5} - 5×10^{-4} M) or local "puffer" application of clindamycin. The depolarization could be induced after pretreatment with either atropine or curare indicating that it was not mediated by activation of either nicotinic or muscarinic receptors. Clindamycin also produced a decrease in the rate of rise and fall and a decrease of the overshoot of directly stimulated action potentials. Further, in the presence of clindamycin the hyperpolarizing afterpotential (HAP) of the action potential was dramatically shortened. The change in the HAP duration by clindamycin appeared to be due to a selective decrease of the slow component of the HAP. In addition, the alteration in the HAP occurred with concentrations lower than those required either to alter the other action potential parameters or interfere with ganglionic transmission.

148.6 4-AMINOPYRIDINE EFFECTS ON FAST CONDUCTING AND MIDDLE CONDUCTING MYELINATED OPTIC TRACT AXONS: IN VIVO STUDY. D.-Y. Ruan*, D. Impelman and D. A. Fox. College of Optometry, University of Houston, Houston, TX 77004.

Recent in vitro studies in rat optic nerve demonstrate that the 4-aminopyridine (4-AP) sensitive potassium channel plays a primary role in action potential repolarization. 4-AP, but not tetraethylammonium (TEA), causes a marked broadening of the compound action potential (CAP) response followed by a postspike positivity (Kocsis et al., Brain Res 383: 357, 1986). Due to the short conduction distance, however, only a single monophasic negative component of the response is present in the recordings. In order to examine the possible differential effects of 4-AP on large diameter, fast conducting t1 optic tract (OT) axons and medium diameter, middle conducting t2 OT axons we utilized an in vivo preparation in 90 day old female Long-Evans hooded rats. CAP recordings were made from distal OT while stimulating the optic chiasm. Time course studies (0-60 min) of response amplitudes, peak latencies, rise times, and CAP duration were determined from single-shock experiments before and after injection of 5 µL of 1 mM 4-AP into distal OT. Rheobase, chronaxie, frequency following, relative refractory periods (RRPs), and percent amplitude recovery were determined from single-shock, paired-shock and train stimulation experiments before and after stabilization (1-2 hours) of the 4-AP response. Time course studies reveal that initially (1-5 min) most t1 and t2 measures are similarly affected by 4-AP. Response amplitude is decreased, peak latency and rise time are increased while t1 CAP duration is markedly increased compared to t2. 20-60 min following 4-AP similar results are observed for t1 and t2 except that during this time period t1 amplitude is partially recovered resulting in a larger amplitude decrease in t2 than t1. Additional studies show that 4-AP markedly increases t1 and t2 RRP, rheobase and chronaxie with the latter exhibiting greater effects in t2 than t1. No effect on absolute percent amplitude recovery is observed for t1 or t2. Furthermore, after 4-AP frequency following is equally decreased in t1 and t2 up to 300 Hz while from 300-700 Hz t2 exhibits a slightly greater decrease. These results suggest that the amplitude decrease and waveform broadening observed by Kocsis et al. primarily result from effects on t2 and t1, respectively. In addition, these data demonstrate that 4-AP produces differential effects on the firing characteristics of t1 and t2 OT axons as assessed by paired-pulse and train stimulation. The single pulse effects on amplitude, duration, rheobase and chronaxie are probably due to prolonged membrane depolarization while the paired-pulse recovery function and frequency following effects are most likely associated with the postspike positivity (i.e., intracellular hyperpolarization).

148.7 **IONIC CURRENTS IN ACUTELY DISPERSED CELLS FROM THE PINEAL GLAND OF THE ADULT RAT.** Luis G. Aguayo* and Forrest F. Weight. Section of Electrophysiology, Laboratory of Physiologic and Pharmacologic Studies, National Institute on Alcohol Abuse and Alcoholism, Rockville, Md. 20852.

Ionic currents of pineal cells were studied using the whole-cell variation of the patch-clamp recording technique. Pineal glands were removed approximately 2 1/2 hrs after light onset from male Sprague-Dawley rats (200-300 g) kept under LD 12:12 with lights on from 6 A.M. to 6 P.M. Single cells were acutely separated with enzymatic and mechanical dispersion techniques. The macroscopic ionic current observed in control external solution (mM: 150 NaCl; 5.4 KCl; 2 $CaCl_2$. 1 $MgCl_2$; and 10 HEPES; pH 7.4) and internal solution (mM: 130 KCl; 1 $CaCl_2$; 2 $MgCl_2$; 10 HEPES; and 11 EGTA; pH 7.35) was dominated by an outward current with little or no apparent inward current. Membrane currents evoked from holding potentials of -50 and -80 mV showed distinctive features with the one from -80 mV having the fastest rising phase and the largest amplitude. Currents obtained in the presence of 1 µM TTX were similar to those obtained in control solutions.

Study of the outward current in external solution without added Ca^{2+} revealed the existence of two distinct outward currents. Depolarizations from a holding potential of -100 mV activated a fast current which reached a peak within 15 ms (at command potentials positive to -20 mV) and decayed completely in about 150 ms. The time to peak of this transient current decreased linearly with the command potential, being 25 and 10 ms at -40 and -5 mV, respectively. This current was activated at potentials more positive than -50 mV and displayed steady-state inactivation at depolarizing voltages with half-inactivation near -80 mV. The second outward current component isolated from a holding potential of -50 mV was activated at potentials positive to -20 mV, reached a steady-state current amplitude within 50 ms and was sustained up to 400 ms. In the presence of 2 mM external Ca^{2+} the I-V relationship for the outward current obtained from -50 mV did not display a region of negative slope conductance (N-shape) and this may suggest that a Ca^{2+}-activated K^+ current did not contribute significantly to the outward current.

We conclude that acutely dissociated pineal cells dispersed at the begining of the light period display two distinct K^+ currents: (i) a transient current similar to the A current (I_A); and (ii) a slowly activating, sustained current similar to the delayed rectifier current (I_K). Under the conditions of our experiments, Ca^{2+}-dependent currents appear to contribute only a small fraction of the total membrane current.

148.8 ELECTROPHYSIOLOGY OF GUINEA PIG MAMMILLARY BODIES *IN VITRO*. A. Alonso* and R. Llinás (SPON: V. Decrescito). Dept. Physiol. & Biophys., New York Univ. Med. Ctr., 550 First Ave., New York, NY 10016.

Intracellular recordings were obtained from both medial and lateral mammillary neurons in guinea pig brain slices. The cells were grouped into two categories according to electrophysiological criteria. Those in the first category were characterized by a high input resistance ranging from 100 to 200 megohms, by the presence of a powerful A-conductance, and by dendritic calcium spiking following blockage of potassium conductance by tetraethylammonium (10 mM). These cells also demonstrated a clear calcium-dependent potassium conductance and, in addition to fast TTX-sensitive sodium-dependent spikes, a slow non-inactivating sodium conductance which could generate long-lasting plateau potentials which were also TTX-sensitive (tetrodotoxin, 10^{-6} gm/ml). Upon electrical stimulation of the peri-mammillary region with a fine bipolar metal electrode, these neurons showed short-latency excitatory potentials followed by inhibitory potentials. At high stimulus strength a large prolonged secondary IPSP was also recorded.

The second type of cell was characterized by the presence of a low-threshold calcium spike and, following replacement of extracellular calcium with barium, by the presence of TTX-insensitive high threshold spikes. These neurons demonstrated only an early synaptic excitation following peri-mammillary stimulation. These two cell types were also distinguished after intracellular HRP injection. Those in the first category were usually fusiform, had medium-sized somata, and thick spiny dendrites. Those in the second group were smaller, with thin and sparsely spined dendrites.

Because the mammillary neurons project massively to the anterior nuclei of the thalamus (Powell & Cowan, J. Anat. 88: 489, 1954), their intrinsic electroresponsiveness may be central in the relaying of rhythmic synaptic input to these nuclei. In particular, the medial septum projects to the mammillary bodies (Swanson & Cowan, J. Comp. Neurol. 186: 621, 1979), and it is known to be a pacemaker for the theta rhythm (Gogolak et al., Brain Res. 7: 201, 1968). Thus, the possibility that the mammillo-thalamic pathway may be important in the propagation of the theta rhythm to the thalamus and cingulate cortex is to be emphasized. [Research supported by NS13742 from NINCDS].

148.9 **THE REGULATION OF ACTIVITY IN MIDBRAIN DOPAMINE NEURONS: ANALYSIS USING IN VITRO INTRACELLULAR RECORDINGS.** AA Grace Departments of Behavioral Neuroscience & Psychiatry, Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.

Intracellular recordings were made from identified dopamine (DA) neurons of the substantia nigra (SN) and ventral tegmentum (VTA) of rat midbrain maintained in vitro. Intracellular staining with Lucifer yellow and HRP revealed three DA cell morphologies: In the SN, dorsal DA neuron somata were fusiform in shape with dendrites oriented along the compacta, whereas the more ventral multipolar DA cells had dendrites extending ventrally as well. In the VTA, dendrites of multipolar DA neurons were oriented in a radial pattern. The dendrites had sparse 3-15 um long protrusions and terminated in fork-like processes.

In contrast to the characteristic irregular or burst firing pattern of DA neurons recorded in vivo, DA cells in vitro fired exclusively in pacemaker patterns. The input resistance ranged from 150-350 megohms, or about 5x that found with in vivo recordings. Spontaneous spikes were driven by a sodium-dependent slow depolarization (SD). TTX administration revealed an underlying low threshold calcium spike (LTS, Llinas & Yarom, 1981) which, although inactivated at resting potentials, could be activated by depolarization from a hyperpolarized state. Thus, the LTS triggered by hyperpolarizing pulse rebound often led to spike discharge. However, larger hyperpolarizing pulses also activated a potassium current (I_A) which slowed the membrane repolarization, thereby blocking the rebound LTS and spike firing. A second calcium spike, the high threshold spike (HTS), was only observed after tetraethylammonium (TEA) administration, suggesting that HTSs are probably of dendritic origin (Llinas et al, 1984). Both action potentials and HTSs triggered afterhyperpolarizations (AHP), which also exhibited voltage-dependent properties.

Thus, DA cells have active currents similar to those of other mammalian neurons, with two exceptions: 1) the presence of prominent SDs driving spontaneous activity, and 2) the blockade of the LTS by strong hyperpolarizing pulses. Other cells with prominent LTSs, upon hyperpolarization, show decreased spontaneous activity coupled with enhanced excitation to depolarization (i.e., a greater "signal/noise" ratio). However, DA cell activity is modulated in an opposite manner to alterations in membrane potential. Thus, spontaneously firing DA neurons exhibit properties which serve to maintain ongoing spike activity (i.e., the LTS triggered from the rebound of a spike AHP would, in turn, activate the SD and subsequent spike), whereas hyperpolarized DA neurons are capable of maintaining their inactive state (i.e., decreased excitatory drive due to the strong anomalous rectification, coupled with attenuation of the LTS by I_A during depolarization). These factors could contribute to the bimodal distribution of DA cell activity. Thus, about 1/3 of DA cells are not spontaneously active in the absence of demand (Grace & Bunney, 1986); whereas spontaneously active DA cells fire at rates distributed normally about 4.6 Hz, with cells rarely firing at rates below 2 Hz. (Supported by USPHS MH42217 & MH30915)

148.10 THE CALCIUM CURRENT AND THE GLUTAMATE RESPONSES IN ISOLATED, IDENTIFIED SPINAL DORSAL HORN PROJECTION NEURONS. L.-Y.M. Huang. Marine Biomedical Institute and Department of Physiology and Biophysics, The University of Texas Medical Branch, Galveston, TX 77550.

Spinothalamic and trigeminothalamic neurons in the spinal cord play important roles in transmitting information related to noxious stimuli. The understanding of the electrical properties of these cells and their responses to various amino acids will provide us with important information about how pain is mediated by the nervous system. We have reported the procedures to isolate and identify these cells and studied the voltage-dependent properties of Na,K channels (Soc. Neurosci. 12:1147, 1987). The properties of Ca currents and the responses to amino acid glutamate are described here. Slow inward current was isolated by blocking I_{Na} with 2 μM tetrodotoxin and inhibiting I_K by replacing intracellular K^+ with Cs^+. Ba or Ca was used as the current carrier in these experiments. The predominately slow inward current started to activate at -25 mV and did not inactivate substantially at the end of 100 msec depolarizing pulse. A second component of Ca current, which activated at more hyperpolarized potentials and inactivated relatively rapidly, was also observed. $CdCl_2$ was able to block, to different degrees, both types of these slow inward currents. These currents have many of the characteristics of the inward long lasting and transient Ca current observed in other preparations. Most of the neurons tested were sensitive to L-glutamate. The current voltage curve of the glutamate responses showed a slight rectification as the membrane was depolarized. The reversal potential of responses was closed to 0 mV. This response was blocked by the presence of 1 mM $MgCl_2$ similar to the N-methyl-D-aspartate (NMDA) seen in other neurons. Supported by NIH NS23061 and NS01050.

148.11 ELECTROPHYSIOLOGICAL PROPERTIES OF LATERAL DORSAL TEGMENTAL NEURONS IN VITRO. K.S. Wilcox, S.J. Grant#, G.R. Christoph. Neuroscience Section, E.I. duPont de Nemours and Company, Inc., Wilmington, DE 19898 and #Dept. Psychology, University of Delaware, Newark, DE 19716.

The lateral dorsal tegmental nucleus (LDT) is the origin of ascending cholinergic projections innervating numerous forebrain structures such as prefrontal cortex, habenula, and thalamus. Electrical stimulation of the LDT in vivo suppresses burst firing in the nucleus reticularis of the thalamus, suggesting that the LDT may affect sensory gating processes in the thalamus (Kayama et al. J. Neurophys. 56: 1310-1320, 1986). We investigated the electroresponsive characteristics of LDT neurons with standard intracellular recording techniques in a guinea pig brain slice preparation maintained in vitro. Microelectrodes were positioned with respect to visual landmarks in a region of the LDT which contains a high density of cholinergic perikarya. This region was determined by an enzymatic NADPH diaphorase stain (Vincent et al., Neurosci. Lett. 43: 31-36, 1983) in coronal sections through the LDT of other guinea pigs. LDT neurons included in the study all had membrane potentials greater than -55 mV and input resistances greater than 50 megohms. Most neurons fired action potentials in two modes: tonically and in bursts. With a background membrane potential less than -65 mV, depolarizing current pulses elicited TTX-sensitive, tonically firing action potentials, with frequency directly proportional to current intensity. At membrane potentials greater than -65mV, depolarization evoked a slow, TTX-insensitive wave of depolarization which served as a generator potential for a high frequency burst of fast spikes. These voltage-dependent characteristics suggest that, as in olivary, thalamic, and habenular neurons, activation of a low-threshold calcium conductance ($LT_{Ca(g)}$) underlies generation of burst activity in the LDT. Furthermore, the presence of $LT_{Ca(g)}$ in LDT neurons and the possibility that at least some of these neurons recorded from were cholinergic suggests that slight hyperpolarization of the membrane potential may serve to amplify responses to excitatory input and thereby enhance the release of acetylcholine in target regions.

148.12 **WHOLE CELL PATCH CLAMP RECORDING FROM DISSOCIATED CULTURES OF HYPOTHALAMIC NEURONS.** R.E. Petroski*, R. Ventimiglia, & H.M. Geller (SPON: M.T. Spoerlein). Department of Pharmacology, UMDNJ-Robert Wood Johnson Medical School and The Graduate School, Rutgers University, Piscataway, NJ 08854.

We have developed methods for growing hypothalamic neurons in dissociated cell culture at low density. Neurons from these cultures have been shown to express tyrosine hydroxylase, several hypothalamic peptides, as well as β-adrenergic and GABA receptors. Because of their small size and precarious location, it has been difficult to perform voltage clamp analysis on hypothalamic neurons *in vivo* or in the *in vitro* slice or explant preparations. Our culture system permits the growth of isolated hypothalamic neurons, 10-25 μm in diameter, suitable for voltage clamp analysis by the whole cell patch clamp technique.

Hypothalami are dissected from E17 rat brains and plated on coverslips containing a monolayer of cortical astrocytes. Patch electrodes of 3-7 MΩ are used to obtain tight seals of 10-50 GΩ. Voltage clamp recording from neurons 3 to 12 days *in vitro* have been performed. Neurons exhibit typical resting membrane potentials of -55mV and input resistances of 200 to 1000 MΩ.

All neurons contain a delayed voltage-dependent outward current. This is blocked by addition of 30mM TEA as well as using Cs^+ as the major cation in the electrode. We have identified a voltage dependent inward current, which is blocked by 1μm TTX. The amplitude of this current in different neurons varies from 1000 pA to less than 100 pA. This does not appear to be a function of development as very young neurons may contain a robust inward current while some older neurons have shown no inward current. Many neurons exhibit a transient outward current immediately following the inward current. This current is facilitated by holding potentials of -80mV and is abolished at -40mV in some neurons. The I-V curve for this current displays the typical "N" shape of the A-current. In other cells, the transient outward current is not affected by resting membrane potential and the I-V curves run parallel to the delayed rectifier. This may be a Ca^{2+} dependent K^+ current.

These neurons do not easily lend themselves to categorization by the types of ion channels they exhibit. Rather, different neurons appear to display quantitative differences in the repertoire of currents they express. Continuing work on the development and pharmacology of these ion channels will be presented. (Supported by N.I.H. NS-19187).

148.13 SYNCHRONOUS ACTIVITY IN LOCUS COERULEUS NEURONS FROM NEONATAL RATS. M.J. Christie,* J.T. Williams and R.A. North. Vollum Institute, Oregon Health Sciences University, Portland, OR, 97201

Locus coeruleus (LC) neurons in brain slices from young rats display rhythmic variations in membrane potential, 5-15 mV in amplitude at a frequency of 0.3-3.0 Hz. These are TTX insensitive, dependent on extracellular calcium and appear to originate in the cellular dendrites (K.C. Marshall and J.T. Williams, Soc. Neurosci. Abstr. 12, 1390P, 1986). In the present study, simultaneous intracellular recordings were made from 59 pairs of LC neurons in submerged slices (300 - 400 μm, 37°C) prepared from young rats (1 day - 6 weeks). Cells impaled were separated by 50 - 300 μm. The rhythmic potentials increased in frequency and declined in amplitude with age, and became undetectable after 27 days. At ages less than 24 days, rhythmic activity was always synchronous between neurons in the same LC (N = 48). Pairs of neurons in opposite LC nuclei did not show this synchrony (N = 3). Spontaneous action potentials usually arose from the peak of the depolarizing phase of the rhythmic potentials, but were often asynchronous between pairs. From 24 to 27 days rhythmic activity, when present, was only partially synchronous (N = 8), but full synchrony could be restored by superfusion with tetraethylammonium (TEA) (10 mM) and 2 mM $BaCl_2$ (2 mM). At 40 days no synchronous rhythmic activity could be observed (3 pairs). Weak electrotonic coupling was found between 8 of 15 pairs of neurons less than 10 days old, but in 0 of 3 pairs greater than 10 days old: in the presence of TTX (600 nM), TEA (20 mM) and $MgCl_2$ (11.5 mM), hyperpolarizations (100 mV, 200 ms) evoked by direct current in one cell produced very small, slower hyperpolarizations (0.3-2 mV) in a second cell 50-150 μm away. These results demonstrate that TTX insensitive rhythmic activity is synchronous throughout the LC of neonatal rats. This synchrony declines with age, at least in slice preparations. Entrainment of rhythmic activity might be due in part to electrotonic coupling between neonatal LC neurons.

148.14 INTRACELLULAR RECORDINGS FROM NORADRENERGIC LOCUS COERULEUS NEURONS IN UNRESTRAINED CATS: ELECTROPHYSIOLOGICAL CHARACTERIZATION DURING SLEEP. A. Hosseini and M.E. Trulson. Dept. Anat., Coll. Med., Texas A&M University, College Station, TX 77843.

The electrophysiological properties of noradrenergic (NE) locus coeruleus (LC) neurons have been characterized in anesthetized rats (Brain Res., 273, 1983, 237). LC neurons exhibit a pronounced post-action potential hyperpolarization followed by a slow interspike depolarization. This gradual depolarization continues to the next spontaneous spike. This pattern of activity appears to account for the automaticity in the discharge rate of LC neurons. It is well known that anesthetics dramatically alter the membrane properties of neurons (Trends Pharmacol. Sci., 5, 1984, 287). Furthermore, it is not possible to examine the membrane properties of neurons during behavior when the animal is anesthetized. Therefore, we developed a technique for recording the intracellular activity of single LC neurons in unrestrained cats. A plate designed to securely hold the slave cylinder of a Trent Wells motorized microdrive was cemented to the cat's skull under pentobarbital anesthesia. After complete recovery from the anesthesia the slave cylinder was attached to the baseplate. The electrode was a 2 mm (o.d.) Omega Dot glass tube beveled by the thick slurry method of Lederer et al. (Pflugers Arch. 381, 1979, 287) with an impedance of 15-30 mΩ and filled with 1 M potassium acetate. Six insect pins were positioned 3 mm apart in a hexagonal fashion around the LC to minimize pulsations. LC neurons were impaled by the use of a 2 msec 20 V DC pulse which was passed through the breakaway box of a M707 WP amplifier. Only intracellular recordings of neurons with stable spontaneous discharge rates for a given behavioral state (Rasmussen et al., Brain Res. 371, 1986, 324) and action potentials of >50 mV were studied. LC cells showed the slow (1.27 ± 0.10 spikes/sec during quiet waking), rhythmic discharge pattern previously described. A hyperpolarization of 4-5 mV occurred after each action potential during quiet waking, and there was a gradual ramp of depolarization preceding each spike. As the cat entered slow wave sleep the overall activity of LC units decreased significantly to 0.2 spikes/sec. During this phase of sleep, the hyperpolarization following an action potential was greater (12 - 14 mV) than during quiet waking periods. When the animal entered REM sleep, LC neurons became virtually silent (0.02 spikes/sec). The hyperpolarization following a spike during REM sleep was about the same (14 - 15 mV) and remained constant for prolonged periods of time. During the few seconds immediately preceding another spike during sleep, there was a rapid depolarization to 6 - 8 mV, and then a slow ramp of polarization immediately preceding the spike.

AUDITORY SYSTEM V

149.1 **CALMODULIN INHIBITORS BLOCK ADAPTATION IN VESTIBULAR HAIR CELLS** D.P.Corey, W.J.Smith*, B.A.Barres and W.J.Koroshetz, Neuroscience Group, Howard Hughes Medical Institute, and Department of Neurology, Massachusetts General Hospital; Program in Neuroscience, Harvard Medical School, Boston, MA

Hair cells in the bullfrog sacculus respond to displacement of their ciliary bundles with the opening of ion channels in the tips of the cilia. There is evidence that these channels respond directly to mechanical stress, and that stress is communicated to the channels by fine filamentous links between cilia (Hudspeth, 1982; Corey and Hudspeth, 1983; Pickles, *et al.*, 1984). In response to a maintained positive displacement of the ciliary bundle, channels open, but then spontaneously close over several tens of milliseconds; the process serves as an adaptation mechanism for hair cells (Eatock, Corey and Hudspeth, *in press*). At the termination of the stimulus, channels close, but then some reopen during the recovery from adaptation.

If the mechanical model for transduction is correct, this adaptation must correspond to a relaxation of the stress applied to the channel, either through a reduction in the spring constant of the link, or through a change in the relative attachment points. Recovery from positive adaptation must correspond to a tensioning process, that reestablishes stress on the channel protein. Changes in bundle stiffness occurring over the same timecourse suggest a similar model (Howard and Hudspeth, 1986).

What molecular constituents of the transduction mechanism mediate the adaptation? It is known that adaptation is accelerated by increased calcium in the endolymph, possibly acting at an intracellular site. We have used the *in vitro* microphonic preparation of the bullfrog sacculus to explore the site of calcium action.

Inhibitors of calmodulin substantially decreased the adaptation rate, at concentrations similar to those required to inhibit calmodulin. The adaptation rate was decreased to less than half the control rate by trifluoperazine (at 50 μM), by W-7 but not the inactive analog W-5 (both at 10 μM), and by calmidizolium (at 5 μM). Higher concentrations almost completely abolished adaptation, but also caused a reduction in total receptor current. All the calmodulin inhibitors also shifted the resting position of the displacement-response curve (DRC) towards negative displacements--corresponding to increased channel activation and thus to increased tension. Lowering endolymphatic calcium produced the same effect as calmodulin inhibitors on both the adaptation rates and on the resting position of the DRC.

Calmodulin in dissociated bullfrog hair cells was localized with a sheep antiserum to calmodulin and a secondary antibody coupled to glucose oxidase. Calmodulin-like immunoreactivity was distributed throughout the cytoplasm and cuticular plate, as in cochlear hair cells (Flock, *et al.*, 1986), but was conspicuously absent from the ciliary bundles. Thus calcium's action on the adaptation process may occur via calmodulin in the cuticular plate, or it may occur through an unidentified calcium binding protein, possibly within the bundle. Calmodulin inhibitors are not particularly specific, and could be inhibiting a calcium-binding protein other than calmodulin.

149.2 DIRECT EVIDENCE FOR ELECTRICAL TUNING OF CHICK COCHLEAR HAIR CELLS. P.A. Fuchs and M.G. Evans*. Dept. of Physiology, Univ. Colorado Sch. Med., Denver, CO 80262.

Recent studies have suggested that cochlear tuning mechanisms may differ in mammals and lower vertebrates. In birds, direct observation of basilar membrane motion has revealed mechanical tuning similar to that seen in mammals. However other, indirect evidence has raised the possibility of electrical tuning of hair cells as seen in turtles and frogs. We examined this latter possibility by making direct electrical recordings from single hair cells isolated from specific regions of the chick cochlea: the apical-most 200 μm where low frequency sounds (<100 Hz) are encoded ('apical cells'), and 200 μm wide sections ranging 1 to 2 mm from the apical tip ('basal cells') where sound frequencies of 400 to 1000 Hz are encoded. Single tall (inner) cells were isolated from the cochleas of 2-6 week old Leghorns using a combination of enzymatic and mechanical dissociation procedures. Tight-seal whole-cell recordings were made at room temperature (22-25°C).

Apical cells had resting potentials near -74 mV. Injection of depolarizing current elicited action potentials and low frequency (5-20 Hz) voltage oscillations that were smaller in amplitude and sinusoidal in shape. In voltage clamp these cells exhibited inward currents at voltages negative to -70 mV, and both early inward, and larger, slower outward currents in the voltage range -50 to +30 mV. Thus the steady-state I-V relation showed both inward and outward rectification and had an 'N-shape' at positive potentials, indicating outward current dependent on Ca entry. Basal cells had resting potentials near -57 mV, and injection of depolarizing current caused small high frequency (100-250 Hz) voltage oscillations. Action potentials were never seen. In voltage clamp basal cells had little or no inward rectifier current, and depolarization above -50 mV elicited large, rapidly activating outward currents, again resulting in an N-shaped steady-state I-V relation. Net inward current usually was not seen in these cells.

The N-shaped I-V relation, and other experiments showing the calcium dependence and sensitivity to tetra-ethyl ammonium of the dominant outward current, indicated that this was a calcium-activated potassium current. In addition to being 2-3 fold larger, basal cell outward currents also activated 20 times more rapidly than did those of apical cells. Kinetic variations in calcium-activated potassium current are thought to underlie electrical tuning of hair cells in turtles and frogs. Thus the bird cochlea may attain its frequency selectivity through a combination of mechanical and electrical tuning. (Supported by grants NS21454 and NS01007 from the NIH).

149.3 ACTION POTENTIALS AND VOLTAGE OSCILLATIONS IN HAIR CELLS FROM THE ALLIGATOR COCHLEA. M.G. Evans* and P.A. Fuchs. Department of Physiology, Univ. of Colorado Sch. Med., Denver, CO 80262.

We have used the tight-seal whole-cell recording technique to record from hair cells isolated from the apical half of the alligator cochlea. Five alligators (A. mississippiensis), 2 months old and 40-50 cm long were used. After decapitation and removal of the cochlea from the otic capsule, single hair cells were isolated by a combination of enzymatic and mechanical dissociation. Experiments were done at room temperature (22-25°C).

All of the successful recordings were from tall hair cells. Resting potentials ranged from -40 to -80 mV. Depolarizing current injections from the resting potential gave rise to two types of response. These were either single action potentials (spikes) that depolarized the cell to a value between 0 and -25mV or decaying voltage oscillations (rings) whose frequency varied from cell to cell (25-160 Hz). Overall, spiking cells were isolated from segments nearer the apex (low frequency end) of the cochlea than were ringing cells, and they usually had larger resting potentials.

In voltage clamp the spiking cells had transient inward followed by noisy outward currents in response to depolarizing voltage jumps from -70 mV. The inward current was found to be a Na current since it was dependent on external Na and was blocked by tetrodotoxin (100 nM). The major component of the outward current appeared to be a Ca-activated K current since it was dependent on external Ca and was blocked by external Cd (1 mM), tetra-ethyl ammonium (TEA, 20 mM) or by replacing internal K with Cs.

The ringing cells had much smaller inward currents under voltage clamp and often had larger outward currents than the spiking cells. The sensitivity of both inward and outward currents to external Ca and Ba, and of the outward current to external TEA or internal Cs, indicated that Ca influx through Ca channels activated the outward K current.

With the exception of the Na current, the currents recorded in alligator hair cells are similar to those recorded in electrically-tuned hair cells from other species. The ringing and spiking responses are especially similar to those seen in the morphologically similar chick cochlea (see P.A. Fuchs and M.G. Evans, this meeting). Since there is evidence for mechanical tuning in both birds and crocodilians, it is possible that they achieve frequency selectivity through a combination of electrical and mechanical tuning. (Supported by grants NS21454 and NS01007 from the NIH).

149.4 **REGENERATION OF SENSORY HAIR CELLS IN THE COCHLEA OF THE CHICKEN.** J.T. Corwin and D.A. Cotanche. Dept. of Zoology and Békésy Lab. of Neurobiology, University of Hawaii, Honolulu, HI 96822 and Dept. of Anatomy and Cell Biology, Medical University of South Carolina, Charleston, SC 29425

In birds and mammals the production of sensory hair cells in the cochlea normally ceases before birth, so it has been assumed that any subsequent loss of hair cells must result in a hearing loss that is irreversible. However, hair cells in the ears of lower vertebrates are produced throughout life, and in the lateral line system these cells can be replaced by regeneration. Recent ultrastructural investigations of sound induced damage in birds have produced indirect evidence suggesting that hair cells in the cochlea also can be replaced by regeneration. Here we report that autoradiographic labelling of newly replicated DNA has confirmed the occurence of hair cell regeneration in the mature cochleae of chickens. Damage in the cochlear sensory epithelium was produced by exposing pairs of ten-day-old chickens to pure tone acoustic stimulation at 1.5 kHz and 120 dB SPL for 48 hr. Immediately after exposure one chicken from each pair was overanesthetized and its cochleae were fixed in 1% OsO_4, and prepared for scanning electron microscopy. In this way the location and the extent of the damage produced by the sound exposure were assessed for each experiment. The other bird from each pair received ^{3}H-thymidine delivered continuously for seven days from two osmotic minipumps that were implanted subcutaneously. The time of pump implantation was varied in different experiments: from just prior to the period of sound exposure, to four days after the sound exposure. All implanted chickens were allowed to recover for ten days after the sound exposure, then their cochleae were fixed, sectioned, and processed for autoradiography. Controls chickens received radioactive thymidine but were not exposed to acoustic overstimulation. Scanning EM of cochleae that were fixed immediately after the sound exposure confirmed that the stimulus caused death and extrusion of hair cells from a limited area in the sensory epithelium. Autoradiographic localization of labelled DNA demonstrated that the damage in that region stimulated the mitotic replication of cells remaining in the sensory epithelium. In the region of damage the nuclei of hair cells and supporting cells were both labelled by ^{3}H-thymidine. Supporting cells which normally would be mitotically quiescent after embryogenesis are spared by this level of acoustic trauma, and it appears that those cells can proliferate, giving rise to progeny which can differentiate either as supporting cells or as replacement hair cells. If similar regeneration could be induced in human ears this might allow recovery from sensorineural deafness that has generally been considered irreversible and untreatable. (Supported by NINCDS and the Deafness Research Foundation)

149.5 **A MONOCLONAL ANTIBODY THAT LABELS SENSORY HAIR CELLS AND NEURONS IN AUDITORY, VESTIBULAR, AND LATERAL LINE SYSTEMS.** H.I. Kornblum, B. Trevarrow, and J.T. Corwin. Békésy Lab. of Neurobiology and Dept. of Zoology, Univ. of Hawaii, Honolulu, HI 96822, and Institute of Neuroscience, University of Oregon, Eugene, OR 97403

Investigations of hair cell development and function have been hampered by the lack of a cell-type specific marker. Znl, a monoclonal antibody raised against zebrafish (Brachydanio rerio), has been reported to label a variety of neural cell types in zebrafish larvae, including sensory hair cells in the otic capsule. We report that this antibody also recognizes hair cells and neurons of the inner ear and lateral line system in the urodele amphibian, Ambystoma mexicanum. Immunocytochemical methods labelled hair cells and neurons, but not supporting cells or accessory structures in the sensory epithelia of juveniles and adults. Labelling was cytoplasmic and was not associated with recognizable organelles or filaments. Labelling was also present in processes and cell bodies of neurons in the VIIIth cranial nerve and the lateral line nerves. Immunoreactive processes were also detectable in the dorsolateral medulla oblongata at the approximate location of primary octavolateralis nuclei and coursing transversely through the reticular formation. Immunoreactive cells were detected in other CNS regions as well.

Regeneration experiments were performed to determine if Znl would label newly differentiated hair cells. Juvenile axolotls were anesthetized, and the tip of the tail was amputated. The tail and its lateral line neuromasts regenerated, and were fixed at different times after amputation. Znl labelling was detectable in newly formed neuromasts within two weeks of amputation. This labelling was confined to hair cells. In at least one neuromast labelling was confined to a single newly differentiated hair cell. The intensity of labelling appeared to be correlated with cell age. Staining of hair cells within newly formed neuromasts was less intense than that of cells in mature neuromasts. In the sacculus, hair cells in the growth zone at the edge of the epithelium were lightly labelled, whereas the older hair cells in the center were heavily labelled.

Znl is a useful marker to distinguish hair cells from supporting cells in both mature and developing sensory epithelia of the auditory, vestibular, and lateral line systems. The similar staining in otic and lateral line hair cells affirms the close relationship between these systems. Although the function of the antigen recognized by Znl is unknown, its presence in receptor cells and neurons in the octavolateralis systems indicates that it may have a function specific to these modalities.

149.6 DC AND CM GRADIENTS IN THE GUINEA PIG COCHLEA. M. Zidanic*[1,2], W.E. Brownell[2], and P. Dulguerov*[2]. [1]Dept. of Neuroscience, Univ. of Florida, Gainesville, FL.; [2]Dept. of Otolaryngology-HNS, Johns Hopkins University, Baltimore, MD 20205.

We are studying cochlear physiology by characterizing extracellular current pathways in silence and how they are modulated by sound stimulation. Micropipets are advanced along a 600 μm radial track that begins outside the spiral ligament (SL) and extends to a point near the modiolus in either scala tympani (ST) or scala vestibuli (SV) of the second turn. DC and stimulus evoked potential waveforms are signal averaged at each depth in response to low frequency tones. Radial potential gradients are computed by taking the spatial derivative of the field potentials.

Standing currents (or DC gradients) directed into the spiral ligament are present in both ST and SV. The peak of the radial DC gradient appears to be within the SL and has a magnitude of 5-10 mV/mm in ST and 10-15 mV/mm in SV. During the presentation of a low frequency tone burst, these DC gradients are sinusoidally modulated. This is a result of magitude and phase gradients of the cochlear microphonic (CM) that exist in the radial dimension. The fundamental component of the modulation of the DC gradient will be referred to as the CM gradient. The CM gradient is of the same magnitude in SV and ST, about 3-7 mV/mm. However, a phase difference of 180 degrees exists between the CM gradient in SV versus ST, indicating that the standing currents are modulated in opposite directions in ST and SV at a given point in time during the tone burst. This relationship holds for all frequencies and intensities tested, covering a range 50-1500 Hz and 60-90 dB SPL.

An intriguing difference between the potential gradient profiles in SV and ST lies in the relationship of the CM gradient to the DC gradient. In SV, the peak of the CM gradient occurs at the same location in the track as the DC gradient peak. Thus, the standing current that flows into the SL from SV is sometimes reduced by as much as 50%, but never changes direction. However, the peak of the CM gradient in ST occurs at a point 160-200 μm modiolar to the DC gradient peak. In 3 experiments, the CM gradient was 3-5 mV/mm larger than the DC gradient at the location of the CM gradient peak. The CM and DC gradients were of nearly equal magnitudes at the CM gradient peak in 3 other experiments. We hypothesize that these variations in ST potential gradient profiles result from electrode tracks with quite different orientations or distances relative to the basilar membrane. A two-dimensional current density analysis technique will be utilized to test this hypothesis.

149.7 RESPONSES OF SINGLE AUDITORY NERVE FIBERS IN THE MONGOLIAN GERBIL. K.K. Ohlemiller and S.M. Echteler. Auditory Physiology Laboratory. Department of Neurobiology and Physiology. Northwestern University, Evanston, IL 60201.

Evidence from the cat indicates that the spontaneous firing rate (SR) of auditory nerve fibers is linked to some aspects of their response to tones. Compared to high-SR fibers, low-SR fibers generally exhibit a higher threshold (Liberman, J. Acoust. Soc. Am., 63:442, 1978), a wider dynamic range, and greater firing rate at saturation (Evans and Palmer, Exp. Brain Res., 40:115, 1980). These findings suggest that low-SR fibers are more resistant to saturation of their response, and may preserve frequency selectivity of the auditory nerve at high intensities (Shofner and Sachs, Hearing Res., 21:91, 1986). The idea that low-SR fibers comprise a distinct class has been generalized to other mammals; however, only the relation of threshold to SR has been extended to other species (Schmiedt, Assn. Res. Otolaryngol. Abstr., 5:12, 1982; Geisler et al., J. Neurophysiol., 37:1156, 1974).

As part of a normative study of single fiber responses in the Mongolian gerbil, we have examined the relation of SR to threshold, dynamic range, and saturation rate at the characteristic frequency (CF). The auditory nerve was accessed through a hole drilled in the round window antrum at the base of the cochlea (Sokolich and Smith, J. Acoust. Soc. Am., 54:283, 1973). A PDP 11/34 computer controlled stimulus parameters and counted intervals. In our tuning curve paradigm threshold was defined as the intensity producing a 2-spike increase in a 50 msec stimulus period. A wide-band noise burst served as the search stimulus.

We find that threshold is only weakly correlated with SR. While the average threshold for fibers of SR below 2 sp/sec is higher than for other fibers, only about one half of these low-SR fibers have thresholds above 20 dB SPL. Saturation rates depend principally on CF, rather than SR. Fibers of CF above 4 kHz have the highest saturation rates, followed by fibers of CF below 2 kHz. Dynamic range appears more closely related to threshold than to SR. The neural audiogram exhibits a notch between 2 and 5 kHz. Fibers with CFs in this range have, on average, higher thresholds, higher spontaneous rates, and lower saturation rates. Tuning curve shape and Q_{10} for these fibers are not indicative of noise-induced damage.

Our data suggest that low-SR fibers (SR < 2 sp/sec) play a role in extending the dynamic range of the gerbil auditory nerve, yet only when a low SR is accompanied by a high threshold. The extended dynamic range of these fibers derives from a gently-sloping rate-intensity function, not a higher saturation rate. Such a link between threshold and dynamic range is predicted by the model of Sachs and Abbas (J. Acoust. Soc. Am., 56:1835, 1974).

149.8 RADIAL AFFERENT TERMINATION PATTERNS IN THE GUINEA PIG COCHLEA. J.H. Siegel. Depts. of Communication Sciences and Disorders and Neurobiology and Physiology, Northwestern Univ., Evanston, IL 60201.

Our recent success in intracellular recording from the spiral ganglion cells (radial afferents) innervating inner hair cells (IHC) of the apical turns of the guinea pig cochlea (Siegel, J.H. and Dallos, P., Hearing Res., 22:245, 1986) has stimulated our interest in better characterizing the synaptic termination patterns of the afferents in this species. The unmyelinated portions of the afferent dendrites within the organ of Corti were serially reconstructed from 0.25 µm sections viewed with an A.E.I. EM-7 microscope at 1 MeV (HVEM facility, University of Wisconsin, Madison).

An average of 12 different afferents contacted one IHC. In most cases, the afferent ran unbranched to a nearby hair cell, forming a single simple synaptic junction. The dendrites of these ganglion cells typically had relatively large diameters and terminated on the IHC at all points around its circumference. A minority of the afferents formed more complex synapses with either more than one presynaptic dense body in the hair cell or a single presynaptic body which contacted the presynaptic membrane at two places. The diameters of the dendrites of these cells were among the smallest encountered. They tended to innervate the hair cell on the side facing the modiolus and sometimes branched.

The termination pattern of radial afferents in the guinea pig appears similar to that reported for the cat (Liberman, M.C., Hearing Res., 3:45, 1980). The most prominent exception is that each active zone at complex IHC afferent synapses in the guinea pig appears to exhibit a presynaptic dense body, whereas complex synapses in the cat appear to exhibit only one presynaptic body, regardless of the number of active zones. Branching also appears more frequent than in the cat. The possible correspondence between the two types of synaptic complex and populations of single eighth-nerve units with low and high rates of spontaneous discharge is discussed.

149.9 ONTOGENIC CHANGES IN COCHLEAR INNERVATION FOLLOWING THE ONSET OF HEARING IN MONGOLIAN GERBILS. S.M. Echteler. Auditory Physiology Laboratory. Dept. of Neurobiol. and Physiol., Northwestern Univ., Evanston, IL 60201.

Previous tracing studies of mammalian cochlear neurons have mapped the pattern of hair cell innervation either during early postnatal life, well before the onset of hearing, or in adulthood. In the present study we provide information on the pattern of innervation of cochlear receptors during the initial stages of hearing in the gerbil, a rodent with a prolonged period of postnatal cochlear maturation.

Horseradish peroxidase was injected via an insect pin ("000") into the cochlear nerve of gerbils beginning at the onset of hearing (12 days after birth) (Woolf and Ryan, Hearing Res., 13:277, 1984). After four to eight hours, animals were perfused through the heart and cochlea with 2.5% glutaraldehyde in 0.1 M phosphate buffer. Following decalcification (0.1 M EDTA) for 2-4 days, cochleae were reacted with diaminobenzidine, embedded in epon, and viewed as surface preparations.

Cochleae examined thus far, ranging in age from 12 to 15 days postnatal, exhibit a pronounced basal to apical gradient in the maturity of inner hair cell (IHC) innervation. Radial fibers projecting to IHCs within the base (high frequency region) of a 13 day old gerbil cochlea have already achieved a mature morphology, with well defined terminal boutons contacting one or two adjacent receptors. Neurons projecting to IHCs within the second and third cochlear turns, however, appear less mature. Many of these neurons exhibit growth cone-like enlargements from which emmanate multiply- branched neuritic processes innervating adjacent or widely spaced IHCs. The relative immaturity of the second and third cochlear turns is also reflected by the presence of kinocilia on IHCs within these regions, contrasting, once again, with basal IHCs, which show a lower incidence of kinocilia at 13 days of age.

HRP injections into the auditory nerves of 16-30 day old animals are now underway to resolve when IHC innervation of the middle and apical cochlear turns becomes mature. These preliminary findings suggest, however, that changes in cochlear innervation occur after the onset of hearing in gerbils. Moreover, the timecourse of these changes corresponds well with the ontogeny of neural frequency tuning in this species (Woolf and Ryan, Dev. Brain Res., 17:131, 1985).

149.10 DEVELOPMENT OF ACETYLCHOLINESTERASE-STAINED NERVE FIBERS IN THE MOUSE ORGAN OF CORTI. H.M. Sobkowicz, M.R. Emmerling* and C.V. Levenick*. Dept. of Neurology, Univ. of Wis, Madison, WI 53706.

Acetylcholinesterase (AChE)-positive innervation was studied in the light and electron microscope, using Karnovsky and Roots, and Topilko methods. With light microscope faintly stained fibers were first seen in one-day old animals. The fibers enter the organ in the intraganglionic bundle, from which they radiate upward via radial bundles. By the 4th day, fibers reach inner hair cells. Here, the fibers divide into two groups. The first group of fibers, and usually the earliest, grows close to the basilar membrane. Most of these fibers form in front of the inner pillars the earliest spiral path in the organ. They then cross as tunnel fibers between tightly apposed inner and outer pillars and enter the outer hair cell region. The tunnel bundles are radially orientated and regularly spaced, some of them ultimately reach the third row of outer hair cells. Individual tunnel bundles appear to innervate outer hair cells in all three rows, within a narrow vertical sector. The first outer spiral bundle appears at this time. The second group of fibers grows up to the inner hair cells, to form the inner spiral plexus and bundle. This bundle is initially formed in short segments and may be discontionuous even in the 6-day old animal. By the 7th postnatal day, numerous AChE-positive fibers and endings are present in the outer hair cell region, and all three outer spiral bundles are formed. The innervation appears to be complete by the 12th day. Electron microscopical studies indicate that AChE-positive and negative fibers enter the organ together. The AChE-positive fibers tend to become positioned just above the border cell of Held; while AChE-negative fibers collect closer to the inner hair cell. Most of AChE-positive fibers are about 0.25 microns in diameter, they show distinct microtubules and occasional mitochondria, but no synaptic vesicles. In addition, a large population of AChE-positive fibers collects in front of inner pillars. The inner spiral plexus contains vesiculated nerve endings, both free or synaptically engaged, which may be either AChE-positive or negative. In our present material, all vesiculated endings forming synapses with inner hair cells were AChE-negative. In a 6-day old animal, both vesiculated and nonvesiculated nerve endings on outer hair cells may stain for AChE. In conclusion: The AChE-positive innervation of outer hair cell develops around birth, independently of and prior to the AChE-positive projections to the afferent system of inner hair cells. The initial projections of tunnel fibers are distinctly radially oriented, generating a columnar pattern of innervation. The enzymatic characterization of developing neuronal endings may precede their ultrastructural differentiation. (NIH NS 15061)

149.11 GABA-LIKE IMMUNOREACTIVITY IN THE ORGAN OF CORTI OF THE DEVELOPING MOUSE. D.S. WHITLON*, H.M. SOBKOWICZ & B.K. AUGUST* (SPON: J. Chan) Dept. Neurology, Univ. of Wis. Madison, WI. 53706.

Surface preparations of cochleas from postnatal mice (ages: newborn, 1,4,8,12, and 15 days) were stained immunohistochemically using an anti-GABA antibody (Wenthold, R.J. et al. Brain Research (1986) 380:7-18).

In the mouse, a few GABA-positive fibers displaying numerous varicosities are already present around birth, throughout the entire length of cochlea. The growing fibers run and ramify in the intraganglionic bundle and their individual paths can be followed with the light microscope. The fibers give off a few collaterals that grow toward the hair cell region as well as toward the spiral ganglion. Sometimes, the collaterals from both regions can be traced back to the same fiber in the intraganglionic bundle. Some end-collaterals seem to wrap and to terminate around spiral neurons. With age, GABA-containing fibers, albeit sparse, can be frequently identified in radial bundles. By the 8th day, the stained radial fibers reach the inner hair cells and form a distinct inner spiral plexus and bundle. A discrete spiral bundle is also formed, by GABA-containing fibers, between the inner hair cells and inner pillars. Tunnel fibers are seen to originate from the latter bundle. By the 12th day, the bundles of tunnel fibers enter the tunnel of Corti at the intervals of one to six pillars, the fibers fan out within small sectors of the outer hair cell region. They arborize and terminate on the outer hair cells of all three rows. The fibers may provide from one to multiple endings.

In conclusion: The GABA-containing neuronal system in the cochlea of the mouse begins to differentiate around birth and continues for at least 12 postnatal days. The GABA-positive neuronal system appears to project to both types of sensory cells and to their afferent neurons. (Supported by NIH Grant NS15061.)

149.12 IMMUNOHISTOCHEMICAL CHARACTERIZATION OF T II CELLS IN THE SPIRAL GANGLION OF THE RAT. A. Hafidi*, R. Romand, and B. Onteniente, Laboratoire de Neurobiologie, Université de Clermont II, 63170 Aubière, France and Laboratoire de Physiologie, Université de Bordeaux I, 33405 Talence Cédex, France.

The spiral ganglion of the cochlea in mammals, contains two type of cells which were differentiated on structural and ultrastructural characteristics of their cell bodies and their connections to the receptor cells. One type of cell which represents only 5% of the whole population can be differentiated by a dense packing of neurofilaments in their perikarion and are called T II cells.

Neurofilaments are the neuron specific class of intermediate filaments. In mammals they are composed of three immunochemically distinct subunit polypeptides with an apparent molecular weight of approximately 200 KiloDaltons (NF 200 KD), 160 KiloDaltons (NF 160 KD) and 68 KiloDaltons (NF 68 KD). A previous study (Berglund and Ruygo 1986, Brain research 383 : 327-332) with a neurofilament antibody which recognized the NF 200 KD and perhaps another protein (Godsave et al. 1986; J. Embryol. exp. Morphol., 97 : 201-223) showed the specific reaction of T II cells by light microscopy.

In our study we used neurofilament monoclonal antibodies and monoclonal antibodies against each neurofilament subunit in order to determine their presence in T II cells. We used the indirect immunofluorescence and the PAP methods for the light microscopic observation while using an antibody against non phosphorilated NF 200 KD, and two others antibodies against phosphorilated NF 68 KD and NF 160 KD.

Some ganglionic cells presented a strong immunofluorescence with the neurofilament antibody. The shape, the position inside the ganglion and the number of reacting cells corresponded well to T II cells found by classical methods. As previously observed, only a few cells in the spiral ganglion reacted with antibodies against the three neurofilament subunits, 68, 160 and 200 KD. The ganglion cell processes, irrespective of cell types, reacted strongly to various antibodies. Peripheral processes could be traced to inner hair cells and outer hair cells. Experiments to characterize at the electron microscopic level the immunohistochemical reaction of antibodies against the three filament subunits in T II cells are at present being undertaken.

149.13 INHIBITION OF INNER EAR ORNITHINE DECARBOXYLASE BY NEOMYCIN IN-VITRO. Charles M. Henley III, Sanford C. Bledsoe, and Jochen Schacht. Kresge Hearing Research Institute, University of Michigan, Ann Arbor, MI 48109 U.S.A.

Ornithine decarboxylase (ODC), a key enzyme in polyamine synthesis, was quantitated in homogenates and subcellular fractions of inner ear tissues from both the guinea pig and the rat. Specific activities of ODC, defined as α-difluoromethylornithine (DFMO)-sensitive decarboxylation of ^{14}C-ornithine, in homogenates of combined inner ear tissues were: guinea pig = 22 ± 1 pmoles CO_2 produced/hr/mg protein, and rat = 134 ± 24. In the guinea pig, homogenates of lateral wall tissues (stria vascularis and spiral ligament) had specific activities of 62 ± 5, those of the organ of Corti (plus VIIIth nerve) 34 ± 10. Subcellular fractionation showed the enzyme associated with the postmitochondrial supernatant. Specific activities in combined inner ear tissues were guinea pig = 44 ± 4 and rat = 133 ± 30. Lateral wall tissues yielded specific activities of 62 ± 25 and organ of Corti = 64 ± 41.

The ototoxic aminoglycoside, neomycin, produced dose-dependent inhibition of ODC in the supernatant fraction with half-maximal inhibition observed at 50 μM drug and almost complete inhibition at 100 μM. Neomycin inhibition of cochlear ODC complements our earlier findings of aminoglycoside inhibition of renal ODC. We are presently investigating the effects of systemic administration of neomycin on auditory brainstem responses and ODC from cochlear, renal, liver and brain tissues from the guinea pig. Since DFMO and neomycin can cause hearing loss in patients and experimental animals it is suggested that inhibition of ODC may be an important factor in the ototoxicity of these drugs.

149.14 QUININE REDUCES NOXIOUS EFFECTS OF LOOP DIURETICS ON COCHLEAR FUNCTION. L.P. Rybak, C. Whitworth*. Dept. of Surgery and Pharmacology, SIU Sch. of Med., Springfield, Illinois, 62708.

Loop diuretics are known to have ototoxic effects in man and animals. These drugs cause a reduction of cochlear function and edema of the stria vascularis. Loop diuretics are weak organic acids, and we have previously shown that prior administration of other organic acids reduced the noxious cochlear effects of furosemide (Rybak and Whitworth, Hear Res 26:89-93, 1987). Studies of the choroid plexus by other investigators have shown that quinine inhibits the uptake of organic acids such as riboflavin (Spector, J Clin Invest, 66:821, 1980) and PAH (Suzuki et al, JPET, 239:927, 1986). Therefore we decided to investigate the interaction of quinine with the loop diuretics furosemide and ethacrynic acid to determine whether the cochlear effects of the latter were attenuated by pretreatment with quinine. Adult chinchillas weighing 400-600 grams were anesthetized with katamine 45 mg/kg IM followed by pentobarbital 30 mg/kg IM. The head was fixed in a head holder. The auditory bulla was opened and a microelectrode was inserted through the round window to measure endocochlear potential (EP). A tungsten wire was placed on the round window membrane to measure eighth nerve action potential (AP) responses to click stimuli. Control animals received 0.5 ml saline while experimental animals were injected with quinine HCl 25 mg/kg IV thirty minutes prior to diuretic injection. Furosemide 25 mg/kg IV or ethacrynic acid 15 mg/kg IV was then injected. Control animals were found to have a large drop in EP following furosemide to only 28.0 + 7.7% of initial value, or ethacrynic acid to 27.7 + 13.0% of initial value. In addition, a considerable elevation of AP threshold was observed following each diuretic in the controls. Animals pretreated with quinine were found to have a significantly smaller reduction of EP following furosemide resulting in values 81.9 + 5.6% of initial value, or ethacrynic acid to values 71.9 ± 9.5% of initial value. A much smaller reduction of AP (N_1) amplitude of 44.3 ± 13.3% and 41.6 ± 13.0% respectively as compared to 25.2 ± 9.8% and 0%, respectively, in controls. No significant differences in urine volumes were noted between experimental and control groups. Quinine is known to cause nonspecific changes in the membranes of epithelial cells which may cause alterations of the transport of organic anions by such tissues. Such an effect on epithelial cells in the cochlea could cause a reduction of uptake of loop diuretics in this organ, resulting in reduced toxicity. (Supported by NIH grant #5R01 NS 22530-02).

149.15 COCHLEAR MICROPHONIC POTENTIALS TO VERY LOUD ACOUSTIC STIMULI ARE ENHANCED BY THE MIDDLE EAR REFLEX.
P.K.D. Pilz*, J.Ostwald*, A.K. Kreiter* and H.-U. Schnitzler* (SPON: H.C. Diener).
Lehrstuhl Zoophysiologie, Universität Tübingen, Auf der Morgenstelle 28, D-7400 Tübingen.

Electrodes were chronically implanted in the middle ear of rats to measure cochlear microphonics (CM) as well as electromyograms of the stapedius muscle.

CM unaffected by the middle ear reflex - measured during the first 5 ms - increase with increasing stimulus intensity up to a sound pressure level of 100 dB SPL (at 10 kHz). At intensities higher than 100 dB SPL CM show a successive decrease with increasing intensity.

For intensities between 85 and 100 dB SPL (at 10 kHz) after a latency of 10 - 20 ms CM amplitude is decreased by the middle ear reflex; this is expected from the known attenuation due to reflex activity. At sound intensities above 100 dB SPL the CM amplitude is enhanced by the middle ear reflex! This enhancement occurs after a latency of 5 - 10 ms.

The outer hair cells in the inner ear are the main source of CM. The decrease of the initial CM to very loud acoustic stimulation is probably due to a decrease of the receptor potential of outer hair cells. The input/output function of outer hair cells shows a maximum at about 100 dB SPL, and a decrease to still louder stimulation (Dallos,P., Cheatham,M.A., 1975, J.Acoust.Soc.Am. 60,510-512). CM increase due to middle ear reflex activity when very loud stimuli are used can therefore be explained by the following mechanism. Due to stimulation above the maximum of the input/output function CM show a low amplitude before reflex activity. Than after a short latency the input to the inner ear is attenuated by the middle ear reflex, the receptor potential of the outer hair cells is shifted back towards the maximum, which enhances CM.

At very loud acoustic stimulation the middle ear reflex seems to serve as a gain control, which prevents overstimulation of the receptor cells in the inner ear.

149.16 COCHLEAR BLOOD FLOW IN NORMOTENSIVE AND SPONTANEOUSLY HYPERTENSIVE RATS.
W.S. Quirk, M.J. Bademian*, H.A. Dengerink*, and J.W. Wright. Department of Psychology, Washington State University, Pullman, WA 99163-4380.

Noise-induced hearing loss has been proposed to be the result of insufficient blood supply to the cochlea (Borg, 1981). Studies of human hypertensive patients (Johnsson and Hansson, 1977;) and the spontaneously hypertensive rat (SHR) model of human essential hypertension (Axelsson, 1983) have identified a relationship between hypertension and noise-induced hearing loss. However, there is no direct experimental evidence describing the physiological mechanisms involved. Previous investigations in our laboratory have measured significant increases in plasma angiotensin II (AII) levels in rats (Wright, 1985). Increases in plasma AII concentrations result in elevated systemic blood pressure in mammalian species (Ramsey, 1982). In an initial experiment these levels of AII were approximated through intracarotid infusion (0, 1, 10, 100, 1000 pmol/kg/min for 5 min) in normotensive Wistar-Kyoto (WKY) and SHR. WKY cochlear blood flow (CBF) increased in response to elevations in systemic blood pressure except at the highest dose utilized (1000 pmol/kg/min) where a decrease in CBF was evident despite continued elevated systemic blood pressure. In SHR a decrement in CBF was apparent despite continuous elevations in blood pressure at every dose utilized.

A second experiment stemmed from the observation that many treatments of otopathologies similar to those approximated in the present study depend on blood transport of therapeutic agents or expansion of blood volume to increase CBF. Therefore we employed two clinical agents, Mannitol (20%) and Dextran 70 (6%), in order to evaluate the effectiveness of these compounds to increase CBF. The data indicate a decrement in CBF in SHR despite elevated systemic blood pressure and expanded blood volume in response to both Mannitol and Dextran infusion.

Taken as a whole these results are interpreted to indicate that there may be a form of autoregulation in SHR during elevations of systemic blood pressure. Since this response is evident in response to infusion of the vasoconstrictive peptide AII as well as plasma volume expanding substances, it is not likely that the mechanisms involved in the mediation of cochlear autoregulation are activated simply by expansion of blood volume. Preliminary data from our laboratory using a pretreatment of the angiotensin receptor antagonist sarile (Sar^1,Ile^8-AII) show a decrease in CBF and systemic blood pressure in response to infusion of AII in both strains, when compared to saline pretreatment. These data indicate that endothelial angiotensin receptors of the cochlear vasculature may, in part, mediate the autoregulatory response in WKY and SHR.

149.17 PHYSIOLOGICAL CORRELATES OF BEHAVIORAL MASKING.
E.G. Freedman* and A.M. Simmons, Dept. of Psychology, Brown Univ. Providence, RI 02912

Acoustic behaviors, such as the mating behavior of frogs, are performed in natural environments in which there is a great deal of interfering background noise. Previous behavioral experiments have shown how effective some anurans are at extracting important acoustic information from extraneous noise. The question remains, however, as to whether their acuity is derived from sharp peripheral filtering or whether a central process mediates the behavior. To investigate this question we have recorded from single units in the eighth nerve and the torus semicircularis (midbrain) of the bullfrog in order to study how cells respond to acoustic signals imbedded in a background of continuous white noise.

Bullfrogs (Rana catesbeiana)were anesthesized with Sodium pentobarbitol. The eighth nerve was exposed through a small hole in the roof of the mouth. For recording from the midbrain, the skull above the optic tectum was carefully removed. Acoustic stimuli (closed-field) were delivered ipsilaterally for eighth nerve recording and contralaterally for midbrain recording.

When a single auditory unit was isolated its Best Excitatory Frequency (BEF), threshold to continuous white noise, and tuning curve were determined. The response to tone bursts at its BEF and threshold intensity was then measured, and continuous white noise was added beginning at threshold level and increasing in 2 dB (spectrum level) steps until the response was masked. The signal-to-noise ratio at the masked threshold (critical ratio) was calculated based on masked thresholds determined in two ways. The masked thresholds were determined on the basis of spike rate increases during the tone burst, and they were also calculated on the basis of the degree to which the response was synchronized (phase-locked) to the stimulus waveform. Physiological results from both the eighth nerve and midbrain were then compared to the results of previous behavioral studies.

Critical ratios (CRs) determined using both rate and synchronization criteria for the eighth nerve closely approximate the CR's determined behaviorally. At any given frequency, however, the critical ratios based on the synchronization coefficient were lower than those based on spike rate. Moreover, the sharpness of tuning of individual units were similar to the animal's tuning determined behaviorally. Cells in the midbrain showed more variability. While some cells were more sensitive (had lower critical ratios) than the behavioral measure, others had higher CR's. We conclude that the bullfrog's acuity in discriminating signals from noise is based primarily on peripheral filtering. [Supported by NIH].

149.18 **COCHLEAR IMPLANTS FOR SENSORINEURAL DEAFNESS: RECEPTOR CODING IMPROVES SPEECH DISCRIMINATION.**
G. S. Wasserman[1] and R. T. Miyamoto[2]. (1) Dept. of Psychological Sciences, Purdue Univ., W. Lafayette, IN 47907 (2) Dept. of Otolaryngology, Indiana Univ. Medical School, Indianapolis, IN 46202.

Cochlear implants (cf. Miyamoto, et al., J. Ind. Med. Assn., 1982, 75, 174) can be viewed as artificial receptors that transduce acoustic energy into bioelectric signals in the auditory nerve. Transduction in natural auditory receptors produces bioelectric signals whose waveform markedly differs from the acoustic waveform (Russell and Sellick, J. Physiol., 1978, 284, 261). This waveform change could: (A) degrade sensory information and thus limit perceptual performance or (B) efficiently code information and hence facilitate performance.

This question led us to do controlled experiments on the effect of receptor coding on cochlear implant performance with speech. The control condition was the commonly-used House implant (described by Fretz & Fravel, Ear & Hearing, 1985, 6, 14S); it creates a waveform that follows the acoustic waveform. The experimental condition added a receptor-coded signal processor (described in Wasserman, Bull. Psychon. Soc., 1981, 18, 161). Within-patient tests were run in an acoustic booth with visual and auditory isolation. Stimuli were prerecorded; testing was computer controlled in a two-alternative forced-choice design. Performance was objectively assessed by computer-monitored patient-controlled response keys.

Word articulation was tested with an adaptation of the House, et al. test (J. Acoust. Soc. Amer., 1965, 37, 158); it presented pairs of monosyllabic words as visual text. One of these words was presented aurally and the patient chose the better of the two possibilities. Receptor coding produced a consistent substantial increase in word discrimination.

Sentence comprehension was examined with a modification of the SPIN test (Kalikow, et al., J. Acoust. Soc. Amer., 1977, 61, 1337). A sentence (minus its last word) was presented acoustically with no visual cues. Two words were presented as visual text with no auditory cue. The patient chose the written word that best completed the audible sentence. Since the patient never heard the word, the patient had to hear out the meaning of the sentence. Many patients cannot perform above chance in this task. Nevertheless, receptor coding can bring a patient whose control performance is at chance up to a substantial, clearly significant level of comprehension.

These data suggest that receptor transduction efficiently codes afferent information for analysis by the brain.

149.19 SURGICAL IMPLANTATION AND BIOCOMPATIBILITY OF CNS AUDITORY PROSTHESIS. J. K. Niparko*, J.J. Zappia*, X. Xue*, D. J. Anderson, R. A. Altschuler. Kresge Hearing Research Institute, University of Michigan, Ann Arbor, MI 48109

Presently employed cochlear implants are not applicable to significant numbers of deaf individuals with bilateral cochlear dysgenesis, ossification or cochlear nerve ablation. Neuroprosthesis placement proximal to the cochlear might achieve activation of the auditory tract in such cases. We are therefore examining the feasibility of implanting the modiolar portion of the cochlear nerve (Md) and the cochlear nucleus (Cn) with microelectrodes. The present histological studies determined the accuracy of placement and the biocompatibility of these electrodes with and without stimulation.

Probes were fabricated on a silicon substrate using thin film techniques. Md and Cn implantations were performed with both wire-tethered and untethered microelectrode probes in anesthetized guinea pigs. Md implants were placed through a post-auricular, transbullar approach to the cochlea. The lateral wall of the cochlea was drilled out exposing the bony modiolus which was penetrated to allow passage of the microelectrode into the cochlear nerve. Cn implantation was accomplished through a posterior craniotomy. The cerebellum was exposed and the paraflocculus retracted or aspirated to expose the pontomedullary junction. Microelectrodes were then inserted in a position ventromedial to the cochleovestibular nerve insertion. Nonstimulated animals were fixed with mixed aldehydes 4 to 8 weeks after implantation. Tissues were examined for accuracy of electrode placement and tissue reaction.

Md implants were consistently placed into the modiolar portion of the cochlear nerve. Loss of spiral ganglion cells occurred in approximately half of the Md implanted animals. Other Md implanted animals demonstrated essentially normal cytoarchitecture. Fibrosis was found lining the implant and wires (when tethered). Cn implants were successfully placed in the ventral cochlear nucleus. A thin rim of gliosis lining the electrode tract and otherwise normal cytoarchitecture was observed in wire-tethered and untethered Cn implanted animals. Electrophysiologic data suggests that physiologic activation of the central auditory system was obtained with Cn implant stimulation.

These results demonstrate tolerance to the Md and Cn implant procedure and implant biocompatibility in most cases. Assessment of tissue reaction with implant stimulation is currently in progress. This Research was supported by NIH Contracts # N01-NS-5-2387 and N01-NS-6-2309.

AUDITORY SYSTEM VI

150.1 FREQUENCY ORGANISATION OF THE AUDITORY MIDBRAIN IN THE BOB-WHITE QUAIL. S.W. Shaver*, L.Z. Wise* and B.J. Frost, (SPON: M.W. Donald), Dept. of Psychology, Queen's University, Kingston, Ontario, Canada, K7L 3N6.

The ground-dwelling Bob-white quail (*Colinus virginianus*) has a complex vocal repertoire and relies heavily on auditory communication in its visually-restricted natural habitat. We have examined the frequency organisation of the midbrain auditory nucleus (nMLD) of this quail using conventional electrophysiological recording techniques in conjunction with 14-C-2-deoxglucose (2DG) metabolic mapping.

A physiological audiogram was generated for ketamine-anesthetised quails by plotting the envelope of multiple frequency tuning curves recorded from many different sites within nMLD. The region of greatest sensitivity in the audiogram is between 1 to 2 kHz, where unit thresholds are as low as 0 dB SPL. Thresholds increase sharply above 2.5 kHz with a slope of around 56 dB / octave, but rise more gradually below 1 kHz, with a slope of 24 dB / octave to 400 Hz. Below 400 Hz, thresholds remain fairly constant (at around 35 dB SPL) to the lower limit of our sound generating system (50 Hz). In common with other avian species, units with sharp frequency tuning are found in tonotopic sequence within the central nMLD, with low frequencies represented dorsally and higher frequencies ventrally. Frequency tuning appears to be broader in the lateral region of nMLD, which in the barn owl is broadly-tuned and contains a neural "map" of auditory space.

We also studied the organisation of iso-frequency laminae in nMLD by injecting the metabolic marker 2DG (150 uCi/kg) in awake quails during exposure to various sound stimuli. In addition to bands of 2DG label in the isofrequency laminae corresponding to the stimulus frequency, a region of dense label is consistently found in the antero-dorsal pole of nMLD, an area receiving input from brainstem nuclei innervated by fibres from the lagena (J.W. Conlee and T.N. Parks, Brain Res. 367:96-113). Many units in this region were highly active in our physiological studies, although we could not drive them with our stimuli. The anechoic chamber in which our experiments are performed is not protected from very low frequency sounds generated by the ventilation system of the building (< 50 Hz) nor from infrasound, and thus a very low frequency confounding stimulus may have been present during all our experiments. This circumstantial evidence, in conjunction with the fact that we were unable to identify a low frequency cut-off in our audiogram, has led us to hypothesise that the antero-dorsal region of quail nMLD is specialised for processing infrasound. Supported by NSERC Grant A0353 and MRC Grant MT7244.

150.2 DEVELOPMENT OF GABA-IMMUNOREACTIVE TERMINALS IN CHICK BRAIN STEM AUDITORY NUCLEI. R.A. Code, G.D. Burd and E.W Rubel. Dept. of Otolaryngology, Univ. of Washington Med. Sch., Seattle, WA 98195.

Two major classes of terminal endings have been described in both n. magnocellularis (NM) and n. laminaris (NL) of the chick brain stem. The excitatory input to NM is from the ipsilateral VIIIth nerve. NM, in turn, provides bilateral excitatory input to NL. The other major input to each nucleus is immunoreactive to glutamic acid decarboxylase (GAD) and gamma - aminobutyric acid (GABA). Development of GABA- immunoreactive (GABA-I) terminals was studied in NM and NL in embryos from E9 to E19 and in posthatch chicks up to 1 year of age. Twenty-three animals were perfused intracardially with buffered, mixed aldehydes and staged according to the Hamburger and Hamilton series. Vibratome sections were incubated overnight in rabbit anti-GABA antisera (Immunonuclear, Inc.), diluted 1:2000-1:4000, or in an affinity-purified rabbit anti-GABA antisera conjugated to keyhole limpet hemocyanin (KLH), diluted 1:1000. Similar staining was observed with either antisera. Control studies included: 1) incubation in normal goat serum without the GABA antiserum; 2) incubation in GABA antisera pre-adsorbed with GABA conjugated to bovine serum albumin (BSA), diluted 1:10, 1:100 or 1:1000. These controls resulted in the absence of GABA-I staining, indicating the antisera used are highly specific for GABA. Sections incubated in GABA antisera pre-adsorbed with either glutamine, glutamate, taurine, or ß-alanine resulted in staining that was similar to that in sections incubated in GABA antisera alone, indicating no cross-reactivity between the GABA antisera and these structurally similar amino acids. In posthatch chicks, GABA-I terminals were observed as puncta circumscribing neuronal soma in both NM and NL. More puncta appear to be present in lateral regions of both nuclei than in medial regions. In E17-19 embryos, GABA-I puncta are also present around cell bodies in NM and NL, but no mediolateral gradient is evident. Around E14-15, there is a transition in the staining pattern: some GABA-I puncta are present; however, most stained structures appear to be axons with varicosities along their length, pre-terminal axonal thickenings or ramifying terminal branches. At E12-14, fewer GABA-I puncta and fibers are present. From E9-11 there is little GABA-I staining in either NM or NL. In summary, the first appearance of GABA-I fibers appears to coincide with the development of inner ear function and synaptic activation of NM by VIIIth nerve fibers, while the appearance of puncta is correlated with the formation of mature end -bulbs of Held on NM cells. Thus, the ontogeny of presumed inhibitory inputs to chick auditory brain stem nuclei temporally correlates with, and could modulate development of excitatory auditory afferent structure and function. This research was supported by NIH grant NS24522 to EWR.

150.3 GLYCINERGIC PATHWAYS IN THE AUDITORY SYSTEM OF THE RAT.
C. Hunter*, E. Chung, P. Pasik, and M.H. Van Woert. Neurobiology Graduate Program, Depts. of Neurol., Anat., & Pharmacol. Mount Sinai School of Medicine, CUNY, New York, N.Y., 10029.

The high levels of glycine (GLY), the dense distribution of GLY receptors as well as electrophysiologic data suggest that this amino acid is a major inhibitory neurotransmitter in the mammalian brain stem. The GLY antagonist strychnine induces seizures in rats which may be triggered by acoustic stimuli. We have studied the glycinergic pathways in the auditory system likely to be involved in controlling sound sensitive seizures in rats using two approaches.

The first experiments utilized the property of glycinergic elements to uptake and retrogradely transport GLY into the corresponding neuronal somata. Iontophoretic deposits of [^{3}H] GLY were made in the ventral nucleus of the lateral lemniscus (VLL). Autoradiographic processing of this material showed labeling of some VLL neurons close to the injection site, and of the majority of nerve cells in the ipsilateral medial nucleus of the trapezoid body (MNTB). Accumulation of silver grains was less dense over neurons of the ventral nucleus of the trapezoid body (VNTB), the superior olivary complex (SO), and a subgroup of medium-sized cells in the region of the nucleus reticularis pontis oralis (NRPOo) on both sides. No labeled somata were found in either ventral cochlear nuclei, or the contralateral VLL. Injections into the thoracic spinal cord or the medullary reticular formation gave negative results in the nuclei under consideration.

A second series of experiments used the immunocytochemical localization of endogenous GLY with a polyclonal antibody, raised against a GLY-BSA conjugate, and the PAP technique. Immunoreactivity was very dense in most of the neurons in the MNTB. Moderate to low staining was observed in some cells of the VLL and SO. These nuclei also showed GLY-positive fibers and puncta. Clusters of labeled neurons were also found in the NRPOo. Control sections treated with the antiserum which had been preadsorbed with GLY-BSA conjugate and coprecipitated with an anti-BSA antibody, were negative.

These findings document the existence of glycinergic pathways from MNTB, SO, and NRPOo, which innervate VLL, as well as the presence of probably projecting GLY-immunoreactive cells in this latter nucleus. The results are supported by the demonstration of high density GLY receptors found in VLL and SO (Zarbin et al., J. Neurosci., 1981). Failure of this pathway may be important in the production of acoustic startle and/or audiogenic seizures in the rat.

Aided by NIH Grants # NS 12341 and NS 11631.

150.4 A COMPARISON OF GABA AND GLYCINE IMMUNOREACTIVITY IN THE GERBIL DORSAL COCHLEAR NUCLEUS
I.R. Schwartz, S.-M. Yu*, G. DiCarlantonio* & R.J. Wenthold, Head & Neck Surgery, UCLA School of Medicine, Los Angeles, CA 90024 & NINCDS, NIH, Bethesda, MD 20892.

Rabbit antibodies against glutaraldehyde conjugates of bovine serum albumin and GABA or glycine (GLY) (Wenthold et al., Brain Res. 380:7-, 1986; Neurosci. In press, 1987), have been utilized to identify GABA and GLY containing cell bodies, terminals and processes in the cochlear nucleus in 20 um frozen, 1-3 um plastic sections and thin sections of mixed aldehyde fixed brains of young adult Mongolian gerbils (Meriones unguiculatus).

In frozen sections processed immunocytochemically and visualized with the Vectastain avidin-biotin-peroxidase complex (ABC) method, differences in the patterns of cell body labeling were very distinct. Incubations with A/GABA labeled small to medium cells preferentially located in the fusiform (FL) and molecular layers (ML) of the DCN, while A/GLY incubations preferentially labeled medium sized and larger cells in the FL and deep layers (DL). Postembedding incubations of adjacent 3 um thick sections with the two antibodies allowed some neurons to be identified as labeling with both. With the antibodies and incubation conditions used the most intense GABA staining was much heavier than the most intense GLY staining. No cells stained intensely for both. Most heavily GABA labeled cells showed light GLY labeling. Many cells which were heavily GLY labeled showed only faint GABA labeling. Electron microscopic examination of material incubated before embedding, visualized with the ABC method, or incubated in the thin section, visualized with goat anti-rabbit IgG-gold, allowed the identification of a number of heavily GABA labeled cartwheel neurons. Several heavily GABA labeled small neurons have been identified as Golgi cells light microscopically, & at least one electron microscopically, by their characteristic size and lumpy soma. At least 3 stellate neurons have been shown at the EM level to be GABA immunoreactive.

In the ML, GABA labeled synaptic terminals were found synapsing on large unlabeled spiny dendrites (presumably belonging either to fusiform or cartwheel neurons) but not necessarily on the spines. A few heavily labeled synaptic terminals were found on labeled cartwheel neuron somata. GABA labeled terminals were most heavily concentrated in the ML & FL, the regions in which cartwheel axons distribute their terminals. Some labeled terminals were found on unlabeled fusiform neurons. Some unmyelinated and thinly myelinated fine axons in the ML were labeled.

In A/GLY incubated material the distribution of labeled synaptic terminals was much more uniform across the ML, FL & DL--a pattern similar to that observed autoradiographically following uptake of H3-GLY by fresh brain slices.

Supported by NIH grants NS14503 & NS09823.

150.5 GABA AND GLYCINE IMMUNOREACTIVITY IN THE GUINEA PIG SUPERIOR OLIVARY COMPLEX.
R.H. Helfert, R.A. Altschuler, and R.J. Wenthold* Kresge Hearing Research Inst., Univ. of Michigan, Ann Arbor, MI 48109; and *Laboratory of Neuro-otolaryngology, NINCDS, NIH, Bethesda, MD 20892.

GABA and glycine (GLY) are believed to be major inhibitory neurotransmitters in the CNS, and may play important roles in the auditory brainstem. This study describes the distribution of GABA and GLY immunoreactivity in the nuclei of the superior olivary complex (SOC), an initial site for the convergence of binaural input and the locale of the neurons of the olivocochlear system.

Guinea pigs were anaesthetized and perfused with mixed aldehyde fixative (4% paraformaldehyde, 0.2% glutaraldehyde in phosphate buffer for GABA; 1.25% glutaraldehyde, 1% paraformaldehyde in phosphate buffer for GLY). Immunoperoxidase immunocytochemistry was performed on free-floating vibrotome sections using antibodies to GABA (1:1500) and GLY (1:1000). Alternate sections were prepared for light microscopy while the remainder were prepared for subsequent electron microscopic evaluation.

Roughly one-half of the neurons within the neuropil of the lateral superior olive (LSO) exhibited GABA immunoractive (IR) labeling; the size of these neurons ranged from 15-25 μm, and their shape varied from round/polygonal to fusiform/oval. GABA IR axons were observed in the envelope surrounding the LSO, and within its neuropil. A very small number of GABA IR puncta were apposed to the perikarya of most LSO neurons. A population of LSO neurons with morphological features similar to those of the GABA IR neurons displayed light GLY IR labeling. The neuropil of the LSO also contained an abundance of densely GLY IR axons and puncta.

In the medial superior olive (MSO), the vast majority of the neurons showed neither GABA nor GLY IR labeling. Rarely an intensely GABA IR MSO neuron, 30 μm in length, was observed among the neurons within the central zone of the nucleus. The neuropil of the MSO likewise contained only sparse distributions of GABA or GLY IR processes.

The superior paraolivary nucleus (SPN) contained small populations each of moderately and lightly stained oval/fusiform neurons 20-25 μm in length. The SPN also contained larger (20-30 μm) polygonal neurons lightly stained with GLY antibody. Like the LSO, the neuropil of the SPN was densely labeled with GLY IR axons and puncta; much less so with GABA.

The principal and elongate neurons of the medial nucleus of the trapezoid body (MNTB) exhibited GLY IR staining. The principal neurons are thought to provide inhibitory input to neurons of the LSO; as such they are most likely the source of the extensive GLY immunoreactivity found within the LSO neuropil. In addition, a small population of MNTB neurons labeled lightly with GABA antibody; these neurons were polygonal, and ranged in size from 20-25 μm.

The ventral and lateral nuclei of the trapezoid body (VNTB and LNTB, respectively) contained small numbers of neurons which were the most intensely GABA IR in the SOC. They were oval and 15-20 μm in length. Larger (25-30 μm), more irregularly shaped, lightly GABA IR neurons were also identified in these nuclei. The VNTB was defined by an intensely GABA IR neuropil. Both the VNTB and LNTB contained 15-20 μm GLY IR neurons similar, morphologically, to the intense GABA IR neurons observed in this region.

Supported by NIH grants NS 24369 and NS 07106.

150.6 CO-LOCALIZATION OF GLYCINE AND GABA IN THE COCHLEAR NUCLEUS.
M.D. Oberdorfer*, M.H. Parakkal*, R.A. Altschuler and R.J. Wenthold, (SPON: J. Fex). Lab. of Neuro-otolaryngology, NINCDS, NIH, Bethesda, MD 20892 and Kresge Hearing Res. Inst. Univ. of MI, Ann Arbor, MI 48109.

Recent findings indicate that GABA and glycine are major inhibitory neurotransmitters in the cochlear nucleus. Immunocytochemical studies localizing glycine, GABA, GAD and the postsynaptic glycine receptor have been used to identify GABAergic and glycinergic synapses throughout the cochlear nucleus. GABA and glycine immunoreactive cell bodies are largely restricted to the dorsal cochlear nucleus (DCN) while most immunoreactivity in the ventral cochlear nucleus is present in terminals and fibers. The overlapping distributions of the GABA and glycine immunoreactivities suggested that they may be co-contained in some cases within the same neural elements. In the present study, we have addressed this question using antibodies against GABA, GAD, glycine and the glycine receptor.

Antibodies against GABA and glycine were made in rabbits or guinea pigs (Wenthold et al. Brain Res. 380, 7(1986); Neuroscience, In Press). Antibodies against GAD were provided by Dr. Irwin J. Kopin, and antibodies against the glycine receptor were provided by Dr. Heinrich Betz. For studies localizing GABA and glycine, guinea pigs were perfused with 4% paraformaldehyde containing 0.25% glutaraldehyde, and for those localizing GAD or the glycine receptor, 4% paraformaldehyde containing 0.1% glutaraldehyde. Vibratome sections were processed as previously described (see above).

Immunofluorescence studies showed co-localization of GABA and glycine in cell bodies in the superficial DCN. With this approach double labeled puncta, suggestive of presynaptic terminals, were seen throughout the cochlear nucleus, but concentrated in the posteroventral cochlear nucleus (PVCN). This analysis was extended to the ultrastructural level in order to determine if glycine receptor immunoreactivity is found postsynaptic to terminals containing GAD or GABA immunoreactivity. Three classes of terminals were found in the DCN and the PVCN, those that were immunoreative for GABA/GAD only, those immunoreactive for glycine receptor only, and those immunoreactive for both GABA/GAD and the glycine receptor. These findings suggest that GABA and glycine may be present in the same cell bodies and terminals in the cochlear nucleus. Futhermore, glycine receptor immunoreactivity is found postsynaptic of terminals containing GABA/GAD immunoreactivity. It remains to be determined if such terminals also contain glycine.

150.7 LOSS OF GABA-IMMUNOREACTIVE NEURONS IN THE INFERIOR COLLICULUS OF THE AGED RAT. D.M. Caspary and B.A. Lawhorn*. Dept. Pharmacology, Southern Illinois University School of Medicine, P.O. Box 3926, Springfield, IL 62708 USA.

The inferior colliculus (IC) is an important auditory structure receiving ascending inputs from the cochlear nuclei (CN), superior olivary complex (SOC), nuclei of the lateral lemniscus (NLL) as well as descending inputs from auditory cortex. A major neurotransmitter role in IC for the inhibitory amino acid, gamma-aminobutyric acid (GABA), is supported by neurochemical, immunocytochemical and neuropharmacologic studies. Temporal response patterns and binaural inhibition reflect inhibitory synaptic interactions in CN, SOC, NLL as well as processing occurring within the IC itself. Intracellular recordings from IC neurons in vivo and in vitro display ipsp's which can be blocked by picrotoxin while bicuculline can block extracellularly recorded binaural inhibition (Kuwada et al., 1980; Moiseff, 1985; Smith, 1986; Faingold et al., 1986). These studies suggest that synaptic inhibition occurs in the IC and that GABA may be involved.

The present study used an affinity-purified antibody against a GABA conjugate (kindly provided by Dr. R.J. Wenthold) to immunolabel neurons and terminals in the IC. Seven pairs of mature (2-8 mo.) and aged (18-29 mo.) Fisher 344 rats and an additional six mature controls were studied. Maps of GABA-positive neurons in the ventral-lateral portion of the central nucleus of the IC were generated, using computer morphometry, to obtain cell counts. Both labeled puncta and neurons were observed throughout the central nucleus of the IC. Immunostained terminals were observed on both large and small neurons. A significant reduction (33%) in the number of GABA-positive neurons was observed in the aged animals when compared to their matched controls (151 neurons/mm^2 vs. 101 neurons/mm^2; $p<0.01$). When the seven aged animals were compared to all 13 controls a 45% reduction in the number of GABA immunoreactive neurons was observed (183/mm^2 vs. 101/mm^2; $p<0.005$). Preliminary observations from two mature-aged pairs suggest that a major proportion of the reduction in the total number of Nissl stained cells can be accounted for by the loss of GABA-positive neurons. The two-dimensional area of GABA-labeled IC neurons displaying nuclei and nucleoli was measured and no age related differences were observed (mean area 225 u^2). Areas of the GABA-positive cells displayed a broad distribution of neuronal sizes comparable to reported sizes for three subpopulations of IC stellate (multipolar) cells. At the upper size range of GABA-positive neurons fusiform profiles were also observed. The present study suggests that in one area of IC in the Fisher 344 rat an age-related loss of GABA mediated inhibitory processes may occur.

150.8 **POSTNATAL DEVELOPMENT OF GLYCINE IMMUNOREACTIVITY IN THE RAT LOWER AUDITORY BRAINSTEM.** **C.R.Snead*, R.A.Altschuler, R.H.Helfert, R.J.Wenthold+. Kresge Hearing Research Institute, University of Michigan, Ann Arbor, MI 48109; and +Laboratory of Neuro-otolaryngology, NINCDS, NIH, Bethesda, MD 20892.**

There is considerable evidence supporting the hypothesis that GABA and Glycine are important inhibitory neurotransmitters in the mammalian central nervous system. Both immunocytochemical and physiological studies have produced evidence of glycinergic activity in the auditory brainstem. In the present study, the pattern of development of glycine immunoreactivity was investigated in the rat at the light microscopic level.

Long-Evans ("hooded") rats were examined at two or three day intervals from birth to 21 days after birth and at 28 postnatal days. The mothers were used as adult controls. All animals were anesthetized with chloral hydrate and fixed by cardiac perfusion with a mixed aldehyde fixative (either 4% paraformaldehyde/0.2% gluteraldehyde or 1% paraformaldehyde/1.25% gluteraldehyde in sodium buffer. Thirty to fifty micron sections were cut on a cryostat or vibratome, incubated 18-36 hours with antibody to glycine, and followed by immunoperoxidase staining.

The pattern of development of glycine immunoreactivity was similar to that previously reported for GABA labeling in the rat pup, with soma in and terminal labeling appearing during the second postnatal week and rapidly increasing in the third week. Both the 21 and 28 day old animals exhibited a pattern of immunoreactivity similar to the adult pattern, although there was evidence of subsequent growth of the lower auditory brainstem nuclei and in absolute numbers of labeled cells and terminals.

150.9 **EFFECTS OF SURGICAL LESIONS UPON AMINO ACID CONCENTRATIONS IN CAT COCHLEAR NUCLEUS**

Donald A. Godfrey, Judy A. Parli*, Michael J. Biavati*, Jon D. Dunn, and C. David Ross. Departments of Physiology and Anatomy, Oral Roberts Univ., Tulsa, OK 74171

Relations of amino acids to neural pathways in the cochlear nucleus are being quantitatively evaluated by a combined lesion and microchemical approach. Surgical cuts were placed in anesthetized cats to unilaterally transect either all centrifugal pathways to the cochlear nucleus by a complete cut just medial to it, just olivocochlear bundle and dorsal acoustic stria pathways by a dorsal cut, or interconnections between rostral and caudal parts of the cochlear nucleus by a transverse intra-nuclear cut. Cats were decapitated 8-10 days after surgery and tissue containing each cochlear nucleus isolated and rapidly frozen. Frozen sections were cut and freeze dried. Cochlear nucleus samples are obtained by microdissection of freeze-dried sections, weighed (0.2-1 µg), then chemically analyzed. Amino acids in each sample are measured by fluorescence of ortho-phthalaldehyde-derivatized amino acids separated by high performance liquid chromatography (HPLC). Activities of some enzymes of amino acid metabolism (glutaminase and aspartate aminotransferase) have also been measured for some additional samples via fluorometric enzymatic microassays.

Within the rostral part of the anteroventral cochlear nucleus (AVCN), GABA concentrations were reduced to approximately half on the lesion side following complete cuts, but were not clearly affected by dorsal or intra-nuclear cuts. Aspartate concentrations appeared to be reduced slightly (by about 20%) on the lesion side, following complete or dorsal cuts, but were not clearly affected by intra-nuclear cuts. Glutamine concentrations were consistently elevated in the lesion-side rostral AVCN following all cuts, by as much as two-fold following complete cuts. Concentrations of other amino acids - glycine, glutamate, taurine, alanine - were not clearly affected by any of the cuts. Aspartate aminotransferase and glutaminase activities were reduced by about 30% in the lesion-side rostral AVCN following the complete cuts, but were not clearly affected by the dorsal cuts.

The results could be consistent with centrifugal GABA-rich and aspartate-rich pathways to the cat rostral AVCN, entering mostly via ventral (presumably trapezoid body) and dorsal (olivocochlear tract or dorsal acoustic stria) routes, respectively. The increased glutamine concentrations on the lesion side may relate to gliosis in the regions of fiber degeneration, since glial cells tend to have relatively high glutamine concentrations.

150.10 CHOLINERGIC, GABAERGIC, AND NORADRENERGIC INPUT TO COCHLEAR GRANULE CELLS IN THE GUINEA PIG AND MONKEY. J.K. Moore. Dept. of Anatomical Sciences, SUNY at Stony Brook, NY 11794.

The cochlear granule cell area receives input from several non-primary afferent systems. Among those systems which can be identified on the basis of transmitter-related enzymes are (1) cholinergic axons and terminals, arising partly from descending systems and partly from intrinsic cochlear sources; (2) GABAergic terminals, potentially representing terminals of either GABA-positive cochlear interneurons or brainstem efferent GABAergic axons; and (3) noradrenergic axons, most likely originating in the locus coeruleus. Because previous observations have indicated that there is marked morphological change in the cochlear granule cell population in primates (Moore, J. Comp. Neurol. 193:609-629, 1980), comparative histochemical studies of the cochlear nuclei were done in the guinea pig and the macaque monkey. Noradenergic and GABAergic afferents were investigated immunohistochemically by the avidin-biotin method, using antibodies to dopamine-β-hydroxylase (DBH), the synthetic enzyme for noradrenalin, and glutamic acid decarboxylase (GAD), the synthetic enzyme for GABA. Cholinergic axons and terminals were identified histochemically, using the Koelle indirect staining method for acetyl cholinesterase (AChE), the degradative enzyme for acetyl choline. In both guinea pig and monkey brainstems, all three types of histochemical staining demonstrated fascicles of reactive axons running between the brainstem and the cochlear nuclei in the acoustic striae and subpeduncular route. In the monkey, the size of the granule cell area is greatly reduced, but terminal staining of all three types was seen in this area. However, the density of reactive elements was less than that in the guinea pig and the marginal area of reactivity was less sharply bounded from the underlying magnocellular part of the cochlear nuclei. In both guinea pig and monkey AChE histochemistry produced a diffuse granular reaction product in the extracellular space of the granule cell layer: AChE staining in the remainder of the nucleus was limited to faint cytoplasmic staining of the larger neurons. In the GAD material, the granule cell layer contains numerous discrete immunoreactive terminals, as well as scattered dense clusters of terminals. In the DBH material, the immunoreactive structures were fine varicose axons crossing the deeper of the nuclei and forming a moderately dense plexus of axons in the peripheral granule cell layer. These results suggest that the macaque cochlear granule cell system, despite morphological change, retains the mammalian function of relaying nonprimary input into the cochlear nuclei.

This project was supported by the Deafness Research Foundation. Monkey brainstems were obtained from Dr. A. Hendrickson. The antibody to GAD was kindly provided by Dr. I. Kopin.

150.11 AN *IN VITRO* PREPARATION OF THE AUDITORY BRAINSTEM IN THE BAT, *EPTESICUS FUSCUS*. J.M. Zook and R.A. DiCaprio. Dept. of Zoological & Biomedical Science and College of Osteopathic Medicine, Ohio U., Athens, OH 45701.

We have developed a slice preparation of the auditory brainstem of the big brown bat, *Eptesicus fuscus*. The slice preparation presents advantages not only for intracellular recording stability but also for the intracellular labeling of large numbers of cell soma and cell processes. Our initial focus has been to exploit the anatomical aspects of the slice preparation while working out the necessary physiological parameters to pursue our main goal: characterization of the synaptic input to the cells that are the source of the olivocochlear bundle.

There are some specific benefits from the use of the bat in this preparation. The brainstem is quite compact and, with the relative hypertrophy of auditory nuclei, this means that the entire extent of the auditory brainstem from cochlear nucleus to inferior colliculus can be included in three to five consecutive 500 μm slices sectioned in the transverse plane. Sections are maintained in a chamber perfused with a temperature-regulated, oxygenated, physiological solution. Preliminary results also suggest that the brain of this poikilothermic mammal may be unusually tolerant to the hypothermic and hypoxic stresses of the slice preparation.

The olivocochlear bundle (OCB) can be studied to particular advantage with the slice preparation. It is possible to selectively target the cells in the superior olivary complex which give rise to this fiber tract. A fluorescent dye (Fast blue or Lucifer yellow) injected into the cochlea of intact subjects is carried by retrograde transport to the OCB-originating cells in the superior olive. After a few days survival these dye-filled cell soma in the superior olive can be localized in the slice by illumination with an appropriate excitation light source. The identity of cells penetrated can be readily confirmed by antidromic stimulation of the OCB bundle as it is separate from other auditory tracts. Penetrated cells can be distinguished by iontophoresis of a second fluorescent dye or horseradish peroxidase. At the end of recording sessions the slice can be lightly fixed and additional cells filled intracellularly by pressure injection with a contrasting label. The combination of iontophoretically-filled, characterized cells and diffusion-filled fixed cells gives us a rich population of cells for study of a specific functional group: the cells of the superior olive which originate the olivocochlear bundle. Filled cells and axons are drawn for comparison with golgi material prepared in this species. Future experiments will use the slice preparation to further characterize this cell population by exploring the morphology and physiology of the synaptic input to individually identified cells.

Supported by NIH Grant NS20986, OURC Grant 756 and the OUCOM.

150.12 HEARING AND THE AUDITORY BRAINSTEM IN A FOSSORIAL MAMMAL, THE POCKET GOPHER. R.S. Heffner[1], M.M. Richard*[2], and H.E. Heffner[1] [1]Dept. of Psychology, Univ. of Toledo, Toledo, OH 43606; [2]Dept. of Psychology, Univ. of New Orleans, New Orleans, LA 70148

Because sound propagation underground and in tunnels is quite different from sound propagation above ground, it is likely that the selective pressures on hearing in underground mammals may be somewhat different from those encountered above ground. As part of an investigation into the selective pressures that have shaped mammalian hearing, we have examined the hearing abilities and central auditory neuroanatomy of a fossorial species, the pocket gopher, Geomys bursarius. The pocket gopher, which is the North American rodent most specialized for underground living, rarely forages above ground but spends almost its entire lifetime in tunnels up to a meter below the surface.

Pocket gophers were tested for both sensitivity to pure tones and for the ability to localize brief noise bursts in the azimuthal plane using the conditioned avoidance procedure. The hearing ability of the pocket gopher is unusual in that it is the least sensitive of any mammal yet tested. In addition, the gopher has the poorest high-frequency sensitivity among rodents and, unlike elephants and humans which have also lost high-frequency hearing, the gopher has not appreciably extended its low-frequency hearing. Finally, the sound-localization acuity of the pocket gopher is the poorest yet encountered in mammals—perhaps not unexpected in a species inhabiting tunnels.

The auditory brainstem was examined using thionin and protargol stains. The dorsal cochlear nucleus is well developed and the ventral cochlear nucleus appears similar to that of other small rodents. The medial superior olive is large, resembling that of gerbils and kangaroo rats, species with similar low-frequency hearing. The lateral superior olive is present but not as well developed as in most rodents, a result which corresponds to the pocket gopher's restricted high-frequency sensitivity.

In conclusion, compared to mammals in general including rodents which live below-ground but forage on the surface, the hearing of the pocket gopher appears to be degenerate but its auditory brainstem has retained an essentially rodent-like character.

150.13 A COMPUTER MODEL FOR PERIODICITY ANALYSIS IN THE AUDITORY MIDBRAIN BASED ON PHYSIOLOGICAL PROPERTIES AND CONNECTIVITIES OF UNITS IN THE COCHLEAR NUCLEUS. G. Langner, J. Decker*, M. Günther*, and B. Hose Inst. of Zoology, TH - Darmstadt, 61 Darmstadt, FRG

Periodicity pitch is a perception evoked by periodic envelopes of acoustic signals covering a range of envelope frequencies from about 20 to 1000 Hz. There are good reasons to believe that pitch perception in this range is based on temporal coding mechanisms. For example, units in the auditory midbrain of many species are tuned to envelope frequencies up to 1000 Hz (Langner,G., Exp. Brain Res., 44:450, 1981; Schreiner, C. and Langner, G., Soc. Neurosci. Abstr., 10:395, 1984; Batra, R. et al., Soc. Neurosci. Abstr., 12: 361.3, 1986). Response properties of units in the midbrain of Guinea fowl and cat were found to be compatible with a cross correlation model (Langner, G., Exp. Brain Res., 52: 133, 1983). One component of this model is a coincidence unit with two inputs, one of them phase coupled to the envelope and the other one to the fine structure of the signal. The fine structure is coded in a reduced way similar to Wever's volley principle. The delays which are necessary for any correlation mechanism are provided in this case by intrinsic oscillations triggered by the envelope fluctuations. This model explains the effect of the signal fine structure on the preference of a coincidence unit for a certain envelope frequency as well as on the pitch perceived by human subjects.

A computer model was developed which consists of a trigger unit (corresponding to on- type cells of the VCN), oscillator units (corresponding to chopper-type cells of the VCN) and a reducer circuit (corresponding to type IV-cells and inhibitory cells of the DCN) and finally a coincidence unit (corresponding to a cell in the midbrain). All components of the model have properties and connectivities which are to a first approximation realized by the actual cell types. The model predicts additional response features for the included cell types and requires some additional connections not yet demonstrated anatomically. It simulates temporal tuning properties of the midbrain units and their complex transient response behavior after stimulus onset. The model reproduces this transient effect using as input the transient temporal responses of auditory nerve fibers.

151.1 PROJECTIONS OF GLOBULAR BUSHY CELLS IN THE CAT.
P.H. SMITH, L.H. CARNEY*, and T.C.T. YIN, Dept. of Neurophysiology, University of Wisconsin-Madison, Madison, WI 53706.

In order to identify synaptic termination sites of globular bushy cells, we have done intra-axonal recording, physiological characterization, and subsequent HRP injection into single globular bushy cell axons in the trapezoid body (TB) of the cat. Entry of the microelectrode tip into a single axon was signaled by a 40-65 mV DC shift and 30-55 mV action potentials. A threshold tuning curve was used to determine the fiber's characteristic frequency (CF). The presence of a primary-like with notch (including onset with low sustained rate) PST in response to short tones at CF and a coefficient of variation within the appropriate range (Young, 1986) were used to identify axons of globular bushy cells physiologically. HRP was injected into these axons. After 12-36 hours survival, the cat was perfused and the tissue was processed using DAB with nickel-cobalt intensification. Morphologically, cells were verified as globular bushy cells by the location and features of their HRP-labeled somata within the posterior anteroventral cochlear nucleus or nerve root area, and the lack of axon collateral branches within the cochlear nucleus.

The main axons of labeled globular bushy cells leave the cochlear nucleus, traveling in the ventral component of the TB, and always give off one or more collaterals before crossing the midline. These collaterals branch frequently as they course dorsally, with terminal endings often in close apposition to cell bodies in the posterior periolivary nucleus, lateral nucleus of the trapezoid body and dorsal periolivary nuclei. Major sites of termination are regions containing somata whose axons project to the ipsilateral cochlear nucleus (Adams, 1983). For terminals studied thus far at the EM level, HRP-filled collateral enlargements contain large round synaptic vesicles. The main axons proceed across the midline and may branch up to 4 times contralaterally. One and occasionally two of the branches end in large calyces of Held in the medial nucleus of the trapezoid body. In addition, other contralateral branches, when they can be followed to termination, end in periolivary nuclei and the ventral nucleus of the lateral lemniscus.

151.2 **DEVELOPMENT OF PROJECTIONS FROM THE HINDBRAIN TO THE INFERIOR COLLICULUS.**
F.H. WILLARD AND G.F. MARTIN. Depts. of Anatomy, Uni. of New England, Biddeford, ME 04005 and Ohio State Uni., Columbus, OH 43210.

The inferior colliculus (IC) receives axons from most auditory regions of the hindbrain. We have studied the development of these projections and their topographic order using the HRP technique to retrogradely label neurons in pouch-young opossums. The opossum is an ideal animal for studying early development since it is born in an immature state, 12 days after conception.

The IC of young opossums, ranging in age from estimated postnatal day (EPND) 5 to 33, received either iontophoretic injections or placements of crystalline HRP. Approximately 24 hours later the brains were removed, sectioned and reacted for HRP. The youngest animals to show retrogradely labeled neurons in all of the appropriate auditory nuclei were operated on EPND 15. However, we found labeled neurons in the superior olivary nuclei and in a precochlear band destined for the dorsal cochlear nucleus (DCN) as early as EPND 5. Retrogradely labeled neurons were first seen in the nuclei of the lateral lemniscus in EPND 10 animals and in the ventral cochlear nucleus (VCN) at EPND 15. In a EPND 20 opossum, an injection limited to the medial border of the central nucleus of the IC resulted in the labeling of neurons in a restricted column along the medial border of the DCN and VCN, suggesting a topographic relationship. Finally, in the EPND 25-33 animals it was possible to place small, disc-shaped injections, oriented in the plane of the fibro-dendritic laminae of the central nucleus. Such injections resulted in well defined columns of labeled neurons in the cochlear nuclei. Injections centered in the ventromedial laminae of the central nucleus labeled neurons in the medial portion of the cochlear nuclei, those centered dorsolaterally labeled neurons in laterally positioned columns.

These results suggest that most hindbrain auditory nuclei have established projections to the IC by EPND 15 and that topographic order in the cochleocollicular connection is detectable shortly thereafter. Well defined topography exists by EPND 33. All of these events appear to take place prior to the onset of detectable hearing or eighth nerve activity as reported by Larsell and et al. (Arch. Otolaryngol. 40:233, 1944). Supported by BNS 8309245 and NS-16165.

151.3 MORPHOLOGICAL SUBSTRATES FOR BINAURAL INTERACTIONS IN THE MIDBRAIN: AFFERENTS TO THE DORSAL NUCLEUS OF THE LATERAL LEMNISCUS.
D.L. Oliver, A. Shneiderman, and C. Henkel. Dept. Anatomy, Univ. Conn. Health Ctr., Farmington, CT 06032 and Dept. Anatomy, Bowman Gray Sch. Med., Winston-Salem, NC 27103.

The dorsal nucleus of the lateral lemniscus (DNLL) may provide a major, inhibitory input to the inferior colliculus (Shneiderman and Oliver, this volume; Adams and Mugnaini, Brain Res. Bull. 13: 585-590, 1984). Yet, the circuitry and the synaptic organization of the DNLL are not well known.

In this study, the inputs to the DNLL in the cat were examined with anterograde and retrograde axonal transport methods at the light microscopic level, and the reciprocal projections of the DNLL were studied with electron microscopic autoradiography. Fibers from anteroventral cochlear nucleus (AVCN) and lateral superior olive (LSO) terminated bilaterally in DNLL, while medial superior olivary inputs were ipsilateral. The contralateral AVCN always provided a heavy input to the DNLL. However, only the dorsolateral part of the DNLL received inputs from the ipsilateral AVCN. No inputs from the dorsal cochlear nucleus were found. The afferent axons formed horizontal layers which paralleled the dendritic fields of DNLL neurons. Inputs were topographical and are probably tonotopically organized. Although most inputs distributed evenly across the DNLL, inputs from the contralateral LSO were heaviest medially and from AVCN laterally.

The reciprocal, crossed projection between the DNLL also had a laminar pattern and dorsal-to-ventral topography that corresponded to injections restricted in either the dorsal or ventral part of the contralateral nucleus. When a cocktail of WGA-HRP and 3H-leucine was injected in the DNLL, the location of the heaviest anterograde labeling contralaterally corresponded to the location of the most intensely WGA-HRP-labeled cells. At the electron microscopic level, most labeled axonal endings from the contralateral DNLL contained pleomorphic vesicles and formed symmetric synapses. These endings were labeled more than 5 times background and constituted 22-32% of all boutons with pleomorphic vesicles. Numerous synaptic contacts were made by labeled endings on medium and large-sized dendrites and on somata. A few endings with round synaptic vesicles appeared to be labeled in one sample.

These data suggest that the reciprocal projections of the DNLL may be inhibitory. Since most ascending inputs to the DNLL may be excitatory, the responses of DNLL cells may be influenced by the laterality of acoustic stimulation. If the neurons in the DNLL on one side are more strongly driven, the crossed projection may suppress activity in the DNLL of the other side.

(Supported by NIH grants NS18391 and NS18627.)

151.4 AFFERENT INPUT TO MEDIAL SYSTEM OLIVOCOCHLEAR NEURONS FROM POSTEROVENTRAL COCHLEAR NUCLEUS IN GUINEA PIG.
A.M. Thompson and G.C. Thompson. Dept. of Oto. & Comm. Sci., Div. of Audiol. & Bioacoustics, and Prog. in Neurosci., Baylor College of Medicine, Houston, TX 77030.

We have previously used the PHA-L (Phaseolus vulgaris leucoagglutinin) anterograde tract-tracing technique to demonstrate neural projections from the posteroventral cochlear nucleus (PVCN) to the superior olivary complex (SOC) in guinea pig. In the present study, we examined whether or not olivocochlear (OC) neurons, located in medial periolivary regions of SOC, are targets of PVCN neural projections.

Iontophoretic injections of PHA-L were made into PVCN in order to label the terminal endings of its projection neurons. Six days later, OC neurons were retrogradely labeled by perfusing HRP through the cochlea. Animals were sacrificed 24 hours after the HRP perfusions and the brain sections were processed to simultaneously visualize both labels. To determine the laterality of the PVCN afferent projections to, and the efferent projections from, OC neurons, both the PHA-L injection and HRP perfusion were done unilaterally in each case with the HRP perfusion either ipsilateral or contralateral to the PHA-L injection. By definition, medial system OC neurons were those HRP-labeled neurons located in dorsomedial (DMPO) and ventromedial (VMPO) periolivary and preolivary (PREO) regions of SOC.

Light microscopic examination revealed PHA-L-immunoreactive terminal varicosities of the PVCN projection neurons contacting medial system OC neurons located in DMPO, VMPO, and PREO regions. Most of the varicosities were en passant type endings making contact with dendritic processes. Additionally, we discovered unique patterns with regard to the laterality of the afferent/efferent projections. The majority of afferent input to the medial OC system originated in the contralateral PVCN and ended upon contralaterally-projecting neurons. This provides evidence that this OC system primarily projects back to the same cochlea from which it received sensory input, thus defining a recurrent cochlear pathway. Conversely, PVCN also projected to other medial system OC neurons that projected to the cochlea contralateral to their PVCN input, demonstrating the existence of a pathway linking the two cochleas. Overall, these results provide the first direct evidence of two cochlear pathways, each originating in one cochlea and projecting to either the same or the opposite cochlea. Both pathways consist of PVCN to medial OC system projections which may provide the anatomical substrate by which the CNS modulates sensory transduction at the auditory periphery.

151.5 BIOCHEMICAL BASIS FOR THE ACOUSTIC CHIASM? K.A. Hutson*, K.K. Glendenning and R.B. Masterton. Dept. of Psychology, Florida State Univ., Tallahassee, FL 32306.

The 'acoustic chiasm' allows the two hemifields of auditory space to become represented in the contralateral side of the upper levels of the neuraxis (Jenkins & Masterton, '82). Because the lateral superior olive is the one binaural nucleus in the hindbrain common to all mammals, it is the prime candidate to be the neural substrate of the 'chiasmatic' process.

However, the cells of LSO are known to be of the EI type: meaning that stimulation of the ipsilateral ear excites and contralateral stimulation inhibits; while the responses at the collicular targets of LSO are almost entirely of the IE type. This clear reversal in laterality from EI at LSO to IE at colliculus occurs despite both LSO's projecting directly, and nearly equally, to both colliculi. Thus, the question arises: how can a virtually complete functional reversal in interaural dominance occur in the presence of only a 50% anatomical decussation.

One obvious possibility is that not all of LSO's projections are excitatory. In the manner of Hunt, Künzle & Cuénod ('75), Streit ('80) and Rustioni & Cuénod ('82) we injected 3H-glycine in one colliculus of otherwise normal cats, sacrificed them from 1 to 48 hrs later, and processed sections through the hindbrain with conventional autoradiographic procedures.

The results show that as little as one hour after the injection, some fibers and cells of the lateral lemniscus become intensely labeled. After 6 hrs, many cells in ipsilateral LSO are intensely labeled. This labeling of cells in ipsilateral LSO stands in sharp contrast to the complete absence of labeling of cells in other auditory nuclei, whether ipsilateral or contralateral to the injection, even after 48 hr survivals. We compared the percentage of cells labeled with glycine with that obtained from an HRP injection in the colliculus. The close approximation of the two percentages suggests that every cell in LSO with an axon ending in the ipsilateral colliculus may be labelable by the retrograde transport of glycine.

It can be noted that if this technique is specific to glycinergic cells (Hunt, Streit, Knecht & Cuénod, '77) and that being glycinergic they are inhibitory in their effect at the colliculus, the curious disappearance of EI responsive cells between hindbrain and midbrain would be resolved. Half of LSO's EI cells reverse their allegiance (from EI to IE) by crossing the midline. The other half reverse their allegiance by remaining ipsilateral but being, themselves, inhibitory: in this sense, the acoustic chiasm is a biochemical 'decussation'.
(NINCDS 18877)

151.6 THE CHEMICAL ACOUSTIC CHIASM: ASYMMETRIC GLYCINE IMMUNOREACTIVITY IN THE BILATERAL PROJECTION FROM THE LATERAL SUPERIOR OLIVE TO THE INFERIOR COLLICULUS IN THE CAT.
R.L. Saint Marie[1], E.M. Ostapoff[1], D.K. Morest[1] and R.J.Wenthold[2]
[1]Dept. Anatomy, Univ. Conn. Health Center, Farmington, CT 06032 and [2]Laboratory of Neuro-Otolaryngology, NIH, Bethesda, MD 20892.

Principal neurons in the lateral superior olive (LSO) are excited by ipsilateral and inhibited by contralateral sound. The LSO, in turn, projects equally to both inferior colliculi (IC). Despite this bilateral projection from LSO, only contralateral stimulation is excitatory to most cells in the IC. Hutson et al. (this volume) suggest that neurochemically distinct excitatory and inhibitory projections from the LSO are the basis for this functional acoustic chiasm. They describe the uptake and retrograde transport of ^{3}H-glycine from the IC by principal cells in LSO, but only ipsilaterally. To verify this neurochemically asymmetric projection, we compared the glycine immunoreactivity of LSO cells following large, unilateral HRP injections in the IC. Glycine immunoreactivity was determined by postembedding PAP histochemistry on semi-thin, Epon-embedded sections.

In the superior olivary complex, the principal cells of the medial trapezoid nucleus were intensely immunoreactive (Gly+), as were their axons projecting to the LSO. Cells in the medial superior olive were unstained, but, like the principal cells in the medial trapezoid nucleus, they had few Gly+ perisomatic endings. In contrast, the cell bodies and proximal dendrites of LSO principal cells were heavily encrusted with GLY+ endings. Of these LSO cells, 40% had Gly+ somata and these were evenly distributed in the LSO.

Of the LSO cells retrogradely labeled from the contralateral IC, less than 1% were GLY+. In the ipsilateral LSO, two populations of retrogradely labeled cells were distinguished: many (>60%) were GLY+ and these occurred throughout the LSO. The remaining ipsilateral projection neurons were GLY- and concentrated in the lateral half of LSO. Retrogradely labeled marginal and hilar cells surrounding LSO had a similar immunostaining pattern.

We conclude that three distinct neuronal populations project to the IC from the LSO. 1) The entire crossed projection to the IC is Gly- and is presumably excitatory. 2) The uncrossed pathway includes a presumed inhibitory projection, which consists of all of the Gly+ principal cells. These results agree with Hutson et al. and suggest a neurochemical basis for the acoustic chiasm and for some of the binaural properties of IC neurons. 3) The remaining neurons of the uncrossed projection are Gly- and are confined to the lateral half of the LSO (frequencies below 10-12 kHz). This latter projection also may be excitatory; its existence implies that sounds below 10-12 kHz are subject to additional processing in the IC. (Supported by NIH grant NS14347)

151.7 CONVERGENCE OF COMMISSURAL AND CORTICOFUGAL INPUTS TO THE RAT INFERIOR COLLICULUS: TERMINAL AXONAL FIELDS AND CELLS OF ORIGIN. Kate D. Games and Jeffery A. Winer. Department of Physiology-Anatomy, University of California, Berkeley, California 94720.

The inferior colliculus, a primary station in the ascending auditory system, receives substantial corticofugal and commissural input. We examined the subdivisions of the rat inferior colliculus (IC) in Nissl and Golgi preparations and used horseradish peroxidase (HRP) to study commissural axons and cells of origin, and the auditory corticofugal projection, to the rat auditory midbrain. Pressure and iontophoretic HRP injections were made in the central and external nuclei of the IC, and reacted with the heavy metal-intensified DAB-$CoCl_2$ or TMB chromogens. Autoradiographic studies with [^{3}H]leucine or experiments with the anterograde transport of HRP seen with TMB were also used to study the auditory cortical projections. Our goals were to: *(1)* study the relation of anterogradely labeled axons and terminals to the pattern of retrogradely labeled cells, and *(2)* discern whether there is overlap or segregation of commissural axons with input from the auditory cortex (K.D. Games and J.A. Winer, *Exp. Brain Res.*, 1986: submitted).

Three major subdivisions of the inferior colliculus were identified. These resembled the architectonic plans proposed by Ramón y Cajal (guinea pig; *Trab. Lab. Invest. Biol.*, 1902, **1**:207-227) and Geniec and Morest (human; *Acta Oto-Laryngol.*, 1971, **suppl. 295**:1-33). The central nucleus, characterized by fibro-dendritic laminae, was bounded laterally by the external nucleus and dorsally by the dorsal cortex. Every subdivision sent and received commissural projections. The dorsomedial IC, including parts of the dorsal cortex, central nucleus, and adjacent intercollicular tegmentum, received the heaviest commissural input but contained few retrogradely labeled cells of origin. Other parts of the IC received comparatively sparse terminations even after HRP injections which labeled all parts of the contralateral cochlear nucleus. Input from the ipsilateral auditory cortex largely overlapped with the commissural projections in the dorsomedial IC, but not in the central nucleus. Commissural axons passing through the dorsomedial IC toward the central and external nuclei formed thin fascicles largely orthogonal to the fibro-dendritic, presumptive isofrequency lamina of the central nucleus. These axons had few branches, and terminated in delicate boutons. The ventral part of the central nucleus was sparsely labeled by either IC or cortical injections.

These observations suggest that the commissural, corticofugal, and cochlear afferents are partially segregated (*e.g.*, corticofugal versus cochlear) and partly overlapping (*e.g.*, corticofugal versus commissural). Thus, both parallel and convergent acoustic pathways are represented in the inferior colliculus.

151.8 THE RAT MEDIAL GENICULATE COMPLEX: NUCLEAR ARCHITECTURE, NEURONAL ORGANIZATION, AND NEOCORTICAL CONNECTIONS. Stuart J. Cheff, David T. Larue, and Jeffery A. Winer. Department of Physiology-Anatomy, University of California, Berkeley, California 94720.

We studied the anatomy of the medial geniculate body in adult rats in Nissl and plastic-embedded preparations, in Golgi impregnations, and after horseradish peroxidase injections in the subdivisions of auditory cortex. We wished to integrate the results of these methods and to compare the chief organizational features of rat medial geniculate body with previous findings in the opossum (D.K. Morest and J.A. Winer, *Adv. Anat. Embryol. Cell Biol.*, 1986, **98**:1-96), cat (J.A. Winer, *Adv. Anat. Embryol. Cell Biol.*, 1985, **86**:1-98), bat (J.J. Wenstrup and J.A Winer, *Proc. Soc. Neurosci.*, 1987, **13**: in press), and human (J.A. Winer, *Hearing Res.*, 1984, **15**:225-247).

We found that most, if not all, major divisions recognized in these species could be delineated in the rat. In particular, the *ventral division* was large and contained tufted principal neurons arranged in fibro-dendritic laminae; these cells projected to auditory cortex in a topographic sequence: laterally situated thalamic cells sent their axons to the caudal aspect of the primary cortical field, while more medial cells projected more rostrally. In the *dorsal division*, two classes of thalamocortical relay cells--one with a bushy and the other with a radiating dendritic branching pattern--were seen; these were devoid of any conspicuous topography in their cortical projection, which lay caudodorsal to the primary field, nor was there evidence of fibro-dendritic laminar organization. The *medial division* contained several types of medium-sized neurons and larger cells, which projected to auditory and non-auditory cortex. In every thalamic division, small neurons were also recognized; these had a few slender dendrites, sparse, often short appendages, and were sometimes labeled by cortical injections. The architectonic parcellation proposed here is consistent with findings of glutamic acid decarboxylase (GAD) immunoreactivity of neurons and puncta (D.T. Larue and J.A. Winer, *Proc. Soc. Neurosci.*, 1987, **13**: in press), and with the distribution of corticothalamic axon terminals in autoradiographic studies (J.A. Winer and D.T. Larue, *J. Comp. Neurol.*, 1987, **257**:282-315). Compared to the cat, the main differences in the rat are the small size of the dorsal and medial divisions, the relative paucity of GAD-positive neurons, and the comparative reduction in the volume of neuropil. The tufted relay neurons in the ventral division appear to have been conserved in evolution and are readily recognized in marsupials, carnivores, insectivores, primates, and rodents as a fundamental feature of the lemniscal auditory pathway.

This research was supported by USPHS grant R01 NS16832. We thank K.D. Games for sharing her experimental results with us, and we are grateful to T. McShane, L. Miranda, and Y. Nam for technical assistance.

151.9 ARCHITECTURE OF GAD-IMMUNOREACTIVE DENDRITES IN RAT MEDIAL GENICULATE COMPLEX: A POSSIBLE SUBSTRATE FOR DENDRODENDRITIC RELATIONS. David T. Larue and Jeffery A. Winer. Department of Physiology-Anatomy, University of California, Berkeley, California 94720.

Since presynaptic dendrites are an important feature in the intrinsic organization of the ventral (lemniscal) division of the cat medial geniculate body (D.K. Morest, *J. Comp. Neurol.*, 1975, **162**:157-194), we wondered whether comparable structures might occur in the rat ventral division, and what their source might be. We studied glutamate decarboxylase immunostained dendrites from adult rats perfused with a formalin-zinc salicylate solution. Free-floating, 25-µm-thick frozen sections were processed by either the peroxidase anti-peroxidase or avidin-biotin procedures at a 1:2000 dilution of primary antiserum. Thalamic subdivisions were defined in Nissl, Golgi, or plastic-embedded preparations, and on the basis of axoplasmic transport studies (J.A. Winer and D.T. Larue, *J. Comp. Neurol.*, 1987, **257**:282-315; S.J. Cheff, D.T. Larue, and J.A. Winer, *Proc. Soc. Neurosci.*, 1987, **13**: in press).

Immunopositive neurons comprise only a small proportion of *ventral division* neurons, their primary dendrites may be 100-300 µm long and their trunks tapered gradually and branched sparsely, terminating in fine sprays (<0.5 µm thick) that form elaborate nests and were often capped with varicose expansions or bouton-like appendages. These dendrites often occurred in close proximity to other dendrites, especially those of larger non-immunoreactive neurons, and, on occasion, near neural somata. Most immunopositive neurons were less than 10 µm in diameter. In the *dorsal division* the number of immunopositive neurons was smaller, cells received few perisomatic puncta, and dendrites were rarely immunopositive beyond their initial 50 µm. *Medial division* immunoreactive neurons were varied in size, received many perisomatic puncta, and had sparse dendritic staining. Control sections incubated in pre-immune serum were free of specific immunostaining.

The form, number, and distribution of puncta differed significantly among thalamic divisions: in the *ventral division*, they were small, numerous, and mainly peridendritic; in the *dorsal division*, they were far finer, exceedingly sparse, and scattered; in the *medial division*, they were large and coarse, as numerous as in the ventral division, and terminated both upon neural somata and in the neuropil. These patterns no doubt embody different forms of GAD-labeled circuitry within the auditory thalamus.

This research was supported by USPHS grant R01 NS16832. We are grateful to Drs. D.E. Schmechel and E. Mugnaini for their kind gift of antiserum, and for technical advice. We thank B. Meksavan, T. McShane, L. Miranda, Y. Nam, Q. Nguyen, and J. Popowits for their assistance.

151.10 BRAINSTEM LOCATIONS OF PHYSIOLOGICALLY CHARACTERIZED STAPEDIUS MOTONEURONS IN CAT : SINGLE UNIT LABELING. S.R. Vacher*, J.B. Kobler and J.J. Guinan,Jr., Eaton Peabody Laboratory, Mass. Eye & Ear Infirmary, Boston, MA 02114; EECS DEPT., M.I.T..

Stapedius motoneurons in the cat are widely distributed around the facial nucleus and the superior olivary complex. From the effects of partial lesions of the stapedius motoneuron pool, it has been suggested that stapedius motoneurons in different brainstem locations might have different inputs and responses properties (McCue, M.P.,and Guinan, J.J., *Soc. Neurosci. Abstr.*, 9:1085, 1983). Recordings from single stapedius motoneuron axons (Kobler, J.B., Vacher, S.R., Guinan, J.J., *Soc. Neurosci. Abstr.*, 11:288, 1985) have shown that these motoneurons can be divided into 5 categories : 1)"Contralateral" units (10%) responded only to sound contralateral to the recording, 2)"Ipsilateral" units (28%) responded only to ipsilateral sounds, 3) "Binaural And" units (5%) responded only when sounds were delivered to both ears, 4)"Binaural-Or" units (44%) responded to sound delivered to either ear, 5)"Tonically active" units (13%) were active even in the absence of delivered sound. The purpose of the present study was to determine whether these electrophysiological categories of stapedius motoneurons are related to the location or morphology of cell bodies in the brainstem.

Cats were anesthetized with ketamine and paralyzed with gallamine. Single axons of stapedius motoneurons were recorded in fascicles which course from the facial nerve to the stapedius muscle. The category of each motoneuron was determined by its response to 100 msec. monaural and binaural tone bursts presented over a wide range of frequencies. Motoneurons were intracellularly injected with horseradish peroxidase (HRP). Labeled cell bodies were visualized with Tetramethylbenzidine in transverse sections of the brainstem.

Twenty-nine physiologically-identified stapedius motoneurons were labeled : four "Contralateral", eight "Ipsilateral", three "Binaural And", twelve "Binaural-Or" and one "Tonically active". The distribution of the thresholds at 1 kHz for these 29 labeled motoneurons was similar to the distribution obtained for all stapedius motoneurons from which we have recorded. Labeled motoneurons were found in all of the previously identified regions of the brainstem which contain stapedius motoneurons. However, motoneurons within a single category were found in relatively circumscribed locations. All four "Contralateral" motoneurons were found ventromedial to the facial nucleus. "Ipsilateral" motoneurons (7/8) were distributed in a layer between the facial nucleus and the superior olivary complex (SOC); one was dorsal to the anterior tip of the SOC. The three "Binaural-And" motoneurons were located dorsal to the SOC. Most of the "Binaural-Or" motoneurons (11/12) were located around the facial nucleus (ventral and dorsal to it); one was dorsal to the SOC. The "Tonically Active" motoneuron was found lateral to the facial nucleus. The cell bodies of the "Contralateral" motoneurons had the largest profile areas (827 μm^2 to 342 μm^2), while the "Binaural And" and "Tonically Active" motoneurons had the smallest areas (233 μm^2 to 292 μm^2). The areas for the other categories of units were distributed between the above extremes.

This work shows that stapedius motoneurons with distinctive electrophysiological properties have similar locations in the brainstem with limited overlap between categories. The results are consistent with the idea that the stapedius motoneuron pool is divided into groups which are spatially segregated in the brainstem and receive different patterns of inputs from the two ears. *(supported by Fogarty International Center 3 F05 TWO 3605-01S1 and NIH grant PO1NS13126).*

151.11 TONICALLY ACTIVE MOTONEURONS INNERVATING THE STAPEDIUS MUSCLE OF THE CAT J.B. Kobler, S.R. Vacher, and J.J. Guinan, Jr., Dept. of Otology and Laryngology, Harvard Medical School, Boston, MA 02115, Eaton-Peabody Laboratory, Mass. Eye & Ear Infirmary, Boston, MA 02114, and Dept. of Electrical Engineering and Computer Science, MIT, Cambridge, MA 02139 USA

Most work on the stapedius muscle has focused on its reflex contractions in response to loud sounds. Preliminary data have been presented indicating that some stapedius motoneurons exhibit activity in the absence of sound (Kobler et al., *Soc. Neurosci. Abstr.* 11:288, 1985); in addition, there have been electromyographic (EMG) recordings of tonic activity in the human stapedius muscle (e.g. Salomon and Starr, *Acta Neurol. Scand.* 39:161 1963). We now provide further direct evidence that tonically active units constitute a discrete sub-group of the stapedius motoneuron pool with special properties.

Experiments were performed on adult cats anesthetized initially with pentothal (5 mg/kg) followed either by decerebration or intermittent i.v. doses of ketamine. Recordings were made from single axons within small fascicles which course on the lateral surface of the muscle. In order to supress contractions of the muscle, the animals were paralyzed with gallamine and artificially respirated. Calibrated earphones were sealed in each external acoustic meatus and the animals were placed in a sound-proof chamber.

More than 1200 stapedius motoneurons were studied in 63 cats. Thirteen percent were found to have some tonic activity (TA) in silence. TA rates varied from <1 spike/sec to 90 spikes/sec with a mean rate of 12 spikes/sec. The intervals between spikes were regular as demonstrated in interval histograms; however, slow fluctuations in TA rates were frequently observed. When tested with 100 ms 1 kHz tone bursts, approximately 95% of units with TA responded to stimulation of either ear whereas only 50% of units without TA responded to stimulation of either ear. In four cats with many TA units, the mean contralateral threshold was lower for TA units than for non-TA units ($p<.05$); for two of these cats the ipsilateral thresholds were also significantly lower ($p<.05$).

In six cats a pair of electrodes was placed on the internal genu of the facial nerve in the floor of the fourth ventricle to stimulate the central portion of the stapedius motoneuron axons. By measuring orthodromic spike latencies following shocks, axonal conduction velocities were computed. Units with TA were found to have significantly slower mean conduction velocities (9.6±2.7 m/sec, N=27) than units without TA (18.3±5.1 m/sec, N=239; $p<.001$). This observation suggests that TA motoneurons have small diameter axons, consistent with the fact that the amplitude of TA unit spikes are relatively low and that these units are often lost quickly. We have also observed that in stapedius EMG recordings the electrical potentials of tonically active muscle units are usually of smaller amplitude than those recruited at high sound levels.

According to reports of stapedius muscle fiber histochemistry (e.g. Teig and Dahl, *Histochemie* 29:1 1972), about 20% of the fibers have characteristics of slow twitch muscle fibers. Given the well documented correlations between activity pattern and muscle fiber type, a reasonable hypothesis is that motoneurons with tonic activity innervate these slow muscle fibers, providing a tension in the muscle which persists in the absence of acoustic stimulation. It remains to be seen whether this background tension is a significant factor in the transmission of sound through the middle ear and to what extent this tonic activity is a function of the state of the animal or its past history of sound stimulation. *Supported by NIH grant PO1 NS13126 and Fogarty International Center 3 F05 TWO 3605-0151.*

152.1 THE COMPLETE SEQUENCE OF A cDNA CODING FOR BETA-NERVE GROWTH FACTOR FROM *MASTOMYS NATALENSIS* M. Fahnestock and R. A. Bell*. SRI International, Menlo Park, California 94025.

Nerve growth factor (NGF) from the submaxillary gland of the male mouse is a 7S complex consisting of three subunits: the βNGF dimer which contains the nerve growth promoting activity; the γ subunit, a member of the kallikrein family of trypsin-like proteases which is implicated in the cleavage of a carboxy-terminal dipeptide from the βNGF subunit; and the α subunit, a kallikrein highly homologous to γNGF but with no enzymatic activity. The female mouse contains much lower levels of these proteins than the male.

Mastomys natalensis is an African rat with high levels of βNGF in both male and female submaxillary glands. Preliminary evidence indicated the *Mastomys* NGF is isolated as a 5.1S complex containing α and β subunits but no γ subunits (Fahnestock et al., J. Cell Biochem. Suppl. 8B, p. 104, 1984). These results suggested that *Mastomys* might contain an altered β subunit, specifically a β subunit lacking the carboxy-terminal dipeptide cleavage site. In order to address this question, we isolated and sequenced a full-length cDNA clone coding for βNGF from *Mastomys*.

Poly A^+ mRNA was purified from male *Mastomys* submaxillary glands using guanidine thiocyanate. Northern analysis of this mRNA using mouse βNGF cDNA (M. Selby and W. J. Rutter, UCSF) as a probe demonstrated a single, strongly-hybridizing band at 1.3kb. The *Mastomys* mRNA was used as a template to synthesize double-stranded cDNA which was inserted into λgt10. This library was screened with the mouse βNGF probe.

A single, full-length cDNA clone coding for *Mastomys* βNGF was selected, and the sequence was determined using the chain termination method. The *Mastomys* βNGF sequence is 90% homologous to the mouse βNGF sequence. In addition, the *Mastomys* βNGF contains the same carboxy-terminal sequence as mouse, Arg-Arg-Gly, which the γ subunit processes in mouse. The sequence demonstrates that mouse and *Mastomys* βNGFs are extremely similar, and suggests that *Mastomys* could contain a γ-like protein that processes the carboxy-terminal dipeptide of its βNGF.

152.2 THE NGF COMPLEX FROM THE AFRICAN RAT *MASTOMYS NATALENSIS*. T.S. Burcham* and E. M. Shooter (SPON: D. Shelton). Dept. of Neurobiology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

The submaxillary glands of the rat *M. natalensis* are a rich source of NGF (Aloe *et al. Exp. Cell Res.*,133:475, 1981). Unlike the mouse, both sexes of *M. natalensis* have submaxillary glands which contain NGF. The male *M. natalensis* and the male mouse have similar w/w quantities of NGF, and the submaxillary glands of the female have approx. half the NGF of the male. NGF has been found in many different cells of many species, yet in none of these instances has an NGF complex been fully characterized. Clearly the NGF from some sources exists as a high molecular weight complex, such as that from guinea pig prostate. We have therefore undertaken a study of the NGF complex from *M. natalensis* to further understand the biological role of the NGF complex and the α and γ subunits.

M. natalensis NGF complex was purified similarly to mouse 7S NGF (Varon *et al. Biochemistry*, 7:1296, 1968). Submaxillary glands from both male and female *M. natalensis* rats (age > 60 d), were processed separately. The glands were homogenized in 10 vols. of 10 μM $ZnCl_2$ at 4°C. The homogenate was filtered and centrifuged at 27,000xg for 15 min. The supernatant was centrifuged again at 100,000xg for 1 h. The supernatant was then concentrated by lyophilization. The lyophilizate was dissolved in 50 mM Tris-Cl/10 μM $ZnCl_2$ (pH 7.4 @ 25°C) and chromatographed on Sephadex G100. The fractions containing NGF activity were pooled, and subjected to DEAE ion-exchange chromatography. The 80 mM NaCl peak was concentrated by ultrafiltration, and then applied to a Sephacryl S400 column. Previous work continued purification with chromatofocusing, and found that the *M. natalensis* NGF complex contained only the α and β subunits. Results which will be presented indicate that the *M. natalensis* NGF complex is >95% pure after the S400 step (as determined by FPLC and non-denaturing-gel electrophoresis) and that chromatofocusing actually results in partial breakdown of the NGF complex into an αβ subunit. NGF and gamma activity were followed throughout the entire purification, and in every instance the peak in NGF activity was also a peak in γ esterase activity. The presence of the α subunit was evidenced by a positive immunoblot assay. When the stability of the *M. natalensis* NGF complex was examined by using the procedure of Palmer and Neet (*J. Biol Chem.* 255:5170, 1980), esterase activity was similar to that of the free γ subunit, suggesting that the NGF protein does not, as in mouse 7S NGF, inhibit γ activity.

A cDNA library has been constructed of both *M. natalensis* male and female poly(A)$^+$ RNA, and the library was screened using mouse NGF cDNA. Clones corresponding to *M. natalensis* βNGF, have been obtained and sequenced. Comparison of the *M. natalensis* β NGF sequence to that of other species will be shown. (This work supported in part by NIH NS07967-02.)

152.3 RETROVIRUS MEDIATED GENE TRANFER OF BETA-NERVE GROWTH FACTOR INTO MOUSE PITUITARY LINE AtT-20. M.P. Short*, D. Wolf*, C. Richer-Landsberg, C.Cepko* and X.O. Breakefield (SPON: W. Koroshetz) Molecular Neurogenetics Division, E.K. Shriver Center, Waltham, MA 02254; Genetics Dept. and Neuroscience Program (Neurology), Harvard Medical School, Boston, MA 02114.

Expression of the biologically active beta subunit of mouse nerve growth factor (beta-NGF) was conferred onto cultured AtT-20 mouse pituitary cells via a replication defective retroviral vector. The retroviral vector, derived from pLJ, includes a full length cDNA for beta-NGF (kindly provided by Dr. A. Ullrich) under the control of the retroviral LTR promoter, and a bacterial neomycin-resistance gene under the control of the SV40 early promoter. The cDNA for beta-NGF corresponds to the shorter mRNA species produced by most tissue which receive sympathetic innervation (Edwards, R.H., Selby, M.J. and Rutter, W.J.,Nature, 319:784, 1986). The retroviral vector was packaged in psi 2 cells. AtT-20 cells which produce essentially no endogenous beta-NGF, were then infected with this viral vector and cloned under neomycin-selection. Clones were evaluated for release of biologically active beta-NGF into the medium by neurite outgrowth by PC-12 cells. The biological activity released was relatively small, 1-10 beta-NGF beta per mg cell protein over 24 hr. Immune precipitation and SDS-polyacrylamide gel electrophoresis of labelled proteins from the media showed that the immunoreactive beta-NGF secreted from cells co-migrated with authentic mature beta-NGF, apparent MW 13000. The amount released over a 24 hr period was increased 2-3 fold by the presence of 10 nM epidermal growth factor or phorbol ester, which have been shown to increase transcription from the retroviral LTR promoter (Elsholtz, H.P. et al., Science 234:155 2, 1986). Following a 24 hr labelling period and replacement of medium, release over several hours was increased by addition of the secretagogue 1 mM 8-bromocyclic AMP, suggesting that at least some beta-NGF was stored in secretory vesicles. These studies, together with those on cultured cells lacking secretory granules, e.g. L cells (Brachet, P. Dicou, E., Exp. Cell Res., 150:234 1984), indicate that the beta-NGF precursor synthesized from the shorter mRNA species can be processed and secreted through either the regulated or constitutive pathway (kelly, R.B., Science 230:25, 1985). This vector thus provides a potential means of conferring beta-NGF expression onto a number of different cell types in culture and in vivo.

152.4 EXPRESSION OF THE cDNA FOR MOUSE BETA-NERVE GROWTH FACTOR (NGF) IN E. COLI. G.-L. Hu* and K. E. Neet (SPON: S. Rochel-Landau). Department of Biochemistry, Case Western Reserve University, Cleveland, OH 44106.

Nerve Growth Factor fulfills an essential role in the development and maintenance of neurons in the sympathetic, sensory, and (shown most recently) central nervous systems. The biologically active beta-subunit is a 13,000 Da polypeptide chain that contains no carbohydrate, possesses three intrachain disulfide bonds, and self-associates into a noncovalent dimer under most native conditions. Relatively little information is available on the structure/function relationships of this important neuronotrophic protein. Manipulation of the structure of NGF by site specific mutagenesis is a promising procedure with which to obtain more detailed information on its structural requirements. Expression of the cDNA for mouse beta-NGF in a bacterial system is the initial step in this process.

An expression vector for NGF was constructed from a pBR322 plasmid vector containing a 1068 basepair insert of nearly full length preprobeta-NGF [Scott, et al. Nature **302**, 538 (1983)] by excising a 373 base pair fragment (HaeII to PstI) encoding the entire mature NGF sequence. The fragment was inserted by blunt end ligation into a plasmid expression vector, pAS1 [Rosenberg, et al. Meth. Enzymol. **101**, 123 (1983)], which contains strong phage transcriptional and translational control elements that provide for regulated expression in E. coli. One recombinant plasmid, pAS1-NGF1(H2), was selected and shown to contain the insert by restriction mapping, southern blot analysis, and nucleotide sequencing.

The NGF protein was produced in E. coli transfected with the pAS1-NGF1(H2) by temperature induction and purified by ammonium sulfate precipitation and ion exchange chromatography. A purified fraction was obtained that demonstrated the authenticity of the expressed protein by appropriate behavior on cation exchange column, by reactivity with both monoclonal and polyclonal antibodies specific for beta-NGF, by size analysis on reducing SDS gel electrophoresis followed by immunotransblots, and, by biological activity that was inhibitable by NGF specific antibodies in the neurite outgrowth assay with PC12 cells.

The current system results in relatively poor yields of bioactive, recombinant NGF protein from E. coli. The low yield may be a result of any of the following: (a) low rates of synthesis of this particular protein, (b) proteolysis of the newly synthesized protein, (c) lack of tolerance of the foreign protein by the bacteria, or (d) the requirement for three disulfides to be correctly formed in the mature NGF. Efforts are underway to evaluate these problems and increase the amounts of NGF obtained. Nevertheless, the current expression of biologically active protein is significant and promises to open new lines of research on the structure and function of NGF. (Supported by NIH Grant NS24380.)

152.5 MULTIPLE MODES OF REGULATION OF β-NERVE GROWTH FACTOR SYNTHESIS IN C6 GLIOMA CELLS. J.P.Schwartz and W.Turner* Lab. of Neuronal Growth and Regeneration, NINCDS, NIH, Bethesda, MD 20892.

Many studies have demonstrated synthesis and release of nerve growth factor (NGF) by glial cells as well as glioma cell lines. We have investigated the regulation of synthesis of NGF in C6 glioma cells by measuring NGF mRNA (using a cDNA probe provided by A.Ullrich, Nature 303:821,1983), as well as NGF content by radioimmunoassay. Northern blot analysis shows a single NGF-hybridizing mRNA, 1.35 kb in size. Both NGF mRNA and NGF protein are increased by agents which elevate intracellular cyclic AMP, such as β-adrenergic agonists and forskolin. NGF mRNA is maximally increased by 2-3 hrs following either 100 nM isoproterenol (IP) or 5 μM forskolin - cyclic AMP is maximally elevated within 15-30 min. The rapidity of the increase of NGF mRNA suggests that regulation is occurring at the level of gene transcription: nuclear run-off assays are being carried out to verify this. The effect of the two agents, IP and forskolin, is not additive, supporting the idea that β-adrenergic regulation of NGF mRNA occurs via changes in cyclic AMP. NGF protein is significantly increased by 2 hrs and reaches a maximal content by 6 hrs - a proportional amount of NGF is released into the culture medium. All effects of IP are blocked by the β-adrenergic blocker propranolol, but not by either of two α-adrenergic blockers, phentolamine or phenoxybenzamine. The glucocorticoid dexamethasone has a small effect on NGF synthesis when added in the presence of dialyzed serum (to remove endogenous steroids) and potentiates the effect of IP. Dexamethasone does not change the cyclic AMP content of C6 glioma cells. The effects of other agents which may affect NGF content in animals, including T_3 and the ganglioside GM1, are being tested on C6 glioma cells as well as on primary cultures of normal glia. These results support the hypothesis that neurons may be able to regulate their own supply of NGF via a variety of neurotransmitter receptors known to be localized on glia.

152.6 K-252a: A SPECIFIC INHIBITOR OF THE ACTION OF NERVE GROWTH FACTOR ON PC12 CELLS. S. Koizumi,* M. L. Contreras, Y. Matsuda,* P. Lazarovici,* and G. Guroff. Section on Growth Factors, National Institute of Child Health and Human Development, Bethesda, MD 20892 and Kyowa Hakko Kogyo Co., Ltd. Tokyo 194, Japan.

K-252a, an alkaloid-like kinase inhibitor isolated from the culture broth of Nocardiopsis sp., selectively inhibits the actions of nerve growth factor on PC12 cells. At a concentration of 200 nM K-252a prevents, in a completely reversible fashion, neurite generation initiated by nerve growth factor. Under comparable conditions, K-252a has no effect on the generation of neurites produced by fibroblast growth factor, nor on the outgrowth produced by dibutyryl cAMP. K-252a also inhibits the induction of ornithine decarboxylase by nerve growth factor, but stimulates ornithine decarboxylase induction by epidermal growth factor and by a number of other effectors. Stimulation of phosphatidylinositol breakdown by nerve growth factor is similarly inhibited by K-252a, while stimulation by epidermal growth factor is enhanced. K-252a blocks nerve growth factor-induced heterodown regulation of the epidermal growth factor receptor, but not epidermal growth factor-induced homodown regulation of the epidermal growth factor receptor. Although the mechanism by which K-252a acts is not known, it appears not to be acting directly at the receptor because binding of NGF to its receptor is unaffected by the presence of 200 nM K-252a. It also does not seem to be acting by inhibiting either protein kinase C or cAMP dependent kinase because ornithine decarboxylase induction by either tumor promoters or dibutyryl cAMP is either unaffected or, in fact, stimulated by K-252a. K-252a, then, provides a new tool for the dissection and study of nerve growth factor-requiring processes in PC12 cells.

152.7 EVALUATION OF THE POTENTIAL ROLE OF PROTEIN KINASE C AND CALCIUM IN THE NGF INDUCTION OF ORNITHINE DECARBOXYLASE IN PC12 CELLS. D.S. Reinhold* and K.E. Neet. Department of Biochemistry, Case Western Reserve University, Cleveland, Ohio 44106.

The rat pheochromocytoma cell line PC12 undergoes a number of cellular responses when treated with nerve growth factor (NGF). Among these responses is the generation of neurites and the induction of ornithine decarboxylase activity (ODC). We have investigated the possible role of protein kinase C and calcium as second messengers in the NGF mediated induction of ODC in this cell line.

PC12 cells treated with 1nM NGF (concentration at which maximal effect is observed) for 5 hours at 37° showed a 20-50 fold induction in ODC activity over control cells, while cells treated with the phorbol ester phorbol 12-myristate 13-acetate (PMA) at concentrations of 50nM or higher produce about a 3-10 fold induction of the enzyme. The induction by each agent was inhibited by either cycloheximide or actinomycin D. However, when the protein kinase C activity of the PC12 cells was down regulated by incubation with 1uM PMA for 24 hours, the induction of ODC by PMA was completely inhibited, while the induction by NGF was not greatly affected. In addition, the maximal induction by NGF in untreated cells was significantly increased when 50nM PMA was added simultaneously with the NGF, suggesting the possibility that the two stimulants were acting through different but additive pathways. The mutant cell line $PC12^{nnr5}$ of Green et al.(Green et al., J. Cell Biol. 102, 830-843, 1986) was also tested for induction of ODC activity and it was found that PMA treatment caused about a 3 fold induction of ODC in these cells, while NGF had no effect on the enzyme levels. We interpret these data to mean that protein kinase C is not responsible for NGF induction of ornithine decarboxylase activity in PC12 cells. In addition to the induction of ODC, protein kinase C does not appear to play a role in NGF binding (both fast and slow) or internalization of bound NGF since down regulation of the kinase by PMA did not affect any of these parameters.

The possible role of phosphatidylinositol metabolism and calcium in the induction process has also been investigated. When cells were incubated with NGF in the presence of 20mM lithium, the induction of ODC activity was completely inhibited. The addition of 3.6mM EGTA or the calmodulin inhibitor W-7 (100uM) to the media also produced a complete inhibition of the NGF induction. Both the EGTA and W-7 inhibitions were partially, if not totally, reversible. These data suggest that both the phosphatidylinositol pathway and calcium may be important in the induction process. (Supported by an American Heart Association Northeast Ohio Affiliate Postdoctoral Fellowship #30-965.)

152.8 EARLY REGULATION BY NGF OF GENE SEQUENCES IN PC12 CELLS. F.Tirone and E.M.Shooter, Department of Neurobiology. Stanford University, School of Medicine, Stanford, CA. 94305.

Nerve growth factor (NGF) is a protein that acts as a regulator of the development and survival of sympathetic and some sensory neurons and as a differentiative factor for chromaffin cells. An in vitro model for the differentiative action of NGF is represented by the clonal cell line PC12, derived from a rat pheochromocytoma. In PC12 the shift from an endocrine to a neuronal phenotype is moreover partially mimicked by analogues of cyclic AMP (cAMP), which acts synergistically with NGF (Gunning,P.W., et al., J.Neurosci., 1:1805, 1981). In PC12 cells cAMP analogues modulate the synthesis and the phosphorylation of the same set of proteins as NGF, elicit the early outgrowth of short neurites and share with NGF the ability to increase the RNA levels of some genes. Moreover, the differentiative effect of NGF is dependent on RNA transcription.

In view of this, we decided to study the process of PC12 cells differentiation by NGF at molecular level, and to evaluate the role played in this by cAMP. The study has been undertaken analysing changes in gene expression due to NGF at the early time periods of its action, when the regulation by cAMP appears to be more likely. We constructed a complementary DNA (cDNA) library of 8000 clones from RNA of PC12 cells treated 1 hour with NGF(100 ng/ml).This library has been screened by hybridizing the bacterial colonies with single strand cDNA probes either from the same RNA used for the library or from RNA of control PC12 cells . In this way we were able to isolate four different clones whose levels of RNA were highly increased by NGF. The RNAs of all four clones were similarly increased by epidermal growth factor (EGF, 5ng/ml) while dibutyryl cAMP (dBcAMP,1 mM) affected only three of them. Northern analysis revealed that the four clones hybridized to four different species of RNA of 3.2, 2.7, 2.6 and 2.1 Kb.The 3.2 and 2.6 kb mRNA were maximally induced by NGF after 1 hour of treatment and then rapidly decreased, while the 2.7 and 2.1 kb mRNA levels showed a maximal induction at 2 hours , followed by a slower decrease. Three of the RNA species were induced as well by dBcAMP (the exception being the 2.1 kb), with a temporal pattern closely similar to the one observed following NGF induction. Partial sequence analysis of these clones, as well as Southern hybridization, did not show homologies with proto-oncogenes. These data show a similarity between NGF- and EGF-induced early gene expression and suggest that in PC12 cells the early increases of RNA levels observed in response to NGF occur, at least in part, through pathways not cAMP-dependent. We are currently evaluating the relevance of these findings in the process of differentiation by further characterizing the four clones.

152.9 ACTIVATION OF PROTEIN KINASE C IN PC12 CELLS MIMICS THE NGF INDUCTION OF THE CELL SURFACE THY-1 GLYCOPROTEIN. F.S. Walsh and P. Doherty. Institute of Neurology, Queen Square, London WC1N 3BG.

The polypeptide hormone nerve growth factor (NGF) has been shown in vitro to elicit a wide variety of cellular responses including promoting the survival and morphological differentiation of neurons dissociated from embryonic sensory and sympathetic ganglia. We have recently shown that NGF treatment of PC12 cells results directly in a 4-fold increase in Thy-1 gene transcription with accumulation of the mRNA species encoding Thy-1 readily detectable within 24hr of growth factor addition (Dickson et al, 1986, EMBO J. 5:3449-3453). In an attempt to elucidate the second messengers involved in the action of NGF, the effect of activators of protein kinase C on the expression of Thy-1 glycoprotein and the neural cell adhesion molecule (N-CAM) has been determined.

The addition of NGF to PC12 cells induced an approximate doubling in the cell surface expression of the Thy-1 glycoprotein and N-CAM after 24hr of culture. Half-maximal induction of Thy-1 was apparent at NGF concentrations (~0.1ng/ml) that had little effect on N-CAM expression. The protein kinase C activators, 12-O-tetradecanoylphorbol-13-acetate (TPA) and phorbol 12,13-dibutyrate (PdBu), were found to mimic the induction of Thy-1, but not N-CAM. When phorbol esters were added together with a maximally active concentration of NGF, their effects on Thy-1 expression were not additive. Treatment with phorbol esters did not mimic NGF induced neurite outgrowth, thus increased expression of Thy-1 is not consequential to morphological differentiation nor does it trigger the latter. The polyadenylation inhibitor cordycepin inhibited NGF and phorbol ester induced increases in Thy-1 expression in a similar fashion. Treatment of PC12 cells with phorbol esters under conditions reported to inhibit protein kinase C activity were found to inhibit NGF induction of Thy-1, but not N-CAM. Treatment of PC12 cells with cholera toxin, an agent that increases intracellular cAMP concentration was without effect on Thy-1 or N-CAM expression. In contrast cholera toxin (0.1-10ng/ml) was found to inhibit the NGF induction of the Thy-1 glycoprotein (Doherty and Walsh, 1987, J. Neurochem, in press).

Our results suggest that NGF can activate the transcription of genes encoding cell surface glycoproteins via at least two independent pathways, one of which directly involves activation of protein kinase C.

152.10 NERVE GROWTH FACTOR ACTIVATES A MAP 2 KINASE IN PC12 CELLS. G.E. Landreth, C. McCabe*, D.S. Smith* and C.K. Gittinger*. Dept. of Neurology, Medical University of South Carolina, Charleston, SC 29425.

Nerve Growth Factor (NGF) acts to direct the morphological and biochemical differentiation of the clonal pheochromocytoma line, PC12. The molecular mechanisms subserving the biological effects of NGF are unknown. We have investigated the ability of NGF to rapidly activate protein kinases, since these enzymes mediate many rapid hormonal effects.

NGF rapidly activated a protein kinase which phosphorylated the microtubule associated protein MAP 2. NGF transiently activated the enzyme, eliciting maximal activity within 5 min of NGF addition which diminished with longer periods of exposure. The NGF-stimulated phosphorylation of MAP 2 was similar to the phosphorylation of an endogenous PC12 cytoskeletal protein, pp250 (J.C.B. 100:677, 1985). MAP 2 competitively inhibited the labeling of pp250. The MAP 2 kinase, like the previously characterized pp250 kinase, had a marked preference for Mn^{2+} over Mg^{2+} and was inhibited by Na^{+}, suggesting the same enzyme species was involved.

The NGF-stimulated MAP 2 kinase remained associated with the detergent-insoluble cytoskeleton following extraction with 0.15% Triton X-100; however, the enzyme was found in both crude nuclear and soluble fractions following subcellular fractionation of PC12 cells. The MAP 2 kinase was isolated following chromatography on DE-52, eluting with 200 mM NaCl. The NGF-stimulated MAP 2 kinase activity did not require Ca^{2+} and was not inhibited by a specific inhibitor of cAMP-dependent kinase.

PC12 cells undergo a dramatic reorganization of their cell surfaces as an immediate consequence of NGF receptor occupancy. The rapid activation of a protein kinase which phosphorylates cytoskeletal proteins may play a role in these events.

152.11 NERVE GROWTH FACTOR-INDUCED CHANGES IN PROTEIN KINASE C LEVELS AND ACTIVITY IN PC12 CELLS. T. Hama, F. L. Huang,* Y. Yoshida,* K.-P. Huang,* and G. Guroff. Section on Growth Factors and Section on Metabolic Regulation, National Institute of Child Health and Human Development, Bethesda, MD 20892

Nerve growth factor (NGF) induces morphological and biochemical changes in its target cells. Among the biochemical changes are alterations in the phosphorylation of several cellular proteins. The phosphorylation of one of these, Nsp100, a cytoplasmic protein, is decreased after treatment of the cells with NGF. We have previously shown (Proc. Natl. Acad. Sci. USA 83, 2353 (1986)) that protein kinase C is involved in the cascade leading to the decrease in Nsp100 phosphorylation. The present experiments explore the short-term and long-term alterations in protein kinase C following NGF treatment.

PC12 cells were treated with NGF (50 ng/ml) for various periods of time between 30 minutes and 7 days. After the treatment, cells were collected and homogenized in 0.25 M sucrose containing 20 mM Tris-HCl, pH 7.5, 5 mM EGTA, 2 mM EDTA, 0.5 mM PMSF, and 50 mM mercaptoethanol. The extract was centrifuged at 100,000 xg and the cytosol collected. The pellet was extracted with 5% NP 40 in the buffer described above. Protein kinase C activity was measured using H3 histone as substrate. Alternatively, the protein kinase C level was examined by Western blots using polyclonal antibodies against protein kinase C or monospecific antibodies against the various isozyme forms of the enzyme.

Thirty to 60 minutes after NGF treatment the protein kinase C activity in the cytosol fraction was 3 to 4-fold elevated. The activity returned to baseline after several hours. Western blots of the same samples showed only a moderate (less than 2-fold) increase in protein kinase C content. Long-term treatment with nerve growth factor (1-2 days) increased the protein kinase C content, as seen in Western blots, about 2-fold. Using antibodies monospecific for the various isozyme forms, it was observed that the cytosolic kinase C is mainly type III, and it is the type III that is increased upon long-term NGF treatment.

From these data we conclude that the short-term increase in cytosolic kinase C activity is due to activation of existing kinase C, and the long-term increase is due to increased kinase C content. These results suggest that protein kinase C has a signaling function in the mechanism of action of NGF and, later, an important role in determining the neuronal characteristics of PC12 cells.

153.1 **DIFFERENTIAL EFFECT OF LOFEXIDINE (LOF) ON FOOD INTAKE IN RABBITS AND PRIMATES.** N.L. Katz, N. Sobaski* J. Young*, D. McGinness*, J.M. Davis and R. F. Schlemmer, Jr., Dept. of Pharmacodynamics, Univ. of Ill. at Chicago and Ill. State Psych. Inst., Chicago, IL 60612.

It is well established that central noradrenergic systems regulate feeding and eating behavior. For example, the central noradrenoreceptor agonist clonidine (CLON) stimulates food intake in both rabbits (Katz et al., Pharmacol. Biochem. Behav., 22:649, 1985) and Stumptail macaque monkeys (Schlemmer et al., Psychopharmacology, 61:233, 1979). Drugs which enhance the urge to eat may be useful in treating anorexia nervosa (Casper et al., Psychiat. Res., in press). With this in mind, we tested the effect of LOF, a drug structurally similar to CLON, on food intake in rabbits and primates.

LOF, in doses ranging from 0.005 to 0.02 mg/kg, failed to increase food intake above baseline control levels during the first and second hour following intramuscular injections into 10 Male New Zealand rabbits. Rabbits treated with 0.02 mg/kg of LOF ate less food over a 24 hour time span in comparison with saline-treated controls. The same rabbits given 0.01 mg/kg of CLON exhibited an increase in feeding behavior significantly greater than baseline control levels after one hour as expected. Doses of LOF of 0.05 mg/kg and greater induced a loss of postural tone, and some of the animals lost their righting reflex.

Twelve Stumptail macaque monkeys were injected intramuscularly with saline and LOF in doses ranging from 0.01 to 0.08 mg/kg. The amount of food eaten was measured 4½ hr. following the injections. At each dose tested, LOF significantly increased food intake above saline-levels. The effect of each dose on food intake was comparable, and no dose differed significantly from any other. A dose of 0.08 mg/kg of CLON increased food intake in the monkeys to the same extent as the LOF.

LOF exhibited a differential effect on food intake in rabbits and primates. It appeared that LOF, in contrast to CLON, had a more marked sedative effect in rabbits. This is the opposite of results of Graf et al., (Arzneim-Forsch, 32(II):931, 1982) who reported that LOF, in contrast to CLON, had less marked central sedative side effects in mice and rats.

153.2 INITIAL AMPHETAMINE ANOREXIA: RELEVANCE FOR TOLERANCE STUDIES. R. Eikelboom and H. Looy*. Department of Psychology, Queens University, Kingston, Canada, K7L 3N6.

While amphetamine (AMPH) anorexic tolerance has received considerable attention only rarely is the initial AMPH anorexia analyzed. But changes in the initial effects of AMPH can confound interpretations of tolerance.

Sensitization of AMPH anorexic effect has been reported to occur (Antelman et al., 1981), but the effect of prior AMPH on baseline milk consumption is unknown. Adult male Sprague-Dawley rats maintained at 80% of ad libitum weight were given a half hour experience with a sweetened milk/water (1:3) solution (milk). Animals then received 10 injections (IP) of 3 mg/kg d-amphetamine sulfate (A, n=17) or saline (S, n=16) over 6 days. Twenty-four hours after the last injection half the animals in each group were injected with AMPH and the other half with saline. A half hour later rats had 30 min milk access. An ANOVA revealed significant AMPH history and current drug effects but no interaction (A-A = 5.6±1.7 (SEM), A-S = 15.1±1.4, S-A = 13.8±3.4, S-S = 20.3±0.9 g consumed). Though prior AMPH has an effect on consumption, there does not appear to be any sensitization of AMPH anorexia.

Experiment 2 looked at weight manipulations. Half the rats (n=17) were maintained at 80% while the remainder (n=17) were not deprived. Animals received 4 daily 30 min exposures to milk. On the next two days saline or AMPH (3 mg/kg) injections (counterbalancing order) were followed half hour later by milk. An ANOVA of milk consumption for the AMPH and the preceding day found that the weight manipulation and the AMPH injection had a significant effect but the interaction was not significant (80-S = 31.1±1.0, 80-A = 10.2±1.8, 100-S = 27.5±1.0, 100-A = 3.2±0.8 g of milk consumption). AMPH anorexia appeared unaffected by weight manipulations.

Experiment 3 investigated milk familiarity. After 48 h of continuous milk rats were deprived to 80% and given a daily half hour of milk. On days 1 and 2 group 1 (n=11) was injected with 3 mg/kg AMPH or saline (counterbalanced) a half hour before milk. Group 2 was injected on days 8 and 9, and group 3 on days 19 and 20. ANOVA revealed significant drug, familarity and interaction effects. Consumption increased with saline (21.5±1.7, 30.5±2.2, and 34.3±1.7 g for groups 1, 2, and 3) but remained stable after AMPH (13.2±1.8, 14.2±3.2 and 13.5±3.6 g respectively). Thus only relative to baseline did the anorexic potency of AMPH increase with familiarity. These findings emphasize the role of baseline consumption in determining AMPH anorexia. Supported by grants from NSERC and OMH.

153.3 **COCAINE REDUCES THE EFFECTS OF α2 BLOCHADE OF NORADRENERGIC STIMULATION WITHIN THE PARAVENTRICULAR NUCLEUS OF THE RAT.** A. Clark* and P. Winn* (SPON: R. Pitman). Dept. of Psychology, University of St. Andrews, St. Andrews, Fife, Scotland KY16 9JU.

Infusion of noradrenaline (NA) into the hypothalamic paraventricular nucleus (PVN) induces feeding (Leibowitz, S. Pharm. Biochem. and Behav. 8: 153-175 1975). Selective pharmacological blockade appeared to indicate that this stimulation acted through post-synaptic α2 receptors (Goldman, C., Marino, L., and Leibowitz, S. Europ. J. Pharm. 115: 11-19 1985) as 6-OHDA lesion of pre-synaptic terminals, inhibition of NA synthesis, β and α1 blockade, were ineffective in inhibiting feeding. Studies of the peripheral sympathetic nervous system show that the response of a preparation to endogenously and exogenously released NA differs when in the presence of selective α-blockade. (Langer, S., Pharmacol. Rev. 32.45: 337-362 1981) suggesting a differential distribution of post-synaptic α1 and α2 receptors with regard to the synapse and its component re-uptake mechanism. A similar hypothesis has been used to explain recent blockade effects to tyramine-induced NA release (Luccelli, A., Barbone, M., and Grana, E., Pharm. Res. Comm. 17,8: 787-801 1985). Using the PVN as a model NA system we hypothesised that exogenously released transmitter exists at higher concentrations surrounding extra-synaptic receptors than at those protected by the pre-synaptic re-uptake mechanism. Were this the case, the extra-synaptic receptor would be of the α2 type. We also predicted that α2 blockade of the response to exogenous NA would be affected if the re-uptake mechanism were to be inhibited, allowing equal concentrations of NA to reach each receptor subtype. Using cocaine (40nmoles in 0.5ul) to block the re-uptake mechanism we found a 100% reduction in the potency of idazoxan (α2 selective) blockade. Idazoxan alone produced a 60% reduction in NA induced feeding. No changes were found in response to prazosin (α1-selective) blockade, nor did the presence of cocaine significantly alter the response to NA alone. We therefore conclude that some of the actions of exogenously administered NA may be due to its differential concentrations at receptor sub-types and thus that pharmacological identification of the receptors effecting a response should account for such topographically induced variations.

153.4 EFFECTS OF SELECTED ANTIDEPRESSANTS ON RAT FOOD INTAKE AND BODY ENERGY BALANCE OF RATS. G. Bautz*, S. Kowalik*, N. Spirt*, and L.A. Campfield (SPON. J. Sepinwall). Neurobiology and Obesity Research, Hoffmann-La Roche, Inc., Nutley, NJ 07110

Recent studies have emphasized 5-HT as a modulator of feeding and body energy storage. In order to further examine this hypothesis, we have compared the effects of five antidepressant drugs that alter 5-HT synaptic concentrations on food intake (FI), body weight (BW) and feed efficiency (FE). Sixty male Charles River rats (CD) were housed individually in metabolic cages with a 12:12 dark/light schedule. Water and powdered chow were available ad lib. and FI and BW were measured daily. After a 10 day baseline period, imipramine (I), amitriptyline (A), tranylcypromine (T), phenelzine (P), and fluoxetine (F) were presented as a food admix at a projected daily dose of 20 mg/kg for 13 days. An additional group received two daily doses of 10 mg/kg of imipramine by gavage (IG). Each of the drugs significantly reduced FI during the 13 day drug treatment period except A (% decrease: I-25%; IG-24%; T-30%; P-7.5%; F-18%). The same four drugs also reduced the rate of BW gain while A had no effect on BW (% decrease: I-46%; IG-36%; T-96%; P-25%; F-55%). FI and the rate of BW gain were maximally reduced during the first week by three of the drugs, with P having its effect during days 8-13. Analysis of FE during treatment demonstrated a significant 28% decrease in weight gained/gram of food eaten for I and a lack of effect for A. IG produced a significant 38% decrease in FE during the first week of dosing, however this effect was not present during days 8-13. Both MAO inhibitors (T and P) reduced FE during treatment. Although T reduced FE by 95%, signs of taste or food aversion was observed. The P group also demonstrated a significant 19% decrease in FE. In contrast to the T treatment, P had its major effect during days 8-13 of treatment. F significantly decreased FE by 45% during treatment. Blood levels of I in the I and IG groups at sacrifice were within the human therapeutic range. These results demonstrate that the five antidepressant drugs studied have differential effects on FI, BW and FE. Given that all five drugs used in this study can increase synaptic 5-HT, these results suggest that subtle differences on the determinates of 5-HT synaptic concentration and/or alternative mechanisms may underlie the observed differential effects on energy balance.

153.5 INTERACTIONS BETWEEN FOOD DEPRIVATION, MAINTENANCE OF TOLERANCE DEVELOPED TO AMPHETAMINE ANOREXIA AND CROSS TOLERANCE TO HALOPERIDOL CATALEPSY: NEUROCHEMICAL AND BEHAVIOURAL IMPLICATIONS. Angela Streather & Riley E. Hinson.* Dept. of Psychology, Univ. of Western Ontario, London, Ontario, N6A 5C2, Canada.

The maintenance of tolerance to AMP anorexia as a function of the level of food deprivation was investigated, as well as the effects of tolerance maintenance on HAL catalepsy. One hundred & twenty rats were administered 15 tolerance induction sessions where 3 mg/kg AMP ip was followed 20 min later by 30 min access to milk. Sixteen control rats received SAL instead of AMP during tolerance induction. Following tolerance induction, the 120 rats that had developed tolerance to AMP anorexia were divided into 12 groups whose mean milk intakes did not differ (~23 ml). Six of these groups continued to be maintained at 85% *ad lib* while the other 6 groups were allowed free access to food. One 85% and one 100% group was assigned to each of the following "extinction" treatments: 2 groups received milk 24h after AMP (AMP-MILK), 2 groups received AMP but no milk (AMP-0), 2 groups received saline followed by milk (SAL-MILK), 2 groups received saline but no milk (SAL-0), 2 groups received milk but no injections (0-MILK), 2 groups received no milk and no injections (0-0). The 2 saline control groups continued to receive saline followed by milk (CONTROL). After 14 training sessions (28 days) all animals received an AMP anorexia test. It was found that all rats in the 100% *ad lib* groups had lost tolerance to AMP anorexia. No loss of tolerance to AMP anorexia was found in the groups that had been maintained at 85% *ad lib*. Subsequently, a HAL catalepsy test (1.25 mg/kg HAL ip) was administered. Catalepsy was tested 45 minutes after HAL injection. The results showed that the animals that had retained tolerance to AMP anorexia were significantly less cataleptic than the animals that had lost tolerance.

These findings indicate that the level of food deprivation is the most important factor in the maintenance or loss of tolerance to amphetamine anorexia. Furthermore, the results demonstrate that the maintenance or loss of tolerance to AMP anorexia is reflected in the amount of catalepsy induced by HAL.

153.6 FEEDING AND PUMPING BEHAVIORS IN ADULT LAMPREYS. R. Kawasaki* and C.M. Rovainen, Dept. of Cell Biology & Physiology, Washington University School of Medicine, St. Louis, MO 63110

Parasitic species of lampreys feed by attaching to fish with their suckers, by forming a hole in the skin by a combination of tissue-liquefying saliva and rasping by the apicalis, and then by sucking and swallowing fluids and/or fragments of tissues. The goal of these experiments is to characterize sucking behaviors, including feeding, by pressure and EMG recordings in restrained spinal unanesthetized animals.

Adult silver lampreys, Ichthymoyzon unicuspis, were tested in a large chamber of lake water near 10°. Their suckers were placed over a hole in a plexiglass plate or onto a pithed goldfish. Vacuum in the sucker was monitored with a pressure transducer through the hole or through a syringe needle. Electomyograms were obtained with paired Teflon-coated silver wires, 125μm diameter, inserted as small hooks into target muscles. Minced goldfish muscle and skin were extracted with saline as test solutions. These and control volumes of lake water were injected under the lip of the sucker through a syringe needle into the sucker cavity.

The feeding behavior recorded in the present experiments is long-lasting (hours), has low frequency cycles of bi- or triphasic pressure changes (to -50-100cm H_2O) (see record below), is initiated by injections of fish extracts into the sucker and pharynx and terminated by injections of lake water, and has distinctive "radular" movements of the apicals. "Attack marks" were observed on a pithed goldfish following attachment and feeding behavior by the lamprey. In contrast to feeding, pumping behavior is characterized by high frequency cycles of monophasic vacuum, is initiated by fluid in the sucker and terminated at resting vacuum or volume, and has repetitive rostrocaudal movements by the apicalis. In conclusion, one distinctive type of periodic suction in the lamprey corresponds to a feeding behavior.

153.7 ATTENTUATION OF THE SEVERE EFFECTS OF FOOD-RESTRICTED INDUCED ANOREXIA IN VASOPRESSIN-DEFICIENT RATS BY SHORT, SEPARATED FEEDING PERIODS. C. H. Wideman and H. M. Murphy, John Carroll University, Cleveland, OH 44118

Brattleboro rats, which lack the hormone vasopressin, have the condition of diabetes insipidus and are referred to as DI rats. DI animals have been shown to be more susceptible to stress than normal animals. For example, DI rats with 22h of food restriction survive for a significantly shorter period of time, have a greater decrease in body weight, and develop significantly more ulcers than control animals (Wideman & Murphy, 1986). In that study, the animals subjected to 22h of food restriction were allowed 2h continuous access to food each day. The purpose of the present study was to determine whether or not two separate feeding periods, each with 1h access to food, would attenuate the deleterious effects noted in DI rats subjected to 22h of continuous food restriction. The subjects were 20 male homozygous DI rats and 20 male Long-Evans (LE) rats that were 5 wks of age and weighed between 80 and 100 g. Animals were randomly divided into 2 subgroups of 10 rats each. Group 1 rats (DI & LE) had ad-lib access to food (control group) and group 2 rats (DI & LE) were food restricted for 22h (experimental group). All rats were placed on a 12h light-12h dark cycle. The animals were subjected to a 7 day habituation period with ad-lib access to food and water, followed by a 9 day experimental period in which control animals had ad-lib access to food and water and experimental animals had ad-lib access to water and 2h access to food each day. These rats were fed during the 2nd and 8th hours of the light cycle. Results of this experiment in which the 2h feeding time was split, were the opposite of results where the 2h feeding time was consecutive for DI rats. DI food-restricted animals in this experiment were better able to maintain body weight and ate and drank significantly more than DI animals in the 2h consecutive feeding situation. In addition, with the split-feeding paradigm, all rats survived throughout the testing period. In comparing DI and LE food-restricted animals, there were no significant differences in % decrease in body weight or % decrease in water intake. DI animals had a significantly lower % decrease in food intake than did LE animals. By consuming a significantly greater % of food, DI rats maintained a similar weight loss pattern as compared to their LE counterparts. In addition, DI food-restricted rats developed significantly more ulcers than did LE food-restricted rats. The results of this study demonstrate that food restriction and vasopressin deficiency do not necessarily lead to severe anorexia and the eventual demise of the organism if the feeding periods provided are sufficiently separated so as to provide some time for digestion of food from the previous feeding period. Anorexia can be significantly attenuated in DI animals by short, separated feeding periods.

153.8 SCHEDULE-INDUCED POLYDIPSIA: ABSENCE OF POLYDIPSIA WITH SCHEDULED DELIVERY OF FOOD POWDER. D. Mumby*, C. H. M. Beck and T. J. S. Huh*. Department of Psychology, University of Alberta, Edmonton, Alberta, Canada, T6G 2E9.

Food deprived rats develop excessive drinking on an intermittent (60-s) schedule of food pellet delivery but not on an identical schedule of food powder delivery. Detailed coding of behavior revealed that the rats receiving powder did not develop any non-drinking behaviors to an excessive degree relative to the behavior of all rats on the first day of testing. Rats switched from powder to pellets, gradually developed polydipsia whereas rats changed from pellets to powder abruptly reduced drinking. In tests in which massed food was delivered, the powder rats appeared less aroused than the pellet rats as indicated by their lower bout frequency of rearing, locomotion, and investigation relative to that of the pellet rats. Pellets were eaten first by both groups in a preference test, in which limited amounts of both pellets and powder were presented simultaneously at the outset.

A number of factors were discounted as potentially contributing to the differences in behavior of the rats receiving powder and those receiving pellets. A cross-over design, using the rats as their own controls, eliminated the possibility that individual differences between members of the two groups could have accounted for the group differences. The food and water delivery mechanisms were the same for both groups. The powder was made from ground, sieved pellets thus eliminating flavor, nutrient content and moisture content as contributing factors to group differences. Equating the duration of access to the food and water mechanisms for the two groups, did not alter group differences.

In summary, schedule-induced polydipsia in rats is in reality, not simply schedule-induced. This polydipsia, known for its excessiveness and persistence, was abruptly terminated in rats without changing the amount of food eaten, the body weight deficit, or the schedule of reinforcement.

153.9 A CHRONIC STARVATION PARADIGM IN FEMALE RATS: STUDIES ON FEEDING, DRINKING, AND BODY WEIGHT REGULATION. J.K. Nishita, M.A. Robinson*, H.L. Sweatt*, M.A. Fichett*, E.H. Ellinwood, Jr., and W.J.K. Rockwell*. Dept. of Psychiatry, Duke Univ. Med. Cntr., Durham, N.C. 27710.

A novel paradigm was designed to study the effects of chronic starvation in developing female rats. In this paradigm, rats were required to crawl through Plexiglass tubes in order to obtain both food and water. Each experimental cage was divided in half by a Plexiglass wall that separated the food bin fixed to one side of the cage from the water source fixed to the opposite side of the cage. Two, 12-cm long tubes embedded in the wall were the only passageways from one end of the cage to the other. If a rat could not squeeze through the tube passageway, it was denied either food or water until its body size would permit the rat to pass across the divider. The onset and the severity of starvation was manipulated by varying the diameter of the tubes.

Sprague-Dawley female rats were time-bred and their litters were culled to 8 pups (6F:2M). Littermates were weighed every 5 days and weaned on postpartum Day 21. Pairs of females were randomly assigned to one of three experimental conditions (SM = small tube, LG = large tube, NT = no tube) on Day 25 for the remainder of the study. Vaginal opening was determined, and daily vaginal smears, body weights, and ingestive measures were taken up to Day 60. All rats easily adapted to the experimental tube apparatus since initially the tube size did not impede passage. Vaginal opening was similar in all pairs of rats (range: Day 33-39) and estrous cycles were not disrupted. Body weight differences between SM vs. NT groups were significantly different as early as Day 40 ($p<.03$), and by Day 43, body weights of SM vs. LG groups were also significantly different ($p<.01$). On Day 58, body weights for LG rats were significantly different from those of NT rats ($p<.04$). Significant changes in food intakes for each pair of rats paralleled those for body weight changes (e.g., On Day 58: SM = 22.6 $\pm$ 1.0g, LG = 34.4 $\pm$ 2.8g, NT = 41.1 $\pm$ 2.8g; $F(2,3) = 15.5$, $p<.03$; Mean $\pm$ SEM). Water intakes, however were not statistically significant (SM = 44.0 $\pm$ 2.0ml, LG = 63.5 $\pm$ 13.5ml, NT = 74.5 $\pm$ 1.0ml).

Previous studies of chronic starvation in the rat have used experimenter-controlled food deprivation and/or diet manipulation. Our paradigm includes the additional feature of permitting the rat to freely adjust its ingestive behavior according to induced body size contraints. Our paradigm may be particularly valuable in developmental studies of long-term malnutrition or clinical disease, such as anorexia nervosa.

153.10 EFFECT OF PURIFIED HUMAN SATIETIN ON MEAL PATTERNS OF RATS. V.E. Mendel and T.W. Castonguay Depts. An. Physiol., An. Sci., Nutr. Sci. and Food Intake Lab., Univ. of Calif., Davis, CA 95616.

Purified human satietin (p hSAT) has been shown to reduce food intake of both fasted (96 hr., J. Knoll, 1975) and non-fasted rats (Mendel, 1986). Semipurified human satietin has been shown to be aversive in rats (Bellinger and Mendel, 1985). If satietin makes animals sick, one would predict that both meal size and meal frequency during the day and night would be reduced in animals injected with satietin.

Twenty-four male Sprague-Dawley rats were divided into two groups (Phase I and Phase II). Phases I and II were run in sequence (14 days for each phase). In both phases, six rats were randomly selected to receive 2mg/kg p hSAT i.p. for 7 consecutive days. All rats received 1 ml sterile saline (St.S) i.p. for 7 days before p hSAT; control rats were injected with St.S. for all 14 days. Each phase (12 rats each) were placed in our individualized, computer monitored, feeding modules to continously measure food intake. Daily water intake was measured manually.

Daily food intake (FI) was reduced on average 22% by2mg/kg/rat, water intake was not significantly reduced. FI reduction occurred largely as the result of a 15.2% reduction of night meal frequency (NMF). Night meal size was not significantly reduced ($P>0.05$). Day meal pattern was unaffected by p hSAT.

These data suggest that purified satietin is not causing nausea because day meal frequency and size were unaffected as was night meal size. Purified satietin appears to affect only NMF.

153.11 DIET-INDUCED CHRONIC ELEVATIONS IN HEART RATE IN SHR AND SPRAGUE-DAWLEY RATS. V.L. Williams*, R.J. Contreras, J.F. Lorden, J.E. Cox, D.C. Tucker. Dept. of Psychology, University of Alabama, Birmingham, AL 35294.

Both genetic and environmental factors are known to influence cardiovascular function. We used Spontaneously Hypertensive Rats (SHR) and normotensive Sprague-Dawley rats to examine the effects of a high fat/high sucrose diet on both heart rate and blood pressure over a 10-week period. Male 60-day old rats were given either a high fat mash and sweetened milk (HF/M) diet or Agway Prolab chow pellets. Blood pressure and heart rate were measured weekly using tail plethysmography under light ether anesthesia. Body weight increased in the Sprague-Dawley rats fed the HF/M diet in comparison with pellet-fed Sprague-Dawley rats. This effect emerged during week 7 and persisted, with HF/M animals weighing 18% more than controls at week 10. The HF/M diet was not as effective in increasing body weight in the SHR rats: weights were 8% higher in HF/M animals at week 10.

The HF/M diet resulted in higher heart rates in both strains ($p<.0001$), although the highest heart rates were seen in the SHR strain ($p<.0001$). This increase persisted for the duration of the study. Differences between strains in response to the HF/M diet were apparent during the early weeks of treatment. Heart rate was the same (X=449$\pm$15 BPM) in both Sprague-Dawley groups at week 1, while SHR's fed a HF/M diet exhibited higher heart rates (X=522$\pm$14 BPM) at week 1 than those fed the pellet diet (X=452$\pm$13 BPM).

Despite the chronicity of differences in heart rate, we failed to see elevations in blood pressure due to the diet. In fact, blood pressure was lower in SHR animals fed the HF/M diet than in pellet-fed SHR controls ($p<.04$). As expected, the blood pressure for both genotypes increased with age ($p<.0001$), and the blood pressure levels of the SHR groups were higher than those of the two normotensive Sprague-Dawley groups ($p<.0002$). We suspect that the failure of the HF/M diet to induce higher blood pressure may be due to the unsaturated fat composition of the diet, which has been shown to protect against hypertension in other studies (Tobian et al, Hypertension, 1982). It is also possible that the HF/M diet will lead to higher blood pressure only in the presence of a more substantial degree of obesity than that observed in the present study or over a longer period of time. The increase in heart rate seen with the HF/M diet is consistent with the short term sympathetic activation shown to result from either a diet high in fat or sucrose as shown in previous studies from other laboratories. Thus, the chronic changes in heart rate seen in the present study may be due to a synergistic effect of both the fat and sucrose constituents of our HF/M diet in promoting sympathetic activation.

This research was supported by NIH Grant HL-38630 to R.J. Contreras.

153.12 ESTROGEN INDUCED ANOREXIA IN THE RAT: AN LICL COMPARISON SUGGESTS IT IS ESTROGEN INDUCED NAUSEA. C.R. Gustavson and J.C. Gustavson*. Psychiatric Ethology Laboratory. University of Texas Medical Branch, Galveston, Texas 77550.

Suppression of food intake after administration of estrogenic compounds is a broadly observed, well documented laboratory phenomena, and the correspondence between high estrogen periods with low food intake has been noted in many different free ranging vertebrates and invertebrates, during a variety of activities, e.g., migration, gestation, hibernation, incubation, lactation and courtship. Adaptive arguments for these observations abound, and have led to many speculations about conceptual CNS mechanisms (e.g., lowered set point) which may account for these observations. Sensitivity of the hypothalamic/pituitary axis to estrogen, and experimental evidence linking hypothalamic structures to food intake are sufficient reasons to base speculations upon, however no data we have reviewed provides more than phenomenological association.

We administered estradiol cypionate in peanut oil (0.4mg/kg body weight, i.m.), lithium chloride (LiCl, 2% body weight, 0.15m solution in tap water, i.p.), or peanut oil to 60 female Sprague Dawley rats 2 hours before, or immediately after, a 15 min. opportunity to consume apple juice. Every 2 hours after the first apple juice opportunity, for 8 hours, apple juice, grape juice, or both were presented for 1/2 hour. The amount of juice consumed was recorded following each presentation. Forty eight hours after juice was first presented, apple and grape juice were made available for 1/2 hour to each rat. The rats were immediately sacrificed. Uteri were rated for estrogen exposure. Blood was collected for estrogen determination.

Rats administered estrogen had enlarged, vascularized uteri compared to LiCl and oil injected animals indicating estrogen injections had the expected reproductive tract impact. Juice intake was suppressed similarly in rats given estrogen and LiCl injections compared to the oil injected rats. Juice intake suppression was delayed and prolonged in the estrogen injected animals compared to LiCl injected subjects. Apple juice intake at the end of the experiment was significantly and similarly lower in rats given estrogen or LiCl injections immediately after their first apple juice exposure compared to rats given estrogen or LiCl 2 hours prior to the first apple juice exposure, or oil injections after the first apple juice exposure.

These results, like our earlier results, suggest estrogen is a potent agent to establish conditioned taste aversions, and is phenomenologically similar to LiCl. We suggest the CNS mechanisms behind estrogen induced anorexia may have more to do with nausea than satiety and set point.

153.13 FUNCTIONAL SPECIFICITY OF HIGH AND LOW AFFINITY CORTICOSTEROID RECEPTORS. L.D. Devenport, S.S. Dallas*, and T.L. Thomas. Department of Psychology, University of Oklahoma, Norman, OK 73019.

Corticosterone (Cort) is variously reported to suppress or stimulate food intake; similar contradictory results are commonly found for body weight (e.g., 1, 2). Our analysis of the problem suggested that the issue might be resolved in terms of dosage and the dual population of Cort receptors, for which much evidence has now accumulated (3). Both Type I and Type II receptors bind Cort, but with high and low affinity, respectively. If these receptor actions could be experimentally separated by relatively pure receptor ligands, then distinctive metabolic actions of each might be revealed.

Aldosterone (Aldo) binds principally with Type I, but the synthetic glucocorticoid, RU28362, binds almost exclusively with Type II receptors. Neither binds significantly with transcortin or albumin. We infused these steroids at doses of 0, 3.4, 17.2, and 86.2 nmol/d with the object of observing patterns of feeding and weight gain corresponding to Type I and Type II receptor activity. Miniature infusion devices (Alza Corp) delivered the hormones in polyethlene glycol to separate groups of adrenalectomized male rats (ns = 8-10) for 28 days. Sham operated intact controls were also included for reference. The effects of the two hormones were linear and opposite: Type I receptor stimulation progressively increased intake and weight gain while Type II stimulation suppressed intake and slowed weight gain.

These findings suggest that Cort itself exerts separate dose-dependent actions that are at first anabolic but progressively more catabolic as Type I receptors become saturated and Type II increasingly stimulated. The results may resolve some contradictory reports of glucocorticoid action. They also suggest that normal fluctuations of Cort may engage qualitatively different processes, basal and peak levels meeting the successive requirements of fuel deposition and later mobilization.

153.14 ESTROGEN PRODUCES CONDITIONED TASTE AVERSIONS IN RATS WHICH ARE BLOCKED BY ANTIHISTAMINE. A.G.Rice*, A.Lopez* and J.Garcia* (SPON: Gary D. Novack), Department of Psychology, UCLA, Los Angeles, Ca. 90024.

Estrogen has many effects upon feeding behavior, metabolism, and body weight. Recently Gustavson has shown that an injection of estradiol cypionate when paired with saccharin flavored water produce conditioned taste aversions (CTA) for saccharin. Estrogen is known to produce nausea in humans and induce the release of histamine in reproductive tissue. Nausea and histamine are both conditions that when paired with a taste subsequently render that taste as unpalatable. People with endocrine disorders such as anorexia nervosa and PMS "sweet cravers" exhibit feeding and taste abnormalities for which the specific cause is not known. It may be that some of the effects of estrogen that are in common with conditions and agents known to produce CTAs have a role in producing endocrine based feeding pathology. Questions arise as to how estrogen functions as a CTA inducing agent. Would a masculinized female be more susceptible to estrogen induced food aversions as males are? Would an antihistamine, by blocking the effects of estrogen induced histamine release, prevent the formation of estrogen produced aversions?

Female and male rats were habituated to a daily drinking schedule of a 10 min measure plus supplemental water. On conditioning day animals received saccharin flavored water followed 30 min later by a s.c. injection of estradiol cypionate. Starting approximately 5 days later animals were again presented with saccharin daily for at least 10 test days. Female rats did not display aversions when doses of .00028 and .00034 mg/g of body weight were used while male rats showed strong aversions at these doses. Using doses of .0016, .0028, and .004 mg/g of body weight female rats did display strong aversions.

For the estrogen implant experiment female rats will be ovarectomized and then implanted with an osmotic minipump containing estradiol cypionate. For the next five days while the pump is implanted, the regular chow food will be taken away and either AIN or C21 diet will be made available during that time. After the fifth day the pump will be explanted and animals will be presented with the choice of both AIN and C21 diets for approximately four days constituting preference tests. Pilot animals using this procedure have already shown that consumption of the paired food is decreased by the third implant day, and that animals reject the paired diet in preference tests.

To test the hypothesis that histamine has a primary role in producing estrogen induced CTAs animals were injected with the antihistamine chlorpheniramine maleate 30 min before saccharin water was presented which was followed immediately by injection of estrogen. When tested a few days later female rats that did not receive the antihistamine showed strong estrogen induced saccharin aversions. Control animals that received only the antihistamine and oil vehicle, or only water and oil vehicles, on conditioning day displayed no aversion to saccharin. Importantly, the group of females that were injected with both the antihistamine and estrogen on conditioning day consumed equal amounts of saccharin as the control animals. This demonstrates that use of an antihistamine can block estrogen induced CTAs and implicates estrogen's effect upon histamine release as having a primary role in degrading the palatability of a paired food. A similar procedure using male rats is in progress.

153.15 GLUTAMATE DECARBOXYLASE ACTIVITY IS INCREASED IN THE VMN-AREA OF HYPERPHAGIC RATS. J. L. Beverly* and R. J. Martin. (SPON: J.M. Bowen). Dept. of Foods and Nutrition, University of Georgia, Athens, GA 30602

The transduction of energy metabolism into neural activity may be mediated by the formation of GABA and have a role in hypothalamic feeding regulatory mechanisms (Panksepp and Meeker, Brain Res. Bull. 5, Supp. 2:453, 1980). We recently reported an increase in glucose flux through the GABA shunt in the VMN-area in some, but not all, models of hyperphagic rats (Beverly and Martin, Fed. Proc. 46:1482, 1987). To further characterize GABA metabolism during hyperphagia the activity of the rate-limiting enzyme in GABA formation, glutamate decarboxylase (GAD), was measured in ventral hypothalami of four rat models: 1) Zucker lean and obese; in Sprague-Dawley rats (200-225 g); 2) after restriction for 7 days at 40% ad libitum (fed as a single meal at 1800 or 0700 hr); 3) 20 days following streptozotocin-induced diabetes; and 4) 35 min. following an injection of insulin (4.5 U/kg, i.p.). Immediately following decapitation a 1 mm slice directly anterior to the median eminence was placed in chilled saline and an 18 gauge (VLH) or 20 gauge (VMN-area) punch removed, homogenized and frozen on dry ice. GAD activity was assayed (Tappaz et al., Brain Res. 108:371, 1976) within 48 hr. Rates of GAD activity were elevated in the VMN-area of all models when compared to respective controls [1) obese = +18%, P=.05; 2) restricted = +35%, P=.001; 3) diabetic = +41%, P=.01; 4) +insulin = +25%, P=.05]. A decreased rate in GAD activity (-16%, P<.05) was noted in the VLH of rats treated with insulin. Attenuation of serum glucose levels by a gastric preload (2 ml of a 50% glucose soln.) blunted both the increases in food intake and GAD activity (+16%, P=.07) in rats treated with insulin. Increasing the amount of insulin injected increased GAD activity, relative to saline controls, in the VMN-area (3U/kg=+15%; 4.5U/kg=+25%; 6U/kg=+90%). Correlations of serum glucose to GAD activity in the VMN-area of r=-58(P=0.001) and VLH of r=.43 (P=.02) were noted. These data suggest an association between glucose availability to GABA-ergic neurons and GAD activity, at least in the VMN-area. The functional significance of increased GAD activity and the interaction of insulin and glucose on GAD activity require further investigation.

153.16 THE EFFECT OF HYPOTHALAMIC LESIONS ON HEPATIC THERMOGENESIS. A. P. Jones & J. Carrillo*, Pitzer College, Claremont, CA. 91711

Investigations into the role of the hypothalmus in the regulation of body weight have a long tradition in the neurosciences. The now classic demonstration by Hetherington and Ranson that electrolytic lesions of the ventromedial area of the hypothalamus produce massive obesity and hyperphagia in rats provided the impetus for much of this research. Early interpretations of this phenomenon tended to focus on the role of the ventromedial area as a "satiety center" with primary emphasis placed on its role in the control of food intake. More recent interpretations however have emphasized the role of the area in metabolic regulation. It has been noted that lesions of the ventromedial area lead to a variety of metabolic disturbances including hyperinsulinemia, increased lipoprotein lipase activity, decreased lipid mobilization and decreased thermogenisis from Brown Adipose Tissue. The role of decreased thermogenesis in the etiology of obesity has gained increased recognition in the last decade. The majority of these studies have focused on deficits in a protonconductance pathway in Brown Adipose Tissue mitochondria. Recently, significant deficits in heat production have also been reported to result from deficiencies in hepatic cytochrome P450 dependent monooxygenase activity. That such deficiencies may impact on body weight is suggested by the finding that P450 is depressed in genetically obese ob/ob mice and Fa/Fa rats and in ovariectomized rats. Given the extensive and metabolically relevant neural connections which have been demonstrated between the liver and the ventromedial area of the hypothalamus we decided to investigate whether lesions of this area affect P450 dependent metabolism.

Female Sprague-Dawley rats weighing 250g. were anesthetized with Nembutol (40 mg/kg) and then received either an electrolytic lesion to the Ventromedial area (exptl grp) or a sham procedure (control grp) which consisted of an identical surgical placement but no current was passed through the electrode. Food intake and body weight was measured for the next two weeks, following which, the animal was sacrificed by decapitation. Brains were placed in formalin for subsequent histological verification of lesion placement and livers were processed for the determination of P450. Animals in the experimental group ate significantly more food and gained significantly more weight than their control counterparts, however P450 levels were virtually identical in the two groups. These data suggest that although depressed P450 levels may be relevant to obesity seen in other animal models, it does not contribute to the obesity in rats with ventromedial hypothalamic lesions.

153.17 RAT SATIETIN (rSAT) INFUSED INTRACEREBROVENTRICULARLY (ICV) DOES NOT PRODUCE CONDITIONED TASTE AVERSION IN RATS. L.L. Bellinger and V.E. Mendel. Dept. Physiol., Baylor Coll. Dentistry, Dallas, TX, 75246 and Dept. Animal Physiol., Univ. of California, Davis, CA, 95616.

Satietin (Knoll, Physiol. Behav. 23:497.1979) is a putative satiety agent found in human serum and a variety of animal sera, including rat. When human (h) SAT was infused ICV in rats it was a strong anorexigenic agent. The mechanism of hSAT action is unknown but in a recent study (Bellinger and Mendel, Pharm. Biochem. Behav. 23:559.1985) hSAT produced conditioned taste aversion when infused ICV. Thus hSAT may be aversive in rats. On the other hand, the aversion may have been due to contaminants or a cross species reaction. In the present study rat plasma was extracted for rSAT. Male Sprague Dawley rats (275-315g) were fitted with chronic third ventricle cannulas. The rats (LD 12:12, lights out at 1330h) were given access to water, in calibrated bottles, for one hour/day (1230-1330h) and food ad libitum for ten days. At the end of this period the rats were divided into two groups (GRP) and infused ICV with 10 ul of saline (SAL), day 1. Thirty minutes later at 1230h the GRP were given either water flavored with (GRP 1) 0.5% banana (BFW) or (GRP 2) 0.5% almond (AFW) extract instead of tap water. Fluid consumption (FC) and food intake (FI) were recorded (1230-1330h and 24h for FI). The next day (day 2), GRP 1 was infused with saline and given AFW while GRP 2 was infused with 100 ug/rat of rSAT and given BFW. On day 3 the rats were given tap water and on day 4 they were given a choice between AFW and BFW. On day 1 FI and FC of the GRPs were similar. Infusion of rSAT on day 2 suppressed both one (2.6±0.4 1.2±0.5g, $P<0.02$) and 24 (13.8±1.2 vs 8.7±1.5g, $P<0.02$) hour FI. No FI differences were seen on day 3. Body weight decreased more after rSAT then after saline infusion on day 2 (-5.8±1.5 vs -12.2±1.5g, $P<0.01$). This difference remained the following day (+1.6±2.9 vs -10.1±2.9g, $P<0.01$) even though FI and FC did not differ between the groups. The GRPs showed neutral preference for BFW and AFW on day 1. The FC of GRP 2 was suppressed after rSAT on day 2 (6.4±1.0 vs 1.9±0.7 ml, $P<0.01$). On day 3 FC of both GRPs was similar. During two bottle testing similar amounts (GRP 1 vs GRP 2) of AWF (11.1±2.3 vs 10.9±3.0 ml) and BFW (7.0±2.0 vs 8.6±2.8 ml) were consumed. These data suggest that rSAT, unlike hSAT, does not produce taste aversion in rats and may not suppress ingestion by aversive means. Therefore, SAT may be a candidate for a physiological satiety agent.

Supported by Baylor University and BCD research funds.

GENE STRUCTURE AND FUNCTION II

154.1 INTERACTIONS OF THE HYPOMYELINATION MUTATIONS shi and shi^{mld} with qk: ANOTHER PIECE OF THE PUZZLE. M.K. Wolf, J.-B. Gow*, M.E. Pomeroy*, and S. Billings-Gagliardi. Department of Anatomy, University of Massachusetts Medical School, Worcester, MA 01655.

Double mutant mice which simultaneously express mutations at two of the loci which produce CNS hypomyelination, qk, shi, or jp, have been bred. Such mice may have phenotypes that suggest complex interactions between the loci. Interactions involving allelic mutations at the shi and jp loci are particularly surprising and unpredictable. Here we compare the white matter morphology of B6C3 hybrid-based $qk/qk*shi^{mld}/shi^{mld}$ ($qk*shi^{mld}$) mice to that of qk/qk*shi/shi (qk*shi) to learn more about these interactions of the myelin genes. Both $qk*shi^{mld}$ and qk*shi are produced by intercrossing the appropriate unaffected double heterozygotes resulting in 5 possible affected genotypes, including the double homozygote. Backcrossing the double heterozygote to the relevant single homozygotes yields 4 of the same possible affected genotypes, but not the double homozygote. In each case, one distinct morphological phenotype produced by the intercrosses is not produced by the backcrosses, confirming that this is the double homozygote (double mutant) phenotype.

At P-21 both qk*shi and $qk*shi^{mld}$ have approximately 20% of the number of myelinated axons found in comparable CNS regions of the single mutants. The vast majority of myelin sheaths present have fewer than 4 lamellae and only partially enclose axons; they are uncompacted, and show accentuated intraperiod lines. No evidence of major dense line has been seen in qk*shi white matter; however, in $qk*shi^{mld}$ a rare sheath has interrupted (abnormal) density at the correct location for the major dense line. This is far less frequent than in shi^{mld} homozygotes of comparable age, but otherwise has the same characteristics. In both double mutants the white matter is filled with parallel bundles of small oligodendrocyte processes. The exuberant whorls and tangles of myelin-like membranes and macrophages characteristic of qk are not present. Thus in both qk*shi and $qk*shi^{mld}$ double mutants the amount of myelin is drastically reduced compared to qk, shi, and shi^{mld}, suggesting intergenic synergism, but the morphology of myelin and oligodendrocytes is like shi or shi^{mld}, rather than qk, suggesting suppression of qk by both shi locus mutations. We conclude: 1. There is morphological evidence for two kinds of strong interaction between qk and both shi^{mld} and shi. 2. shi and shi^{mld}, which interact very differently with jp locus mutations, interact similarly with qk. Supported by NIH grant NS-11425 (Javits Award).

154.2 QUANTITATIVE DIFFERENCES BETWEEN USA AND SWISS shi^{mld}/shi^{mld} MICE. S. Billings-Gagliardi, J.-M. Matthieu*, D.A. Kirschner*, A.-L. Kerner*, and M.K. Wolf. Dept. of Anatomy, U. Mass. Med. School, Worcester, MA 01655; Lab. de Neurochimie, CHUV, U. de Lausanne, Lausanne, Switzerland; Dept. of Neuroscience, Children's Hospital, Boston, MA 02115.

Studies of the dysmyelinating mouse mutation shi^{mld} in our laboratories in the USA and Switzerland report different CNS myelin protein levels and white matter morphology. To resolve the apparent discrepancies, we exchanged breeding stocks and reinvestigated both sets of animals. Parallel developmental studies (15-80 days) confirm substantial quantitative differences between shi^{mld}/shi^{mld} mice (abbreviation: shi^{mld}) with Billings-Gagliardi and Wolf's "USA" versus Matthieu's "Swiss" genetic backgrounds. 1. Behavior: USA shi^{mld} have fewer and less severe convulsions, longer lifespan, and more chance of rearing offspring. 2. Biochemistry: In both Swiss and USA shi^{mld} CNP specific activities and MBP measured by RIA in total brain homogenates increase with age; however, at 50 days and older the levels of both proteins are twice as high in the Swiss. 3. Morphology: At a given age, the number of optic nerve axons myelinated is always greater in Swiss shi^{mld}. The proportion of myelin sheaths containing "MDL", i.e., any apposition of cytoplasmic membrane faces (usually partial and/or abnormal in shi^{mld} myelin) increases dramatically between 20 and 50 days in both Swiss and USA animals; however, twice as many sheaths have "MDL" in the Swiss, except at the youngest age.

These differences between Swiss and USA shi^{mld} could reflect either different mutant alleles at the shi locus or different regulatory genes influencing the expression of the same shi allele in Swiss and USA mice. Evidence for the regulatory gene hypothesis is provided by MBP measurements in homogenates of 30-day wild-type Swiss and USA brains. Swiss wild-type have significantly more MBP (23.11 ± 1.04 ng MBP/µg brain homogenate protein, $n = 8$) than USA (16.88 ± 0.37, $n = 13$). This hypothesis was further tested by crossing Swiss and USA shi^{mld} to obtain hybrid "international" mice. If Swiss and USA mice carry two different shi locus alleles, one might expect the "international" shi^{mld} double heterozygote to have intermediate protein and morphological measurements, as has been observed for the shi/shi^{mld} double heterozygote . However, "international" shi^{mld} have more MBP and CNP, and acquire significant amounts of "MDL" earlier than either Swiss or USA shi^{mld}, suggesting heterosis of multiple regulatory genes. Supported by NIH grants NS11425, 20824, 07264 and Swiss National Science Foundation grant 3.142.85.

154.3 A cDNA CODING FOR THE CARBOXY-TERMINAL REGION OF RABBIT NEUROFILAMENT PROTEIN H: A PROBE FOR THE ROLE OF H IN NEURODEGENERATIVE DISEASES. D. Soifer, K. Mack* and H.M. Wisniewski*. NY State Institute for Basic Research in Developmental Disabilities; and CSI/IBR Center for Developmental Neuroscience, Staten Island, NY, 10314.

Neurofibrillary tangles are only found in neurons which normally express the high-molecular weight neurofilament protein, NFP-H. Several antibodies raised against neurofilaments, especially the tail domain of NFP-H, have been reported to react with paired helical filaments (PHF) on tissue sections. We have prepared a cDNA library, in the expression vector, lambda gt11, from rabbit brain mRNA. A cDNA clone which directed the synthesis of a fusion protein which reacted with monoclonal antibodies against epitopes near the carboxy terminal of NFP-H, has been selected and characterized. This cDNA is 889 bases long and codes for the c-terminal-184 amino acids of NFP-H. The selected cDNA hybridizes to a 4.7 kB message on northern blots of rabbit brain RNA. The sequence of the cDNA includes highly repetitive regions, including one duplicated 60-base segment. The deduced amino acid sequence includes 9 serine residues, each surrounded by a similar group of amino acids: Ala.Lys.Ser.Pro.(Glu,Val).Lys. (5 have Glu., 4 have Val). These serines, adjacent to predicted beta-turns at each proline, are presumably sites for phosphorylation. Comparison of the sequence of the rabbit cDNA with the sequence of a similar region of a rat cDNA (Robinson et al, FEBS LETT 209:203 1986) indicates stretches of homology, especially in one 49-base segment. Although both cDNAs code for very hydrophilic polypeptides, there is considerable species diversity between the primary structures of the tail regions of the rat and rabbit NFP-H proteins. This diversity may account for the failure to induce tangles of neurofilaments in animals, such as rats, following treatment with doses of aluminum which are sufficient to induce such tangles in rabbits and to bring on seizures and behavioral pathology in both rats and rabbits. (Supported by the ALS Association and the NY State Office of Mental Retardation and Developmental Disabilities.)

154.4 DNA SEQUENCES INVOLVED IN MPTP NEUROTOXICITY. C. Mamalaki, R.C. Douglas*, S.G. Carlson*, C.M. Dersch* and M.M.S. Lo. National Institute on Drug Abuse, Addiction Research Center, Baltimore MD 21224.

Pheochromocytoma (PC12) cells infected with a recombinant retrovirus and selected on MPP+ (an active metabolite of MPTP) produced resistant mutants. The phenotypes and genotypes of 48 different mutants were analysed. The neurochemical analysis showed a distinct group of mutants which lacked catecholamine uptake, whereas two other groups have either completely normal or defective dopamine uptake. Other neurochemical markers appear to be either normal or reduced.

The chromosomal location of viral integrants showed in most cases only a single copy of the retroviral sequence. Restriction enzyme and Southern blot analysis of ten selected clones, using probes derived from the viral sequence, showed proviral sequences integrated into the same three chromosomal regions. These regions contain putative genetic sequences which normally code for proteins involved in MPTP neurotoxicity

DNA sequences from two of these gene targets were cloned from the MPP+ resistant mutants in EMBL3 or λgt11. These sequences have been subcloned into pBR and characterised by detailed restriction mapping. The presence of corresponding cellular mRNA in normal PC12, fibroblasts, and tissues was analysed by Nothern blot using probes derived from the rescued genomic flanking sequences. The expression and function of these genetic sequences will identify proteins, such as dopamine uptake and mitochondrial enzymes, which are involved in MPTP toxicity. These proteins may be also involved in the action of other neurotoxic and cytotoxic substances of abuse.

154.5 MOLECULAR CLONING OF cDNA TRANSCRIBED FROM MESSENGER RNA OF THE ALZHEIMER BRAIN. IDENTIFICATION OF cDNA FOR AMYLOID AND GLIAL FIBRILLARY ACIDIC PROTEIN. S.B. Zain*, M. Salim*, S. Rehman*, E.M. Sajdel-Sulkowska, W.G. Chou*, R.E. Majocha*, K. Moore* and C.A. Marotta. Harvard Med. Sch.; Massachusetts General Hosp., Boston, MA 02114; Mailman Res. Ctr., McLean Hosp., Belmont, MA 02178; and Univ. of Rochester, Rochester, NY 14642.

Recent reports have identified β-amyloid cDNA from recombinant cDNA libraries derived from non-Alzheimer tissues. However, progress in understanding the molecular basis of Alzheimer's disease (AD) may ultimately depend upon the direct analysis of gene products expressed in the AD brain itself. GFAP was the initial focus of interest in a recombinant cDNA library from Alzheimer mRNA since the glial-specific marker is a known protein that continues to be synthesized in lesioned areas. Previously, we demonstrated that high levels of GFAP are synthesized in vitro by mRNA of the AD brain (these Proceedings, 12:1400, 1986). Postmortem poly(A+) RNA was prepared from an AD brain frozen 2.5 hours after death and handled by routine autopsy procedures. The characteristics of the synthesized cDNA and of the identified GFAP-specific recombinants in the λgt11 expression vector system, the structure analysis of the inserts, and the size and levels of expression of the corresponding mRNA in control and AD tissues will be presented. Northern blots established that there was no apparent difference between the stability of the mRNA from the routinely obtained autopsy tissues when compared with mRNA from an oxygenated rapid autopsy case (0.5 hr. postmortem, courtesy A. Roses, Duke). Consequently, routine autopsy cases were used for cloning. The previous cDNA library was screened with monoclonal antibodies made to a synthetic β-amyloid peptide (Benes et al, these Proceedings, 1987) and with a corresponding synthetic oligonucleotide. A short cloned insert corresponding to a segment of the β-amyloid sequence was identified and characterized. A second Alzheimer cDNA library was generated from 5 hr. postmortem mRNA and screened with the β-amyloid insert and positive clones were obtained. Data on the sequence analysis, the Northern blot analysis and cellular localization of the corresponding AD mRNA will be presented. Structural comparisons between AD and non-AD sequences will be made. Supported by AG02126, CA11198, and McKnight Foundation.

154.6 **UNEXPECTED CNS TUMOR CYTOLOGY IN WILD TYPE AND MUTANT SV-40 T-ANTIGEN TRANSGENIC MICE.** Kevin A. Kelley* and Karl Herrup. Dept. of Human Genetics. Yale Medical School, New Haven, CT 06510

Transgenic mice were created by the injection of a few hundred copies of the early region of SV-40 into one-cell mouse embryos. The injected sequences came from either wild-type virus or a mutant that produces a modified form of T-antigen (Tag) that is transformation defective. A previous report from Brinster *et al.* (Cell 37:367, 1984), suggested that the injection of the wild type gene leads to the reproducible appearance of choroid papillomas.

Three transgenic animals were made from injection of the early region of the wild type virus. All of them died before 35 days of age. In addition, several stillbirths were found; one that we were able to assay proved to be DNA positive. Two animals were sacrificed at 28 postnatal days after becoming critically ill. One had a well developed choroid papilloma in the lateral and fourth ventricles, but the second showed no signs of choroid plexus involvement. Examination of the brain revealed an unusual persistence of the ventricular zone in the anterior horn of the lateral ventricle. Associated with this finding was an apparent continued migration of cells from this region anteriorly into the olfactory bulb.

Seven transgenotes were made from injection of the mutant Tag. Thus far, 3 have died -- one at P36 and two at 4.5 months; the brain of one older mouse has been examined histologically. Situated medially and beneath the cerebellum was a mass of tumor tissue containing two basic cell types: a small, undifferentiated and apparently mitotic type and a second type that resembled, in Nissl stain, a large motor or sensory neuron.

The appearance of these brains suggests several conclusions. First, there is a clear correlation between the age of death and Tag genotype (wild type/early death, mutant /later death). Second, Tag in the genome is associated with several pathologies besides choroid papilloma and the apparent neural nature of some of the unusual cells suggests that this may be an effective model system in which to develop new immortal CNS cell lines. Finally, the histological appearance of each transgenic mouse is seemingly unique. This suggests either that the site of chromosomal integration or a stochastic "second-hit" required for tumorigenesis is influencing the particular spectrum of cells that respond to the presence of the Tag gene.

154.7 RAPID "EXON SCANNING" TO DETECT POINT MUTATIONS IN GAD AND OTHER CANDIDATE GENES FOR NEUROGENETIC DISEASES. D.L. Kaufman*[1], J.N. Lederman*[1], A.M. Wong*[1], J.H. Menkes*[2,3], and A.J. Tobin[1,4,5] (SPON: H. Pardes). Departments of [1]Biology, [2]Pediatrics, and [3]Neurology, [4]Brain Research Institute, and [5]Molecular Biology Institute, University of California, Los Angeles, CA 90024.

Glutamate decarboxylase (GAD) is a "candidate gene" for a number of hereditary diseases, including those leading to seizures, abnormal movements, and psychosis. Lesions within a candidate gene may be too subtle to be identified by Southern analysis. Moreover, cloning and sequencing a candidate gene such as GAD, which extends over 70 kb, may be too labor intensive to be useful to evaluate hypotheses of candidate genes in disorders that may be genetically heterogeneous. For GAD and other genes expressed principally in the brain, direct studies of proteins and mRNAs are generally limited to animals and to postmortem human tissue. In order to determine whether brain GAD is altered in neurogenetic diseases, we therefore have developed a technique to scan samples of genomic DNA for the presence of point mutations within the exons of candidate genes.

Our method is an extension of the method of Myers, et al. (Science 230, 1242, 1985), which employs ribonuclease to detect most (but not all) mismatched base pairs in hybrids between genomic DNA and RNA transcripts of cloned DNA fragments. Using transcripts of cDNA clones rather than genomic DNA clones, we find that -- for human beta-globin -- ribonuclease A cleaves RNA probes both at exon-intron boundaries and at mismatched bases within the exons of the DNA of patients with hemoglobinopathies. This result establishes the feasibility of exon scanning for mutations in the GAD gene in neurogenetic diseases. It also establishes the utility of this approach for determining exon-intron boundaries.

We have used exon scanning to search for point mutations in the GAD genes of patients with the following conditions: pyridoxine-dependent seizures (6 cases), petit mal (absence) epilepsy (4 cases), juvenile myoclonic epilepsy (4 cases), familial complex partial epilepsy (1 case), familial autism (1 case), febrile seizures (1 case), and Ramsey Hunt disease (2 cases). Our analysis has not revealed point mutations in GAD for any of these cases. Southern blotting analysis, however, has identified a small, highly polymorphic intron within the human GAD gene.

This work was supported by grants to JHM and AJT from the Dystonia Medical Research Foundation, to AJT from NINCDS (#NS 22256), and by a NINCDS program project grant to Dr. A.V. Delgado-Escueta (#NS 21908).

154.8 MOLECULAR ANALYSIS OF tko: A BEHAVIORAL MUTATION IN DROSOPHILA. C. S. Royden and L. Y. Jan. Dept. of Physiol. and Howard Hughes Med. Inst., University of California, San Francisco, CA 94143.

The technical knockout mutation, tko, is one of a family of behavioral mutations in Drosophila melanogaster which cause flies to be paralyzed temporarily by a jolt of the culture vial, i.e. these flies become "bang sensitive". Two indirect arguments suggest that tko might affect neuronal excitability. First, another "bang-sensitive" mutation, bang senseless (bss), shows enhanced excitability at the larval neuromuscular junction (Jan and Jan, PNAS 75: 515-519, 1978). Second, a suppressor of tko, no-action-potential, temperature sensitive (nap^{ts}), also suppresses several mutations causing enhanced excitability such as bss and Sh (Shaker) (Ganetzky an Wu, Genetics 100: 597-614, 1982). We began to study the gene coding for tko in order to gain some insight into the defects which cause bang-sensitivity.

The tko gene has been well mapped genetically to a region of the X chromosome just distal to the well known zeste gene. This region has recently been cloned (Mariani et. al., EMBO J 4: 2045-2052, 1985). We used P-element mediated transformation to show that a 3.1 kb fragment of genomic DNA from this region complements two alleles of tko: l(1)tko$k11$, a lethal allele, and tko^{25t}, which causes the behavioral defect. This 3.1 kb fragment contains only one complete transcript, 0.68 kb in length. We have isolated cDNA clones corresponding to this transcript and have sequenced these clones as well as the corresponding genomic DNA.

The cDNA sequence contains an open reading frame coding for a protein with remarkable homology to the Euglena gracilis chloroplast ribosomal protein S12 and to the Escherichia coli ribosomal protein S12. This homology raises the possibility that the tko gene product may be a mitochondrial ribosomal protein. A defect in mitochondrial function could affect ion gradients and energetics in neurons and muscles, resulting in behavioral abnormalities. We can not exclude the possibility that the tko gene product could have evolved from S12 into a non-ribosomal protein of similar function, e.g. a protein that interacts with RNA. Experiments by which we hope to resolve these possibilities are in progress.

154.9 **TYPE II Ca^{2+}/CALMODULIN-DEPENDENT PROTEIN KINASE IN DROSOPHILA.** D.S. Leonard*, J.B. Wall*, P.C. Pugh*, and M.B. Kennedy (SPON: T. Sejnowski). Div. of Biology, 216-76, California Institute of Technology, Pasadena, CA 91125.

The availability of cDNA clones for the subunits of rat brain Type II Ca^{2+}/calmodulin-dependent protein kinase (Type II CaM kinase) makes it possible to characterize genes for homologous kinases in an organism well suited for carrying out genetic analyses of their function. In preparation for such a study, we looked for an homologous kinase in D. melanogaster. A kinase activity with properties similar to the rat brain kinase was measured in Drosophila homogenates. This activity is more concentrated in fly heads than in bodies. Its specific activity in head homogenates is approx. 1/5 that of the kinase in rat brain homogenates. The Drosophila kinase is dependent on calcium and calmodulin, phosphorylates synapsin I at the proper site and is inhibited by a monoclonal antibody that specifically inhibits the rat brain enzyme.

We used this antibody to precipitate the subunits of the Drosophila enzyme. SDS-gel electrophoresis of the precipitated proteins revealed three major subunits of molecular weights 60, 58, and 52 kDal. These subunits can be autophosphorylated and are the major "endogenous substrates" in fly head homogenates. The set of three subunits was purified to approx. 50% homogeneity by methods used to purify the rat kinase. The partially purified Drosophila enzyme acquires a calcium-independent kinase activity following autophosphorylation, as does the rat enzyme. Thus, these regulatory properties of the rat kinase are conserved in the Drosophila kinase.

The conservation appears to extend to the nucleotide sequence level. Blots of restricted Drosophila genomic DNA were probed with a labeled cDNA containing the full coding region for the rat brain β-subunit (Bennett, M.K. and Kennedy, M.B. PNAS 84, 1794-1798, 1987). This probe hybridized strongly to a 6.5 kilobase restriction fragment of fly DNA under reduced stringency conditions (allowing about 33% mismatch). We are now screening Drosophila genomic and cDNA libraries for clones that encode the subunits of the Drosophila kinase.

Supported by NIH and the McKnight Foundation.

154.10 NEURONAL AND GLIAL EXPRESSION OF THE *DROSOPHILA MELANOGASTER* DOPA DECARBOXYLASE GENE. W.A. Johnson*, C.J. Beall*, S.J. Bray*, B.A. Morgan*, C.A. McCormick*, & J. Hirsh*. (SPON: D.D. Potter) Dept. of Biological Chemistry, Harvard Medical School, Boston, MA 02115.

A cis-regulatory element selectively required for expression of the *Drosophila melanogaster* dopa decarboxylase gene *(Ddc)* in the central nervous system has previously been identified (Scholnick et al, 1986, Science **234**, 998-1002). Here we show that at least one additional regulatory element is required for normal neuronal expression of *Ddc* in the larval central nervous system. We find that *Ddc* is normally expressed in about 125 discrete neurons and in a diffuse network comprising a subset of cortical glial cells. The expression of in vitro altered *Ddc* genes was studied by immunohistochemical staining with anti-*Ddc* antibodies following germline reintegration with P element vectors. Normal neuron-specific *Ddc* gene expression requires both the initially identified element (element I) which is 60 bp upstream from the RNA startsite, and an additional regulatory element located 800 to 2,200 bp upstream. This latter element is required for neuronal expression, but is not necessary for glial expression of *Ddc*. Combinatorial interactions between multiple regulatory elements may serve to specify a precise pattern of cell-specific gene expression.

We have examined the consequences of selectively depleting *Ddc* expression in the CNS. The *Ddc* primary transcript is alternately spliced to yield mRNAs that encode distinct hypodermal and CNS *Ddc* protein isoforms (Morgan et al, 1986, EMBO J. **5**, 3335-3342). A mutation in the CNS-specific exon leads to a selective deficit of CNS *Ddc* enzyme activity and serotonin. Strains lacking immunocytochemically detectable CNS serotonin are fully viable. These strains are being assayed for more subtle physiological and behavioral abnormalities.

154.11 ISOLATION OF cDNA CLONES ENCODING RAT BRAIN CALMODULIN. M. E. Lewis, D. F. Tyrrell, Jr.*, J. M. Roberts-Lewis, B. Weiss, R W. Manning*, and L. G. Davis. Medical Products Department. E. I. du Pont de Nemours and Co., Wilmington, DE 19898 and Department of Pharmacology, Medical College of PA/EPPI, Philadelphia, PA 19129.

The calcium-binding protein, calmodulin (CaM), influences several key enzyme activities in brain, including calcium-dependent adenylate cyclase, phosphodiesterase, and protein kinase activities. CaM appears to modulate dopaminergic activity via adenylate cyclase, and it has recently been shown that chronic, behaviorally sensitizing treatments with amphetamine result in an increase in striatal CaM levels (Roberts-Lewis et al., Brain Res. 384, 383-6, 1986). In order to further study the regulation of CaM, we have isolated and sequenced several cDNA clones encoding rat brain calmodulin. To isolate these clones, we screened a lambda gtll rat brain cDNA library with radiolabeled synthetic oligonucleotide probes which were designed according to published cDNA sequences for eel and chicken CaM. Positive plaques were picked, grown, and the DNA insert was subcloned into pUC-18 for partial sequencing to confirm the identity of the clones. The appropriate inserts were restriction cut from pUC-18 and ligated into M13 mp19 for Sanger dideoxy sequencing. Three cDNAs were sequenced that corresponded to the known nucleotide sequence for CaM, which is strongly conserved across species. Nevertheless, there was considerable variation in codon usage for CaM mRNA between rat, chicken, and eel. We are presently using single-stranded, M13-derived probes for Northern and in situ hybridization analyses of CaM mRNA regulation in rat brain.

154.12 MOLECULAR CLONING OF THE cDNA FOR ARPP-21, A CYCLIC AMP-REGULATED PHOSPHOPROTEIN ENRICHED IN THE BASAL GANGLIA. T. Kurihara*[1,2], M. Ehrlich[1], J. Horiuchi[1], and P. Greengard[1]. (SPON: C.C. Ouimet) Laboratory of Molecular and Cellular Neuroscience, The 1. Rockefeller University, 1230 York Avenue, New York, NY 10021; 2. Suntory Institute for Biomedical Research, Wakayamadai, 1-1-1, Shimamotocho, Mishimagun, Osaka, 618, Japan.

ARPP-21 (cAMP-regulated phosphoprotein, Mr=21,000) is a cytosolic substrate for cAMP-dependent protein kinase, and is highly enriched in the basal ganglia (Walaas, S.I., Nairn, A.N., and Greengard, P., J. Neurosci. 3:302-311; Ouimet et al., Soc. Neurosci. Abstr. 12:1022, 1986). This neuron-specific phosphoprotein has been purified to homogeneity from bovine caudate nucleus and its amino acid sequence has been partially determined (Hemmings et al., Soc. Neurosci. Abstr. 12, 770, 1986).

Poly A^+RNA prepared from bovine caudate nucleus was used to construct a cDNA library in a modified Okayama-Berg plasmid vector. Partial amino acid sequences of bovine ARPP-21 were used to synthesize two non-overlapping oligonucleotide probes (32mer and 41mer) for screening of this library. The longest postively hybridizing clone, pTKA1, was chosen for further analysis. The identity of the clone was confirmed by comparison of the partial nucleotide sequence with the known peptide sequence of ARPP-21. Post-translational modification of specific amino acid residues was found to occur.

pTKA1 (2.5Kb) was subcloned into the pGEM4 vector to synthesize an antisense RNA to be used in Southern and Northern blot analyses. Following hydridization to bovine caudate poly A^+ RNA, a single band of 2.5 Kb was detected. Regional distribution of ARPP-21 mRNA was examined in the bovine central nervous system. Hybridization with total cellular RNA from multiple regons revealed that the mRNA was highly concentrated in the caudate nucleus, but could not be detected in the substantia nigra. The distribution pattern of ARPP-21 mRNA was therefore somewhat different from that of DARPP-32 mRNA, the product of which is also a neuronal phosphoprotein highly enriched in the basal ganglia. Developmental analysis of ARPP-21 in the mouse striatum indicated that its expression occurs postnatally, corresponding temporally with maturation of striatal neurons and their processes. Southern blot analysis of bovine and rat genomic DNA digested with several restriction enzymes indicated that the genomic structure is highly conserved between these two species.

154.13 **GENES AND MESSAGES ENCODING THE ALPHA, BETA, AND BETA-PRIME SUBUNITS OF BRAIN TYPE II CaM KINASE.** M.K. Bennett, R.F. Bulleit*, and M.B. Kennedy (SPON: K. Ocorr). Div. of Biology, California Institute of Technology, Pasadena, CA 91125.

Brain Type II Ca^{2+}/calmodulin-dependent protein kinase is a dodecameric holoenzyme composed of varying proportions of two types of structurally-related subunits, 50kD α-subunits and 60kD β-subunits. The major forebrain holoenzyme is composed of ~9 α- and ~3 β-subunits, whereas the cerebellar holoenzyme is composed of ~2 α- and ~8 β-subunits. In addition, a minor subunit of 58kD, termed β', is often present in the forebrain holoenzyme and is more prominent in the cerebellar holoenzyme. Tryptic peptide maps of the β'-subunit reveal that it is closely related to the β-subunit, thus several labs have suggested that it is derived from the β-subunit by proteolysis.

We have examined whether these distinct but related subunits are coded for by separate genes or are generated by alternative processing of the transcript of a single gene. Rat genomic DNA was digested with four different restriction endonucleases, separated by agarose gel electrophoresis and blotted to nylon filters. The blots were probed with labeled cDNAs containing portions of the coding region for either the α- or β- subunit (see accompanying abstract). The α-subunit probe hybridized strongly to a single band in each of the four digests, suggesting that the α-subunit is encoded by a single gene. The pattern of bands recognized by the β-subunit probe was more complex, but also suggested the β-subunit is encoded by a single gene. Proof will await more detailed analysis of the gene structure. The bands labeled most strongly by the α-subunit probe were distinct from those recognized by the β-probe indicating clearly that the α- and β-subunits are encoded by different genes.

Among several cDNA clones that encode the β-subunit, we found two independent clones with an identical discrete deletion of 45 bases from the middle of the coding region. Messages complementary to these clones would encode a protein 15 amino acids shorter than the β-subunit, with a molecular weight of approximately 58 kD. Such messages could encode the β'-subunits. To see if such messages are present in the brain, S1 nuclease protection experiments were performed in which labeled probes including the 45 bases were hybridized to brain poly(A)$^+$ RNA, then digested with S1 nuclease. A small proportion of the labeled probes were digested to fragments of the size predicted if messages with the 45 base deletion were present. Thus, the β'-subunit may be synthesized on a distinct message. The most likely source of such a message is alternative splicing of a single β-subunit gene.

Supported by NIH, the Pfeiffer Foundation and the McKnight Foundation.

154.14 **cDNA CLONES CODING FOR THE α-SUBUNIT OF BRAIN TYPE II Ca^{2+}/CALMODULIN-DEPENDENT PROTEIN KINASE.** R.F. Bulleit*, M.K. Bennett, J.B. Hurley*, and M.B. Kennedy, Div. of Biology, California Institute of Technology, Pasadena, CA 91125.

The Type II Ca^{2+}/Calmodulin-dependent protein kinase (Type II CaM kinase) is an abundant brain enzyme comprising ~1% of total brain protein. It is a large holoenzyme composed of 50k(α) and 60k(β) subunits. The major forebrain isozyme is an oligomer of ~9 α- and ~3 β-subunits, whereas the cerebellar isozyme contains ~2 α- and ~8 β-subunits. Within brain, about half of the kinase is soluble and distributed throughout the cytoplasm. Another portion is concentrated in postsynaptic densities where the α-subunit is indistinguishable from the "major postsynaptic density protein."

Recently our laboratory identified and sequenced cDNA clones containing the full coding region of the β-subunit (Bennett, M.K. and Kennedy, M.B. PNAS 84, 1794-1798, 1987). We now report the selection and sequencing of several cDNA clones coding for the α-subunit. A size selected rat brain cDNA library cloned into PBR322 was obtained from Gary Schull of the Univ. of Cincinnati. The library was screened with 2 probes, a 45 nucleotide "guessmer" (45mer) based on a partial amino acid sequence of the α-subunit and a restriction fragment from the β-subunit cDNA covering the N-terminal half of the coding domain. The β-subunit cDNA appears homologous to the α-subunit message since it will hybrid select mRNAs that code for both α and β-subunits and it hybridizes at low stringency to α-subunit mRNA on Northern blots.

From this library a single clone was selected (ck4-1α) that contains a 1.3kb insert that hybridized with both probes. A second size selected rat forebrain cDNA library cloned in λ-gt10 was screened with ck4-1α to identify clones covering the entire coding region. Several clones were selected. Those with the longest inserts were characterized further. They all hybridize on Northern blots to a 5.4kb band that is recognized by the 45 mer and is more abundant in forebrain than cerebellum. Restriction maps indicate that these cDNAs are all distinct from β-subunit cDNAs and that the entire region coding for the α-subunit is represented. The sequences of the α-clones contain regions of strong homology to the β-subunit as well as regions of divergence.

Northern analysis reveals that the 5.4 kb message for the α-subunit is far more abundant in the forebrain than in the cerebellum, while the 4.8 kb message for the β-subunit is expressed at roughly equal levels in the two brain regions. This presumably accounts for the difference in subunit composition of the holoenzymes from the two brain regions.

154.15 MOLECULAR CLONING OF cDNA FOR SYNAPTIC GLYCOPROTEINS
I.G. Johnston*, T. Paladino*, J.W. Gurd and I.R. Brown.
Departments of Zoology and Biochemistry, University of Toronto, Scarborough Campus, West Hill, Ontario, Canada M1C 1A4

The potential structural diversity and resultant informational content of the carbohydrate moiety of glycoproteins make these molecules highly suitable for roles in the establishment and maintenance of synapses. While it is known that changes in glycoprotein composition accompany synapse formation and development, it has proven difficult to characterize these proteins in precise molecular detail. We report here an approach to the isolation of cDNA probes for novel members of this class of protein. Briefly, synaptic junctions were isolated from bovine brain and concanavalin A-binding glycoproteins selected by affinity chromatography. This glycoprotein fraction was injected into mice and the resultant antisera used to screen a rat brain cDNA library constructed in the expression vector lambda gt11. Of the approximately 200,000 plaques screened, 6 reacted positively with the antisera. The cDNA inserts from these plaques have been purified and the structure and expression of the corresponding genes analysed by Northern and Southern blots, in situ hybridization, and DNA sequencing.

Northern blot analysis indicated that 5 of the 6 clones recognized a single RNA species of 3.2 kb, while the sixth clone recognized a 1.3 kb species. Partial DNA sequencing of each clone showed no significant homology with any sequence registered in the GenBank DNA database. The clone designated SC1 detects the 3.2 kb message at abundant levels in the adult rat brain and much lower levels in heart. This message is absent in liver and kidney. The SC1 message is expressed at a relatively low level in brain at birth and increases substantially through postnatal day 20. It is found primarily on membrane-bound rather than free polysomes as is expected for a message encoding a glycoprotein. Clone SC2, which recognizes the 1.3 kb message, is present at high levels in brain but at much lower levels in all other tissues examined. SC2 is also found primarily on membrane-bound polysomes. In situ hybridization indicated that SC2 displays a predominantly neuronal pattern of expression which is most clearly seen in the cerebellum where binding is observed over granule cells and is especially intense over Purkinje cells. Results obtained from hippocampal regions are also consistent with SC1 expression in neurons although glial expression also seems likely. In order to establish the subcellular localization of proteins encoded by SC1 and SC2, antibody probes are required. To this end, fusion proteins have been isolated from bacterial lysogens carrying the SC1 and SC2 inserts in the lambda expression vector. (Supported by grants from NSERC to I.B. and from MRC to J.G.).

154.16 THE NCAM GENE OF THE MOUSE: SEQUENCE ANALYSIS OF LONG AND SHORT NCAM TRANSCRIPTS.
W.Wille[1], D.Barthels[1]*, M.J.Santoni[2]*, C.Ruppert[1]*, and C.Goridis[2]* (SPON: European Neuroscience Association). [1]Institut für Genetik, University of Cologne, Federal Republic of Germany, and [2]Centre d'Immunologie INSERM-CNRS de Marseille-Luminy, Case 906, Marseille, France.

The NCAM cell surface glycoproteins are the best described cell-cell adhesion molecules of the vertebrate nervous system. Their significance for the development of the CNS has been well established (Gennarini, G. *et al.*, J Neurosci. 6:1983, 1986). Three protein isoforms of NCAM with apparent mol. wts. of 180,000, 140,000 and 120,000 (NCAM-180, -140 and -120) are expressed in mouse tissues. However, the final number of different gene products of the NCAM gene is still unknown. There are indications that the different sizes of NCAM proteins are translated from different transcripts (Hansen, O.C. *et al.*, J. Neurochem. 44:712, 1985). In Northern blots, hybridizing NCAM-cDNA fragments to poly(A)$^+$RNA from neonatal mouse brain, at least 5 transcripts can be recognized, which are differently regulated during neuro-ontogenesis.

A single copy gene seems to encode all NCAM mRNAs which are generated by differential splicing. Using either short cDNA fragments (Goridis, C. *et al.*, EMBO J. 4:631, 1985) or synthetic oligonucleotides carrying sequences of the NCAM gene, we screened cDNA libraries. For this purpose we especially constructed a cDNA bank of neonatal (P2) mouse brain in gt11.

The complete sequences of short (Barthels *et al.*, EMBO J., 6:in press) and long NCAM transcripts from the cap site(s) to the polyadenylation signals have been determined. The analysis of the AA-sequence allows to suggest a likely model of relationship of the NCAM gene product to the immunoglobulin gene superfamily. The extracellular part of NCAM which is identical for the three protein isoforms, seems to consist of 5 S-S bonded globular domains. Alternative splicing has been mapped by S1 nuclease protection assay.

Supported through grants of the SPP "Biochemie des Nervensystems" Wi563/3-3 & Wi563/3-5 to W.W. and institutional grants from INSERM and CNRS and a specific grant from the Association pour la Recherche contre le Cancer to C.G.

PEPTIDES: RECEPTORS

155.1 **TRIAZOLOBENZODIAZEPINES INHIBIT TRH BINDING IN BOVINE BRAIN.**
M.R. Kozlowski, M.L. Stachon*, K.L. Longo*, D.A. Bostick*. New Leads Department, Pfizer Central Research, Groton, CT 06340.

Binding sites for thyrotropin-releasing hormone (TRH) with the characteristics of receptors have been found in brain tissue by several investigators. Binding of TRH, or its more active analog MeTRH, to these sites has been shown in several studies to be inhibited by benzodiazepines from a number of classes, including the imidazobenzodiazepine, midazolam. The present report explores the effects of another class of benzodiazepines, the triazolobenzodiazepines, on 3H-MeTRH binding to brain tissue.

Binding of 3H-MeTRH to bovine hippocampal homogenate was measured using standard filtration binding assay technology. Inhibition experiments employed 1nM 3H-MeTRH as ligand, and 1uM TRH to define non-specific binding. Four triazolobenzodiazepines were examined: adinazolam, alprazolam, estazolam, and triazolam. Midazolam, chlordiazepoxide, diazepam, and flurazepam were also tested for comparison.

All 4 triazolobenzodiazepines tested inhibited 3H-MeTRH binding, as summarized in Table 1. The IC50 values were in the micromolar range, as found for the other benzodiazepines tested. These values showed a high degree of variability, probably owing to the poor solubility of these compounds at high concentrations. Hill coefficients were near 1 for alprazolam, estazolam, and triazolam; but less than 1 for adinazolam. The Hill coefficients for the other benzodiazepines tested were also equal to 1 in some cases, but less than 1 in others. Thus, the triazolobenzodiazepines inhibit TRH receptor binding in a fashion similar to that of benzodiazepines of other classes.

TABLE I.

Inhibition of 3H-MeTRH binding. Values are the mean ± S.E.M. from 3 determinations.

Compound	IC50 (μM)	Hill Coefficient
Adinazolam	**223.3 ± 78.4**	**0.53 ± 0.06**
Alprazolam	**46.0 ± 28.8**	**0.98 ± 0.25**
Estazolam	**467.7 ± 178.9**	**0.79 ± 0.13**
Triazolam	**19.3 ± 0.5**	**0.74 ± 0.28**
Chlordiazepoxide	**6.9 ± 1.8**	**0.62 ± 0.05**
Diazepam	**113.0 ± 58.4**	**1.01 ± 0.26**
Flurazepam	**67.3 ± 16.6**	**0.88 ± 0.07**
Midazolam	**3.3 ± 2.2**	**0.58 ± 0.22**

155.2 ONTOGENY OF CGRP BINDING SITES IN THE RAT CENTRAL NERVOUS SYSTEM.
S. Inagaki, S. Kito, and M. Tohyama 3rd Dept. of Int. Med., Hiroshima Univ. Sch. of Med., Hiroshima 734, 2nd Dept. of Anat., Osaka Univ. Med. Sch., Osaka 530 Japan

In the present study we studied ontogenical development of CGRP binding sites in the rat brain by in vitro macroautoradiography. Wistar albino rats at embryonic day 21 (E21) and postnatal days (P) 1, 7, 14, 28 and 56 were killed by decapitation. Cryostat sections 15μm thick were cut, thaw-mounted on gelatin coated slides. The procedures of autoradiographic study were done as described before (Inagaki et al., Brain Res., 374 (1986) 287). Briefly, slide-mounted sections were preincubated in 50 mM Tris-HCl buffer(pH 7.4) containing 0.02% bovine serum albumin, 2mM EGTA and 5mM MgCl , and then incubated for 60 min at room temperature in the preincubation buffer containing 0.2nM of I-human CGRP (hCGRP, Amersham) with or without unlabeled rCGRP. After rinsing, incubated slides were dried and juxtaposed to tritium-sensitive film and stored at 4°C for 1 week.

The distribution of CGRP binding sites undergoes major modifications during ontogeny. Medium to high densities of CGRP binding sites are evenly present soon after in most lower brainstem nuclei at early ontogenical stages, while uneven concentrations (very low to high) of sites are seen at adult. In the forebrain, densities of CGRP binding sites are generally very low at E21 and P1. At P7 moderate numbers of sites are already seen in the amygdala and certain small regions of the striatum, and these sites increase and reach high densities at P14 in the amygdala and at P28 in the striatum. At P14, CGRP binding sites are moderate in density in other forebrain nuclei such as the taenia tecta, olfactory tuberculum, nucleus accumbens, and piriform and insular cortex. These become to be dense at adult. On the other hand CGRP binding sites in the thalamus are already present at embryonic and early postnatal stages until P14 but decline at adult. Moderate to high densities of binding sites occur rather evenly throughout the lower brainstem nuclei during E21 to P14 except in the nucleus of spinal tract of trigeminal nerve, vestibular nuclei and inferior olive where sites are denser than in other regions at P7-14, while sites in certain nuclei in related to the auditory and visual systems such as inferior and superior colliculi and medial geniculate body are scarce until P7, increase after P14 and become to be dense at adult.

155.3 VASOACTIVE INTESTINAL PEPTIDE INDUCED PHOSPHORYLATION IN PRIMARY CULTURES OF CORTICAL ASTROCYTES. R.F. Alderson, D.A. Kniss and D.E. Brenneman, Lab. Dev. Neurobiology, NICHD, NIH, Bethesda, MD. 20892.

Astrocytes have been shown to express plasma membrane receptors for a variety of hormones and the binding of these ligands can elicit similar second messenger responses as seen in other cell types (McCarthy K.D. et. al.,J. Neurochem.,44:723,1985). The receptor for vasoactive intestinal peptide (VIP) has been partially characterized (Paul S. and Said, S.I., J. Biol. Chem. 262:158,1987) and the intracellular effects of VIP are thought to be mediated through the formation of cyclic AMP. We have identified a binding site for VIP on cortical astrocytes. In addition, the formation of cyclic AMP and the protein phosphorylation induced by VIP was examined.

Primary cultures of glial cells were prepared by the method of McCarthy K.D. and de Vellis, J.,J. Cell Biol.,85:890,1980) from rat cortex at post-natal day 2. GFAP positive cells were found to make-up 90% of the cell population. The presence of VIP receptors in these cultures was demonstrated in membrane preparations. The specific VIP binding site is composed of a high and low affinity component. The non-specific binding was found to be approximately 40% of the total binding. The ability of VIP to increase cyclic AMP levels in astrocytes was also tested. A 10 min. incubation with 10^{-6} M VIP resulted in a 2.2 fold increase in the levels of cyclic AMP as compared to the control (14.7 compared to 6.8 pmol/mg protein). However, a ten minute incubation with 10^{-10} M VIP failed to significantly increase cyclic AMP levels.

Experiments designed to examine VIP-induced protein phosphorylation were conducted on astrocytes plated at a density of 5.0 (10^5) cells/60 mm dish. The ATP pools of the cells were labeled by incubation in the presence of ^{32}P-orthosphosphate in DMEM for 4 hours. The effect of the VIP treatment on the extent of protein phosphorylation was evaluated by 2 dimensional gel electrophoresis. The second dimension gels were heated to 40^{o} C for 1 hour in 1M NaOH to hydrolyze the phosphoserine and phosphothreonine bonds enabling the phosphotyrosine residues to be visualized (Cheng Y. E. and Chen L. B., PNAS,78:2388,1981). A one minute incubation with 10^{-10} M VIP produced an increase in the ^{32}P content of two proteins; (I) 410 k Da\pI = 5.05 and (II) 82 k Da\pI = 5.2. After a 10 min. incubation in the presence of 10^{-10} M VIP, phosphoprotein I was no longer visible, protein II remained approximately unchanged and an additional protein was observed having the molecular weight of 50 k Da and a pI = 5.2 (III) . Moreover, a 50 k Da protein whose content of ^{32}P was not observed to be affected by VIP treatment in the alkalinated gels was shifted from a position with a pI of 4.8 to that of 4.5. When the astrocytes were treated with 10^{-6} M VIP for 1 min. only protein III appeared to have a higher ^{32}P content and the 50 k Da protein was found to be shifted to the 4.5 pI position. The identification of these proposed VIP-induced phosphoproteins and the analysis of their phosphoamino acid composition are underway.

155.4 EGG-LAYING HORMONE BINDS SPECIFICALLY IN SEVERAL TISSUES OF APLYSIA CALIFORNICA. J.V.A. Choate, G.T. Nagle, S.D Painter and J.E. Blankenship. Marine Biomedical Institute, University of Texas Medical Branch, Galveston, TX 77550.

Egg-laying activity in the marine mollusc Aplysia has become a model system for understanding how peptides regulate behavior. The neuroendocrine bag cells in this animal release a family of peptides, including the 36-amino acid egg-laying hormone (ELH), during a discharge of repetitive activity that normally precedes egg laying. ELH diffuses into the hemolymph and interstitial spaces to reach its target tissues, which include the gonad (ovotestis), certain identified neurons in the abdominal and buccal ganglia, as well as other reproductive and neural tissues. ELH specifically excites target neurons for prolonged periods. It also acts directly on the ovotestis to release ripe oocytes into the reproductive tract, but the specific target cell(s) in the ovotestis has not been identified. In order to better understand the mechanism of action of ELH on its targets, we have initiated binding studies as a first step toward characterizing the receptor for this neuroendocrine hormone.

The ligand used in these studies was purified bag-cell ELH labelled with ^{125}I by the Iodogen procedure. A mixture of three ELH-related peptides (A-ELH family) from the atrial gland, an exocrine organ in the oviduct of A. californica, was used as displacing ligand. These peptides are 78-83% homologous to ELH in primary structure, are equipotent in causing egg laying, and are available in large quantities. Three target tissues were examined for the presence of specific binding sites for ELH: pooled abdominal and buccal ganglia, the ovotestis, and the reproductive tract caudal to the atrial gland. Tissues were homogenized and a crude membrane preparation (P_2 pellet) was obtained by differential centrifugation. The membranes were incubated in nanomolar concentrations of ^{125}I-ELH, and a 1500-2000-fold excess of A-ELH was used as displacer. The incubations were terminated using vacuum filtration. Our preliminary studies indicate that ^{125}I-ELH binds in a saturable manner in all three tissues and is specifically displaced by an excess of A-ELH. The apparent density of binding sites was calculated for each tissue (pmol/mg protein): reproductive tract, 1.0-1.2; ganglia, 0.9-1.0; ovotestis, 0.1-0.2. Supported by NINCDS NS23169 (JEB) and NS22079 (SDP), and by NSF BNS85-17575 (GTN). We gratefully acknowledge the assistance of Drs. T.F. Murray and G. Mpitsos of Oregon State University.

155.5 GUANINE NUCLEOTIDE MODULATION OF ^{125}I-DESAMINOTYROSINYL-PHE-NORLEU-ARG-PHE-AMIDE BINDING TO FMRF-AMIDE RECEPTORS IN HELIX ASPERSA. K. Payza. Whitney Marine Lab, Univ. of Florida, St. Augustine, FL 32086.

Guanine nucleotides have been shown to modulate agonist binding to many neurotransmitter receptors coupled to second messenger systems. Since the actions of FMRFamide on various molluscan tissues have been associated with increases in cAMP, the effects of guanine nucleotides on FMRFamide receptor binding were investigated in the gastropod mollusc Helix aspersa. ^{125}I-desaminoTyr-Phe-norLeu-Arg-Phe-amide (daYFnLRFamide) binds reversibly, saturably, and specifically to Helix neural and cardiac membrane preparations, with a K_D of about 12 nM. A lower affinity site is also present. The SAR of peptides in inhibiting binding correlates with that of stimulating the isolated, perfused Helix heart, and is similar to the SAR of other molluscan bioassays.

GTP decreases the binding of ^{125}I-daYFnLRFamide to FMRFamide receptors in neural and cardiac membranes of Helix. Based on Scatchard analysis of radioligand binding, the GTP effect appears as a reduction in the number of high affinity sites. The non-hydrolyzable GppNHp is about as effective as GTP, whereas GDP is less potent. Furthermore, the nucleotides GMP and ATP have virtually no effect on the binding.

The specificity of the interaction suggests that Helix neural and cardiac FMRFamide receptors are coupled to a G-protein, and that GTP plays a role in modulating the binding and cellular actions of FMRFamide. (NIH grant HL-28440).

155.6 FUNCTIONAL RECEPTORS FOR ATRIAL NATRIURETIC FACTOR ON CEREBELLAR NEURONS. A. Novelli, D. Collado* and R.C. Henneberry*. Molecular Neurobiology Section, Laboratory of Molecular Biology, National Institute of Neurological and Communicative Disorders and Stroke, National Institutes of Health, Bethesda, MD 20892.

Atrial Natriuretic Factor (ANF) was the term used by deBold in 1981 to describe the potent natriuretic, diuretic, and hypotensive peptides released by the mammalian heart.In peripheral tissues ANF has been shown to stimulate the synthesis of cGMP and is thought to exert its physiological effects by inhibiting effects of Angiotensin II. ANF and its receptors have been found widespread in the brain, and ANF receptors have recently been reported in the blood-brain barrier. We now report the presence of functional ANF receptors on mammalian neurons.

Cerebellar granule cells were cultured from 8 day old rat pups. ANF receptors were demonstrated by binding of iodinated ANF and by stimulation of guanylate cyclase by the various peptides of the ANF family. cGMP synthesis in response to ANF increased rapidly, peaking at about 3 min.; 50% of the total cGMP was released from the neurons by 20 min. Increased cGMP synthesis in response to ANF was present as early as day 2 after plating granule cells, and increased about 2-fold by day 6. ANF was effective in stimulating guanylate cyclase at low concentrations, with an EC_{50} of 10nM. The possible role of ANF in the regulation of the water content of neurons in normal and neuropathological conditions will be discussed.

155.7 TRITIATED D-ALA1-PEPTIDE T RECEPTOR BINDING TO MOUSE MACROPHAGES RAT HIPPOCAMPAL MEMBRANES AND HUMAN T-CELL LINE. C.C. Smith, P. Williams, P.L. Hallberg, E. Sternberg, C.B. Pert and M.R. Ruff. (SPON: P. Herscovitz). Section on Brain Biochemistry and Pre-Clinical Studies, Clinical Neuroscience Branch, National Institute of Mental Health, ADAMHA, Department of Nuclear Medicine, Clinical Center, NIH, Bethesda, Maryland 20892.

We have recently deduced the portion of the AIDS viral envelope which attaches to the CD4 receptor in the first step of the process by which viruses gain entry into cells containing CD4, the HIV virus receptor. This attachment sequence occurring in the second variable region from the N-terminus in the California isolate where it was first identified, is the octapeptide peptide "peptide T", ASTTTNYT. It became apparent, that the core sequence is TTNYT, peptide T [4-8], since this sequence or similar CD4 receptor analogs, can be found in all 21 AIDS viral envelopes sequenced to date, and in the envelope sequence of HTLV-I, HTLV-II, simion AIDS and HIV-II, all thought to utilize CD4 as an entry protein.

To rapidly evaluate the relative potency of the pentapeptide analogs which we have been collecting so as to precisely define the conformational structural requirements for CD4 activity, we devised a receptor binding assay utilizing ^{3}H-D-Ala1-peptide T-NH_2. This compound binds with high affinity to membrane preparations, so that 0.1 mg wet weight of rat hippocampus in 2 ml buffer binds 2,000 to 3,000 cpm after 3 h at 30°C with 0.2 nM radiolabeled peptide added: binding is displaceable to 100 cpm. The AIDS viral envelope, gp120, at extremely low concentrations(10^{-10}-10^{-12}M), inhibits peptide T binding. The percent specific binding ranges between 95-99%.

Sensitivity to structural changes are readily detectable in this rapid filtration assay. It is generally observed that d-substitution of any amino acid in the core pentapeptide sequence, TTNYT, will decrease affinity by at least one order of magnitude, as will d-threonine substitution in the 8 position of the octapeptide T. As first demonstrated by monocyte chemotaxic bioassays, the pentapeptides are more potent than the octapeptide T and its analogs. Although differences are not as pronounced in the membrane binding assays, the rank order of potency of a large number of synthetic peptide analogs displace binding with an order of potency that is quite similar in all three tissues. This rank order of potency correlates very closely with that determined by chemotaxis.

Relative potency of these peptides as well as the sequences found in all CD4 trophic viruses, will be presented. Moreover, these radioreceptor assays appear to rapidly and accurately predict the potency of the various peptides in their ability to block viral infectivity in vitro.

155.8 RECEPTORS FOR SENSORY NEUROPEPTIDES MAY BE INVOLVED IN THE PATHOPHYSIOLOGY OF RHEUMATOID ARTHRITIS P.W. Mantyh, C.R. Mantyh*, P. Popper, S.R. Vigna*, L. Kruger, A.I. Basbaum, J.D. Levine, and J.E. Maggio. (SPON:C.Clemente) Center for Ulcer Research and Education; Brain Research Institute, UCLA, Los Angeles, Ca 90024; Dept of Anatomy and Medicine, UCSF, San Francisco, Ca 94143 and Dept of Pharmacology, Harvard Medical School, Boston, Ma 02115

Previous reports have established that several neuropeptides are synthesized and released by subpopulations of primary afferent neurons. These neuropeptides include bombesin, calcitonin gene related peptide, somatostatin, and substance P (SP). It has also been hypothesized that several of these neuropeptides are involved in mediating the inflammatory and immune response peripherally and in conveying nociceptive information centrally. For example previous data has shown that SP immunoreactivity is increased in the arthritic joint and release of SP immunoreactivity from the spinal dorsal horn is enhanced in polyarthritic rat. In many systems when neurotransmitter release is increased, postsynaptic receptors undergo a corresponding downregulation. To investigate whether SP and the other sensory neuropeptide receptors exhibit a similar downregulation we used quantitative receptor autoradiography to explore if receptor binding sites for these neuropeptides change in the spinal cords of arthritic rats compared to normals. The experiments were performed on 250-350 g male Sprague-Dawley rats and the arthritis was induced by intradermal injection of 0.1 ml of a 10 mg/ml suspension of Mycobacterium butyricum in mineral oil. Twenty one days later the severity of arthritis was assessed, the animals were sacrificed, the lumbar and sacral spinal cords dissected out, sectioned on a cryostat and processed for quantitative receptor autoradiography. Littermates injected with vehicle served as controls. In laminae 1 & 2 of the spinal cord, receptor binding sites for bombesin were reduced by 53.3%, somatostatin 60.0%, substance P 35%, whereas CGRP receptor binding sites remained unchanged. These results indicate that receptors for several sensory neuropeptides are downregulated in the spinal cord in adjuvant-induced arthritis and especially in the areas known to receive the thin fiber nociceptive input (i.e. 1 & 2). These results suggest that certain neuropeptide systems are preferentially affected in an inflammatory pain state such as arthritis. In addition each receptor binding site appears to show a different degree of change. These results suggest that several neurotransmitter systems may be involved in the pathophysiology of rheumatoid arthritis and in signalling nociceptive information in the spinal cord. These results offer a rational approach to determining how sensory neuropeptides are involved in the pathophysiology of rheumatoid arthritis and in designing analgesic compounds to combat the pain and inflammation associated with arthritis. Supported by Southern California Arthritis Foundation, Sloan Foundation and NIH 23970.

155.9 DISTRIBUTION OF GONADOTROPIN RELEASING HORMONE ANALOG BINDING SITES IN THE RAT CENTRAL NERVOUS SYSTEM. L. Jennes, B. Dalati* and P. M. Conn*. Department of Anatomy, Wright State University Medical School, Dayton, OH 45435 and Department of Pharmacology, University of Iowa College of Medicine, Iowa City, IA 52242.

Gonadotropin releasing hormone (GnRH) has been implicated as a neurotransmitter in the central nervous system and may be involved in the facilitation or maintenance of certain reproductive behaviors. Accordingly, we conducted a study designed to use well-characterized GnRH agonists which can be labeled to high specific activity in order to identify the intracerebral binding sites of this releasing hormone. The distribution of GnRH binding sites in the central nervous system of the rat was studied with in vitro autoradiography. The GnRH agonists Buserelin (Hoechst, [D-Ser(tBu)^{6}-Pro^{9}-NHEt]-GnRH) and Leuprolide (Abbott, [D-Leu^{6}-Pro^{9}-NHEt]-GnRH) were iodinated with chloramine T to a specific activity of 0.8 mCi/μg as assessed by self-displacement in a receptor assay using a pituitary membrane preparation as source for GnRH receptors. About 50% of the ligand bound to the pituitary GnRH receptor in the above assay. Frozen sections were incubated for 2 hours in the presence or absence of 10 μM unlabeled GnRH in 100 pM iodinated agonist, rinsed, dried then placed against X-Omat AR Kodak diagnostic film. Specific, displaceable analog binding was measured in the lamina glomerulosa and plexiformis externa, the nucleus olfactorius anterior pars externa, and the frontal cortex at the sulcus rhinalis. In the septum, GnRH binding sites were evident only in the lateral and dorsal portions of the nucleus septi lateralis but neither in the nucleus medialis nor in the diagonal band. In the hypothalamus, only a small number of GnRH receptors were detectable in the mediobasal portion while further caudally, the entire interpeduncular nucleus was heavily labeled with radioactive GnRH agonists. Specific GnRH binding sites were also detected in the central gray and in the superior collicle. In the hippocampal formation, GnRH agonists bound to the dorsal and ventral subiculum as well as to receptors in the areas CA1 through CA4; in the amygdala only a few binding sites were measured. On a qualitative basis, the highest number of GnRH receptors in the central nervous system were found in the parasubiculum. The results suggest that specific receptors for GnRH exist in select areas of the central nervous system where the peptide may regulate sensory, behavioral and endocrine events. This project was supported by WSV Academic Challenge Grant and NIH HD 19899.

155.10 ELECTRON MICROSCOPIC LOCALIZATION OF NEUROTENSIN RECEPTORS IN THE SUBSTANTIA NIGRA OF THE RAT. A. Beaudet, K. Leonard,* M. Vial,* E. Moyse,* P. Kitabgi,* J.P. Vincent* and W. Rostène. Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada H3A 2B4, Centre de Biochimie du CNRS, Parc Valrose, 06034 Nice and INSERM U-55, Hôpital St. Antoine, 75012 Paris, France.

The pars compacta of the substantia nigra (SN) contains among the highest concentrations of neurotensin (NT) binding sites in rat brain (Moyse et al., 1987). Chemospecific lesion studies (Palacios and Kuhar, 1981) and combined autoradiographic/immunocytochemical experiments (Szigethy et al., 1986) have indicated that these binding sites are mainly associated with the cell bodies and dendrites of nigrostriatal dopamine (DA) neurons. In the present study, specifically labeled NT binding sites were localized in rat SN by electron microscopic (EM) autoradiography. Lightly pre-fixed, vibratome-cut slices of rat midbrain tegmentum were incubated with 0.1 nM ^{125}I-NT in the absence (total binding) or in the presence (non-specific binding) of an excess of non-radioactive NT. Following several buffer rinses, bound radioligand molecules were cross-linked to tissue proteins with glutaraldehyde. The slices were then post-fixed in OsO_4, dehydrated in ethanols, embedded in plastic and serially sectioned for light (LM) and EM autoradiography.

In LM autoradiographs of material incubated with ^{125}I-NT alone, the labeling was intense throughout the pars compacta of the SN. Silver grains predominated over the neuropil, but some were clearly visible over the endothelium of capillary blood vessels and along the plasma membrane of neuronal perikarya and proximal dendrites. The addition of non-radioactive NT to the incubation medium reduced the radioautographic labeling by 70-85% except over capillaries, which remained selectively labeled.

In EM autoradiographs from sections incubated with ^{125}I-NT alone, most of the silver grains were shared, i.e. overlaid more than one cellular profile. These shared grains were shown by line source analysis to originate from membrane bound radioactive sources, and their distribution was therefore assumed to reflect that of membrane-bound NT receptors. After subtraction of non-specific binding, 49% of shared grains were ascribed to axo-dendritic appositions. Most of these appositions were devoid of junctional specializations, but a few exhibited well differentiated asymmetrical synapses. Axo-somatic, dendro-somatic, dendro-dendritic and dendro-glial appositions, although less frequently encountered, were proportionally as densely labeled as axo-dendritic ones. In contrast, axo-axonic and axo-glial interfaces were only rarely labeled. These observations suggest that within the rat SN, NT receptors: (1) are predominantly associated with the plasma membranes of the perikarya and dendrites of presumptive DA neurons and (2) are rather uniformly dispersed along these plasma membranes rather than being concentrated exclusively opposite abutting axon terminals.

156.1 STABILITY OF DOPAMINE AND DOPAC, BUT NOT HVA AND 3-MT IN ALZHEIMER'S DISEASE. CONTRAST WITH PARKINSON'S DISEASE. D.G. Morgan, J.O. Marcusson*, M.N. Gordon, L.Ljung*, E. Yang*, M. Gorgy*, S.P. Lerner*, B. Winblad*, C. Gottfries*, E.D. Bird, P. Riederer*, W. Tourtellotte*, and C.E. Finch. Andrus Gerontology Center and Dept. of Biological Sciences, University of Southern California, Los Angeles, CA USA 90089-0191 and Dept. Of Pathology, University of Umea, Sweden S-90187.

Alzheimer's disease (AD) and age-matched control (CTL) brain specimens of caudate nucleus (CN) and putamen (PUT) were obtained from Umea Sweden, Gothenburg Sweden, Boston USA, and Vienna Austria (total n = 22-27 per group). Parkinson's disease (PD) and CTL (n = 13-15 per group) specimens were obtained from Vienna Austria, and Los Angeles USA (thus CTL for AD and PD are different specimens). Homogenates were a) acidified for analysis of dopamine (DA) and metabolites by HPLC, b) used to prepare membranes for D-1 and D-2 dopamine receptor assays, and c) assayed for choline acetyltransferase (CAT) activity.

HPLC analysis found small (nonsignificant) declines in DA and DOPAC concentrations in AD, but significant declines of homovanillic acid (HVA) (-35% CN; -45% PUT) and 3 methoxy tyramine (3-MT) (-30% in both CN and PUT). Serotonin declined by -35% in PUT, but was normal in CN. 5-HIAA levels did not change. CAT declined by -30% in CN and -25% in PUT, but these trends were not statistically significant. DA receptors were also stable in AD, with small (10-15%), nonsignificant declines in CN and PUT for D-1 and D-2 receptors.

In PD, DA and DOPAC were reduced by -90% in CN and PUT, much more than in AD. However, HVA was reduced by only -40% in CN, and -60% in PUT, while 3-MT was decreased by -55% in CN and -80% in PUT. This generally smaller reduction in HVA and 3-MT metabolites of DA implies enhanced DA release in those terminals which remain in PD. Serotonin was reduced in PD by -36% (CN) and -67% (PUT), with no significant change in 5-HIAA.

PD and AD present striking contrasts concerning striatal DA metabolism. In AD, DA and the "intraneuronal" metabolite, DOPAC, are stable, while both decline by approximately 90% in PD. The two "extraneuronal" metabolites which pass through catechol-O-methyl transferase, HVA and 3-MT, are reduced in both disorders. Assuming the "extraneuronal" metabolites are indicators of dopamine release, we conclude that in AD, the dopamine synaptic machinery is intact, but functioning at a reduced level compared to CTL. In PD, the DA synaptic machinery is severely compromised, but operating at an enhanced rate to compensate for the deficit, perhaps driven by exogenous L-DOPA. Supported by The John Douglass French Foundation (DGM) and AG-05142 (CEF).

156.2 AUTORADIOGRAPHIC STUDY ON NEUROTRANSMITTERS AND NEUROPEPTIDES RECEPTORS IN ALZHEIMER'S DISEASE AND PARKINSON'S DISEASE. S.Katayama, S.Kito, R.Miyoshi 3rd Dept. of Int. Med., Hiroshima Univ. Sch. of Med, Kasumi, Hiroshima, 734 Japan (SPON: Y. Yamamura)

Recently the degeneration of cholinergic cell bodies in the nucleus basalis Meynert(NbM) has been detected in the brains of Alzheimer's disease(AD) (Whitehouse et al.,1981). Although AD and Parkinson's disease(PD) have distinct clinical and biological features, these two diseases share some common characteristics, that is , greater chances suffering from dementia in PD and higher incidence of extrapyramidal signs in AD than age matched controls. In this study, we examined receptor distributions of various neurotransmitters and neuropeptides, such as muscarinic, nicotinic acetylcholine, dopamine, noradrenaline, glutamate, aspartate, somatostatin, neuropeptide-Y and corticotropin releasing factor receptors in the human autopsied brains of AD and PD.

The employed methods were in vitro autoradiography on cryostat sections with use of ^{3}H- or ^{125}I-labeled radioactive ligands, including ^{3}H-QNB, ^{3}H-pirenzepine, ^{3}H-nicotine, ^{3}H-lisuride, ^{3}H-aspartate, ^{3}H-glutamate, ^{125}I-somatostatin--14(thy^{11}), ^{125}I-neuropeptide-Y and ^{125}I-tyrosyl-corticotropin releasing factor. The obtained autoradiograms were computer analysed by IBAS II of Zeiss Company and receptor densities were quantitatively calculated. This study was also to aim at differentiating cortical and subcortical dementias from view points of receptor densities and distributions.

In AD, ^{3}H-QNB binding sites in the NbM and ^{3}H-glutamate binding sites in the hippocampus were decreased, while in PD ^{3}H-QNB binding sites were increased in the putamen. As for somatostatin binding sites, two layer formation of somatostatin receptors were observed in the control cerebral cortex, that is, low and high densities in the superficial and deep layers, respectively. This layer formation disappeared in AD brains as the results of decreased receptor densities especially in the deep layer. Such changes of somatostatin receptors were not observed in PD brains. In PD brains, changes of the receptor distribution were more widespread than having been expected. ^{3}H-lisuride binding sites were increased in the globus pallidus(D2 receptor) and decreased in the parahippocampal gyrus and cerebellum (adrenergic receptor). It is considered that to compare neurotransmitter receptor changes between these two disorders will contribute to understanding of pathophysiology underlying these most important degenerating processes in the central nervous system.

156.3 SOMATOSTATIN CONCENTRATIONS AND BINDING SITES ARE DIFFERENTIALLY ALTERED IN DEMENTIA ASSOCIATED PARKINSON'S DISEASE AND PROGRESSIVE SUPRANUCLEAR PALSY. J. Epelbaum, F. Javoy-Agid*, C. Kordon and Y. Agid*, U. 159 INSERM, U. 289 INSERM, Paris, France.

Somatostatin (SRIF) concentrations are decreased post mortem in cortical regions of patients with senile dementia of the Alzheimer type (SDAT). In the present work, we tested wether somatostatinergic parameters were also modified in the brain of patients with other neurological diseases leading to dementia such as Parkinson's disease (PD) and progressive supra-nuclear palsy (PSP). The results indicate that SRIF concentrations, as measured by RIA in different cortical regions, hippocampus, caudate, putamen and hypothalamus, are decreased significantly, as compared to controls, only in the frontal (57 % decrease) and entorhinal cortex (55 % decrease) and hippocampus (59 % decrease) of demented parkinsonians while they are unchanged in PSP and non demented parkinsonians. SRIF receptor concentrations, as measured by 125I-Tyr0-DTrp8-SRIF binding in saturation experiments in 4 individual brains for each groups and binding at saturating concentration of ligand (n = 17, for controls, 11 for parkinsonians, 14 for demented parkinsonians and n = 9 for PSP), are not modified in the frontal cortex of the parkinsonians (Kd = 2.1 $\pm$ .4 nM ; Bmax = 464 $\pm$ 35 fmol/mg protein), demented parkinsonians (Kd = 3.0 $\pm$ .8 ; Bmax = 481 $\pm$ 140) or PSP patients (Kd = 2.8 $\pm$ 1.3 ; Bmax = 514 $\pm$ 100) as compared to controls (Kd = 2.1 $\pm$ .6 Bmax = 435 $\pm$ 55). The results demonstrate that somatostatinergic parameters in the cortex are differentially affected in SDAT, PD and PSP.

Both concentrations and binding are decreased in SDAT while only the levels of the peptide are reduced in demented parkinsonians ; in keeping with the occurrence of tangles and plaques in the cortex of these patients. In contrary, in PSP where the cortex is roughly spared somatostatin parameters are not modified as compared to controls.

156.4 **STABILITY OF L-GLUTAMATE RECEPTORS AND DECREASE IN A CaCl-DEPENDENT [^{3}H]-L-GLUTAMATE BINDING SITE IN ALZHEIMER'S DISEASE.** J.W. Geddes, D.T. Monaghan, R.J. Bridges, and C.W. Cotman, Department of Psychobiology, University of California, Irvine, CA 92717.

Cognitive deficits in Alzheimer's disease (AD) may result, in part, from the loss of specific neurons in the hippocampal region. The vulnerable neurons, including stellate neurons in layer II of the entorhinal cortex and pyramidal neurons in CA1 and subiculum, are thought to utilize glutamic acid as a neurotransmitter. We have examined the status of the major classes of glutamate receptors in the hippocampus in AD and have previously reported that the disease is not associated with a large decrease in N-methyl-D-aspartate (NMDA) or in kainate (KA) receptors, except in cases with severe cell loss (*Science* 230: 1179, 1985; *Br. Res.* 399: 156, 1986). In addition, using the specific agonist ^{3}H-α-amino-3-hydroxy-5-methyl-4- isoxazolepropionic acid (AMPA) to label the quisqualate (QA) receptors, we have found little change in QA receptor density or distribution in AD patients. The pharmacology of this site was identical to that described previously in the rodent brain.

In contrast to these data, Young and colleagues have reported a striking loss of NMDA and QA receptors in the hippocampus of AD patients (*J. Neurochem* 48: 543, 1987). Young and coworkers performed their binding assays in the presence of $CaCl_2$ which, from recent studies, induces [^{3}H]-L-glutamate binding to non-receptor sites. We have therefore examined glutamate binding using the protocol of Young and coworkers and compared the results to those obtained under our conditions in an effort to resolve these differing findings. We confirm the decrease in [^{3}H]-L-glutamate binding in AD when binding assays are done in the presence of Ca^{2+}(2.5 mM) and Cl^{-}(50mM). The same pattern of glutamate binding persisted in the presence of NMDA (200 μM), AMPA (100μM), QA (2.5 μM) and in the presence of both NMDA and AMPA or QA.

Thus, the pharmacology of Ca/Cl-dependent glutamate binding site which decreases in AD is not consistent with NMDA or QA receptors. The binding is, however, similar to the Ca/Cl-dependent glutamate binding site described previously in the rodent brain. This binding has been associated with a Cl^{-}-dependent, Ca^{2+}-stimulated glutamate transport site which we and others have recently characterized in both astrocytes and synaptic plasma membranes. A decrease in the ability to remove excitatory amino acids may contribute to the vulnerability of glutamate-using neurons in AD. Alternatively, the decreased uptake of glutamate may be secondary to the disease-induced loss of glutamate-using neurons.

156.5 CHOLINERGIC RECEPTORS IN ALZHEIMER'S DISEASE: CHARACTERIZATION USING RECEPTOR BINDING ASSAYS. R. Quirion, D.M. Araujo, Y. Robitaille*, P.A Lapchak (Spon: N.P.V. Nair). Douglas Hospital Res. Ctr. and Dept. of Psychiatry, McGill University, Montreal, Québec, Canada H4H 1R3.

There is evidence to suggest that in human brain, the densities of cholinergic receptors may be altered by neurological disorders such as Alzheimer's disease (AD). However, it is not clear what subtype(s) of cholinergic receptor and what brain region(s) are most affected by the disease. The present study sought to clarify this point by characterizing the binding of radioligands selective for M_1 and M_2 muscarinic receptors and for the nicotinic receptor, to normal (n=4) and AD (n=6) human brain membrane preparations. [^{3}H]N-methylcarbamyl choline (MCC) was used to quantitate nicotinic receptor binding; [^{3}H]pirenzepine and [^{3}H]acetylcholine (ACh), under muscarinic conditions (see Quirion and Boksa, 1986), were used to study M_1 and M_2 muscarinic receptors, respectively. Human brain tissue was homogenized and suspended in buffer of the following composition (in mM), Tris.HCl 50, NaCl 120, KCl 5, $CaCl_2$ 2, $MgCl_2$ 1, (pH=7.4), for [^{3}H]MCC and [^{3}H]ACh binding, and in Krebs buffer for [^{3}H]pirenzepine binding. Then, supernatant was discarded and the membrane pellet was washed twice and resuspended in fresh buffer. The final membrane pellet was incubated with various concentrations of radioligand for 60 min at 4°C for [^{3}H]MCC and [^{3}H]ACh, and at 25°C for [^{3}H]pirenzepine. [^{3}H]MCC bound specifically, saturably, and with high affinity to a single class of nicotinic sites in both control and AD brains. However, there was a significant decrease in [^{3}H]MCC binding sites in AD compared to control brains. This decrease was most apparent in frontal (68%) and temporal (66%) cortex. [^{3}H]ACh (in the presence of 20 µM nicotine and 100 µM DFP) bound with high affinity to an apparently single class of sites in both cortical and sub-cortical structures, but the maximal number of sites labelled by [^{3}H]ACh was not markedly different for AD compared to control brains. The results obtained for [^{3}H]pirenzepine binding are not clear at present, but suggest that there may be a modest increase in M_1 muscarinic receptors in AD brains compared to controls. In summary, the results show that various cholinergic receptors may be differentially affected in AD. However, it appears that of the three receptor subtypes studied, M_1 and M_2 muscarinic and nicotinic, the latter is the most markedly altered in AD. The significance of this finding is not immediately apparent, but may be of therapeutic importance in the treatment of neurological disorders such as AD. (Supported by MRC, Canada and FRSQ, Québec).

156.6 DIFFERENTIAL EFFECTS OF DORSAL AND VENTRAL CHOLINERGIC STRIATAL LESIONS. B. Diamond, J. Johnson*, K. Sethi*, R. Borison Department of Psychiatry and Health Behavior, Medical College of Georgia, Augusta, GA 30912

The mediation of striatal dopamine (DA) effects via acetylcholine (ACH) has been characterized. It was the aim of this study to examine the role of ACH on DA mediated behaviors within the dorsal and ventral striatum. Three groups of male Sprague Dawley rats (250 g) were used. One group served as control while two other groups had bilateral injections with the cholinergic neurotoxin AF64A (3 nM/0.5 l) into either the dorsal or ventral caudate nucleus. Animals were given apomorphine (APO 0.5 mg/kg) or amphetamine (AMPH 3 mg/kg) once a week and stereotypy assessed. Animals with dorsal AF64A lesions exhibited spontaneous grooming, rearing and increased locomotion. Both APO and AMPH exacerbated these behaviors and produced intense chewing and gnawing on the cage grid whereas they produced only a slight increase in locomotion and grooming in controls. In contrast, animals with AF64A ventral lesions exhibited reserpine-like symptoms with spontaneous chewing and teeth clattering. DA agonist treatment did not produce a supersensitive response in these animals. These results demonstrate the selective nature of the ACH system within the striatum and provide evidence for the neuroanatomical involvement of ACH in movement disorders.

156.7 **HUMAN POSTMORTEM FRONTAL CORTICAL α_2 ADRENERGIC RECEPTORS.** G.N. Ko, B.J. Wilcox, M.A. Raskind*, M.M. Murburg*, and D.M. Dorsa. Univ. of Wash., and GRECC, Seattle VAMC, Seattle, WA 98108.

Improvement in memory in nonhuman primates has been reported to be associated with stimulation of post synaptic α_2 adrenergic receptors in the lateral frontal cortex (Arnsten, A.F. Science 230:1273, 1985). In light of this, information on the anatomy and pharmacology of human frontal cortical α_2 receptors may contribute to our understanding of disease associated cognitive impairment such as seen in Dementia of the Alzheimer's type (DAT), a condition in which central adrenergic abnormalities have been documented. The purpose of the present study was to demonstrate the existence of α_2 adrenergic receptors in the frontal cortex of human postmortem brain specimens using in vitro autoradiography.

Unfixed frontal cortex material from Brodmann's Area 8 and 9 was obtained, cut and mounted on brass microtome chucks. Coronal cryostat sections of 16μ thickness were thaw mounted on subbed microscope slides and allowed to air dry at room temperature before being stored. [^{3}H]para-aminoclonidine (PAC, 40 Ci/mmol) was used to label α_2 adrenergic binding sites in the mounted tissue sections (Unnerstall, J.R. Brain Res. Rev. 319:69,1984). Briefly, sections were preincubated for 30 minutes at room temperature in Krebs-phosphate buffer (pH 7.4 at 25°C) containing 100μM Na+ -GTP. Adjacent sections were then washed for 10 minutes at room temperature in the incubation buffer alone (0.17 M Tris HCl, pH 7.6 at 25°C plus 10 mM $MgCl_2$). Sections were then incubated for 60 minutes at room temperature in buffer containing a range of PAC concentrations between 0.05 to 25 nM. Nonspecific binding was assessed utilizing the above ligand in the presence of 10^{-5} M phentolamine. After a 10 minute wash at 4°C in incubation buffer and a rinse in cold deionized water, the sections were dried under a stream of cool dry air. Labeled tissue was then apposed to tritium sensitive film which after exposure and development was scanned by a computer based image analysis system (Dumas, Drexel University). Radioactive plastic standards calibrated to tissue containing known amounts of radioactivity were used to generate standard curves for quantitation.

PAC binding was displaceable by phentolamine in the dorsolateral frontal cortex. Saturation data and photomicrographs of autoradiograms will be presented.

The present results provide evidence for the existence of α_2 adrenergic receptors in human frontal cortex analogous to those described in nonhuman primate brain. These data suggest that a comparison of α_2 receptor density in the frontal cortex of normal and DAT brain tissue is feasible.

156.8 BILATERAL CHANGES IN CORTICAL M1 AND M2 RECEPTORS FOLLOWING UNILATERAL LESIONS OF THE RAT NUCLEUS BASALIS OF MEYNERT: AN AUTORADIOGRAPHIC STUDY. J.R. Atack*, G.L. Wenk, M.V. Wagster, K.J. Kellar, P.J. Whitehouse and S.I. Rapoport (spon. A. Noronha). Lab. of Neuroscience, NIA, NIH, Bethesda; Dept. of Neuropathology, Johns Hopkins School of Medicine, Baltimore and Dept. of Pharmacology, Georgetown University School of Medicine, Washington DC.

In Alzheimer's disease, cortical nicotinic receptors have been reported to be reduced, but changes in cortical cholinergic receptors are equivocal (Whitehouse & Au, Prog. Neuro-Psychopharm. Biol. Psych. 1986:10;665). However, it is not clear to what extent these changes are related to a degeneration of the cortical cholinergic input from the nucleus of Meynert (NbM) per se. We have therefore examined cortical cholinergic receptors in male albino rats with unilateral lesions of the NbM.

Animals received unilateral ibotenic acid lesions of the left NbM and were sacrificed after either 1 week (n=12) or 13 weeks (n=6). Sham operated rats were used as controls and were sacrificed after 1 week (n=7). 2-3 mm thick coronal brain slices were prepared immediately anterior to the hippocampus and were subsequently sectioned at 10 um intervals for autoradiography. Cortical tissue anterior to this tissue was retained for choline acetyltransferase (ChAT) and protein assays. Muscarinic M1 and M2 receptors were visualised directly using 3H-pirenzepine and 3H-oxotremorine, respectively. High- and low-affinity N-methyl scopolamine (NMS) binding sites were defined as carbachol-sensitive and carbachol-insensitive NMS sites, respectively. Nicotine receptors were identified using 3H-acetylcholine.

One week after lesioning, ipsilateral ChAT activity had fallen significantly ($p<0.05$) to 49% of control values (mean ± SD = 14.7 ± 3.5 and 30.0 ± 8.1 nmol/hr/mg protein, respectively). By 13 weeks, ChAT activity (23.9 ± 4.0 nmol/hr/mg protein) had increased significantly ($p<0.05$) by 63% relative to 1 week lesioned animals. Contralateral ChAT activity was unchanged at both 1 and 13 weeks. M1 receptor binding was unchanged at 1 week relative to controls, but at 13 weeks had decreased significantly ($p<0.05$) in both the left and right hemispheres by 31% and 39%, respectively. On the other hand, M2 receptor binding increased significantly ($p<0.05$) at 1 week postlesion in both the left and right hemispheres (33% and 54% increase, respectively), but returned to normal levels by 13 weeks. There were no significant differences between groups with respect to either nicotinic or high- or low-affinity NMS binding.

Since none of the receptors changed in parallel with ChAT activity, these results suggest that none of the receptors studied are specific for presynaptic cholinergic nerve terminals. Furthermore, bilateral changes in M1 and M2 receptors indicate that there is intrahemispheric regulation of these binding sites.

156.9 TETRAHYDROAMINOACRIDINE BLOCKS POTASSIUM CHANNELS AND INHIBITS SODIUM INACTIVATION IN MYXICOLA. Charles L. Schauf and Albert Sattin. Department of Biology, Indiana University-Purdue University, Indianapolis and Department of Psychiatry Richard L. Roudebush V.A. Medical Center and the Indiana University School of Medicine, Indianapolis, Indiana 46223

Tetrahydroaminoacridine (1,2,3,4 tetrahydro-9-aminoacridine; Tacrine; THA) is a potent, centrally-active anticholinesterase that appears to relieve some of the symptoms of moderate-to-severe senile dementia of the Alzheimer type (Summers et al., New Engl. J. Med. 315: 1241, 1986). In voltage-clamped Myxicola giant axons internally and externally applied THA blocked K^+ channels with a K_D of 100 uM and slowed K^+ activation. Whereas external THA had no effect on the Na^+ conductance, internal THA initially slowed the rate of inactivation of conducting Na^+ channels, and then rendered inactivation biphasic, the initial phase being 2-3 times faster than in control axons. Internal THA decreased maximum inward Na^+ currents by 35-50% and induced a significant steady-state non-inactivating inward current accompanied by an increase in the amplitude and time constant of Na^+ tail currents. At negative potentials the effect of THA was small, but for positive voltages Na^+ tail currents were prolonged and developed an initial plateau. It appears that THA may occlude Na^+ channels by entering them and rendering THA-occluded channels resistant to fast inactivation, and also that THA cannot easily dissociate from open channels. The K_D for the effects of internal THA on the Na^+ conductance was 10 uM. Internal concentrations of THA as high as 100 uM did not alter the time- or voltage-dependence of Na^+ activation, behavior expected if the initial rapid decline in inward current was not due to Na^+ inactivation, but rather reflected blockade by THA. THA had no effect on prepulse-induced fast or slow inactivation. In contrast to THA, doses of physostigmine greatly in excess of those needed for maximal inhibition of cholinesterases have no effects on ionic currents in axons. The muscarinic acetylcholine receptor agonist RS86 was also tested and found to be ineffective up to concentrations of 1 mg/ml. Effects of THA on ion channels may account for CNS hyperexcitability seen in some patients treated with THA. Since THA is a potent anticholinesterase, ion channel effects may contribute to its putative anti-dementia action in clinical states involving a CNS deficiency of ACh by selective augmentation of ACh release and/or the negation of autoreceptor effects of endogeneous ACh. (Supported by NSF Grant BNS 86-96095 and National Multiple Sclerosis Society Grant 1911A4, and by the Veterans Administration Research Service.)

156.10 MUSCIMOL BINDING IN THE SUBSTANTIA NIGRA OF DAY 16 AND ADULT RATS. J.N.D. Wurpel*, A. Tempel, E.F. Sperber and S.L. Moshe. Departments of Neurology and Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461

Previous studies have shown that microinjections of muscimol (a GABA-A agonist) into the substantia nigra (SN) exert an anticonvulsant effect in adult rats, while similar injections are proconvulsant in 16 day old rat pups. We performed receptor binding studies in day 16 and adult rats in an effort to evaluate the receptor-dependent component of this difference of GABA pharmacology in the SN.

Adult (250-300g) and 16 day old (25-30g) rats were decapitated and the SN and cerebellum (CB) rapidly dissected and placed in ice cold saline. Crude membrane homogenates were prepared in 70 volumes of 50mM Tris-HCl then centrifuged twice at 48,000 x g, preincubated at 37 C for 45 minutes, and centrifuged again. Binding assays (^{3}H-muscimol; specific activity 17.5-30.8 Ci/mmol range 0.2-150 nM) were performed in triplicate. Protein concentrations were: 70-200 ug/tube for 16 day old pups; 100-200 ug/tube for adult rats. Results are from at least 3 separate experiments.

Computer assisted scatchard analysis revealed two affinity states present in SN and CB of day 16 and adult rats. In the cerebellum, there were no differences in the number of high ($B_{max}1$) and low ($B_{max}2$) affinity receptor sites (expressed as fmole/mg membrane protein).

In the SN, the B_{max} of the low affinity site was equivalent in both age groups. In contrast, the SN of 16 day old pups contained fewer high affinity receptor sites than the adult SN (13% adult values). The K_d's (nM) of the high (K_d1) and low (K_d2) affinity sites did not differ between 16 day old and adult rats.

(mean±SE)	Substantia nigra		Cerebellum	
	$B_{max}1$	$B_{max}2$	$B_{max}1$	$B_{max}2$
Pups	32.5±4.8	3168±511	247±45	2450±474
Adult	253±63	2433±120	300±76	3267±780

This SN specific difference in the number of high affinity receptors may be responsible for the age related effects of muscimol on seizures, accounting for the lack of an anticonvulsant effect in rat pups. (Supported by NIH Grant NS-20253 from NINCDS).

156.11 DIFFERENTIAL PATTERNS OF NEUROTRANSMITTER RECEPTOR MODIFICATIONS IN SENILE DEMENTIA AND PARKINSON'S DISEASE REVEALED BY AUTORADIOGRAPHY. R. Cortés[1,2], M.M. Dietl[2], M. Camps[2], E. Soriano[2], J. Zezula[2], A. Pazos[2], J.C. Reubi[1], A. Probst[1] and J.M. Palacios[2]. (SPON. E.S. Tolosa). [1]Dept. of Neuropathology, Inst. of Pathology, University of Basle, Switzerland, CH-4003. [2]Preclinical Research, Sandoz Ltd., Basle, Switzerland, CH-4002.

Receptor autoradiography was used to examine regional neurotransmitter receptor modifications in postmortem brain tissue from patients dying with senile dementia (SD) or Parkinson's disease (PD) in comparison with a control population. Receptors for amine (acetylcholine, dopamine, serotonin), aminoacid (GABA, glutamate) and peptide (neurotensin, substance P, somatostatin) neurotransmitters were examined. Losses of receptors were often associated with the loss of specific neuronal populations, e.g., neurotensin and somatostatin receptors decreased in the substantia nigra in PD and substance P receptors in the nucleus basalis in SD. However, dopamine (D_1 and D_2) and benzodiazepine receptors were unchanged in PD in the substantia nigra and basal ganglia, where animal experiments have localized these receptors to cell bodies and terminals of the nigrostriatal and striatonigral pathways. Several receptors were examined in the hippocampal formation in SD. Three patterns of receptor modification were observed: 1) Normal densities of receptors (i.e., muscarinic cholinergic, GABA/benzodiazepine and glutamate) in cases with numerous senile plaques and low or moderate neuronal loss in the CA1 field; 2) Marked losses of all neurotransmitter receptors in the CA1 accompanying a severe neuronal decrement (more than 50 %); 3) Generalized receptor losses (i.e. dopamine D_1, serotonin-1 and somatostatin) in the dentate gyrus, CA3 and CA1, apparently unrelated to the degree of neuronal loss. Receptor alterations were also found in regions distal to site of the neuropathological lesion, i.e. dopamine D_1 and somatostatin receptors were decreased in the putamen in SD, and benzodiazepine receptors were increased in the cerebellum in PD. These results illustrate that different patterns of receptor plasticity operate in neurodegenerative diseases in the human brain, and that animal models do not always reflect the changes occurring in human brain disease.

156.12 PRE- AND POSTSYNAPTIC STRIATAL DOPAMINE NEUROTRANSMISSION IN MPTP-TREATED PRIMATES. J.R. Barrio*, S.C. Huang*, J.S. Schneider*, J.M. Hoffman*, A. Luxen*, N. Satyamurthy*, M. Bahn*, R.E. Keen*, C. Nissenson*, J.C. Mazziotta, and M.E. Phelps. UCLA School of Medicine, Los Angeles, CA 90024.

1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) induces Parkinson-like symptoms in primates by damage to the nigro-striatal dopaminergic system. Nemistrina monkeys (n = 3) (3-5 Kg) injected with MPTP (IV, 0.25 mg/Kg, in 5 doses administered over a three week period) were subjected to serial PET scans after IV administration of 6-[F-18]fluoro-L-DOPA (FD) (IV, 5-10 mCi, specific activity: 5 Ci/mmol). Tomographic tissue-time activity curves of caudate (CA), cerebellum (CB) and temporal cortex (TC) and their ratios (CA/CB and CA/TC) were analyzed. No significant differences were observed in MPTP-pretreated, asymptomatic animals compared with controls (n = 6, CA/CB = 2.2 ± 0.6 and CA/TC = 1.6 ± 0.2, 3 h). However, animals with severe motor deficits showed no time-dependent accumulation of radioactivity in CA (CA/CB = 1.0). This is consistent with post-mortem striatal biochemical analysis (98%, 97% and 99% decrease in dopamine, DOPAC and HVA, respectively) and histological data (90% cell loss in the substantia nigra pars compacta). Postsynaptic function was evaluated in vivo with 3-(2'-[F-18]fluoroethyl) spiperone (FESP) and PET using a double-injection procedure. Controls (n = 6) and MPTP-treated symptomatic monkeys (n = 2) were injected with FESP, (bolus injection, IV, 4-6 mCi), first with a high specific activity (0.2 - 10 Ci/μmole) followed by a lower specific activity (20-40 Ci/mmole) 90 min later. The difference in the striatum kinetics between the two injections is dependent on the specific activity of the radioligand and on the dopamine-D2 receptor density (Bmax) in the striatum. Using this procedure no significant difference in the estimated Bmax (24.3 ± 12.0 pmole/g) was found between the MPTP-treated (symptomatic) and the normal control animals. Consistent with this observation in vivo, in one symptomatic animal, in vitro 3H-spiperone binding showed a receptor (dopamine-D2) density (Bmax) of 21.2 pmol/g tissue and a normal KD value of 35 pM. These results suggest that FD is useful for selectively assessing presynaptic neuronal degeneration caused by MPTP, also known to occur in Parkinson's disease. The preservation of dopamine postsynaptic receptor integrity in these studies is also in agreement with the symptomatic improvement observed after administration of L-DOPA in MPTP-injected primates and Parkinson's patients.

156.13 DOPAMINE D_1 AND D_2 RECEPTORS AND DYSKINESIA IN PARKINSONIAN MPTP-TREATED MONKEYS. P.J. Bédard, R. Boucher, P. Falardeau and T. DiPaolo. Lab. Neurobiologie, Hôp. Enfant-Jésus and Dept Molecular Endocrinology, Laval Univ Research Center and Laval University, Qué. Canada, G1J 1Z4.

Twelve monkeys were rendered severely parkinsonian by 1 methyl-4-phenyl, 1, 2, 3, 6 tetrahydropyridine 0.3-1.5 mg/kg administered intravenously. They were then divided into four groups. The first received no further treatment except supportive care. The other three groups were treated respectively with L-DOPA/carbidopa 50 mg/kg, (mixed D_1D_2 agonist) bromocriptine 5 mg/kg (D_2 agonist) and SKF 38393 5 mg/kg (D_1 agonist). The drugs were given once a day orally for one month. L-DOPA/carbidopa and bromocriptine treatment relieved the parkinsonian symptoms while SKF 38393 was ineffective. No dyskinesia was seen in monkeys on bromocriptine or SKF 38393 as opposed to the L-DOPA treated animals where the dyskinetic response appeared to increase with time. The animals were sacrificed three days after their last dose with an overdose of pentobarbital. MPTP alone induced a significant increase (25% p 0.01) in the number of [^{3}H]spiperone binding sites (Bmax) in the caudate nucleus and in the putamen. The Bmax of spiperone binding in the L-DOPA treated monkeys was on average 18% lower (p 0.01) than in the animals treated with MPTP alone. Bmax for the bromocriptine-treated group was 29% (p 0.01) less than in the MPTP-treated group or 11% (p 0.05) less than in the L-DOPA-treated monkeys. The SKF 38393 treatment induced a decrease of Bmax of 23% (p 0.01) as compared to animals treated with MPTP alone and no significant change compared to the L-DOPA or bromocriptine-treated animals. Thus D_1 receptor stimulation causes no behavioral effect but can affect the D_2 receptors. These changes could in turn be related to the incidence of L-DOPA induced dyskinesia. Supported by MRC of Canada, the Parkinson Foundation of Canada and Sandoz Canada.

156.14 ALTERATIONS IN REGIONAL NEUROPEPTIDE CONCENTRATION IN MPTP-TREATED MICE. B. Levant, G. Bissette, Y.-M. Parker* and C. B. Nemeroff. Laboratory of Psychoneuroendocrinology. Duke University Medical Center, Durham, NC 27710

The neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), causes destruction of nigrostriatal dopamine (DA) neurons and subsequent symptoms resembling Parkinson's disease (PD) in humans and subhuman primates. The MPTP-treated mouse has recently been proposed as an animal model of PD (Heikkila et al., 1984, Science, 224:1451-1453). Regional alterations in a variety of neuropeptides have been reported in human patients with idiopathic PD (Bissette et al., 1985, Ann. Neurol., 17:324-328; Agid and Javoy-Agid, 1985, TINS., 8:30-35). One goal of these studies was to examine neuropeptide alterations in this murine model of PD. Adult (8 week old), male, Swiss-Webster mice were injected daily with MPTP (30 mg/kg, IP) for 5 consecutive days. The mice were killed on day 10, the brains rapidly removed, frozen and dissected into 12 discrete regions. Brain regions were extracted and assayed for neuropeptide concentration by sensitive and specific radioimmunoassays previously described in detail. When compared to controls, the concentration of NT was decreased in the frontal cortex ($p<0.01$), caudate ($p<0.01$), and preoptic area ($p<0.02$) of the MPTP-treated animals. An increase in BOM concentration was found in the amygdala ($P<0.04$) whereas a decrease in the concentration of this peptide was observed in the preoptic area ($P<0.05$) of the MPTP-treated animals. Degeneration of nigrostriatal neurons was verified by reversed-phase HPLC assay of caudate•samples for DA, DOPAC, HVA, 5-HT and 5-HIAA. Caudate DA, DOPAC and HVA concentrations were decreased to 12% ($P<<0.01$), 28% ($P<<0.01$), and 42% ($P<0.01$) of control respectively. A decrease in 5-HT concentration to 69% of control ($P<0.02$) was found while 5-HIAA exhibited a nonsignificant increase to 118% of control, indicating a slight increase in 5-HT turnover. Although substantial depletion of striatal DA was observed in the MPTP-treated mice, the brain regions exhibiting changes in neuropeptide concentration differed substantially from those demonstrated in human IPD. The MPTP-treated mouse would therefore appear not to be a satisfactory model of human PD with respect to neuropeptide changes. The effects of MPTP on regional neuropeptide concentrations in aged mice should be investigated.

158 SYMPOSIUM. THE ROLE OF NECTINS (CELL BINDING MOLECULES IN NEURAL DEVELOPMENT. L. Glaser, Univ. of Miami (Chairperson); E. Ruoslahti*, La Jolla Cancer Research Foundation; A.F. Horwitz*, Univ. of Pennsylvania School of Medicine; S.R. Hoffman, Rockefeller Univ.; R. Bunge, Washington Univ. School of Medicine; N. Ratner*, Washington Univ. School of Medicine.

The session will focus on the molecular bases by which cells recognize and respond to molecules in the extracellular matrix, with particular emphasis on cells in the nervous system. The symposium will start with a discussion of well characterized molecules involved in cell extracellular matrix interactions and proceed to the description of specific biological phenomena which require these interactions. The structural basis for cellular recognition of matrix proteins such as fibronectin and collagen will be described by Erkki Ruoslahti, (La Jolla Cancer Research Foundation) and the characterization of the cellular receptors for fibronectin and laminin will be summarized by A.F. Horowitz, (University of Pennsylvania School of Medicine). Cytotactin a recently discovered cell adhesion molecule involved in neuron glia interaction has been studied in detail by S.R. Hoffman, (Rockefeller University), who will summarize his observations in this system. One of the most complex and also best understood systems in which cells interact with the extracellular matrix as part of this cell differentiation process, is the interaction of Schwann cells and neurons with the basal lamina that they generate. The role of basal lamina in axon ensheathment and myelination will be discussed by R. Bunge, (Washington University School of Medicine), who has pioneered work in this field. The mitogenic response of Schwann cells to neurons depends on the presence of proteoglycans in the neuronal cell surface. The purification of a neuronally derived Schwann cell mitogen and its relationship to cell surface proteoglycans will be discussed by Nancy Ratner, (Washington University School of Medicine).

159 SYMPOSIUM. STRUCTURAL COMPUTER SIMULATIONS IN DEVELOPMENTAL AND SYSTEMS NEUROBIOLOGY. J. M. Bower, Caltech (chairperson); S. Fraser, Univ. Calif. Irvine; R. Linsker, IBM Watson Research Labs; L. Finkel*, Rockefeller University; C. Koch, Caltech; R. Traub, IBM Watson Research Labs.

This symposium will consist of a series of talks which demonstrate the use of structural simulations in studying the development and functional organization of complex neural networks. These computer models are based on the real anatomical and physiological properties of the part of the brain being studied. As such, modeling results are often directly related to experimentally addressable questions, a point which will be brought out in each of the presentations.

Scott Fraser will present his recently developed single axon-based model simulating the development of the retinotectal projections in frogs. Predictions of the model will be contrasted with recent experimental results. **Ralph Linsker** will describe his network-based hierarchical developmental model of the mammalian visual system (retina to cortex). The receptive field organizations of the simulated neurons that emerge from the model will be compared to known receptive field properties at different levels of visual processing. **Leif Finkel** has been exploring the dynamic interactions in topographic maps of cerebral cortex and the possible structural mechanisms underlying their reorganization following experimentally induced changes in peripheral stimulation. **Christof Koch** will describe his recent work modeling the electrical properties of single vertebrate neurons and modeling calcium dynamics in postsynaptic structures (spines and soma) following repetitive synaptic input. **Roger Traub** will present his model of hippocampus with which he has explored network mechanisms underlying epileptic and nonepileptic activity. **James Bower** will describe a structural simulation of piriform (olfactory) cortex which suggests the network properties underlying the rhythmic patterns of activity seen during olfactory discrimination and the possible consequences of this activity for olfactory processing.

160.1 RETINAL TRANSPLANTS IN PHOTOTOXIC RETINOPATHY. M. del Cerro, M. F. Notter, L. Qi Jiang, D. A. Grover, and C. del Cerro. Univ. of Rochester Sch. of Med., Rochester, NY 14642.

We have found (del Cerro et al., 84, 85, 86) that the developing retina can be successfully transplanted into normal adult eyes. Based on these results we examined the feasibility of transplanting neuroretinal cells into retinas that have late-stage phototoxic retinopathy. For this purpose adult albino Lewis rats that had been continuously exposed to fluorescent light illumination for three weeks served as hosts. The donors were 1-2 day old rats from either Lewis or Long-Evans strains. The transplants were placed in one eye, leaving the contralateral eye as a control. The trasnplanted material consisted of a strip of neural retina, or a 2 µl suspension of neural retinal cells. The transplants were labelled with 3H-thymidine, Fast Blue, or both. Survival time ranged from 10 to 30 days.

Fundus examination of control eyes showed palor caused by a considerable reduction of the retino-choroidal vascular bed after light irradiation. Host eyes showed the growth of the transplant and focal rearengement of vascularity. Histologically the irradiated eyes showed massive destruction of the outer retinal layers; no outer nuclear layer was present in the central or mid -peripheral retina, and only one or two discontinuous rows of rod cells was visible in the periphery. The transplants appeared as masses of retinal tissue, rich in photoreceptors cells, with their inner and outer segments growing on the host retina. Physical continuity, and common vascularization, existed between transplants and hosts. The results show that it is feasible to repopulate neuroretinal cells in the extensively damaged adult eye. The functional significance of this finding are being explored.

Supported by NEI grant 05262 and by the Rochester Eye Bank.

160.2 SCHWANN CELL MYELINATION IN DAMAGED RETINA: ENHANCEMENT WITH PERIPHERAL NERVE IMPLANTS. M. R. Wells and U. Vaidya. Neurochemistry Research Laboratory, Veterans Administration Hospital and Dept. of Physiology, George Washington University, Washington, D.C. 20422.

Schwann cells have been shown to myelinate retinal axons after retinal lesions made through the sclera in neonatal animals and to a very limited exent in adults (Perry and Hayes, J. Neurocytol. 14: 297-307; 1985). The present study examined the potential of implanted Schwann cells to enhance the myelination retinal axons in damaged retina of juvenile and adult rats.

Either adult, male Wistar rats (approx. 250 g body wt.) or 5 day old animals of both sexes were used for experiments. In both groups, retinal lesions were made throurgh the sclera near the optic disc. In half of all animals, a small piece (1.5 mm) of sciatic nerve (autograft) was removed and inserted into the lesion. A 30 day survival was allowed for all groups. Retinas were examined either as whole mounts or in 1 u sections of plastic embedded material.

Adult animals receiving only retinal lesions had little or no myelination of retinal axons. As observed previously (Perry and Hayes 1985), young animals had much more myelination by Schwann cells after similar lesions. In implanted animals, myelination was variable, but much greater in adult animals compared to lesioned, unimplanted adults. Any increased myelination in young animals produced by the implant was obscured by a large variation. The myelination of retinal axons differed qualitatively between young and adult animals. In young animals, myelination was more diffuse and not limited to areas near the site of implantation. In adult animals, myelination of retinal axons appeared to occur adjacent to blood vessels and in areas disturbed by the process of lesioning and implantation.

The results suggest that implants of peripheral nerve into the the retina of adult rats enhances the myelination of retinal axons by Schwann cells in areas directly or indirectly injured by the lesion. In the developing retina of young animals, Schwann cell migration and myelination may be greater due to the incomplete formation of glial processes. As suggested in other studies (Blakemore et al., Acta Neuropathol. 71: 295-300; 1986), astrocytic processes may limit the extent of Schwann cell migration and myelination in retina. The migration and association of Schwann cells with unmyelinated or demyelinated axons in injured areas of CNS may be an important factor in the regeration of axons into peripheral nerve bridges.

160.3 RECONSTRUCTION OF THE DAMAGED SEPTOHIPPOCAMPAL CIRCUITRY BY A COMBINATION OF FETAL GRAFTS AND TRANSIENT NGF INFUSION. G. Buzsáki, R.G. Bickford, S. Varon, D.M. Armstrong and F.H. Gage. Univ. of California, San Diego, Sch. of Med., Neuroscience Dept., M-024, La Jolla CA 92093.

The fimbria-fornix (FF) and the overlying neocortex were removed unilaterally by aspiration in 64 rats. Half of them received intraventricular infusion of nerve growth factor (NGF) for two weeks. In half of the NGF-treated rats and half of the untreated rats, fetal hippocampal grafts (TPL, E16) were placed in the lesion cavity. All rats were equipped with recording microelectrodes from 4 to 5 months after the initial surgery. EEG and unit activity were monitored during running in a wheel, drinking and immobility.

The number of surviving cells in the medial septum increased in the FF only < TPL < NGF < NGF+TPL groups order. Cell savings in the TPL group was observed only in rats in which the transplant fused with the host septum. Reinnervation of the host hippocampus, as assessed by the density of acetylcholinesterase (AChE)-staining, was most complete in group NGF+TPL extending from the dentate gyrus to CA1-CA3 fields, and the extent of reinnervation decreased from TPL > NGF > FF groups. AChE-positive reinnervation never exceeded the posterior curvature of the hippocampus, however. Depth profiles of EEG revealed a positive correlation between the power of rhythmic slow activity (theta) and the density of AChE- positive reinnervation. The best restoration of theta was observed in group NGF+TPL. Similar to normal rats, theta was present only during waking and absent during drinking and sitting still. Granule cells and interneurons discharged rhythmically during running, and the spikes were phase-locked to theta waves recorded from the contralateral (intact) hippocampus. Large amplitude theta waves were also present in rats with relatively few surviving neurons in the medial septum. Sharp waves (SPW, up to 4mV) were present in all groups during immobility and drinking. In groups FF, TPL and NGF and in some rats of group NGF+TPL SPWs and concurrent population bursts of neurons were observed also during walking and running. In TPL rats strong single pulse stimulation of the perforant path induced epileptic discharges in the host hippocampus.

These findings suggest that the combination of NGF treatment and fetal grafting saves the majority of septal area cells, results in a more complete reinnervation of the host hippocampus and consequently better physiological recovery. They also suggest that theta may be produced by a relatively small group of surviving "pacemaker" cells.

160.4 **ALTERATIONS IN BLOOD-BRAIN BARRIER BY ADRENAL MEDULLARY TRANSPLANTS IN CNS PAIN MODULATORY REGIONS.** J. Sagen and G. D. Pappas, Dept. of Anatomy, Univ. of Illinois at Chicago, Chicago, IL 60612.

We have been concerned with the changes in pain sensitivity brought about by the transplantation of adrenal medullary tissue into the pain modulatory regions of the periaqueductal gray (PAG) and spinal cord subarachnoid space. It has been shown that the blood-brain barrier may be altered by the transplantation of peripheral neural tissue into the CNS. The intravascular injection of the protein tracer HRP indicates that such transplants retain their *in situ* permeability to macromolecules and allow some substances that normally do not pass the blood-brain barrier (BBB) to enter brain parenchyma. We were interested in the pharmacological relevance of these alterations in BBB. Chromaffin cells transplanted into the PAG or spinal cord produce analgesia when stimulated by nicotine, presumably by inducing release of catecholamines and opioid peptides from chromaffin cell granules. To assess pharmacological changes in BBB, rats with adrenal medullary implants were pretreated with either mecamylamine, a ganglionic antagonist with which normally passes the BBB, hexamethonium, a ganglionic blocker that normally does not pass the BBB, or saline vehicle. In saline pretreated animals, nicotine induced potent analgesia. This analgesia was completely blocked by mecamylamine, but was minimally affected by hexamethonium. Results of this study indicate that, although permeability to proteins may be altered by the transplantation of peripheral neural tissues to the CNS, the BBB to charged molecules may not be altered. Preliminary studies using D-ala-met-enkephalinamide (DALA), a long lasting opioid peptide derivative with limited ability to pass the BBB, indicate that adrenal medullary transplants improve penetration of peptides into the CNS, since systemic injections of low doses of DALA induced analgesia in implanted, but not control animals. Thus, transplants of peripheral neuronal tissue apparently allow some, but not all substances to bypass the BBB. Supported, in part, by NIH grant NS-07630.

160.5 ORIGINS OF VASCULATURE WITHIN FETAL CNS TISSUE TRANSPLANTED TO THE BRAIN. J.M. Krum and J.M. Rosenstein. Dept. of Anatomy, George Washington Univ. Sch. of Med., Wash. D.C. 20037

Pieces of fetal cerebral cortex transplanted to the brain grow rapidly and develop a vascular network throughout their substance. We examined the mechanism of vascular integration within these transplants (taken from E18-E21 donors) which were placed within the fourth ventricle of 10 - 15 day old Wistar rats.

DNA synthesis within endothelial cells served as an index of capillary growth. Tritiated thymidine was administered to recipient animals to determine angiogenic patterns at various postoperative time periods ranging from one day to one month. After processing for light microscopic autoradiography, host and graft endothelial labelling indices were determined in order to establish the temporal sequence and location of vascular proliferation. The vascular ultrastructure within each transplant was also examined. Some recipients were pre-labelled with ^{3}H thymidine prior to transplantation to determine if host vessels invaded the grafts; conversely, some transplants were pre-labelled in utero to determine if their vascular anlage survived.

After 24 hours, the majority of vessels present within the grafts appeared to be adjacent, mature host pial vessels with associated collagen and fibroblasts, which had been surrounded by the fetal cells. By 72 hours, small diameter vessels were proliferating rapidly within the transplants; ultrastructurally, these appeared to be a mixture of both pial and embryonic vasculature. The now completely engulfed host vessels were also heavily labelled at this time. One week old transplants contained a complex microvascular network which continued to proliferate, although at a lesser rate, while the incorporated host vasculature was quiescent. After one month, both vascular components had ceased to proliferate.

Pre-labelled transplants contained labelled vasculature even after one week, indicating that fetal CNS vessels survive grafting and presumably continue to grow. Transplants within pre-labelled recipients contained labelled, mature pial vessels at their margins as well as smaller labelled vessels located more deeply within the grafts. These results suggest that the vasculature which develops within intraventricular CNS transplants is chimeric, consisting of intrinsic fetal vessels which anastomose with capillary sprouts originating from passively incorporated pial vessels. Preliminary studies indicate that intraparenchymal CNS grafts develop a similar vascular composition, consisting of both fetal vascular anlage and host cerebral vessels. The nature of graft vascularization, particularly at brain surfaces where non-neural tissue can be incorporated, may play a role in barrier permeability at these transplantation sites.
(Supported by NS-17468).

160.6 BIODEGRADABLE POLY (DL-LACTIDE-CO-GLYCOLIDE) MICROCAPSULES FOR CONTROLLED RELEASE OF CATECHOLAMINES : A NOVEL DELIVERY SYSTEM TO THE CNS. A.McRae-Degueurce, D.L. Dillion*,R.M.Gilley*& T.R. Tice* U-259 Univ. of Goteborg Goteborg, Sweden & Southern Research Institute Birmingham, Al 35255

Injectable controlled release peptide,antibiotic and steroid delivery systems have been developed in which these substances were encapsulated within biodegradable Poly (DL-lactide-co-glycolide)s. The microcapsules serve 2 functions: first, they protect substances from degradation ;second, they release substances at a controlled rate at therapeutic doses in a target site for desired time periods _ up to months. In view of the success and advantages of this system it appeared of interest to apply this technology to the CNS as a means to deliver agents which do not cross the blood brain barrier or are rapidly degraded. In the present investigation L-DOPA or dopamine were encapsulated in biocompatible biodegradable Poly (DL-lactide-co-glycolide). The capsules range in size from 10-30µm in diameter.Rats received bilateral injections of 6-OHDA in the medial forebrain bundle. Following recuperation from the lesions the animals received a unilateral injection of the capsules (suspended in 2µl of saline) in the striatum. Rodents were perfused with 4% paraformaldehyde either 24 or 48 hours after receiving the capsules The brains were processed for immunocytochemistry with a tyrosine hydroxylase antibody. The results demonstrated intense fluorescence in the region where the capsules had been implanted. The contralateral striatum was devoid of fluorescence. Because, the injectable capsules appear to be ideal to deliver controlled release of drugs or other substances to specific brain regions this technology has considerable potential for both clinical and basic research.

160.7 INCREASED HYPOTHALAMIC CATECHOLAMINE CONCENTRATIONS AND DECREASED PROLACTIN LEVELS BY FETAL HYPOTHALAMIC TRANSPLANT IN IMPOTENT AGED MALE RATS. H.H. Huang*, J.Q. Kissane*, and E.J. Hawrylewicz. Department of Research, Mercy Hospital and Medical Center, Chicago, IL 60616.

We and others have reported that aged rats showed an elevated level of prolactin and a reduced level of gonadotropins, which in turn, caused a decrease in reproductive function. This can be due in part to the decreased catecholamine and GnRH activities in the hypothalamus of aged rats. Recently we have found that sexuality and fertility can be enhanced by fetal hypothalamic transplant in aged male rats. The present study was designed to investigate whether the restoration of reproductive function in impotent aged male rats by fetal hypothalamic transplant was through the increase of hypothalamic catecholamines and reduction of prolactin release. Eighteen to 20 month old impotent male rats received an anterior hypothalamus removed from a 17-19 day old male fetus and placed into the third cerebral ventricle, just anterior dorsal to the median eminence. Controls were either without surgery or grafted with cerebral cortical tissue. Just before and 3 months after transplantation, blood samples were collected from the aged males for prolactin measurement. Before and one to two months after transplantation, each grafted rat or control animal was put overnight into a cage which contained four young proestrous female rats. Vaginal smear of each female was monitored early the next morning. Sperm seen in the vaginal smear was regarded as copulation and ejaculation. The test was repeated twice. Finally, the animals were terminated and brains were removed and frozen with dry ice for catecholamine determination. Seven of 10 hypothalamus-grafted males (HG) restored their sexuality. None of 7 untreated controls (UC) changed their reproductive function and only one of 4 cerebral cortex grafted males (CG) copulated with one female. Serum prolactin in the HG rats which showed restoration of reproductive function were significantly lower than those of controls (112.7 ± 13.0 vs. 237.5 ± 40.9 (UC), 246.7 ± 25.5ng/ml (CG), $p < 0.02$). However, the concentrations of norepinephrine (NE) and dopamine (DA) in the median eminence (ME) and arcuate nuclei (ARC) of the HG rat's hypothalamus were significantly higher than those of UC and CG controls (91.3 ± 10.6 vs. 57.3 ± 9.7, 62.5 ± 12.0 ng NE/mg protein in the ME $p<0.05$; 71.3 ± 14.5 vs. 29.9 ± 4.5 ng NE/mg protein in ARC $p < 0.05$; 77.7 vs. 31.4 ± 9.4, 28.0 ± 5.2 ng DA/mg protein in the ME $p < 0.05$; 15.3 vs. 6.2 ± 0.9, 7.2 ± 0.3 ng DA/mg protein in ARC $p < 0.05$). Catecholamines and prolactin in HG rats which did not respond to the transplantation were not significantly different from the controls. These results indicate that the fetal hypothalamic grafts can survive and differentiate in the brain of impotent aged male rats and rejuvenate the neuroendocrine and reproductive function in senescent rats. (Supported by NIH Grant AG-04351-01).

160.8 MICROVASCULAR CORRELATES OF NEURAL GRAFTING IN THE ENDOCRINE HYPOTHALAMUS OF THE BRATTLEBORO RAT. D.E. Scott, Department of Anatomy and Cell Biology, Eastern Virginia Medical School, Norfolk, VA 23501

This investigation has focused upon the neurovascular criteria that characterize neural grafting followed by changes in urine osmolarity and water consumption in Brattleboro host rats with Diabetes inspidus (DI). Male DI host rats were housed in metabolic cages for one week prior to surgery in order to determine water consumption and urine concentration values. Fragments of anterior hypothalamus were garnered from 17 day post-coitus fetal rats, minced in Eagle's Solution and stereotaxically introduced (with an 18 GA spinal needle) into the third cerebral ventricle of DI host rats. Rats were killed at various times post-surgery and prepared for routine microangiography, transmission electron microscopy and immunocytochemistry following techniques described previously. In all host rats that exhibited alterations in their physiological parameters of water consumption and urine concentration, several consistant morphological criteria were evident. Unfenestrated endothelia with distinct basal laminae were not restricted to the ventral regions of grafts but were commonly observed throughout all regions. Viable grafts commonly exhibited fenestrated capillary endothelia and distinct perivascular spaces. These were observed chiefly at the base of grafts in neuroanatomical continuity with the host median eminence. Magnocellular neurites with neurosecretory (peptidergic) inclusions were in contact with both fenestrated and unfenestrated capillaries of the graft. Viable grafts derived their blood supply from the entire periventricular stratum as well as the underlying host median eminence. It would appear that the distalward growth of vessels into graft parenchyma involves the fusion of endothelial primorida with different phenotypic characteristics. Magnocellular nerve cell bodies were observed on the surface of grafts and in the living state were in direct contact with host cerebrospinal fluid. Alternative routes for the neuroendocrine transduction and the central delivery of neuropeptide hormones into host vasculature are discussed. Supported by EVMF program grant.

160.9 **THE OUTGROWTH AND DISTRIBUTION OF PROCESSES FROM NEOCORTICAL GRAFTS TRANSPLANTED INTO THE CORTEX OF ADULT HOSTS.** J.A. Zaslow*, L.M. Smith and F.F. Ebner, Center for Neural Science, Brown University, Providence, R.I.

The purpose of these experiments was to study outgrowth from embryonic neocortical tissue transplanted into adult hosts using the cell surface antigen Thy-1.1 as a marker to identify donor tissue in the host brain. The Thy-1 antigen is a glycoprotein which exists in two distinct allelic forms known as Thy-1.1 and Thy-1.2.

Cortical cells were removed from E-14 mouse embryos that express the Thy-1.1 allele. The cells were prepared in two ways for implantation into adult Thy-1.2 host cortex: donor tissue was either left intact as rectangular solids of cortical neuroblasts and radial glia or they were dissociated into individual cell suspensions. The intact embryonic cortex was implanted without further manipulation. The cell suspensions were prepared by mechanical dissociation in 0.5% trypsin before being centrifuged, washed, and injected into the host cortex. The dissociation procedure removes any processes from the developing neurons and strips the radial glia of their long supportive processes leaving only round cell bodies in the injection suspension.

The OX-7 Thy-1.1 monoclonal antibody (Serotec) does not immunolabel any cells or processes in the Thy-1.2 host cortex. The transplanted cells and processes stand out clearly against the negative host cortex as a spherical dense area surrounded by a lighter haze of immunoreactivity. Examination of the host brain immediately surrounding the transplants shows numerous immunoreactive processes and some glial cells outside of the transplant. In addition, patches of immunoreactive processes are seen in the corpus callosum between the transplant and the midline, in the underlying white matter and, in a small number of cases, in the internal capsule. Many fewer processes were observed around the cell suspension transplants than around the chunk transplants. This stands in contrast to the apparently greater innervation of the cell suspensions by the host brain specific thalamic fibers (Erzurumlu and Ebner, Neurosci. Abs., 1986). We are examining the ultrastructure of the processes around the transplants to determine whether they make synaptic contacts with host neurons in the neuropil surrounding the transplants.

Clearly labeled Thy-1.1 positive astrocytes were found outside the transplant in the corpus callosum, in the underlying white matter, and in the internal capsule. Thy-1.1 labeled neurons are seen outside the transplant, but always near the host/transplant border. These results support the hypothesis that the intact glial cells of the chunk transplants remain functional and may provide an environment which enhances the outgrowth of graft cell neurites.

(Supported by NIH grant #13031).

160.10 **CAUDAL VERSUS ROSTRAL REGIONS OF EMBRYONIC RAT RHOMBENCEPHALON: FLOW CYTOMETRY, CELL CULTURE, IMMUNOCYTOCHEMISTRY, AND TRANSPLANTATION.** N. König*, H. Mansour*, MJ. Drian*, F. Sandillon*, F. Favier*, L. Marlier* and A. Privat* (SPON: European Neuroscience Association). Lab. de Neurophysiol., USTL, 34060 Montpellier Cedex, France (NK); INSERM 249 / CNRS 8402, Montpellier (HM, MJD, FS, LM and AP) and Service Comm. Cytométrie de Flux CNRS, Montpellier (FF)

The rhombencephalon is a major source of monoaminergic afferences to almost every region of the developing central nervous system. The present study aimed at comparing the cell populations situated between the pontine flexure and the onset of the spinal cord (caudal part) to those situated between the rhombencephalic isthmus and the pontine flexure (rostral part). The rationale for this subdivision was that descending monoaminergic fibre systems originate mainly in the caudal part, whereas ascending fibres originate in the rostral part. Embryos were obtained by laparotomy from anaesthetized rats (gestation days 13 and 14). Rhombencephala were dissected out and divided into caudal (C) and rostral (R) parts. Dissociated cell populations were fractionated by sedimentation in calcium and magnesium free (Puck's) saline. Then, they were either analyzed by flow cytometry (forward- and right-angle scatter) or plated for cell culture. Cells expressing serotonin, thyrosine hydroxylase, or dopamine, were detected by immunocytochemistry. Cell suspensions of C or R rhombencephalon were transplanted into the transected spinal cord of adult rats, and the survival and growth of serotonin expressing neurons were monitored by immunocytochemistry. The principal results were as follows: Compared with R cells, C cells had higher sedimentation velocities, and the C populations contained a higher percentage of cells with low right-angle and high forward-angle scatter values. These differences might be linked to the developmental advance of C cell populations. In cell culture, the C populations established a strikingly reticulated neurite pattern, in contrast with the more diffuse pattern of the R cells. Both populations contained serotonin, tyrosine hydroxylase, and dopamine immunoreactive cells; however, the relative percentages of these subpopulations were different and depended upon the age of the embryos. When transplanted into the transected spinal cord of adult rats, both C and R serotonin expressing cells survived and growed well; however, the innervation pattern was different (the C cells seemed to innervate preferentially the dorsal horns). Behavioural analyses will have to show if these different innervation patterns correspond to distinct functional properties.

GABA AND BENZODIAZEPINE: PHARMACOLOGY I

161.1 SPONTANEOUS BICUCULLINE SENSITIVE SINGLE CHANNEL CURRENTS IN OUTSIDE OUT MEMBRANE PATCHES OBTAINED FROM MOUSE SPINAL CORD NEURONS. D.A. Mathers* (SPON: J.A. Pearson). Dept. of Physiology, Univ. of British Columbia, Vancouver, B.C., Canada.

The application of γ-aminobutyric acid (GABA) to outside-out patches obtained from cultured mouse spinal cord (SC) neurons triggers the opening of ionic channels permeable to chloride ions. However, even in the absence of exogenously applied GABA, spontaneous, chloride dependent single channel currents are seen in many of these patches (Hamill et al., Nature 305:805, 1983). The present experiments were aimed at clarifying the nature of these events.

Primary dissociated cultures of SC neurons were obtained from embryos of C57BL mice at day 13 of gestation. Cultures were maintained in Minimum Essential Medium with 10% horse serum for 2-3 weeks prior to use. Patch clamp recordings were made in the outside-out patch configuration using a List EPC-5 amplifier. The external membrane face was bathed in a solution of composition (mM): Tris Cl 137, KCl 4, $CaCl_2$ 1, $MgCl_2$ 1, Hepes 10, pH = 7.4. The inner membrane face was exposed to a solution containing Tris Cl 140, KCl 3, $MgCl_2$ 1, EGTA 11, Hepes 10, pH = 7.4. Replacement by $Tris^+$ of the bulk of Na^+ and K^+ ions blocked current flow in cation permeable channels in these patches. Drugs were applied to the external membrane face by bath perfusion. Membrane patches were voltage-clamped to a potential of -60 mV at 20-22°C.

The frequency of spontaneous single channel currents varied widely from patch to patch. In some cases no events were detected, while in others channel openings occurred at a frequency of up to 40 Hz. Open time distributions for these events were well fit by the sum of two exponential terms with mean parameters as follows: fast time constant, τ_f = 0.38 ± 0.04 ms (mean ± S.E.M.), slow time constant, τ_s = 2.8 ± 0.57 ms. The mean ratio of the number of events present in the fast and slow fit components was 46 ± 20.5. These spontaneous events were blocked by application of the specific GABA antagonist bicuculline methiodide (2-10 μM) to the external membrane face. In patches where a high frequency of spontaneous single channel current was seen, application of 5 μm GABA resulted in a wave-like response, while in patches with little spontaneous activity, a smoother, monophasic response to GABA was seen. These observations suggest that the spontaneous events seen in some SC cell membrane patches reflect the activity of GABA sensitive channels.

161.2 POTENTIATION AND ANTAGONISM OF ADENOSINE-EVOKED DEPRESSION OF RAT CEREBRAL CORTICAL NEURONAL FIRING BY Ro 15-1788 AND Ro 5-4864. R.E. Stair*, M.H. O'Regan* and J.W. Phillis. Dept. of Physiol., Wayne State Univ. Sch. of Med., Detroit, MI 48201.

The mechanism of action of the benzodiazepines has long been a matter of interest to the scientific community. In addition to the general consensus that GABA plays a major role, there has been evidence suggesting that inhibition of adenosine uptake may be involved in benzodiazepine effects. Ro 15-1788 and Ro 5-4864 are benzodiazepine receptor ligands which have been reported to have mixed agonist/antagonist properties in various behavioral paradigms. They are also known to be adenosine uptake inhibitors. The effects of Ro 15-1788 and Ro 5-4864 on adenosine and adenosine 5'-N-ethylcarboxamide (NECA) -evoked depressions of rat cerebral cortical neuronal activity were studied. Iontophoretically applied Ro 15-1788 had both antagonistic and potentiative interactions with adenosine. Reductions in the magnitude of adenosine-evoked depressions of firing were evident during the period of Ro 15-1788 application, with a longer lasting potentiative effect becoming apparent upon termination of the Ro 15-1788 application. Iontophoretic application of Ro 5-4864 showed a similar pattern of antagonism and potentiation of adenosine-evoked depressions, during and immediately after application. Larger applications of Ro 15-1788 had a depressant action on neuronal firing which could be antagonized by caffeine (20 mg/kg, i/v), an adenosine receptor blocker. Applications of Ro 5-4864, in general, seemed to increase spontaneous neuronal activity. Depressions of cell firing evoked by NECA, an uptake resistant analog of adenosine, were consistently antagonized by both Ro 15-1788 and Ro 5-4864. These results indicate that Ro 15-1788 and Ro 5-4864 can act as adenosine antagonists and also have potentiative actions, which are likely to be due to their reported ability to inhibit adenosine uptake. These findings may account for some of the mixed agonist/antagonist actions of these drugs that have been described in the literature, and further support the adenosine hypothesis of benzodiazepine action.

161.3 MODULATION OF GABA-STIMULATED CHLORIDE INFLUX INTO MEMBRANE VESICLES FROM RAT CEREBRAL CORTEX BY TRIAZOLOBENZODIAZEPINES, NONBENZODIAZEPINES AND β-CARBOLINES. T. Obata* and H. I. Yamamura (P. Deshmukh). Department of Pharmacology, University of Arizona Health Sciences Center, Tucson, AZ 85724

Benzodiazepines are widely used as anxiolytics, anticonvulsants, sedative-hypnotics and muscle relaxants. After the discovery of specific high affinity binding sites for benzodiazepines, the search of new benzodiazepine ligands resulted in the discovery of additional chemical classes of drugs. One is a group of nonbenzodiazepines such as CL218872, CGS9896, PK9084, buspirone and zopiclone, and the other β-carbolines such as β-CCM, β-CCE and DMCM. It has been found that the binding sites for benzodiazepines are closely associated with GABA receptors and chloride channels, suggesting the existence of GABA/benzodiazepine receptors chloride channel complex. To elucidate the biochemical functional coupling between GABA and benzodiazepine receptors and chloride channels, we examined the effect of triazolobenzodiazepines, nonbenzodiazepines and β-carbolines on GABA-stimulated $^{36}Cl^-$ uptake by membrane vesicles from rat cerebral cortex. Membrane vesicles (200 ul) were preincubated at 30°C for 10 min. Chloride influx was initiated by the addition of 200 ul solution containing $^{36}Cl^-$ (0.2 uCi/ml)and GABA. After incubation for 3 sec, the reaction was terminated by the addition of ice-cold buffer followed by rapid vacuum filtration through Whatman GF/C glass microfiber filters pretreated with 0.05% polyethylenimine. The content of $^{36}Cl^-$ on filters was determined by liquid scintillation counting. GABA stimulated $^{36}Cl^-$ uptake by membrane vesicles from rat cerebral cortex in a concentration-dependent manner at 3-300 uM. This concentration-response curve was shifted to the left by 1 uM alprazolam and a significant enhancement was observed with $^{36}Cl^-$ uptake stimulated by 30 uM GABA. Among triazolobenzodiazepines, alprazolam and triazolam significantly enhanced GABA (30 uM)-stimulated $^{36}Cl^-$ uptake at 0.1-10 uM. Adinazolam showed a small enhancement at 0.01-1 uM followed by the inhibition of GABA-stimulated $^{36}Cl^-$ uptake at 10-100 uM. β-CCM,β-CCE and DMCM inhibited GABA-stimulated $^{36}Cl^-$ uptake. Ro15-1788, a benzodiazepine antagonist, antagonized the enhancement by 1 uM of alprazolam and the inhibition by 1 uM DMCM of GABA-stimulated $^{36}Cl^-$ uptake. But the inhibition of GABA-stimulated 36Cl- uptake by 30 uM adinazolam was not antagonized by Ro15-1788. Nonbenzodiazepine agonists thus far examined except CL218872 had little effect on GABA-stimulated $^{36}Cl^-$ uptake. CL218872 showed a small enhancement at 1-10 uM followed by a significant inhibition of GABA-stimulated $^{36}Cl^-$ uptake at 100 uM. These results indicate that benzodiazepines allosterically modulate the GABA-gated chloride channel through benzodiazepine receptors and that high concentrations of adinazolam may directly block the GABA-gated chloride channel.

161.4 EFFECT OF FOOT SHOCK STRESS ON $^{36}Cl^-$ EFFLUX FROM RAT BRAIN SYNAPTONEUROSOMES. A. Concas*, S. Mele* and G. Biggio (Spon: P.L. Onali). Department of Experimental Biology, Chair of Pharmacology, University of Cagliari, Italy.

Recently we have found that, similarly to β-carbolines and opposite to benzodiazepines (BZ), an emotional stress (handling or foot shock) decreases the density of low affinity GABA receptors in the rat cortex. Since GABA receptors appear to be associated to a chloride channel whose opening is triggered by the binding of GABA to the GABA receptors, we have studied the effect of foot shock stress on the efflux of $^{36}Cl^-$ from synaptoneurosomes of rat cortex. Foot shock stress delivered continuously for 20 min decreases $^{36}Cl^-$ efflux (25%) from cortical synaptoneurosomes of handling-habituated (unstressed) rats but failed to have the same effect in the synaptoneurosomes of naive (stressed) rats. The presence in the dilution buffer of pentobarbital (500 u M), GABA (100 uM) or muscimol (50 uM), reversed the stress-induced decrease of $^{36}Cl^-$ efflux from synaptoneurosomes of handling-habituated rats. On the contrary the GABA antagonists bicuculline (500 uM) e picrotoxin (1 uM) decrease $^{36}Cl^-$ efflux from synaptoneurosomes of stressed and unstressed rats. Moreover, since ^{35}S-t-butylbicyclophosphorotionate (^{35}S-TBPS) has been shown to specifically label a site on the chloride ionophore associated with the GABA/BZ receptor complex, in an attempt to further clarify the molecular events involved in the action of stress we have studied the effect of foot shock stress on ^{35}S-TBPS in the rat cortex. ^{35}S-TBPS binding to fresh unwashed cortical membranes was enhanced by foot shock stress an by bicuculline (1 uM) and inhibited by GABA mimetics (10 uM) and anxiolytic benzodiazepine, recognition site ligands (1 uM). These results indicate that stress decreases the function of Cl^- channels coupled to the GABA/BZ receptor complex.

161.5 DECREASE ON $^{36}Cl^-$ UPTAKE IN MEMBRANE VESICLES FROM BRAIN OF STRESSED RATS. M. SERRA*, S. MELE* AND G. BIGGIO. Department of Experimental Biology, Chair of Pharmacology, University of Cagliari, Italy

The chloride ionophore, a component of the GABA/benzodiazepine/barbiturate receptor complex, is regulated by GABA. Thus, we studied the effect of foot shock on $^{36}Cl^-$ uptake in membrane vesicles prepared from cerebral cortex of handling-habituated (unstressed) and naive (stressed) rats. Foot shock, delivered continuously for 20 min decreased by 20% ($p<0.05$) the basal chloride influx in brain vesicles of handling-habituated rats, but failed to change the basal $^{36}Cl^-$ uptake in brain vesicles of naive ones. GABA (1 uM) added to the membrane vesicles of handling-habituated foot-shocked rats increased the chloride influx to approximately the level of unstressed rats but failed to change the basal $^{36}Cl^-$ uptake in brain vesicles of unstressed rats. GABA (10-25 uM) produced a similar dose dependent increase in Cl uptake in both handling-habituated and naive rats. The GABA antagonist bicuculline (50 uM) decreased (25%) the basal $^{36}Cl^-$ uptake of unstressed (handling-habituated) rats but failed to further decrease the basal chloride influx of stressed (handling-habituated - foot shocked and naive) rats. The results indicate that foot shock stress produces a down regulation of the chloride channel function. This finding is consistent with the hypothesis that the emotional states related to stress decrease GABAergic transmission at the level of the GABA/benzodiazepine/barbiturate, receptor complex.

161.6 CHARACTERIZATION OF RAT BRAIN GLUTAMIC ACID DECARBOXYLASE (GAD). Y.-C. Chang and D.I. Gottlieb. Department of Anatomy and Neurobiology, Weashington University School of Medicine, St. Louis, MO 63110.

We previously described monoclonal antibodies (MAbs) specific for vertebrate glutamic acid decarboxylase (GAD) (Gottlieb et al., PNAS 83: 8808). Here we have purified GAD from the adult rat brain using a GAD-1 MAb immunoaffinity column. The purified enzyme was analyzed by SDS-PAGE and consists of a major band of 59 kDa, and bands of 63 and 55 kDa. This pattern is very similar to the enzyme purified from the chicken brain. The rat 59 kDa protein was purified further by preparative SDS-PAGE. Its N-terminus is blocked. Cyanogen bromide cleavage peptides were isolated and sequenced. Eight peptides yielded 103 sequenced amino acids. Dr. A. Tobin kindly supplied sequence information on a cDNA coding for feline GAD. (Kaufman et al., Science 256: 1138; Kobayashi et al., J.Neurosci., in press). The sequence from rat brain protein can be aligned with the feline cDNA coded sequence such that 63 of 103 amino acid residues are identical and 18 of 103 are conservative changes. We propose that the 59 kDa protein recognized by GAD-1 is homologous to the enzyme coded for by the cDNA described by Kaufman et al. and that differences between the two are caused by evolutionary variation.

The proteins purified by GAD-1 immunoaffinity chromatography are recognized by two extensively utilized antisera to GAD, that of Oertel et al. (Neuroscience 6: 2689) and E. Roberts and his colleagues (PNAS 71: 269). Each of these antisera react strongly on Western blots with all bands from the GAD-1 purified enzyme. Thus the enzyme recognized by GAD-1 is either identical to or highly homologous to that recognized by the two most widely used antisera.

Rat brain homogenates were separated into cytosolic and crude membrane fractions by centrifugation at 100,000xg. About 40% of the GAD activity was found in the cytosol and 60% in the membrane fraction. The latter could not be removed by extensive washing and homogenization in 2M NaCl but could be solubilized by 0.2% Triton X-100. This indicates a strong association with some type of membrane in the neuron. This solubilized enzyme was purified with GAD-1; its SDS-PAGE pattern was indistinguishable from the cytosolic enzyme.

A newly selected MAb, GAD6 stains the 59 kDa proteins but not the 63 kDa protein on Western blots. In homogenates of the brain quickly homogenized in SDS, GAD6 stains only the 59 kDa protein indicating that this protein is a major form of the enzyme in the brain and not an artefact of degradation. Because the 55 kDa form does not stain, this form may be generated during the immunoaffinity purification. (Supported by NIH grant NS12867.)

161.7 EFFECT OF RO 15-4513 ON NIGRAL-PARS RETICULATA NEURONS. G.P.Mereu+,N.Passino,M.Diana,F.Marrosu+,S.Aramo and G.L.Gessa. Depts.of Exp.Biology* and of Neurosciences; Inst.of Neurology+.University of Cagliari, Italy

Pars Reticulata (PR) neurons are inhibited by drugs that facilitate GABA transmission. They include benzodiazepines (BZs) and ethanol (ETH) among others. Vice versa,these cells are activated by GABA antagonists and by the so called BZ receptor "inverse agonists". We studied the effect of RO 15-4513, a newly synthesized azido analogue of the BZ antagonist RO 15-1788,on the spontaneous firing of PR cells and its interference with the action of ETH,diazepam (DIA) and RO 15-1788 upon these neurons.Indeed RO 15-4513 has recently been found to effectively antagonize the behavioural and biochemical effects of both ETH and BZs.

Extracellular single unit activity from identified PR neurons was recorded in male Sprague-Dawley rats prepared as d-tubocurarine-paralyzed, and locally anesthetized subjects. The intravenous (i.v.) administration of Ro 15-4513 at doses of 0.5-2.0 mg/kg caused a marked increase in the firing rate of most neurons tested (12 out 15).Maximal stimulation (about 130 % above baseline) was often elicited by a single dose of 0.5 mg/kg i.v.while higher or additional doses produced no further increase.The stimulatory effect of RO 15-4513 upon PR cells was counteracted and prevented by the i.v.injection of 1.0 mg/kg of Ro 15-1788.As expected,the i.v.administration of DIA (1.0 mg/kg) or ETH (1.0 g/kg) reduced the firing rate to 50-25 % of baseline.The inhibition produced by DIA and ETH was readily reversed by the subsequent administration of 0.5 mg/kg of Ro 15-4513.

The finding that Ro 15-4513 potently stimulated PR cells and antagonized the inhibition by DIA,and that these effects were eliminated by Ro 15-1788,indicates that this compound is a BZ receptor inverse agonist as suggested by Bonetti et al.(1984).Moreover our results have provided the electrophysiological evidence that RO 15-4513 is an ETH antagonist and support the idea that the CNS effects of ETH are mediated,at least in part, by an interaction with the GABA-BZ receptor complex. They also suggest that BZ receptor inverse agonist might result in a class of clinically effective ETH antagonists.(Supported by an Italian MPI grant to G.P.M.)

161.8 RO 15-4513, AN AZIDO ANALOGUE OF THE BENZODIAZEPINE ANTAGONIST RO 15-1788, INCREASES DOPAMINE TURNOVER IN THE PREFRONTAL CORTEX AND PRODUCES PROCONFLICT EFFECTS IN THE RAT. O. Giorgi, M.G. Corda, B. Longoni* and G. Biggio. Department of Experimental Biology, Chair of Pharmacology, University of Cagliari, Italy.

The mesocortical dopaminergic (DAergic) neurons projecting to the prefrontal cortex (PFCx) are activated in response to stress. Thus, electric foot-shock increases DA metabolism in the PFCx, as reflected by the enhanced content of dihydroxyphenylacetic acid (DOPAC), and this effect can be reversed by benzodiazepines (BZDs). Moreover, the anxiogenic ß-carbolines FG 7142 (20 mg/kg, i.p.) and ß-CCM (8 mg/kg, s.c.) also increase the turnover rate of DA in the PFCx, indicating that BZD recognition sites play a modulatory role on the mesocortical DAergic system. Ro 15-4513 is an azide derivative of the BZD antagonist Ro 15-1788 that binds with high affinity to BZD recognition sites. In addition, Ro 15-4513 has proconvulsant effects in mice and antagonizes the effects of ethanol both in vitro and in vivo in rats. The present study was aimed at characterizing the pharmacological effects of Ro 15-4513 on the mesocortical DAergic system. Ro 15-4513 stimulated DA metabolism in the PFCx of the rat in a dose-dependent manner (5-20 mg/kg, i.p.). When given at a dose of 20 mg/kg, Ro 15-4513 increased DOPAC content in the PFCx by 52%. The BZD antagonist Ro 15-1788 failed to affect per se the DOPAC content in the PFCx, but at the dose of 40 mg/kg, i.p. reverted the increase in DA metabolism induced by Ro 15-4513 as well as by FG 7142 and ß-CCM. Taken toghether with previous reports, the above results indicate that Ro 15-4513 interacts with BZD recognition sites in the CNS as a partial inverse agonist. Behavioural and biochemical data support this view. Thus, in membrane preparations from the rat cerebral cortex, Ro 15-4513 concentration-dependently (0.1-10 μM) antagonized the increase in ^{3}H-GABA binding induced by 5 μM diazepam. Moreover, in the Vogel's conflict test, Ro 15-4513 (2-10 mg/kg, i.p.) enhanced the shock induced suppression of drinking in rats. Finally, at a dose of 10 mg/kg, i.p., Ro 15-4513 potentiated the convulsive effects induced by isoniazid (350 mg/kg, s.c.).

161.9 ACCELERATED DESENSITIZATION BY BENZODIAZEPINE OF $GABA_A$ RECEPTOR-MEDIATED $^{36}Cl^-$ INFLUX IN PRIMARY CULTURE OF RAT CEREBELLAR NEURONS. J. Kardos, A. Guidotti and E. Costa. FIDIA-Georgetown Institute for the Neurosciences, Georgetown University Medical School, Washington, D.C. 20007.

Primary cultures of rat cerebellar neurons, 6-7 days in vitro, contain 95% granule cells, 3-4% GABAergic interneurons and express the GABA/benzodiazepine Cl^- ionophore receptor complex (J. Neurosci., 5, 2432, 1985). Preincubation (performed for 10 min at gradually decreasing temperature) preceeded the $^{36}Cl^-$ influx experiments usually conducted at 4°C in Earle's balanced salt solution (EBSS), pH 7.5. The $^{36}Cl^-$ influx was terminated 7 sec later by rinsing the dishes (less than 3 sec) with EBSS containing 1 mM furosemide and picrotoxin. The concentration response curve of GABA stimulated influx of $^{36}Cl^-$ was biphasic. Maximal stimulation (2 to 3 fold; 100 nmole/mg prot/20 sec) was reached between 1 to 10 uM GABA; higher concentrations of GABA (10 to 100 uM) led to a smaller stimulation of $^{36}Cl^-$ influx. Bicuculline methiodide (10^{-3} M) inhibited the effect of GABA. Bicuculline (0.1 to 1 uM), in a dose related fashion, reduced basal $^{36}Cl^-$ influx presumably by reducing the effect of small amounts of endogenous GABA released from the GABAergic cells in culture. Consistent with the reported relative potencies of enantiomeric dihydromuscimols, $^{36}Cl^-$ influx was stimulated by (S)-(+) dihydromuscimol. The $GABA_B$ receptor agonist (-)-baclofen (1 uM) failed to stimulate Cl^- influx supporting the concept that stimulation of $^{36}Cl^-$ influx by GABA involves $GABA_A$ receptors. The $GABA_A$ receptor-mediated increase of $^{36}Cl^-$ influx was shifted to the left by application of 1 uM diazepam, clonazepam, or oxazepam. This effect was stereospecific. Moreover, the effect of diazepam was blocked by 1 uM flumazenil (RO-151788) which per se failed to change GABA stimulated $^{36}Cl^-$ influx. In contrast, the anxiogenic beta-carboline-3-carboxylate derivative DMCM decreased the action of GABA. The mitochondrial type benzodiazepine ligand, RO5-4864 failed to enhance the GABA-stimulated increase of $^{36}Cl^-$ influx. These results indicate an involvement of central type benzodiazepine recognition sites. The addition of GABA (3 to 10 uM) or benzodiazepines (1 uM) to neurons, preincubated for 15 min with 10 to 100 uM GABA followed by extensive washing, failed to activate $^{36}Cl^-$ influx. The GABA response is decreased with time (from 7 to 30 sec) and this decrease is accelerated in the presence of diazepam. Taken together, these data suggest that GABA, in a time and concentration dependent-manner, desensitizes the receptor. In addition, benzodiazepines accelerate the desensitization of the $GABA_A$ receptor operated Cl^- channels.

161.10 DIFFERENTIAL DEVELOPMENT OF TOLERANCE TO THE ANTICONVULSANT AND BEHAVIORAL EFFECTS OF ZOLPIDEM AND MIDAZOLAM. B. Zivkovic, G. Perrault*, D.J. Sanger* and E. Morel*. Laboratoires d'Etudes et de Recherches Synthélabo (L.E.R.S.), 31 Av. P.V. Couturier, 92220 Bagneux, France.

It is well documented that tolerance develops to the anticonvulsant and sedative effects of benzodiazepines. Zolpidem is a novel short-acting hypnotic of imidazopyridine structure which binds to a macromolecular element of brain membranes which also binds benzodiazepines (Arbilla et al., Eur. J. Pharmacol. 130: 257, 1986). Due to the similarities in the mechanism of action of zolpidem and benzodiazepines, the ability of zolpidem to induce tolerance to its anticonvulsant and sedative effects was compared to that of midazolam, a benzodiazepine which has a relative potency and duration of action similar to that of zolpidem.

Tolerance to the anticonvulsant effects was studied in mice. The animals received zolpidem (30 mg/kg, po, bid) or midazolam (30 mg/kg, po, bid) for 10 consecutive days; 36 hours after the last administration the ability of these drugs to antagonize convulsions induced by isoniazid (800 mg/kg, sc, ISO) or pentylenetetrazole (125 mg/kg, sc, PTZ) was studied. As shown in the table, the potency of zolpidem in antagonizing ISO- and PTZ-induced convulsions was similar in mice repeatedly treated with zolpidem and in mice repeatedly treated with saline. In contrast to zolpidem, midazolam was 3 times less active after its repeated adminstration.

Drug	ED_{50} (mg/kg)					
	ISO+		PTZ+		FR-10*	
	Acute	Repeated	Acute	Repeated	Acute	Repeated
Zolpidem	1.0	1.2	7.2	12	0.6	1.2
Midazolam	0.5	1.6	0.4	1.2	1.7	10

+ ip route, * sc route

Development of tolerance to the sedative effects was studied in rats trained to press a lever in a standard operant test chamber to obtain food pellets according to a fixed-ratio 10 schedule (FR10). Repeated administration of zolpidem produced only a small change in its potency in suppressing the rate of lever presses whereas repeated administration of midazolam decreased the potency of this benzodiazepine by a factor of 6 (see table). There was no evidence of cross-tolerance between the sedative effects of these two drugs.

These findings demonstrate that less tolerance develops to the anticonvulsant and sedative effects of zolpidem than to the effects of midazolam and suggest that the mechanisms of action of the two drugs are not identical.

161.11 MODULATION OF ^{36}CHLORIDE FLUX BY MIDAZOLAM IN INTACT CULTURED NEURONS FROM THE CHICK EMBRYO CEREBRUM. C.L. Thompson* and E.M. Barnes, Jr. Depts. of Biochem. and Physiol. and Mol. Biophys., Baylor Col. of Med., Houston, TX 77030.

A biochemical/pharmacological assay of GABA receptor function at the cellular level, by monitoring ^{36}Cl ion flux in cultured cerebral neurons, has previously been developed in our laboratory [Thampy, K.G., and Barnes, Jr., E.M. (1984) J. Biol. Chem. 259, 1753-1757]. This assay has been used to assess the modulatory interaction of a water-soluble benzodiazepine, midazolam, with GABA-gated Cl channels in this system. Neuronal monolayers on vinyl plastic coverslips were incubated in fresh DMEM at 37° for 15 min, rinsed, and then transferred to HEPES buffered saline at 22° containing 40 mM K, ^{36}Cl (5 µCi/ml), and effector ligands. The 10 sec uptake assay was terminated by rapid transfer to ice-cold saline.

Midazolam had no effect on ^{36}Cl uptake by neurons when added simultaneously with ^{36}Cl. A 5 min incubation of neurons with midazolam prior to addition of ^{36}Cl produced the maximal stimulation. Longer intervals of preincubation resulted in a progressive loss of the ability of midazolam to stimulate ^{36}Cl uptake. This fading of the response was even more pronounced when GABA was present and is therefore likely to reflect desensitization. Under optimal conditions, 0.1 nM to 1 µM concentrations of midazolam stimulated the basal Cl flux, observed in the absence of exogenous GABA, from 50% to 270%, respectively. For this response, the EC_{50} of 6 nM correlated well with the Ki value (8 nM) for displacement of [^{3}H]flunitrazepam from cortical membranes. Picrotoxin (100 µM) or bicuculline (100 µM) completely abolished the midazolam stimulation. These antagonists, however, had no effect themselves on the basal Cl uptake. This suggests that midazolam potentiated the effect of endogenous GABA, whose release was promoted by high K medium. Indeed, when assayed at 5.4 mM K, the midazolam effect was lost. Midazolam was also unable to further stimulate ^{36}Cl flux in the presence of a saturating (50 µM) dose of GABA. In order to remove endogenous GABA, neurons were preincubated in depolarizing medium containing 131 mM K and 5.4 mM Na. Under these conditions, midazolam was ineffective unless GABA was added. A kinetic analysis of ^{36}Cl flux suggested that 10 nM midazolam reduced the apparent $K_{0.5}$ for GABA from 5 µM to less than 2 µM without affecting the Vmax. In addition to providing a method for studying the effects of benzodiazepines on endogenous neurotransmission, our findings are consistent with electrophysiological experiments demonstrating that these compounds potentiate GABA responses.

161.12 PRESENCE AND DISTRIBUTION OF A PUTATIVE PRODUCT OF PROCESSING OF DIAZEPAM BINDING INHIBITOR IN HUMAN BRAIN. C. Ferrarese, M. Frigo*, R. Piolti*, F. Tamma*, A. Cappellini *° and L. Frattola*. Dept. of Neurology, University of Milan and °Dept. of Pathology, Ospedale San Gerardo, via Donizetti 106, 20052 Monza, Italy.

Diazepam Binding Inhibitor (DBI), a 104 aminoacid polypeptide which coexists with GABA and elicits proconflict responses in the rat, has been purified and characterized also in human brain. Tryptic digestion of rat and human DBI yelds 8 peptidic fragments; the fifth one in both species maintains the same pharmacological properties of the DBI molecule. The rat fragment, which is 18 aminoacids long and is called octadecaneuropeptide (ODN), has been found in rat brain by radioimmunoassay (RIA) and is co-released with DBI and GABA from neurons in primary culture. We investigated the presence of the corresponding human fragment, 20 aminoacids long and called eicosapeptide (EP) (table), in various autoptic and bioptic human brain areas. Using antibodies raised in rabbits against synthetic EP, we performed a specific RIA in acetic acid extracts of normal autoptic brain areas (cerebral cortex, cerebellum, dentate gyrus, nucleus caudatus, thalamic nuclei -MD and VPL-, hypothalamus, mamillary bodies, substantia nigra, periaqueductal grey, choroid plexus) of fresh bioptic samples and of bioptic samples kept at room temperature for different times. Significant differences of EP-like immunoreactivity (EP-L.I.) content were found in the different brain areas, with the highest amount in cerebellum (550 ± 45 pmol/mg prot), followed by dentate gyrus (500 ± 37 pmol/mg prot) and cerebral cortex (350 ± 48 pmol/mg prot); lower amounts were detected in the other brain areas). Reverse-phase HPLC analysis of the extracts from different areas revealed one major peak of EP-L.I., with the same retention time in fresh and autoptic samples, corresponding to authentic E.P.

The regional distribution of EP-L.I. in the different brain areas is similar to that of DBI: these data support the hypothesis of a physiological role of this peptide as a product of processing of DBI, with similar pharmacological profile. Modifications of DBI and of its product of processing in pathological brain areas and in cerebro-spinal fluid of subjects with neuropsychiatric disorders can now be studied.

TABLE: Aminoacid sequence of tryptic fragment #5 of human and rat DBI

Human	QATVGDIMTERPGMLDFTGK	(EP)
Rat	QATVGDVNTDRPGLLDLK	(ODN)

TROPHIC INTERACTIONS I

162.1 THE REGENERATION BLASTEMAS OF ANEUROGENIC LIMBS ARE ANTIGENICALLY DISTINCT FROM THOSE OF NORMALLY-INNERVATED LIMBS IN NEWT LARVAE. D. M. Fekete & J. P. Brockes. MRC Cell Biophysics Unit, 26-29 Drury Lane, London, England WC2B 5RL.

The limbs of urodele (tailed) amphibians regenerate after amputation by forming a localized growth zone, called the blastema, at the distal tip of the limb stump. Under normal circumstances, division of the blastemal (progenitor) cells requires nerves at the amputation plane during the first several weeks of regeneration. No such requirement for nerves exists during early development as amputated limbs can regenerate at stages prior to the arrival of axons. Furthermore, the nerve requirement can be circumvented by allowing a limb to develop in the near absence of nerves (the 'aneurogenic limb'). The mechanism of aneurogenic regeneration is unknown, but may involve a system of nerve-independent growth control similar to that occuring during normal development.

We have used monoclonal antibodies to identify the blastemal cells that arise after amputation in these different circumstances. One antibody, called 22/18, was previously shown in adult newts to react with a subset of blastemal cells whose division is dependent on the nerve, but not with normal, uninjured tissue (Kintner and Brockes, J.E.E.M. 89: 37, 1985). We have recently shown that 22/18 does not react with developing limb buds nor does it stain the blastemas of such buds unless amputation is performed after the nerves reach the amputation plane (Fekete and Brockes, Development, 99: 589, 1987). We now report that 22/18-staining is much reduced in the blastemas of sparsely-innervated limbs compared with normal controls.

Aneurogenic limbs were created by joining two newt embryos (*Pleurodeles waltl*, head process stage) at the flank by parabiosis. At the tail process stage the epibranchial placodes and most of the neural tube and neural crest were removed from one member from the level of the hindbrain to the 10-14th somite. 3-4 weeks later, the forelimbs had developed to the 2-digit stage and were amputated through the proximal humerus. After 5-10 days, when early bud-stage blastemas were evident, the parabiotic pairs were fixed, frozen-sectioned and immunostained as described by Fekete and Brockes (1987). The unoperated host animal served as an important internal positive control in these experiments. Nerves were detected using a rabbit antiserum directed against the 70kD neurofilament protein (gift of P. Hollenbeck). In all cases, a few axons were detected in the 'aneurogenic limbs' but these were drastically reduced in number compared with host limbs. Eight such sparsely-innervated limbs (n=6 animals) were found to have reduced levels of 22/18 immunoreactivity compared with host blastemas. Five of these aneurogenic limbs were completely 22/18-negative.

In summary, 22/18 appears to be specific for regeneration versus development, and specific for blastemal cells that arise after amputation in the presence of the nervous system versus its absence (in either development or the aneurogenic limb). The antibody reactivity seems to mark a cell transition involved in the imposition of nerve-dependent growth control.

162.2 EFFECT OF MUSCLE FIBER DEGENERATION ON THE MAINTENANCE OF IDENTIFIED NERVE TERMINALS IN THE LIVING MOUSE. M.M. Rich and J.W. Lichtman, Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110

Evidence from a number of laboratories argues for two seemingly different ways a postsynaptic cell may maintain synaptic terminals. Either the continuous release of diffusible factors by target cells is responsible for stable synaptic connections or the association of presynaptic terminals with membrane bound, or extracellular molecules is sufficient. With regard to the latter idea, McMahan, Sanes and colleagues have demonstrated that motor nerve terminals can reside for long periods on synaptic basal lamina when the underlying muscle fibers have degenerated (e.g., J. Cell Biol. 78: 176).

To directly assess the consequences (or lack thereof) of muscle fiber death on motor nerve terminal maintenance, we viewed the same neuromuscular junction in living mice before and various times after muscle fiber degeneration. Muscle fibers in the adult mouse sternomastoid muscle were caused to degenerate by cutting or freezing them on either side of the endplate band. Care was taken to avoid any damage to the innervating nerves. Before, and various times (1 day to 3 months) after damaging the muscle, the endplates were visualized by staining the nerve terminals with 4-Di-2-ASP (a mitochondrial probe; J. Neurosci. 7: 1207) and the muscle cell's acetylcholine receptors were stained with fluorescently tagged α-bungarotoxin. Light and electron microscopical sections of the muscle were used to confirm muscle fiber loss and the presence of basal lamina ghosts.

Within several days of muscle damage, changes in the staining of individual motor terminals were obvious. Nerve terminals that previously contained continuous strips of contacts became spotty in appearance, suggesting that many of the synaptic contacts had detatched. At about 1 week following muscle damage, the muscle fibers regenerated in the basal lamina ghosts and new acetylcholine receptors were visible. These new receptors were inserted only under the maintained sites of contact. Thus the new acetylcholine receptor distribution was quite spotty and corresponded to the maintained distribution of nerve terminal contact. By labeling the initial receptor sites with rhodaminated bungarotoxin and the new receptors with fluoresceinated bungarotoxin we found that only at the spots where nerve terminal still could be stained were new acetylcholine receptors present. Our results suggest that muscle fiber degeneration rapidly eliminates nerve terminal contacts and thus that the presence of the postsynaptic cell may be important for the day to day maintenance of nerve terminals.

162.3 DENDRITIC GEOMETRY OF SYMPATHETIC GANGLION CELLS IS REGULATED BY POSTGANGLIONIC TARGET SIZE. James T. Voyvodic, Washington University Medical School, 660 S. Euclid, St. Louis, Mo. 63110

Dendrites of sympathetic neurons in the rat superior cervical ganglion (SCG) continue to grow in adulthood; furthermore, the growth of these dendrites is largely independent of the presence of preganglionic innervation (Voyvodic, 1987 J. Neurosci. 7:904-912). Since dendritic length increases in proportion to the overall size of the animal (op. cit.), the question arises whether dendritic geometry is regulated by the size of the peripheral target tissues that these cells innervate. In the present study I have assessed the retrograde regulation of dendrites by measuring ganglion cell geometry after experimental alteration of the relative size of a peripheral target (the submandibular salivary gland). The approach I have adopted takes advantage of the fact that ganglion cells axotomized early in life do not survive. Thus, partial denervation of the submandibular gland at birth effectively changes the ratio between the size of the target and the number of SCG cells that innervate it.

In newborn male Holtzman rats a portion of the postganglionic sympathetic nerve innervating the right submandibular gland was exposed and one of the branches of the nerve was transected. Care was taken not to disturb the other branches. Animals were evaluated at 12 weeks of age. The partial denervation had no effect on the weight of the submandibular gland; however, in operated animals the number of SCG cells innervating the gland was only 5 to 30% of the number in control animals. Therefore, the ratio of target size to the number of innervating ganglion cells was significantly increased compared to normal animals.

Ganglion cell geometry was assayed by intracellular injection of 6-carboxyfluoroscein and HRP into cells projecting to the submandibular gland; such cells were identified by retrograde labelling with another fluorescent label (Di-I). In control animals, cells projecting to the submandibular gland had a mean dendritic length of 3411 um, $\pm$ 359 um (SEM) and bore an average of 5.8 primary dendrites ($\pm$ 0.6 SEM). In experimental animals, the mean dendritic length was 5667 um, $\pm$ 586 (SEM) with an average of 16.8 primary dendrites ($\pm$ 1.4 SEM). Thus, cells innervating relatively larger targets elaborate more complex dendritic arbors.

These results suggest that the growth of ganglion cell dendrites is regulated by retrograde signals from the peripheral target.

162.4 DEVELOPMENT OF FUNCTIONAL Na-CHANNELS IN CULTURED SYMPATHETIC NEURONS IS DEPENDENT ON THE PRESENCE OF TARGET CELLS - A NEW TYPE OF TROPHISM. J.C. Prat*,Taruna D. Wakade* and Arun R. Wakade (SPON: J. Ranck) Dept. of Pharmacology, SUNY Health Science Center at Brooklyn, New York 11203.

Neurotrophic molecules produced by effector organs are essential for the survival of various types of neurons. Nerve growth factor, supports the surival of sympathetic neurons in culture, where they develop a dense neurite network and acquire noradrenergic characteristics. However, it is not known whether the cultured sympathetic neurons are functionally identical to their counterparts developing in the body. In the present study we have compared the functional behavior by inducing release of ^{3}H-norepinephrine (^{3}H-NE) by electrical stimulation of sympathetic neurons of almost identical age but growing in the chick embryonic heart and in culture, with and without heart cells. We demonstrate here a very close correspondence between the functional behavior of neurons developing with the heart cells, either in vitro or in vivo. For example, electrically-evoked (10 Hz for 60 sec) release of tritium from ^{3}H-NE-loaded heart was blocked by 10 nM tetrodotoxin (TTX), 0.25 mM Ca and potentiated by 3 mM tetraethylammonium (TEA). In sharp contrast, the release evoked by stimulation of ^{3}H-NE-loaded cultured neurons (1 Hz for 15 sec) was not blocked by 300 nM TTX, low Ca, or potentiated by TEA. Veratrine, although produced a large increase in tritium release from the heart, had very little effect on the release from cultured neurons. However, when neurons were co-cultured with dissociated heart cells, the evoked release was blocked by TTX, low Ca, potentiated by TEA, and veratrine induced a massive release. Neurons grown in a medium conditioned by the heart cells, or co-cultures of heart and neuronal cells, did not respond to TTX and veratrine. A dramatic alteration in the functional behavior of neurons by co-culturing with heart cells indicates that the effector organ has an important role in the development of normal ionic conductances of sympathetic neurons growing in the body and culture.

162.5 REGULATION OF MOLECULAR COMPONENTS OF THE SYNAPSE IN THE DEVELOPING AND ADULT RAT SUPERIOR CERVICAL GANGLION. K. Wu* and I.B. Black. Dept. of Neurology, Division of Developmental Neurology, Cornell Univ. Med. Coll., New York, N.Y. 10021.

The rat superior cervical sympathetic ganglion (SCG) was used to begin studying regulation of molecular components of the synapse. Ganglion postsynaptic densities (PSD's) exhibited a thin, disc-shaped profile electron microscopically, comparable to that previously described for brain. Moreover, the presumptive major ganglion PSD protein (mPSDp) was phosphorylated in the presence of Ca^{2+} and calmodulin, bound ^{125}I-calmodulin, and exhibited an apparent Mr of 51 KD, all characteristic of the brain mPSDp. These initial studies indicated that ganglion and brain mPSDp's are comparable, allowing us to study synaptic regulation in the well-defined SCG. To obtain sufficient quantities of the ganglion mPSDp, we used synaptic membrane fractions. During postnatal development, calmodulin binding to the mPSDp increased 411-fold per ganglion from birth to 60 days, whereas synaptic membrane protein rose only 4.5-fold. Consequently, different synaptic components apparently develop differently. Moreover, denervation of the SCG in adult rats resulted in an 85% decrease in mPSDp calmodulin binding, but no change in synaptic membrane protein two weeks postoperatively. Our observations suggest that the presynaptic innervation regulates specific molecular components of the postsynaptic membrane structure in a selective fashion. (Supported by NIH Grants NS 10259 and HD 12108. I.B.B. is the recipient of a McKnight Research Project Award).

162.6 INSULIN GROWTH FACTORS REGULATE MITOSIS OF PRESUMPTIVE SYMPATHETIC NEUROBLASTS. E. DiCicco-Bloom and I.B. Black. Div. of Developmental Neurology, Cornell Univ. Med. Coll., New York.

Since mature mammalian neurons do not divide, initial developmental generation is critical for adult brain organization. Although the process of neurogenesis has been studied descriptively, governing mechanisms are unknown. We have developed a new system for defining regulation of the mitotic cycle in presumptive neuroblasts to analyze this problem.

Dissociated embryonic rat superior cervical ganglia were cultured in fully defined medium; after exposure to ^{3}H-thymidine from hours 24 to 48, incorporation (Inc) was assessed by scintillation spectroscopy or immunocytochemistry (IC) and autoradiography (AR).

To identify cultured cells, we performed IC for tyrosine hydroxylase (TH): virtually all cells expressed this important neurotransmitter phenotypic trait. Subsequent AR revealed that 25 to 35% of TH cells simultaneously exhibited nuclear labeling (labeling index, LI), suggesting that DNA synthesis occurred in culture. Identification of single cells, containing two labeled nuclei at different stages of the cell cycle, suggested that mitosis was ongoing. Our observations indicated that a virtually pure population of TH ganglion cells, cultured in fully defined medium, synthesized DNA and underwent mitosis in vitro.

To define factors controlling Inc, we assayed cultures incubated in media lacking individual components. Insulin (Ins) deletion produced the most marked effect, reducing Inc 4-fold. The ED50 for the hormone was 500ng/ml. Conversely, Ins more than doubled the LI over non-Ins controls while not altering cell numbers, indicating that increased Inc reflected increased cells entering the mitotic cycle. Ins did not non-selectively stimulate multiple metabolic processes, since protein synthesis was not affected.

Since Ins is but one of a family of growth promoting factors, we also examined effects of insulin-like growth factor (IGF) I and II. IGF I replicated the Ins effect with an ED50 of 1 ng/ml, exhibiting a 500-fold greater potency than Ins. In contrast, IGF II barely doubled Inc at 100 ng/ml. Thus, all Ins family factors stimulated mitosis, probably acting via the IGF I receptor. Further, nerve and epidermal growth factors and interleukin 2 had no effect on the LI, suggesting Ins factors are highly specific mitogens for presumptive ganglion neuroblasts. (Supported by NIH Grants HD 00676, BRSG S07 RR 05396, a Teacher-Scientist Award from the Mellon Fdn., and a McKnight Research Project Award).

162.7 ENDOGENOUS OPIOID SYSTEMS REGULATE GROWTH OF NEUROTUMOR CELLS IN CULTURE. P.J. McLaughlin and I.S. Zagon. Dept. Anatomy, The M.S. Hershey Med. Ctr., The Pennsylvania State University, Hershey, PA 17033.

Exogenous and endogenous opioid agonists are known to inhibit human and animal tumor growth in vivo in a stereospecific and naloxone reversible manner. Paradigms using opioid antagonists to perturb interaction of endogenous opioids and opioid receptors (= endogenous opioid systems) have demonstrated that tumorigenic events are regulated by a delicate equilibrium between opioids and receptors, and suggest that endogenous opioids exert a tonic and inhibitory influence on neoplasia. In order to ascertain if these mechanisms act at the cellular level, the role of endogenous opioid systems on growth was examined in cultures of neuroblastoma cells (= NB). Cultures of S20Y NB were seeded and, beginning 24 hr later, various concentrations (10^{-6}M to 10^{-10}M) of methionine-enkephalin (= met-enk), or sterile water (= CO), were added to the media; drug and media were changed daily. Cells were counted (trypan blue exclusion test) 12, 24, 48, 72, and 96 hr after initial drug exposure. Growth curves demonstrated a dose-dependent inhibition of NB, with 10^{-6}M met-enk reducing cell number by over 60%. Growth inhibition was not observed in NB cells cultured in media containing both met-enk and naloxone. The mitotic index of NB cells grown in 10^{-6}M met-enk for 48 hr was 72% less than CO. To further assess the role of endogenous opioid systems in NB growth in vitro, the opioid antagonist naltrexone (= NTX) was added daily to cultures in dosages of 10^{-4}M to 10^{-8}M. A dose-dependent stimulation of growth was recorded. A dosage of 10^{-6}M NTX, for example, increased cell number at 24, 48, and 72 hr by 1.7-2.4 fold from CO; the mitotic index at 48 hr was 60% greater than CO. To determine if S20Y NB cells in culture expressed opioid binding sites, assays of 72 hr CO cultures were conducted with ^{3}H-DADLE and ^{3}H-met-enk. Specific and saturable binding to both ligands, with Kd values of 0.30 and 2.13 nM, respectively, and Bmax values of 10.2 and 19.6 fmol/mg protein, respectively, were noted. Radioimmunoassays revealed that both β-endorphin and met-enk were detected in media from log phase cells cultured for 3 days at levels notably above those found in media prior to culturing. S20Y NB cells also contained measurable levels of both endorphin and enkephalin. Our studies show that endogenous opioids directly regulate cell proliferation, and may do so through an autocrine-like mechanism.

Supported by NIH grants NS-20623 and NS-20500.

162.8 **BRAIN ASTROCYTE POPULATIONS ARE CONTROLLED BY A MITOGEN INHIBITOR WITH EGF RECEPTOR IMMUNOREACTIVITY.** M. Nieto-Sampedro, J.T. Broderick* and F. Gómez-Pinilla Dept. of Psychobiology, Univ. of California, Irvine, CA 92717

Brain injury causes a time-dependent increase in *in vitro* astrocyte mitogenic activity both adjacent to the lesion and in deafferented areas which is presumably responsible for the astrocyte proliferation observed after the lesion. A comparison of the shape of the dose-response curves of mitogenic activity in extracts of normal brain tissue and tissue adjacent to an injury suggests that the increase in activity is achieved to a large extent through a decrease in the inhibition of the mitogen/s.

Epidermal Growth Factor (EGF) is a well characterized mitogen the sequence of which occurs in a variety of membrane-bound or secreted proteins, including plasminogen activator, low density lipoprotein receptor and tumor growth factor. Its action appears to be mediated by a transmembrane glycoprotein with tyrosine kinase activity, the.EGF receptor (EGFR). While investigating the identity of the rat brain cells that bear EGFR immunoreactive material (EGFR-IR) we found that EGF receptor immunoreactivity first appeared in astroglia at about day 16 postnatal,was maximal at 19 days postnatal and then became weaker as the animals reached adulthood. Adult brain astrocytes stained weakly if at all for EGFR. This situation changed dramatically after injury. One to three days after ablation of the entorhinal cortex of an adult rat, GFAP-positive astrocytes adjacent to the injury site and in the deafferented hippocampus became intensely EGFR positive. Both GFAP and EGFR immunostaining continued to increase over the next 15 days as a thick layer of fibrous astrocytes covered the injury boundary. In the deafferented dentate gyrus EGFR/GFAP positive astrocytes become very prominent and migrated towards the outer molecular layer.

When tested for their effect on the *in vitro* incorporation of ^{3}H-Thymidine into purified astrocytes promoted by brain extracts, two anti-EGFR antibodies (one mouse monoclonal and another rabbit polyclonal) caused a remarkable enhancement. A similar effect was achieved by pre-treating the brain extracts with the antibodies immobilized on Protein A-Sepharose beads. The antibodies themselves did not have any direct effect on the glial cells, indicating that they acted by removing a mitogen inhibitor from the brain extracts. This inhibitor seems to share epitope/s with the EGFR. Injection of the antibody into the rat cortex caused the rapid appearance of numerous EGFR/GFA-positive astrocytes at the injection site.

The localization of EGFR immunoreactivity and the action of anti-EGFR both *in vitro* and *in vivo* suggests that a protein immunologically similar to EGFR may be involved in controlling the conversion of resting astrocytes into reactive astrocytes.as well as in astrocyte proliferation.

Supported by grant AG 00538-09 A from the National Institutes of Aging.

162.9 LOCALIZATION OF CELLS IMMUNOREACTIVE FOR EPIDERMAL GROWTH FACTOR (EGF) RECEPTOR IN THE ADULT AND DEVELOPING RAT FOREBRAIN. R.Loy, J.E.Springer and S.Koh. Dept. Neurobiology and Anatomy, Univ. Rochester Med. Center, Rochester, N.Y. 14642.

EGF is likely to be an important trophic factor in the CNS. Immunocytochemically EGF has been localized to a variety of cells in the basal forebrain. In CNS cultures, EGF stimulates cellular differentiation and myelination, secretion of extracellular proteins, and glial enzymatic activity, presumably through specific receptors for EGF (EGF-R). We investigated the localization of these receptors immunocytochemically using a monoclonal antibody to rat EGF-R, IgG-151, produced and characterized by C. Chandler and E. Shooter, and purified and generously provided by E. Johnson. Eight female and two male young adult Long Evans rats were anesthetized and perfused with 1-4% paraformaldehyde in PBS. Five rat fetuses, aged 14, 15 and 18 days of gestation, and one rat pup one day old, were decapitated and the brains or whole heads immersion-fixed for 24-48 hours. Coronal or horizontal frozen sections were processed by the avidin-biotin immunoperoxidase method, using an affinity-purified secondary antibody. In the adult brains, large, multipolar EGF-R immunoreactive cell bodies are found in the nucleus basalis, vertical and horizontal limbs of the nucleus of the diagonal band of Broca, and the medial septal nucleus. Immunoreactive neurons are also scattered throughout the caudate/putamen and in the lateral septal nucleus, bed nucleus of the stria terminalis, the olfactory tubercle, the basolateral, basomedial and lateral nuclei of the amygdala. Additional immunoreactive neurons occur in layers II-VI of the cingulate and neocortex and within the hippocampal formation. These latter are most likely interneurons, based on their morphology and distribution within the molecular and infracellular layers. Immunoreactivity associated with fiber tracts and terminal fields occurs in stratum oriens and stratum lacunosum of Ammon's horn and in the molecular layer of the dentate gyrus, in the fornix, caudate/putamen, olfactory tubercle, piriform cortex and neocortex. Immunoreactive cells appear by as early as embryonic day 14 in the nucleus of the diagonal band and nucleus basalis. These observations suggest that sensitivity to EGF develops very shortly in these cells following neurogensis. It is interesting to note that some neurons in these basal forebrain regions show a similar early development of receptors to nerve growth factor (NGF). These multipolar neurons have widespread projections to the neocortex and hippocampus, some of which are cholinergic. In contrast to the localization of cells which express NGF receptors in the adult rat brain, cells which express EGF-R are more widespread, and presumably represent a more divergent population of transmitter-specific systems. Supported by NSF grant BNS-8511564.

162.10 **NEUROTROPHIC EFFECTS OF HIPPOCAMPAL MEMBRANES ON PRIMARY CULTURES OF RAT SEPTAL NEURONS.** M.B. Emerit*, J. Segovia*, and B.C. Wise. FIDIA-Georgetown Institute for the Neurosciences, Georgetown University, Washington, D.C. 20007.

Primary cultures of rat septal neurons prepared from rat fetuses 17-days in gestation and maintained under serum-free conditions are used to study the survival, growth and maturation of the CNS cholinergic neuron. Under our culture conditions, greater than 98% of the cells are neurons while the remaining cells are identified as astrocytes. Immunocytochemical staining for choline acetyltransferase (ChAT) indicates that 3-5% of the cell population are cholinergic neurons. Cultured septal neurons express ChAT activity (maximal activity seen at 6 days in vitro (DIV)) and develop the ability to synthesize acetylcholine (Ach) (maximal in situ synthesis seen at 10 DIV). Treatment of septal neurons with hippocampal membranes (20 ug protein/ml) prepared from 21 day old rats increases the rate of expression (maximal activity seen at 4 DIV) and the maximum levels of ChAT activity (1.5- to 2-fold increase). In contrast, soluble extracts of the hippocampus are 10-fold less potent than membranes in stimulating the expression of ChAT activity. Membranes prepared from cerebellum and other brain regions, with the exception of striatum, have negligible or low activities toward stimulating ChAT activity in septal neurons. The activity present in hippocampal membranes is developmentally regulated with highest levels observed in membranes prepared from 14-21 day old rats. Anti-NGF antibody while inhibiting the effects of NGF treatment does not block the stimulatory effect of membranes on ChAT activity. Furthermore, treatment of septal neurons with maximal amounts of NGF (100 ng/ml, 1.6-fold increase in ChAT) and hippocampal membranes (20 ug protein/ml, 1.75-fold increase in ChAT) results in an additive increase in ChAT activity indicating that the membrane effect is not due to NGF and that different mechanisms may be involved in the two trophic activities. Trophic activity is released from membranes by trypsin treatment, 0.5 M NaCl, incubation at 37°C or detergent solubilization. Trypsin digestion of detergent solubilized membrane extracts, in contrast to heat denaturation, does not result in diminished trophic activity of the extract. Sephadex G-75 chromatography of a 0.5 M NaCl extract of membranes indicates a molecular weight greater than 66,000 daltons for the active factor. However, since activity in solubilized membrane extracts is not inactivated by trypsin, it is possible that a peptide fragment is the active component. These results indicate that hippocampal membranes contain neurotrophic activity which may be important for the terminal differentiation and synaptogenesis of cholinergic neurons.

162.11 **A MUSCLE-DERIVED FACTOR(S) INDUCES DIFFERENTIATION OF CATECHOLAMINE TRAITS IN CULTURED RAT CORTEX.** *L. Iacovitti, T. Shirao, D.J. Reis.* Div. of Neurobiol., Cornell Univ. Med. Coll., New York, NY 10021.

We have previously reported a) that a population of embryonic rat cortical neurons can express the catecholaminergic (CA) enzyme tyrosine hydroxylase (TH) *in vitro* but not *in vivo* (J. Neurosci. *7* : 1264, 1987) and b) that their number can be dramatically increased by co-culture with muscle. In this study we sought to a) further characterize the muscle factor(s) mediating this effect and b) determine whether this factor(s) regulates TH expression by increasing the survival of TH neurons or by inducing CA differentiation in a greater number of cortical neurons.

Confluent cultures of skeletal muscle cells from the L6 cell line were harvested, homogenized in phosphate buffered saline (PBS, 60×10^6 cells/ml) and centrifuged at $40,000 \times g$ for 1 hr to separate soluble and insoluble fractions. Cerebral cortex from embryonic day 13 rat was dissociated and grown in culture in media containing either a) 80% PBS (control), b) 80% soluble muscle fraction (0.06-9.12 mg total protein/ml) or c) 80% insoluble muscle fraction (resuspended in PBS to a final concentration of 1.0-10.0 mg protein/ml). We found that the soluble but not the insoluble fraction of muscle produced a dose-dependent increment in the number of TH immunoreactive cortical neurons, increasing their number 12-fold at the highest concentration of factor tested (control: 1472 ± 162; soluble: $18,662 \pm 960$; insoluble: 1196 ± 261 TH cells/culture). The soluble agent(s) will diffuse into the media as evidenced by a 4-6 fold increase in TH cell number in cultures grown on 100% conditioned media (CM) generated from muscle. The active factor(s) is stable to freeze-thawing (3x), to incubation at 4°C for 48 hrs, to heating at 90°C for 30 min, and to trypsin treatment (100 µg/ml, 37 °C, 2 hrs).

To establish whether this factor(s) was a survival or a differentiation factor, total cell survival was determined by measuring DNA content in cultures fed either control media or 100% CM. All cultures contained the same amount of DNA (3.07 ± 0.22 ng/culture) despite a dramatic difference in the number of TH neurons present in the different media (control: 1417 ± 178; CM: 6580 ± 359 TH cells/culture), indicating that CM does not affect cell survival but rather contains a factor(s) promoting CA differentiation in cortex. The increase in TH cell number in CM-fed cultures was paralleled by a comparable increase in TH catalytic activity (control: 202 ± 67 cpm in 1021 ± 129 TH neurons vs. CM: 976 ± 121 cpm in 4906 ± 359 TH neurons). However, other CA traits were not induced by CM: the CA enzymes aromatic L-amino acid decarboxylase, dopamine β-hydroxylase and phenylethanolamine N-methyltransferase were not detected immunocytochemically nor were endogenous CA's or the uptake of exogenous CA's seen with histofluorescence. Finally, since the number of TH neurons declined to near 0 by 14 days *in vitro* in both control and CM fed cultures, it suggests that this factor(s) does not alter the phenotypic fate of these neurons.

The results of these studies indicate that muscle contains a thermally-stable, trypsin-resistant diffusable factor(s) which will initiate but not perpetuate expression of the CA enzyme TH in cultured rat cortex. Expression of other CA traits does not appear to be similarly regulated. These findings suggest a possible role for muscle factors in the normal signaling of CA differentiation in central neurons.

162.12 EXTRINSIC INFLUENCES ON THE GROWTH OF HYPOTHALAMIC DOPAMINERGIC NEURONS *IN VITRO* J.P. Grierson*, R. Ventimiglia & H.M. Geller. (SPON: M.F. MacDonnell) UMDNJ-Robert Wood Johnson Medical School and The Graduate School, Rutgers University, Piscataway, NJ 08854.

We have designed a series of experiments to investigate the role of the extracellular environment in the control of growth of dopamine neurons of the hypothalamus. In particular, these studies have addressed the influence of glial cells and serum constituents on the growth and morphology of these neurons.

Dissociated neuronal cultures were prepared from fetal rat (E17) hypothalami and plated onto an astrocyte monolayer. Control cultures were maintained on cortical astrocytes and in Dulbecco's-modified Eagle's medium (DMEM) plus Bottenstein and Sato's N2 (defined) medium with added thyroxine. Indirect immunocytochemistry using an anti-tyrosine hydroxylase (TH) antiserum (A. W. Tank, S.U.N.Y.) was performed on cultures at various ages from 1 to 12 days in culture and TH-immunoreactive neurons were drawn onto 1 mm^2 graph paper (final magnification 400x) using a camera lucida. Using these figures the area of the cell body was calculated, along with the number and length of processes, number of branches and total neurite length.

TH immunoreactivity appears to be constitutively expressed in dopaminergic neurons of the hypothalamus and can be used as reliable marker for dopaminergic neurons. TH positive neurons accounted for about 0.2% of the total neuronal population and could be identified as early as 2 days in culture. TH-positive neurons maintained in defined medium, displayed a variety of morphological forms (as has been noted *in vivo*). Neuritic extension continues rapidly until day 6 *in vitro*, at which point it stabilizes. Neurons grown in DMEM plus fetal calf serum had significantly shorter neurites, while there was no difference in somatic area, number of processes or number of neuritic branches. The effect of gonadal steroids added to the defined medium is currently under investigation.

To test the hypothesis that astrocytes of the corresponding brain area might provide a better substrate for growth than dissimilar astrocytes, hypothalamic neurons were plated onto monolayers of hypothalamic astrocytes. Initial results indicate that the two glial populations are equally able to support the wide variety of TH-positive neurons and there is no difference between the various morphological parameters. The presence of fibroblasts in the glial monolayers seems to inhibit neurite extension of TH-positive neurons, in contrast to what has been observed for other types of neurons in dissociated culture. Ongoing work is evaluating the effect of dissociated pituitary cells on these neurons. (Supported by grants from N.I.H. and N.S.F. (H.G.) and a Merck Fellowship (R.V.).

ACTION POTENTIALS AND ION CHANNELS VIII

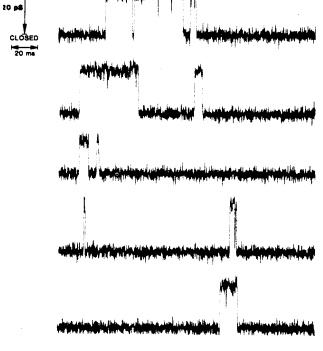
163.1 **CONTROL OF SODIUM CHANNEL MOBILITY IN NERVE: BRAIN ANKYRIN AND FODRIN ASSOCIATE WITH VOLTAGE-DEPENDENT SODIUM CHANNELS** Y. Srinivasan*, L. Elmer†, J. Davis†, V. Bennett†, and K.J. Angelides† (SPON: H. Epstein). Dept. Physiology and Molecular Biophysics, Baylor College of Medicine, Houston, TX 77030 and Dept. Cell Biology, Johns Hopkins School of Medicine, Baltimore, MD.

The voltage-dependent Na^+ channel lends unique excitbility characteristics to nerve and muscle cells. Since certain neurologic disorders may be associated with an anomalous distribution of these molecules on cell surfaces we have examined their localization, lateral mobility, and elements that may segregate Na^+ channels in developing and mature neurons using fluorescently labeled channel toxins, channel specific antibodies, and cytoskeletal protein specific antibodies. Fluorescence recovery after photobleaching (FRAP) indicates that channels may be restricted by the cytoskeleton. By fluorescence immunocytochemistry and FRAP we have found that on mature neurons Na^+ channels are segregated and immobilized to the axon hillock and presynaptic terminal while on developing neurons they are freely mobile and diffusely distributed. The immobilization of the Na^+ channel on mature neurons appears to parallel the appearance of specific cytoskeletal elements and the development of the cytoplasmic matrix within the hillock imposes an additional barrier to the diffusion of Na^+ channels.

Biochemical studies have shown that brain ankyrin and fodrin bind to and co-purify with Na^+ channels from rat brain through sequential DEAE-, hydroxylapatite, wheat germ agglutinin-Sepharose chromatography, and through sucrose gradient centrifugation. Quantitative immunoblots show that enrichment of the Na^+ channel protein is paralled by enrichment of brain ankryin and approaches a 1:1 stoichiometry at the hydroxylapatite step. Moreover, the [^{3}H]-saxitoxin binding activity associated with the channel can be quantitatively precipitated from the solubilized and purified preparation with anti-ankyrin antibodies in the presence of increasing concentrations of added brain ankyrin or with fodrin linked to Sepharose 6. Preliminary direct binding studies with [^{125}I]-ankyrin show a K_d of 20 nM for the Na^+ channel. Together with the photobleach data a model emerges where Na^+ channels are distributed and maintained at specific regions of the axon by their interaction with ankyrin isoforms. (Supported by grants from the NIH and the Muscular Dystrophy Association).

163.2 SYNTHESIS OF AN ION-CHANNEL FORMING PEPTIDE PREDICTED FROM THE PRIMARY STRUCTURE OF THE VOLTAGE SENSITIVE SODIUM CHANNEL. S. Oiki*, W. Danho*† and M. Montal, Department of Neurosciences, Roche Institute of Molecular Biology, and †Peptide Research Department, Hoffmann-La Roche Inc., Nutley, New Jersey 07110.

We proposed a model for the arrangement and folding of the polypeptide chain of the voltage sensitive sodium channel within the bilayer (*FEBS Lett.* 193:125-134, 1985). The model consists of 4 homologous regions, each containing 8 membrane-spanning structures, probably α-helical. Four amphipathic helices, one from each homologous region, are postulated to form a negatively charged channel lining. The tetrameric array provides a conductive polar pathway traversing the non-polar membrane interior. We propose here a synthetic approach to study channel proteins inspired by the testability of the model. In order to locate the ion channel forming domain 4 peptides 21-22 amino acids long, encompassing the sequence encoding the putative amphipathic helices of each of the 4 homologous domains, were synthesized by solid-phase peptide synthesis. We focus here on the results obtained with 1 peptide identified as Sc_1, (*FEBS Lett.* 193:125-134, 1985) with the sequence (from the rat brain channel I (Noda *et al. Nature* 320:188-192, 1986): DPWNWLDFTVITF-AYVTEFVDL. The peptide lipid solution in hexane is spread into monolayers at an air-water interface (0.5 M NaCl, 10 mM HEPES, 1 mM $CaCl_2$, pH 7.2) and, subsequently, bilayers are formed by the apposition of 2 monolayers at the tip of patch pipettes. As shown in the figure, at an applied constant voltage of 100 mV, the current flowing through individual channels is clearly discerned. Conductance histograms show that the most frequent event has a single channel conductance, γ, of 20 pS. However, smaller (γ = 10 pS) and larger (γ = 40-50 pS) events are detected with significantly lower frequency of occurrence, under these conditions. The single channel open and closed lifetimes for the 20 pS events are in the ms time range. The synthetic 22mer channel forming peptide provides opportunities to study by protein engineering the mechanisms of ion permeation through sodium channels.



163.3 **ARE GLIAL AND NEURONAL SODIUM CHANNELS THE SAME?**
B.A.Barres, L.L.Y.Chun*, and D.P.Corey. Program in Neuroscience, Harvard Medical School; Department of Neurology and Neuroscience Group, Howard Hughes Medical Institute, Massachusetts General Hospital, Boston, MA

Type 1 astrocytes in the rat optic nerve express functional voltage-sensitive sodium channels (Barres *et al.*, 1986). We used the patch-clamp technique to compare directly the properties of the glial sodium channels with those in neurons. Acutely dissociated, immunohistochemically identified postnatal retinal ganglion cells and optic nerve type 1 astrocytes were studied under identical experimental conditions. Glial whole-cell currents activated at more hyperpolarized potentials: -41 ± 1.7 mV compared to -31 ± 2.9 mV for neurons. Similarly, the voltage at which half of the channels were inactivated occurred at a more hyperpolarized potential: glia -80 ± 5.8 mV, neurons -55 ± 4.0 mV. The kinetics of the whole-cell glial current were also significantly slower, taking longer to peak and longer to decay. The current decay time constants at -30 and 0 mV test steps were: glia 3.0 and 1.3 msec; neurons 1.8 and 0.5 msec. The amount of TTX required to block the current by half was identical: glia 2.8 ± 1.6 nM; neurons 2.6 ± 1.1 nM.

The properties of single sodium-channel currents were studied using cell-attached recording. Averages of single channel currents were significantly different, and reproduced the whole-cell kinetic differences. The glial first latencies were strongly voltage-dependent, as are those of neuroblastoma cells (Aldrich, Corey and Stevens (1983)). However, the glial first latencies were significantly longer than those found in retinal ganglion cells. In addition, average glial open-times were longer. The observed single-channel differences account for the slower whole-cell glial current.

So far, the slow channels have not been observed in neurons and their expression appears confined to glia: retinal ganglion cells and cortical motor neurons express only the fast channel, while type 1 astrocytes and ependymal cells express only the slow form. But other glial cells express the fast sodium channel: O2A progenitor cells in the optic nerve, which differentiate into oligodendrocytes and type 2 astrocytes, express a channel with voltage-, time-, and TTX-dependence identical to that in neurons. Interestingly, the type 2 astrocyte expresses a mixed phenotype: 85-90% fast form and 10-15% slow form. Thus far, the slow form of the sodium channel seems to be co-expressed with the RAN-2 surface antigen. Type 2 astrocytes begin to express RAN-2 as they mature, and astrocytes from *cortex*, which lack RAN-2, appear (in preliminary experiments) to have the *fast* form of the channel. In other experiments, the cortical astrocyte channels have been found to have low TTX sensitivity (Bevan *et al.*, 1985) suggesting that CNS sodium channels do not fall into just two groups.

The differences between the fast and slow channel types may occur because of a different amino acid or subunit composition, posttranslational modification or local environment. Both types can occur together in cell-attached patches on type 2 astrocytes, arguing against a difference in local cytoplasmic or membrane environment.

163.4 THE DIFFERENTIAL EFFECTS OF MYELIN AND AXONAL DEGENERATION ON THE EXPRESSION OF EXCITABLE ION CHANNELS ON SCHWANN CELLS.
S.Y. Chiu* (SPON: W. Welker). Dept. of Neurophysiology, University of Wisconsin, Madison, WI 53706.

A recent study (Chiu 1987, J. Physiol.,386,181-203) has shown that myelination led to an apparent alteration of ion channel properties on Schwann cells. In a normal adult rabbit sciatic nerve, whole-cell patch-clamp recordings at the cell body region of Schwann cells showed a voltage-gated sodium current in cells which lacked myelin, but not in those cells which produced myelin.

This report further studies the changes in the TTX-sensitive voltage-gated sodium (I_{Na}) and TEA-sensitive potassium current (I_K) in these Schwann cells when the axon was transected, and to correlate these changes with myelin and axonal degeneration. Whole-cell recordings were performed on Schwann cells associated with myelinated and non-myelinated axons in the distal nerve stump of transected 10-week-old rabbit sciatic nerves at 0-13 days after in vivo Wallerian degeneration. Axonal degeneration was determined from cross-sectional electron-microscopy of whole nerve bundles. The degree of myelin degeneration was assumed to be proportional to the measured whole-cell membrane capacity which should decrease when myelin was detached from a Schwann cell. Indeed, in the myelin-forming Schwann cells, but not in the non-myelin-forming ones, the measured capacity decreased 9-fold at 13 days.

In the non-myelin forming Schwann cells in which only axonal, but not myelin, degeneration occurred, I_{Na} decreased slowly when axons degenerated. Both declined to about 50% by day-3, and further to 17-27% by day-6.

In myelin-forming Schwann cells in which both myelin and axonal degeneration occurred, I_{Na} and I_K increased progressively as Wallerian degeneration persisted. Furthermore, an inverse relation existed between whole-cell capacity and current density, suggesting that the appearance of these currents might be related to the loss of myelin.

An hypothesis is suggested that the expression of excitable Na and K channels on a Schwann cell is under opposite regulations by degenerating myelin and axons. The post-transectional decrease in I_{Na} in the non-myelin forming cells suggests that axons normally exerted a positive influence on Schwann cells to express Na channels, and that when the axons died, the cell ceased to express these channels. On the other hand, the post-transectional increase in Na and K currents in the myelin-forming cells is probably a result of the degeneration of myelin, and not of axons.

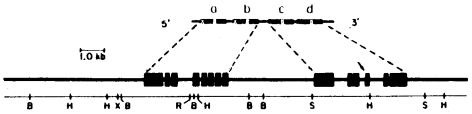
163.5 **Genomic Organization of a Drosophila Gene with Homology to Vertebrate Sodium Channels.**
A. Wei, A. Butler*, N. Scavarda*, D. Pauron*, and L. Salkoff. Dept. Anat. & Neurobiol., Washington Univ. Sch. Med., St. Louis, MO 63110.

A Drosophila gene was isolated which encodes a large polypeptide with an organization virtually identical to vertebrate sodium channels. Four homologous domains, containing all putative membrane spanning regions, are conserved, and repeated in tandem with connecting sequences of usually lower conservation. All regions of the protein presumed to be critical for channel function are highly conserved. These include regions proposed to function in voltage-sensitive gating, inactivation and ion selectivity. Most strikingly conserved are the 24 putative gating charges of the vertebrate protein, all of which are found in identical positions in the Drosophila sequence. Ten introns interrupt the coding regions of the four homologous domains. Two conserved intron positions flank a region proposed to function as an ion selectivity filter. The coding region of the gene is contained within 12Kb of genomic sequence. Northern blots reveal a developmentally regulated message of about 10-14Kb. This transcript is most abundant during embryonic and pupal stages, and far less abundant in adults. At very early embryonic stages (0-8hrs), a second, shorter transcript is seen. This may represent an alternate form of the message, differentially spliced from the same gene. The gene cytologically maps to the tip of the right arm of the the second chromosome, in region 60D-E. This position is close to, but not coincident with the seizure locus (60A-B), which has been proposed to code for structural components of the sodium channel. Through cross-homology, two independent, non-overlapping genomic clones were isolated which also map to this region. The sequenced gene may be one member of an extended gene family elaborated through gene duplication.



Genomic map showing all exons (filled boxes) of the four homologous domains (a,b,c,d) of the channel gene. A diagram of the deduced polypeptide subdividing each homologous domain into six transmembrane segments is presented at the top. The single exon in the conserved linker c-d is indicated by an arrow. Exons of the linker regions a-b and b-c are not indicated. Restriction enzyme recognition sites for BamHI, EcoRl, HindIII, Sall, and XhoI are shown.

163.6 EXPRESSION OF SODIUM CURRENTS IN EMBRYONIC *DROSOPHILA* NEURONS: DIFFERENTIAL REDUCTION BY ALLELES OF THE *PARA* LOCUS.
D.K. O'Dowd, S. Germeraad and R.W. Aldrich. Department of Neurobiology, Stanford University, Stanford, CA 94305.

The $para^{ts}$ mutants, like several other temperature-sensitive paralytic mutations in *Drosophila*, have been proposed to affect sodium channels based on physiological and pharmacological evidence. The mutant adults paralyze at 29° (as opposed to wildtype above 40°) (Suzuki et al., PNAS 68, 890, 1971), show altered membrane excitability manifest as a change in excitation threshold (Siddiqui and Benzer, PNAS 73, 3253, 1976; Wu and Ganetzky, Nature 286, 814, 1980) and exhibit reduced sensitivity to veratridine in cultured larval neurons (Suzuki and Wu, J. Neurogenet. 1, 225, 1984). However, the binding of a high affinity ligand for the sodium channel, TTX, appears normal (Kauvar, Mol. Gen. Genet. 187, 172, 1982). We have investigated the hypothesis that *para* affects sodium channels by direct examination of sodium currents in embryonic neurons.

As described previously, sodium currents can be recorded from voltage-clamped *Drosophila* neurons differentiating in gastrula-stage embryo cultures (O'Dowd and Aldrich, Soc. Neurosci. 12, 43, 1986). Our initial examination of the whole cell sodium currents in $para^{ts2}$ neurons revealed a striking reduction in the percentage of cells expressing sodium currents after 24 hours of culture. Under these culture conditions 65% of wildtype neurons express sodium currents. $para^{ts2}$ cells exhibited a 34% reduction in the percentage of cells with measurable sodium currents. Extending our observations to other alleles has shown that the magnitude of the reduction of sodium channel expression in the population is allele dependent, $para^{ts1}$ and $para^{ST76}$ exhibiting 22% and 95% reductions, respectively. In contrast, the percentage of neurons with outward potassium currents in cultures from each of the three *para* alleles is not different from wildtype.

The mechanism of action of *para* in these cultured neurons could be through a direct effect on sodium channel structure, biosynthesis or membrane insertion or through an indirect mechanism which reduces the viability of a class of cells normally expressing sodium currents. The currents observed in *para* neurons showed voltage-dependent activation and inactivation similar to wildtype, although at this time we cannot rule out the possibility of subtle changes in gating. Detailed examination of the voltage- and time-dependent properties of the sodium currents and the survival of mutant neurons under various culture conditions will be useful in differentiating between the possible mechanisms. 163.7 CLONING AND SEQUENCING OF cDNA FOR A PROBABLE POTASSIUM-CHANNEL COMPONENT FROM THE SHAKER LOCUS OF DROSOPHILA. T.L.Schwarz*, B.L.Tempel, D.M.Papazian*, Y.N.Jan, and L.Y.Jan. Howard Hughes Medical Institute and Dept. of Physiology, UCSF San Francisco, CA 94143.

The Shaker locus of Drosophila melanogaster is thought to code for a structural component of an A-channel, a type of K^+-channel (for review see Tanouye et al., Ann. Rev. Neurosci. 9,255.) We have cloned 200kb of genomic DNA from this region and used it to isolate several cDNA. These cDNA appear to represent a family of transcripts produced by alternative splicing of a large transcription unit whose exons are spread over 60kb of the genome and span the locations of many Shaker mutations.

The cDNA whose sequence we report here is 2.9kb long and is probably not full length since a preliminary analysis of wild type and mutant RNA reveals larger transcripts. The cDNA contains a single, large, open reading frame that is flanked on either side by stop codons, and therefore might contain the entire coding sequence. If the first methionine within the open reading frame is taken as the translational start site, a protein of 616 amino acids is predicted. This protein appears to be an integral membrane protein; it contains a highly hydrophobic central region with hydrophilic regions at either end. Within the hydrophobic region we have identified 6 hydrophobic stretches of 19 or more amino acids that are likely to cross the membrane.

A computer search for homology with sequences in the Dayhoff protein database detected significant homology of the Shaker product to the vertebrate Na^+-channel. The homology consists of a stretch of 120 amino acids that are 27% identical. This region includes, in the Na^+-channel, a sequence called S4 that may be involved in the voltage-dependent gating of the channel. The S4 has been hypothesized to form a transmembrane alpha helix along which positive residues are regularly arrayed (Noda et al.,Nature 312,121; Catterall, Ann. Rev. Biochem. 55,953; Guy and Seetheramulu, PNAS 83,508; Greenblatt et al., FEBS Lett. 193,125). The Shaker sequence preserves the essential features of the S4 region: there are 7 positively charged residues each of which is separated from the next by 2 hydrophobic amino acids. This sequence is a seventh potential membrane-crossing.

Although proof that this cDNA is a structural component of a K^+-channel must await physiological tests, the hypothesis is strengthened by the structural properties described above. The existence of homology between the Shaker product and Na^+-channels suggests that these proteins are descended from a single, voltage-sensitive ancestor, and that the homologous region may constitute a voltage-gating domain that is present in other channels as well.

163.8 A NEW BEHAVIORAL MUTANT IN DROSOPHILA MELANOGASTER, WITH A PHENOTYPE OF NEURONAL HYPEREXCITABILITY. L.C. Timpe, W. Moats*, Y.N. Jan and L.Y. Jan. Dept. of Physiol. and Howard Hughes Med. Inst., Univ. of Calif. San Francisco, San Francisco, Calif. 94143.

We are interested in identifying new mutations in genes whose products are ionic channels, or whose products are necessary for the normal expression and function of ionic channels. Since the autosomal chromosomes of Drosophila have been searched for behavioral mutants much less thoroughly than has the X chromosome, we looked for new mutations on an autosome, the 3rd chromosome. Flies were fed the chemical mutagen ethyl methanesulfonate, and balanced lines were made for individual mutagenized chromosomes. About 2000 lines were screened for temperature-sensitive (ts) paralysis, and for leg shaking under ether anesthesia. Roughly 12 new ts paralytics were found; one of these, $groggy^{ts}$ (grg^{ts}), has been characterized by intracellular recordings from the larval neuromuscular junction preparation.

Recordings from muscle fibers in grg^{ts} larvae reveal spontaneous depolarizations of the membrane at room temperature. For several reasons we believe that these depolarizations are the result of spontaneous firing of the motoneurons: 1.) the spontaneous depolarizations resemble components of the evoked junctional potentials in amplitude and time course, 2.) both kainic acid (5mM) and glutamate (5mM), which block evoked junctional potentials, block the spontaneous depolarizations as well, 3.) tetrodotoxin (3uM) also blocks the spontaneous depolarizations in muscle. Tetrodotoxin is known to block action potentials in motoneurons in this preparation. The neurophysiological phenotype of grg^{ts} has been mapped to the right arm of the 3rd chromosome, between curled (50.0) and stripe (62.0).

Of the many potential explanations for a phenotype of neuronal hyperexcitability, we have tested the possibility that it is due to a defect in a voltage-sensitive potassium current. Using the two microelectrode voltage clamp technique, we measured the amplitude of the transient outward current, the "A" current, in pupal indirect flight muscle. The A current has the same size and rate of inactivation in grg^{ts} pupae as in controls. We then measured the amplitude of the delayed rectifier, or "K" current, in larval muscle of Shaker/Y ; grg^{ts}/grg^{ts} double mutants. The Shaker mutation in these flies abolishes the A current, allowing a better separation of the K current. Again the K current in grg^{ts} larval muscle has the same amplitude as in controls. Thus the defect does not appear to be in the A or K channels which are expressed in muscle. If the mutant phenotype is due to a defective potassium channel, the grg^{ts} mutation may affect a Ca^{++}-dependent channel, or perhaps a potassium channel which is found only in nerve.

163.9 FOUR DISTINCT POTASSIUM CHANNELS IN CULTURED *DROSOPHILA* MYOTUBES. M.S. Brainard* W.N. Zagotta and R.W. Aldrich. Department of Neurobiology, Stanford University, Stanford, CA 94305

A number of mutations have been shown to affect potassium channels in *Drosophila* muscle (see Salkoff and Tanouye Physiol. Rev. 66:301-329 1986). Single channel analysis of the effects of such mutations will prove a powerful approach for studying the molecular mechanisms of ion channel gating. As an initial step towards studying the effects of mutants at the single channel level we have characterized wildtype potassium channels in cultured embryonic myotubes using whole-cell, inside-out and outside-out configurations of the patch clamp technique.

The myotubes differentiate *in vitro* from primary cultures of mid-gastrula stage embryos of *Drosophila*. The cultures were incubated at 26°C for 8 to 36 hours prior to recording. Recording solutions contained physiological concentrations of K^+ with internal Ca^{++} buffered to 10 nM with 11 mM EGTA. The whole-cell outward currents exhibited a characteristic developmental appearance, beginning with an A-type current between 8 and 12 hours followed at later developmental times by slowly inactivating and delayed K currents.

At least four different types of potassium channels contribute to these whole-cell currents: A fast transient 13 to 16 pS A-type potassium channel (A1) (see abstract by Zagotta and Aldrich), a slow transient 16 to 20 pS channel, a 40 pS channel that does not inactivate during voltage pulses up to 240 ms and a 50 to 70 pS channel with little voltage dependence between -50 and 80 mV. Other channel types, including one with a conductance of 9 pS, are occasionally but rarely seen.

The 16 to 20 pS channel ensemble averages inactivate with a time course slower than that of the macroscopic A-current. Channel openings with mean duration of 5 to 10 ms occur in well defined bursts. The latency to first opening is strongly voltage dependent, but there is little voltage dependence occurring in the open durations. The channel shows significant inactivation by 500 ms prepulses over a range of voltages from -80 to 0 mV.

The 35 to 40 pS channel exhibits an increasing open probability with depolarization to voltages between -10 and 70 mV. This voltage dependence is due to a decrease in closed durations at more positive voltages. The open durations are voltage independent with a mean of 1 ms.

Gating of the 50 to 70 pS channel is relatively voltage-independent, with mean open durations of 1 to 3 ms. between -50 to 50 mV. Open probability is independent of internal calcium concentration between 10 nM and 500 uM. The channel has complex gating, with occasional abrupt changes between high and low probability modes. [Supported by Training grants NIMH MH17047 to M.S.B. and NIH NS07158 to W.N.Z. and NIH NS23294 and a Searle Scholars Program Fellowship to R.W.A.]

163.10 SINGLE A-TYPE POTASSIUM CHANNELS IN WILD-TYPE AND *SHAKER DROSOPHILA* MYOTUBES. W.N. Zagotta* and R.W. Aldrich. (SPON: R. Numan). Department of Neurobiology, Stanford University, Stanford, CA 94305

The ability to combine single-channel analysis with genetic and molecular manipulations makes *Drosophila* an ideal system for the study of ion channel gating mechanisms. Mutants at the *Shaker* locus have been shown to alter or eliminate a fast transient potassium current, known as A-current, in muscles of pupae and larvae (Salkoff and Wyman, Nature 293:228-230, 1981; Wu and Haugland, J. Neurosci. 10:2626-2640, 1985). In one *Sh* allele, Sh^5, the voltage-dependent gating of the A-current was altered. We have used the patch-clamp technique on cultured embryonic myotubes to study the gating behavior of single A-current channels and the alteration of their gating by the Sh^5 mutation.

A-currents can be recorded from myotubes which differentiate *in vitro* from primary cultures of *Drosophila* embryos at mid-gastrula stage. This A-current channel (type A_1) is distinct from another A-current channel found in cultured larval neurons which is not altered in *Shaker* mutants. It is expressed early in the myotube differentiation in relative isolation from other potassium channels. The density of other channels in the membrane increases later in development. The current through the A_1 channels possesses many similarities to the A currents recorded in pupal and larval muscle. It is blocked by 5mM 4-aminopyridine and is half inactivated after 500 ms prepulses to voltages between -30 mV and -35 mV. The A_1 channel current is absent in myotubes homozygous for the Sh^{KS133} or Sh^{P} alleles or deficient between the B55 and W32 chromosomal breakpoints.

The single A_1 channels have a conductance between 13 and 16 pS and a single exponential open duration distribution with a mean of 1.5 to 3.0 ms independent of membrane voltage. The voltage dependence of the macroscopic inactivation arises primarily from an increase in opening rates at higher voltages. While the channel does not open in obvious bursts, reopenings contribute to a second, slower inactivation time constant. A five-state sequential kinetic model can account for the kinetics of the single channels and ensemble averages over the activation voltage range. In myotubes from Sh^5 mutants, the macroscopic current-voltage relation and prepulse inactivation curve are shifted 10 to 20 mV in the depolarized direction. Detailed examination of the single A1 channels in Sh^5 mutants have begun to elucidate which rate constants in the model are altered by this mutation. [Supported by NIMH Training grant NS07158 to W.N.Z. and NIH NS23294 and a Searle Scholars Program Fellowship to R.W.A.]

163.11 HIGH EXTERNAL POTASSIUM ALTERS THE VOLTAGE-DEPENDENT GATING OF TWO DISTINCT K^+ CHANNELS IN *DROSOPHILA* LARVAL CNS NEURONS. C. K. Solc and R. W. Aldrich. Dept. of Neurobiology, Stanford University, Stanford, CA 94305.

The gating of ion channels was originally thought to be independent of the concentration and species of the permeant ions. Recent work from several laboratories, including studies done by Armstrong and co-workers, shows that elevating the concentration of external K^+ slows the closing of voltage-dependent K^+ channels. We report here the effects of elevating external $[K^+]$ on the gating of A-channels and single sustained K^+ channels in larval Drosophila CNS neurons.

Neurons in primary cultures from larval *Drosophila* brain express several distinct voltage-dependent K^+ channels (Solc and Aldrich, Soc. Neurosci. Abst. 12:44, 1986.), including a transient A-type channel and a sustained channel (K_1). The gating of both channels is altered when the external solution is changed from a low $[K^+]$ solution (2 mM KCl, 140 mM NaCl) to a high (symmetrical) $[K^+]$ solution (140 mM KCl). Whole-cell A-current recorded in low $[K^+]$ activates within 5 msec, inactivates along a double exponential time course with time constants of ~30 msec and ~300 msec, and reverses at ~-80 mV. In high $[K^+]$ the current reverses, as expected, at 0 mV but the macroscopic inactivation rate increases by ~50%. The faster inactivation in high $[K^+]$ is seen in both inward (V_C <0 mV) and outward (V_C >0 mV) A-currents when compared to (outward) A-currents in low $[K^+]$ at the same voltages. Thus it cannot be due to a series resistance error or ion accumulation, nor can it be accounted for by a shift in voltage, as the macroscopic inactivation rate of the A-current is relatively voltage-independent.

Single sustained K_1 channels in low $[K^+]$ solution begin to open at voltages positive to -20 mV. The single-channel current-voltage relation reverses at ~-65 mV, is linear between 0 and +50 mV, and has a slope conductance in this range between 20 and 60 pS. In high $[K^+]$ the reversal potential shifts to 0 mV and the slope conductance increases by 50 to 100%. In addition, the probability of being open (P_o) in high $[K^+]$ increases to 0.6 to 0.8 between -100 mV and +100 mV. The increase in P_o is due to a large decrease in the mean closed durations. In low $[K^+]$ the channel rarely opens at voltages below -40 mV, but in high $[K^+]$ the frequency of opening in this voltage range increases to 300 to 500 sec^{-1}. At higher voltages (V_C >-20 mV), closed duration distributions recorded in both solutions can be fitted by a sum of three exponentials. In low $[K^+]$, 30 to 40% of the closed durations are shorter than 0.8 msec, while in high $[K^+]$, 80 to 90% of the closed durations are shorter than 0.8 msec. High $[K^+]$ also has small effects on the open durations at higher voltages. These results are consistent with the idea that high external $[K^+]$ alters gating either by direct interactions with the channel, or through the release of modulatory substances from other cells in the chamber. [Supported by NS23294 and a Searle Scholars Program fellowship to R.W.A. and by an NSF graduate fellowship to C.K.S.]

163.12 GENETIC AND PHARMACOLOGICAL SEPARATION OF FOUR POTASSIUM CURRENTS IN *DROSOPHILA* LARVAE. Satpal Singh and C.-F. Wu. Dept. of Biology, Univ. of Iowa, Iowa City, IA 52242.

Muscle fibers in *Drosophila* larvae have been reported to exhibit four K^+ currents; a fast and a slow voltage-activated K^+ current, and a fast and a slow Ca^{++}-activated K^+ current. A clear separation of all the four K^+ currents by treatments which selectively eliminate single currents will be helpful in understanding the mechanisms underlying these currents. A distinction among various K^+ currents will also have a bearing on the question as to whether the voltage-activated and the Ca^{++}-activated currents pass through separate sets of channels or are manifestations of different activation mechanisms for the same type of channels. The two voltage-activated K^+ currents have been already distinguished from each other by using *Shaker* mutations which affect only the fast current between them (Salkoff and Wyman, Nature 293: 228, 1981; Wu and Haugland, J. Neurosci. 5: 2626, 1985). We now report a clear genetic and pharmacological distinction among all the four K^+ currents in the muscle fibers of *Drosophila* larvae.

Two-microelectrode voltage-clamp experiments were performed on muscle fibers of normal and mutant larvae. The *slowpoke* mutation (Elkins et al., PNAS 83: 8415, 1986) provided a distinction between the two Ca^{++}-activated K^+ currents. Although this mutation eliminated the fast Ca^{++}-activated K^+ current, we found that it did not affect the slow Ca^{++}-activated K^+ current. The two fast currents could be separated from each other by either *Shaker* or *slowpoke* which eliminated respectively the voltage-activated and the Ca^{++}-activated current. At present no mutation is known to remove completely either the voltage-activated or the Ca^{++}-activated slow K^+ current. However, it was possible to make a pharmacological distinction between these two currents by the use of quinidine. Quinidine at a concentration of 1 mM completely eliminated the voltage-activated slow K^+ current without any apparent effect on the Ca^{++}-activated slow K^+ current. All of the four K^+ currents in the larval muscle fibers of *Drosophila* can therefore be distinguished completely from one another. A combined use of mutations and pharmacological agents in this system allows us to extract individual currents to analyze their properties without contamination from other currents.

63.13 MOLECULAR ANALYSIS OF EAG: A GENE AFFECTING POTASSIUM CHANNELS IN DROSOPHILA. R. Drysdale* and B. Ganetzky. Lab. of Genetics, Univ. of Wisconsin, Madison, WI 53706

Mutations of the *eag* locus in *Drosophila* cause spontaneous repetetive firing of action potentials in motor axons and abnormal release of neurotransmitter at the larval neuromuscular junction (Ganetzky and Wu, J. Neurogenet. 1: 17, 1983). Voltage clamp studies of larval body wall muscles (Wu *et. al.*, Science 220: 1076, 1983) as well as single channel recordings from dissociated neurons (Sun and Wu, Abstr. Soc. Neurosci. 11: 787, 1985) indicate that *eag* $^+$ is intimately involved in the function of potassium channels. To elucidate the function of the *eag* product we undertook a molecular analysis of the gene. We cloned over 60kb of genomic DNA, beginning by taking advantage of a chromosomal inversion broken both at *eag* and in a previously cloned gene (Drysdale and Ganetzky, Abstr. Soc. Neurosci. 11: 788, 1985).

We have now analyzed the cloned region in a collection of *eag* mutant alleles to define the extent of the *eag* gene and to identify the coding regions. By southern blotting experiments five mutations, including a deletion, insertions and the original inversion breakpoint were located on the molecular map of the region. These mutational sites encompass a region of 40kb. At least one of the transposable element insertions is capable of back mutation to *eag* $^+$. These revertants have lost the transposon from its previous site of insertion. Several mRNA transcripts derived from the *eag* region have been identified and corresponding cDNA clones have been isolated from wild type cDNA libraries. To identify which of the transcription units corresponds to the *eag* coding region we are now comparing transcription in this region in *eag* mutant, revertant and wild type strains.

164.1 RESPONSE OF SI CORTICAL NOCICEPTIVE NEURONS TO SMALL INCREASES IN NOXIOUS THERMAL STIMULI APPLIED TO THE FACE OF TRAINED MONKEYS. D.R. Kenshalo, Jr., E.H. Chudler, F. Anton* and R. Dubner. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892.

Previous studies have reported neurons in the primary somatosensory cortex of monkeys that respond to noxious thermal stimuli applied to the face of anesthetized monkeys. However, the response characteristics of these neurons have not been determined in the awake monkey. In the present study, we examined the response properties of SI cortical nociceptive neurons in behaving monkeys trained to detect small temperature changes in the noxious range.

Monkeys initiated a trial by pressing an illuminated button. A contact thermode, positioned on the upper lip, subsequently increased in temperature from a baseline of 38°C to temperatures of 44° to 48°C (T1). After a random foreperiod of 3 to 9 sec, the thermode increased in temperature an additional amount (T2). The monkey received a fruit juice reward for releasing the button within 2 sec of the onset of T2. If the monkey released the button prior to the onset of T2, no reward was delivered and the temperature returned to baseline. Neural activity was recorded while the animal performed the thermal detection task. In addition, mean detection speed to the onset of T2 was determined.

To date, 22 SI neurons have been isolated that increased their discharge frequency to noxious thermal stimuli applied to the face. Twenty-one of these neurons were classified as wide-dynamic-range and one as nociceptive-specific. All of the neurons had receptive fields comprising 1 or 2 divisions of the trigeminal system.

Thirteen neurons increased their discharge frequency in a graded fashion to increasing heat intensities. The remainder of the neurons (9) responded to noxious thermal stimulation, but did not grade their response in a systematic fashion. In 8 cortical nociceptive neurons, when T2 ranged between 0.2° to 1.0°C from a preceding T1 of 46°C, the peak discharge frequency was positively correlated with the intensity of the temperature change and the mean detection speed.

These data demonstrate that SI neurons respond to noxious thermal stimuli applied to the face of unanesthetized, trained monkeys. It appears that at least two populations of nociceptive neurons exist. One type of neuron encodes small changes in noxious thermal stimulation and may participate in the monkey's ability to detect temperature changes in the noxious range. The other type of neuron does not encode the intensity of noxious thermal stimulation, but may play a role in arousal or alerting responses to noxious stimulation.

164.2 DIRECT PROJECTION OF THE CORTICOSPINAL TRACT TO THE SUPERFICIAL LAMINAE IN THE RAT USING THE ANTEROGRADE TRANSPORT OF *PHASEOLUS VULGARIS*-LEUCOAGGLUTININ. E.J. Casale and A.R. Light. Dept. of Physiology, Univ. of North Carolina, Chapel Hill, NC 27514.

We have previously reported that the corticospinal tract (CST) arising from the sensorimotor cortex (SMC) in the rat projects to medial portions of laminae I and II within the cervical enlargement. These studies utilized the TMB method of visualizing anterogradely transported WGA-HRP. Although this method is sensitive, preterminal axons cannot be distinguished from synaptic terminals. In order to verify whether the CST terminates within these laminae, *Phaseolus vulgaris*-leucoagglutinin (PHA-L) was used as an anterograde tracer allowing direct visualization of axons and boutons.

PHA-L (10%) was pressure-injected via multiple penetrations throughout the extent of the SMC on one side in Sprague-Dawley rats. Following 4 weeks survival, rats were perfused transcardially with buffered 4% paraformaldehyde/10% saturated picric acid. Cervical and lumbar enlargements and cerebral cortices were cut on a Vibratome, and sections processed using the avidin-biotin complex, immunoperoxidase method (Vector Labs).

Within the SMC, many cells were labeled in a Golgi-like manner. Diffusion of PHA-L was very restricted, and large areas of SMC remained free of label. Within the spinal cord labeled axons were found throughout all segments. In the white matter, most labeled axons were found within the contralateral dorsal column; a few axons were found within the ipsilateral dorsal column and ventral funiculus. In the contralateral gray matter, labeled axons were found in all laminae. Within the dorsal horn, the majority of labeled axons were found within laminae III-V, and had a predominantly rostrocaudal orientation. Swellings which appeared to be boutons *en passant* were observed at regular intervals along most axons; preliminary electron microscopic observation showed that all swellings contained vesicles. The presence of synaptic boutons within laminae I and II was confirmed. Most labeled boutons were found in the most medial 1/3 of these laminae, and many arose from collaterals of axons terminating in deeper dorsal horn laminae as well.

The presence of terminal labeling within the medial portions of laminae I and II suggests that the SMC is capable of modulating the activity of spinal neurons which have receptive fields on the extremities, and which may be nociceptive-specific.

164.3 DIRECT SOMATOSENSORY PROJECTIONS FROM THE SPINAL CORD TO THE HYPOTHALAMUS AND TELENCEPHALON. R. Burstein, K. D. Cliffer and G. J. Giesler, Jr., Dept. of Cell Biol. and Neuroanat., University of Minnesota, Minneapolis, MN 55455.

A variety of somatosensory stimuli can cause marked changes in the firing of neurons in the hypothalamus and telencephalon. The pathway for somatosensory information from the spinal cord to these areas has been generally believed to be multisynaptic. In the present study, we have used anatomical and physiological techniques to demonstrate the existence of a direct somatosensory projection from the spinal cord to the lateral and medial hypothalamus (LH, MH), the basal forebrain (BF), the septal nuclei (SN), and the nucleus accumbens (NA) in rats.

Retrograde tracers (Fluoro-gold, WGA-HRP and rhodamine-labeled microspheres) were injected into the above-mentioned areas and, after appropriate processing, the spinal cord was examined for retrogradely labeled cells. An anterograde tracer, PHA-L, was injected iontophoretically into cervical or lumbar spinal cord. The hypothalamus and telencephalon were then processed for immunohistochemical visualization of fibers and varicosities labeled for PHA-L. In physiological experiments, neurons in the dorsal horn of the spinal cord were antidromically activated from the hypothalamus and physiologically characterized.

Retrograde tracers injected into the LH labeled approximately 2500 neurons distributed bilaterally (60% contralateral, 40% ipsilateral) throughout the length of the spinal cord. Approximately 50% were found in the nucleus proprius, 25% in the lateral spinal nucleus, 10% in the marginal zone, and 10% in the area around the central canal. Injections into the MH labeled a comparable number of neurons bilaterally (50% contralateral, 50% ipsilateral) in a similar distribution. Injections restricted to the SN, the BF, or NA each labeled fewer cells in the spinal cord than did injections into the hypothalamus. The distributions of neurons labeled by these telencephalic injections were similar to those produced by hypothalamic injections.

PHA-L injected into the cervical and lumbar enlargements labeled fibers and varicosities in LH, MH, BF, medial SN, nucleus of the diagonal band of Broca, NA and in the supraoptic decussation, including the caudal portion of the optic chiasm.

Ten dorsal horn neurons were antidromically activated from the contralateral LH. These neurons responded to innocuous mechanical stimuli but were more strongly activated by noxious mechanical or thermal stimuli.

These findings, obtained by three independent techniques, demonstrate that neurons in the spinal cord project further rostrally than had been previously shown, carrying somatosensory information directly to the hypothalamus and telencephalon. Since the hypothalamus, septal nuclei and nucleus accumbens are all believed to participate in the expression of emotional behavior, it will be important to determine whether direct spinal projections to these areas play a role in the production of emotional responses to somatosensory stimulation.

164.4 THE PRIMATE DORSOLATERAL SPINOTHALAMIC PATHWAY. A.V. Apkarian, R.T. Stevens, and C.J. Hodge, Department of Neurosugery, SUNY Health Science Center, Syracuse, NY 13210, USA.

There are two distinct spinothalamic pathways in cat, a dorsolateral spinothalamic tract (DSTT) comprised of lamina 1 cell axons and a ventral spinothalamic tract (VSTT) comprised of laminae 4-10 cell axons. The DSTT and the VSTT cross segmentally and ascend to the thalamus in the dorsolateral funiculus (DLF) and the ventral quadrant (VLQ) respectively. Both of these pathways can transmit nociceptive information to the lateral thalamus in the cat. The purpose of this study was to determine whether there is a similar DSTT in primates.

Injections of WGA-HRP were made into the somatosensory thalamus of macaque and squirrel monkeys. Some animals had thoracic spinal cord VQ or DLF lesions made ipsilateral to the injection site. After a 5 day survival time, the animals were sacrificed and the tissue processed for HRP histochemistry using the tetramethyl benzidine technique. Laminar locations of retrogradely labeled neurons were collected from all levels of the spinal cord.

The results for both types of primates studied were similar with minor variations. The average numbers of spinothalamic cells per section in the cervical and lumbar enlargements were 2 to 10. Spinothalamic neurons were found in the cervical and lumbar enlargements in laminae 1 through 10 with particular concentrations in laminae 1,4,5,7 and 8. In the cervical enlargement 25-55% of spinothalamic neurons were found in contralateral lamina 1. Between 15 and 25% of lumbar spinothalamic neurons were found in contralateral lamina 1. Lesion of the thoracic VQ ipsilateral to the thalamic WGA-HRP injection resulted in nearly complete loss of labeled cells in contralateral lumbar laminae 7-10. However, there was still a large number of labeled neurons found in contralateral lumbar lamina 1, and there was only a partial loss of the contralateral lumbar lamina 5 label. Lesion of the thoracic DLF resulted in a large decrease in the number of contralateral lumbar lamina 1 cells labeled. In the DLF lesion animals only 1-3% of the contralateral lumbar spinothalamic population was found in lamina 1. The spinothalamic cell distributions in the cervical enlargement of the lesioned animals were similar to those found in the control animals.

These results indicate that there is a prominent DSTT in primates, which, as in cats, is the primary ascending route for lamina 1 cell axons, the most prominent nociceptive specific input to the thalamus. It is reasonable then to assume that a nociception signaling DSTT exists in humans.

164.5 COLLATERAL SPINOTHALAMIC TRACT PROJECTIONS TO MEDIAL AND/OR LATERAL THALAMUS EXAMINED WITH MULTIPLE RETROGRADE FLUORESCENT LABELING IN THE CAT. A. D. Craig, Jr., A. J. Linington* & K.-D. Kniffki. Divisions of Neurobiology and Neurosurgery, Barrow Neurological Institute, Phoenix AZ 85013 and Physiologisches Institut der Universität, D-8700 Würzburg, FRG.

Previous physiological data indicate that spinothalamic tract (STT) cells that project to medial and/or lateral thalamus in the cat, in particular lamina I STT cells, have significantly different response characteristics that correlate with their axonal projections. These functional and structural differences could be reflected in the differential distribution within the spinal gray matter of STT cells afferent to medial and/or lateral thalamus. The present study tested this hypothesis with the multiple retrograde fluorescent labeling method in the cat.

Multiple injections of 0.5-1.0 µl of 2% Diamidino Yellow (DY) and 2% Fast Blue (FB) were placed in medial and lateral thalamus, respectively (or vice versa), at sites which were extrapolated from recordings in each case in lateral thalamus and which were designed to include all major STT projection regions. Survival times were successively extended (up to 5 wks) to maximize labeling in both the cervical and lumbar spinal cord. Single- and double-labeled cells were located and counted in sagittal, transverse and horizontal sections from segments C5-7 and L5-S2.

Labeling observed with fluorescent tracers was quantitatively similar to labeling in control cases injected with horseradish peroxidase. On average, 2088 STT cells were counted in the segments examined, of which 46% were in lamina I, 8% in lamina V, 5% in lamina VI, 20% in lamina VII and 21% in lamina VIII. Of the entire population, 54% projected only to medial thalamus and 30% only to lateral thalamus, while 16% projected to both. This same overall projection pattern was found for STT cells in laminae I, VII and VIII, but STT cells in laminae V and VI were labeled predominantly from lateral thalamus. In three cases labeling in lamina I from medial thalamus was reduced (to less than that from lateral thalamus in L7) because the injections had missed part of the nucleus submedius. Lastly, STT cells were differentially distributed within lamina I; cells in its ventrolateral aspect generally projected only to medial thalamus, while cells in its dorsomedial aspect projected predominantly to lateral thalamus.

The projection pattern of lamina I STT cells presently observed corroborates the previous physiological findings. It is most striking that about half of the STT originates in lamina I, and that half of these cells project only to medial thalamus. The probable existence of further anatomical correlates of functionally distinct classes of STT cells is indicated.

164.6 SINGLE-UNIT RESPONSES IN MONKEY MEDIAL THALAMUS DURING NOCICEPTIVE AND NONNOCICEPTIVE DISCRIMINATION TASKS. G.H. Duncan, M.C. Bushnell and J.S. Feine*. Faculté de médecine dentaire, Université de Montréal, Montréal, Québec, Canada H3C 3J7.

Medial thalamic nuclei have been implicated in the processing of nociceptive and other somatosensory information, although their specific role is not known. Changes in arousal modify the responsiveness of many of these neurons (Casey 1966), suggesting a role in the affective aspects of perception. The current study evaluates the contribution of medial thalamus to discriminative processes and the importance of behavioral factors to neuronal responsiveness in monkeys performing discrimination tasks involving noxious heat, innocuous cold, and light stimuli.

A rhesus monkey was trained to detect small changes in the temperature of a thermode on the face. Following a light cue the monkey began a trial by pressing a lever, after which the thermode changed from a temperature of 37°C to one between 29°C and 48°C. After a variable time, the temperature changed again, and the monkey released the lever to receive a juice reward. A similar task using visual stimuli was also employed. Single unit responses were recorded while the monkey performed the tasks.

Of the 34 medial thalamic cells examined, 19 responded during the behavioral tasks. The most common response occurred at trial initiation (18 of 19 cells), and was usually related to both the sensory (signal light onset) and motor (lever press) events; however, sometimes the response was synchronized more closely to one event than the other. These cells did not respond to irrelevant lights in the task, indicating a lack of simple visual inputs. Six of the cells that responded in the task discharged after the first temperature change; the firing frequency usually continued to increase throughout the stimulus period of 3-9s, suggesting an anticipatory role. Three of these 6 cells responded during all levels of temperature and light, while the others responded differentially to heating and cooling. Eight of the 19 responsive cells discharged after the final stimulus which cued the monkey to release the lever. Usually both thermal and visual relevant cues evoked firing, but some cells responded preferentially to noxious heat cues, including small temperature changes that the monkey did not detect. When the cells that responded in the task were examined outside the task, 3 cells responded maximally to noxious stimuli and 3 to tap, while the others were not driven by innocuous or noxious tactile stimuli.

These data indicate that the responsiveness of medial thalamic neurons to sensory stimuli is highly dependent on the behavioral significance of those stimuli. However, some of these cells appear to respond to noxious thermal stimuli independently of the animal's behavioral response.

Supported by the Canadian MRC and FRSQ.

164.7 'INHIBITORY' RESPONSES TO NOXIOUS STIMULI OF NEURONS LOCATED IN THE PERIPHERY OF THE VENTROPOSTEROMEDIAL NUCLEUS (VPM_P) OF THE CAT. C. Vahle-Hinz, J. Brüggemann* and K.-D. Kniffki. Physiologisches Institut, Universität Würzburg, D-8700 Würzburg, FRG.

Studies from various laboratories have recently demonstrated that the ventral periphery of the ventroposterolateral nucleus (VPL_{vp}) is remarkably distinct from VPL proper: it receives among other inputs those from the spinothalamic tract and holds nociceptive neurons.

In a combined electrophysiological and histological study on the neuronal representation of noxious stimuli applied to the cat's face, mouth and canine teeth in the region of the thalamic ventrobasal complex, nociceptive neurons were found to be located in the ventral periphery of VPM and its parvocellular part (VPMpc) and in the dorsal periphery of VPMpc. The noxious stimuli used were graded pinch and radiant heat applied to the skin, and rapid cooling of the teeth, a stimulus which activates nociceptive intradental fibers exclusively.

Nociceptive neurons (n=144) either responded to these stimuli alone (nociceptive specific neurons) or in addition also to low threshold mechanical stimulation of skin and fur (multireceptive neurons). While most neurons were excited by noxious and innocuous stimulation, for four nociceptive specific and five multireceptive neurons the ongoing activity in the absence of intentional stimulation was reduced by these stimuli. For six of these nine neurons only 'inhibitory' receptive fields were found in several areas of the face, whereas three neurons in addition had excitatory receptive fields to innocuous mechanical stimulation. In one of the latter, 'inhibition' of the excitatory response to low threshold mechanical stimulation was effected by noxious pinch in a different part of the head.

The occurrence of 'inhibitory' responses to noxious as well as innocuous stimuli of nociceptive neurons shows that the organization of the nociceptive system in VPM_P is more complex than previously thought. Interaction between excitatory and inhibitory responses may play a role in the analysis of the signals which reach the thalamus with respect to their nociceptive or non-nociceptive components. This might especially hold for information processed by multireceptive neurons, which constitute 42% of the nociceptive neurons in VPM_P.

164.8 MEDULLARY SUBSTRATES MEDIATING ANTINOCICEPTION PRODUCED BY ELECTRICAL STIMULATION OF THE VAGUS IN THE RAT. A. Randich and S.A. Aicher. Department of Psychology, The University of Iowa, Iowa City, IA 52242.

Electrical stimulation of afferents of the right cervical vagus inhibited the tail-flick reflex elicited by noxious heat in barbiturate-anesthetized rats. Electrical stimulation was initiated 20 seconds prior to a tail-flick test trial and the intensity of stimulation was adjusted to produce an increase in tail-flick latency from a group mean of 3.85 seconds to a 10 second cut-off (parameters of stimulation were 20 Hz, 2 msec, and a group mean of 3.6 V). This inhibitory effect was eliminated in rats receiving local anesthetic blockade (0.5 ul microinjections of 4% lidocaine) of either the nucleus tractus solitarii (NTS), the lateral reticular nuclei (LRN), the nucleus raphe magnus and medullary reticular formation (NRM-MRF), or the nucleus raphe obscurus (NRO) regions of the medulla. Similarly, the vasodepressor and bradycardic effects of vagal stimulation were either attenuated or eliminated by local anesthetic blockade of these regions. Microinjection of the non-specific glutamate antagonist γ-D-glutamyl-glycine (DGG) into the NTS regions also eliminated vagally-evoked inhibition of the tail-flick reflex, hypotension, and bradycardia. Conversely, microinjection of glutamate into the NTS region resulted in inhibition of the tail-flick reflex, hypotension, and bradycardia. These findings with DGG and glutamate support a role for glutamate as the neurotransmitter of the primary vagal afferents mediating these antinociceptive and cardiovascular responses. These results are discussed in terms of vagal afferent influences on somatosensory, somatomotor, and cardiovascular function. This research was supported by NIH grant 18341.

164.9 DIFFERENTIAL EFFECTS OF INTRACARDIAC BRADYKININ AND CAPSAICIN ON T_2-T_4 DORSAL HORN AND ASCENDING TRACT NEURONS IN THE CAT. D.C. Bolser*, M.J. Chandler, D.W. Garrison and R.D. Foreman. (Sponsored by R. Thies) Depts. of Physiology & Biophysics and Allied Health Education, Univ. of Okla. HSC, Okla. City, OK 73190.

Intracardiac injections of an algesic substance, bradykinin (BK), stimulates cardiac receptors with sympathetic afferent fibers and excites upper thoracic dorsal horn, spinoreticular and spinothalamic tract neurons receiving viscerosomatic convergent inputs in cats and monkeys. Capsaicin (CAP) stimulates thin-fiber somatic and visceral afferents and is a potent algesic agent. The effects of intracardiac injections of CAP on thoracic spinal neurons have not been investigated. The purpose of this study was to compare the effects of intracardiac CAP and BK on dorsal horn and ascending tract neurons in the upper thoracic spinal cord.

Nine cats were anesthetized with α-chloralose, paralyzed with pancuronium, and bilaterally vagotomized. A catheter was placed in the left atrium for intracardiac injections of BK and CAP. Bipolar electrodes were placed in the C_1 spinal cord segment for antidromic activation of ascending tract neurons. The left grey matter of the T_2-T_4 spinal cord was searched with microelectrodes for extracellular potentials of neurons receiving excitatory input from both somatic and cardiopulmonary (CP) sympathetic afferent fibers.

Twelve neurons were studied (11 dorsal horn, 1 tract neuron). Left atrial injections of BK (4μg/kg) and CAP (5μg/kg) produced different effects on 9/12 neurons. Bradykinin excited these neurons while CAP produced a variety of effects (decrease in activity in 5 neurons, no change in 3, increase followed by decrease in activity in 1). Intracardiac injections of BK and CAP produced similar effects in 3 neurons (increase in activity for 1 neuron, decrease for 2 neurons). Control injections of BK or CAP into the aorta produced either no response or variable effects on neuronal firing rates that were different in direction and latency from intracardiac injections of BK or CAP for 10/12 neurons.

These results lead to the suggestion that some chemosensitive cardiac receptors can produce inhibitory effects on upper thoracic spinal neurons. These data also provide evidence that intracardiac BK and CAP may stimulate different classes of cardiac receptors, each of which can have different effects on upper thoracic spinal neurons. (Supported by NIH grants HL22732, HL07430 & NS08150).

164.10 VISCEROSOMATIC CONVERGENCE ONTO T_2-T_5 SPINAL CORD DORSAL HORN CELLS FROM DISTAL ESOPHAGUS, HEART, AND SOMATIC FIELDS IN CAT. D.W. Garrison, M.J. Chandler, and R.D. Foreman. Depts. of Allied Health Education and Physiology and Biophysics, Univ. of Okla. HSC, Okla. City, OK 73190.

Esophageal disease and spasm often produce painful sensations in the same somatic fields as angina pectoris. The referral of visceral pain to somatic fields is often the explanation for this situation. One way to account for the similarity of somatic symptoms is for esophageal, cardiac, and somatic input to excite the same dorsal horn cells. Excitatory convergence onto dorsal horn cells has been shown for cardiac afferents and for somatic afferents from the left triceps and left thoracic wall in response to noxious stimuli. It has not been shown that afferent input from the distal esophagus excites dorsal horn cells in the upper thoracic cord or that this input converges with cardiac and somatic input. The purpose of this study was to determine (1) if T_2-T_5 dorsal horn cells are excited by distal esophageal input and (2) if these same cells are excited by somatic and/or cardiac input.

Experiments were performed on 22 vagotomized cats that were anesthetized with alpha-chloralose and paralyzed with pancuronium. The left side of the T_2-T_5 spinal cord was searched for spontaneously firing dorsal horn cells that responded to distension of the distal esophagus by 3cc-15cc of water injected into a Foley catheter. Thirty eight cells that were excited by esophageal distension were analyzed for responses to (1) noxious somatic pinch of the left triceps and left thoracic wall and (2) injection of an algesic substance, bradykinin, into the left atrium.

Of the 38 cells with esophageal input, 29 (76%) had excitatory cardiac and somatic input. Four (11%) of these 38 cells had excitatory somatic input but inhibitory cardiac input. The remainder of the cells, 5 (13%) had excitatory somatic input but did not respond to bradykinin injections.

These data show for the first time that distal esophageal input excites dorsal horn cells in the T_2-T_5 region of the spinal cord and that the same dorsal horn cells are excited by noxious input from the heart and somatic fields. This relationship may help explain the similarities of somatic symptoms between esophageal disease and angina pectoris. (Supported by Univ. Okla. HSC Faculty Senate Award 43038700 and NIH Grants HL22732 & NS08150)

164.11 DIFFERENTIAL EFFECTS OF VISCERAL SPINAL AFFERENT INPUT ON LUMBOSACRAL SPINOTHALAMIC TRACT (STT) CELLS IN THE MONKEY. S.F. Hobbs, U.T. Oh*, M.J. Chandler, and R.D. Foreman. Dept. of Physiology and Biophysics, Univ. of Okla. HSC, Okla. City, OK 73190.

Stimulation of cardiopulmonary and greater splanchnic sympathetic afferents excites but does not inhibit STT cells in the upper thoracic spinal segments. These observations led to the hypothesis that sympathetic afferents excite STT cells in all segments of the spinal cord. To test this hypothesis the responses of lumbosacral STT cells to electrical stimulation of cardiopulmonary sympathetic afferents, splanchnic nerve afferents, and lumbar sympathetic afferents were tested.

Seventeen monkeys (macaca fasicularis) were anesthetized with α-chloralose and paralyzed with pancuronium. The gray matter of the spinal cord between L_1 and S_1 was searched for extracellular action potentials of cells that were antidromically activated from the ventroposterolateral nucleus of the thalamus. All cells were excited by somatic manipulation of the left hindlimb or tail and were classified as wide dynamic range, nociceptive specific, or high threshold inhibitory. Of the 34 cells studied, electrical stimulation of cardiopulmonary sympathetic afferents inhibited 28 (82%), excited 1 (3%) and did not affect 5 cells. Electrical stimulation of the splanchnic nerve inhibited 25 of 33 cells (76%), excited 5 (15%) and did not affect 3 other cells. Thus, cardiopulmonary and splanchnic sympathetic afferents, which project to the thoracic cord, primarily inhibited STT cells in the lumbosacral cord. In contrast, electrical stimulation of lumbar sympathetic afferents inhibited 12 of 34 cells (35%), excited 10 (29%), and did not affect 12 cells. These effects of lumbar sympathetic afferents were significantly related to segment level (Fisher's exact test, $P<0.001$). Of the 22 cells affected by lumbar sympathetic afferent input, all 9 STT cells located between L_1 and L_3 were excited whereas all but one cell (12/13) located between L_4 and S_1 were inhibited.

These results show that sympathetic afferent input can excite and inhibit STT cells depending on the site of afferent projection and the segments of the spinal cord being studied. Thus, sympathetic afferent input arising from an organ may excite STT cells in the region of the cord that receives the projections of these afferents and may inhibit STT cells in other segments of the spinal cord. The inhibitory effect at more distant segments may enhance the excitatory effect by improving the signal-to-noise ratio of the STT system. Presumably, the differential response facilitates the ability to localize a noxious visceral stimulus and to produce appropriate reflex and behavioral responses.

Supported by NIH Grants HL22732 and HL07430 and NS08150.

164.12 VISCEROSOMATIC INHIBITION OF LUMBOSACRAL SPINOTHALAMIC TRACT (STT) CELLS IN MONKEYS: ROLE OF C_1-C_2 SPINAL CORD. U.T. OH*, S.F. Hobbs, M.J. Chandler and R.D. Foreman, Dept. of Physiology and Biophysics, Univ. of Okla. HSC, Okla. City, OK 73190.

Electrical stimulation of cardiopulmonary (CP) sympathetic afferent fibers and noxious pinch of forelimb triceps muscles inhibit lumbosacral STT cells. We hypothesized that either supraspinal or long propriospinal pathways are necessary for this inhibitory effect.

To test if supraspinal pathways are necessary, the inhibitory effect of electrical stimulation of CP sympathetic afferents and pinch of forelimb triceps muscles on lumbosacral STT cells was tested before and after complete spinal section at C_1. Four monkeys (Macaca fascicularis) were anesthetized with α-chloralose and paralyzed with pancuronium. STT cells in L_2 to S_1 spinal segments were antidromically activated from the ventroposterolateral nucleus of the thalamus. The same STT cells were also antidromically activated from the thoracic cord to identify cells after cord cuts. Stimulation of both visceral and somatic afferents inhibited all cells before cord cuts. After C_1 cuts inhibition of spontaneous cell activity was not markedly affected by pinching the triceps (4 of 4 cells) or electrical stimulation of CP sympathetic afferents (3 of 4 cells). These data indicate that supraspinal pathways are not necessary for this inhibitory effect and that long propriospinal pathways are involved.

Because the CP sympathetic afferents and the afferents from the forearm triceps muscles project to the upper thoracic and lower cervical cord, we hypothesized that these afferents did not reqire long propriospinal pathways originating from the upper cervical cord to produce inhibition of lumbosacral STT cells. To test this hypothesis we recorded from 11 STT cells in 11 monkeys using the same methods and protocols as above, but cord transections were made between C_2 and C_6. In 8 of 11 STT cells the inhibition resulting from pinching the triceps muscle was abolished after making these cuts. In 8 of 10 STT cells the inhibition resulting from activating CP sympathetic afferents also was abolished after these cuts were made. The effects of C_1 cuts compared to C_2-C_6 cuts were significantly different ($P<0.05$) for the inhibition of the lumbosacral STT cells resulting from triceps pinch and nearly significant ($P<0.09$) for the inhibition due to the stimulation of CP sympathetic afferents.

These results show that propriospinal cells in the C_1-C_2 cord are important for mediating the inhibition of the lumbosacral STT cells by noxious stimulation of both visceral and somatic afferents that project to the upper thoracic spinal cord. However, these data do not exclude the possibility that supraspinal pathways also play a role. Supported by NIH Grants HL22732, HL07430 and NS08150.

165.1 QUANTITATIVE ANALYSIS OF GAD mRNA LEVELS DURING CEREBELLAR DEVELOPMENT IN RAT, M.D. Willcutts*[1], W.S.T. Griffin[2], and M.R. Morrison[1], [1]Departments of Neurology and Biochemistry, UTHSCD, Dallas, Texas, 75235, and [2]Pediatrics Department, UAMS, Little Rock, Arkansas, 72205.

Glutamate Decarboxylase (GAD; EC. 4.1.1.15) catalyzes the biosynthesis of gamma-aminobutyric acid (GABA) and is the rate-limiting enzyme controlling the steady state levels of GABA in the nervous system. GABA is the principle inhibitory neurotransmitter in mammalian brain. Alterations in GABA concentrations have been associated with seizures, anxiety, and motor disorders. GABAergic neurons are widely distributed throughout the brain and are well-correlated to GAD activity.

We have analyzed the level of GAD mRNA throughout cerebellar development in the rat. We have obtained a 2.4 kb cDNA clone of feline GAD (courtesy of Dr. A.J. Tobin), subcloned into pSP65 (Kaufman et al., 1986, Science 232:1138). We generated sense and anti-sense 2.4 kb GAD RNA transcripts to serve as standards, controls, and probes for GAD mRNA. Total and poly(A)$^+$ RNA were isolated from the cerebral cortex and cerebellum of fetal rats (E20) along with 4-day (P4), 6-day, 10-day, 14-day, 21-day, 30-day, and adult rat. The RNA isolates and sense/anti-sense GAD mRNA standards were separated by MOPS/HCHO agarose gel electrophoresis and electroblotted onto Zeta Probe nylon membranes. The membranes were probed with P^{32}-labeled anti-sense GAD RNA. After hybridization and washing, GAD mRNA signals were detected by autoradiography on Kodak SB5 film and then quantitated by making densitometric comparisons to the GAD RNA standards.

GAD mRNA was present in both the cerebral cortex and cerebellum at E20. The GAD mRNA level was 0.008% of the total cerebellar poly(A)$^+$ RNA. Cerebellar levels reached one-half the adult value during the third week of postnatal life. GAD mRNA levels rose exponentially throughout cerebellar development, reaching a plateau in the adult at 0.04% of the poly(A)$^+$ RNA population.

The approximate GAD mRNA content of GABAergic neurons (purkinje, golgi, stellate and basket) was calculated assuming: (1) mRNA is confined to a spherical perikaryon in all cells; (2) that the mRNA content/cell is proportional to the perikaryon volume.

Age	Molecules GAD mRNA/Purkinje Cell
E20	70
P6	250
Adult	1500

These results indicate that E20 Purkinje cells transcribe GAD mRNA prior to their final positioning and synaptic development. The cerebellar GAD mRNA increase parallels the progression maturation of the GABAergic system, and suggests that transcription is the major site of GAD gene regulation during cerebellar development. 165.2 IN SITU HYBRIDIZATION DEMONSTRATES VASOPRESSIN GENE TRANSCRIPTION IN HYPOTHALAMIC NEURONS OF CROSSBRED HYPERTENSIVE X DIABETES INSIPIDUS RATS. J.T. McCabe[1], K. Almasan*[,2], E. Lehmann*[,2], J. Hänze*[,2], R.E. Lang*[,2], D.W. Pfaff[1], and D. Ganten*[,2]. [1]Neurobiol. & Behav. Lab., Rockefeller Univ., NY, NY 10021-6399 and [2]German Institute for High Blood Pressure Res., Heidelberg, F.R.G.

In situ hybridization, Northern blotting, and solution hybridization assay were used to identify vasopressin (VP) gene transcription in five strains of rats: Long-Evans (LE), Wistar-Kyoto (WKY), Spontaneously Hypertensive Stroke-Prone (SHRSP), Brattleboro (diabetes insipidus: DI), and crossbred hypertensive x diabetes insipidus (SHRDI).

In situ hybridization with single-stranded VP-specific probes (exon C of VP gene, radiolabeled by SP6 transcription), identified individual magnocellular hypothalamic "VP" neurons, and parvocellular neurons of the suprachiasmatic nucleus. Confirming previous investigations (McCabe, et al., Neuroendo., 44:361, 1986), DI rats transcribe their mutant VP gene (Schmale, et al., Nature, 308:705, 1984), and the present in situ hybridization experiment extends these findings for SHRDI rats. Magnocellular hypothalamic "VP" neurons of DI and SHRDI rats appeared hypertrophic, and possessed similar levels of VP gene transcript. In a single experiment where all 5 strains of rats were processed concomitantly, the estimated relative levels of VP gene product in supraoptic nucleus neurons were LE 3.0; WKY and SHRSP 2.2; DI and SHRDI 0.8.

Quantitative solution hybridization (n=7-8/group, all 3 months of age) confirmed LE rats had the highest hypothalamic content of VP mRNA ($\bar{X}$ + SEM: 1661 + 91pg), WKY and SHRSP strains lesser amounts (1351 + 105 and 1094 + 67, respectively), and DI rats contained the lowest (571 + 40). A Newman-Keuls test (at least $p<0.05$) indicated these differences in hypothalamic "VP" mRNA content across strains were significant: i.e., LE>WKY>SHRSP>DI (relative levels 3.0; 2.4; 2.0; 1.0, respectively).

Previous studies have observed several physiological abnormalities in SHRs, including alterations in brain, pituitary, plasma, and urinary levels of VP, and VP is a potent vasoconstrictor. However, no simple causal relationship between plasma or urinary VP concentration and blood pressure is evident. Since results from solution hybridization for entire hypothalami suggest a small, but significant, 20% diminution of VP mRNA content in SHRSPs relative to WKYs, and SHRDI rats suggest VP in brain is not necessary for the development or maintenance of hypertension, further studies must determine if the level of VP mRNA in paraventricular neurons which project to the brainstem are different between hypertensive and normotensive non-diabetic rats. Descending VP cells may exhibit important alterations in mRNA content that can only be detected by careful single-cell analyses.

165.3 DIFFERENTIAL EXPRESSION OF VASOPRESSIN ALLELES IN THE BRATTLEBORO HETEROZYGOTE. T.G. Sherman and S.J. Watson. Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109-0720, U.S.A.

Several recent studies from our laboratory have shown that homozygous diabetes insipidus rats (HO) of the Brattleboro strain prove to be an interesting model system in which to study neurosecretory neurons which have a history of chronic stimuli for secretion. In many cases, neurons adapt to chronic secretion stimuli by progressing through a linear series of post-translational and translational mechanistic modifications which greatly increase the levels of available peptide for secretion. These cellular adaptations culminate in increased transcriptional activity, contributing to higher cytoplasmic levels of mRNA coding for the peptide precursors. In Sprague-Dawley rats, for example, chronic salt-loading has been shown to lead to increased cytoplasmic levels of vasopressin, dynorphin and oxytocin mRNAs in the magnocellular neurons of the hypothalamus. In the homozygous Brattleboro rat, an animal which proves to be developmentally and chronically hyperosmotic, the resting levels of oxytocin mRNA are equivalent to a salt-loaded control Long Evans (LE) rat, as expected. Similarly, dynorphin mRNA, co-localized with vasopressin mRNA in the magnocellular hypothalamus, is also increased, although to a much greater extent (8-fold) than that attainable by a six-day salt-loading regimen (3-fold). The mRNA transcripts for AVP from the mutated AVP gene in these animals, however, are found to be 40-50% of that for controls, and yet remain regulatable by further osmotic challenges, increasing their cytoplasmic pool levels in response to a part-time exposure to 2% saline over 6 days.

These results prompted us to investigate the expression of the two different alleles of the AVP gene in the Brattleboro heterozygote (HE) in response to chronic salt-loading. Using a modification of a solution-phase mRNA:cRNA hybridization/RNase A/T1 protection assay, we hoped to distinguish between the two transcripts by RNase cleavage at the point deletion site in the defective Brattleboro gene. This proved to be a very sensitive and quantitative assay, confirming all previous results obtained by Northern analysis. For example, the concentration of AVP mRNA in the LE and HE animals are 60 amoles in the PVN and 120 amoles in the SON, whereas each of these nuclei contain approximately 130 amoles of oxytocin mRNA. The HO rat, however, contains only 20-25 amoles and 70 amoles of AVP mRNA in the PVN and SON, respectively. Each of these mRNA levels increases from 60-100% with a six-day regimen of chronic intermittent salt-loading. Furthermore, we have been able to show that both AVP alleles are expressed in the Brattleboro heterozygote, although at an approximate molar ratio of 30:1, normal versus defective mRNA. This ratio changes dramatically with osmotic challenge, apparently favoring the defective gene product, resulting in an approximate 9:1 ratio. We are investigating whether this apparent differential regulation is due to differences in message half-life or differential transcription rates. Research performed with the assistance of NIMH post-doctoral grant F32-MH09239 to T.G.S.

165.4 GENE EXPRESSION OF NEUROPEPTIDES RELATED TO CRF AFTER ADRENALECTOMY. M.K.-H. Schafer*, J.P. Herman, E. Young, R. Thompson, J. Douglas, T.G. Sherman, H. Akil and S.J. Watson (SPON: E. Valenstein). Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109.

It has been well-established that removal of adrenal glands causes an increase of CRF biosynthesis in the parvocellular subdivision of the paraventricular nucleus (PVN). Vasopressin (AVP), normally produced in the magnocellular portion of the same nucleus, has been reported by a number of laboratories to be coexpressed with CRF after adrenalectomy. The function and the changes in expression of other neuropeptides known to coexist with subsets of CRF containing neurons such as the opioid peptides, prodynorphin and proenkephalin, and neurotensin are less well-understood.

In this study we analyzed the distribution of mRNA for CRF, AVP, oxytocin (OXY), prodynorphin (DYN) and proenkephalin (ENK) in the different subdivisions of the rat PVN and quantify the changes of their mRNA content after adrenalectomy and dexamethasone treatment using in situ hybridization.

5 male Sprague-Dawley rats were bilaterally adrenalectomized, a control group sham-operated and an additional third group dexamethasone injected (2x100 µg/day). After a period of 14 days the animals were perfused with 4% paraformaldehyde, the brains removed and frozen in liquid nitrogen. Prior to perfusion blood samples of each animal were collected and plasma levels of corticosterone and β-endorphin were established to confirm successful adrenalectomy. 10 µm serial sections were cut through the hypothalamus on a Bright cryostat. ^{35}S-UTP labeled riboprobes with high specific activity complimentary to AVP, OXY, CRF, DYN and ENK (courtesy of Dr. S. Sabol, NIH) mRNA sequences were prepared with the pSP6 and pGEM transcription systems. Hybridization to tissue sections was carried out at saturation conditions for 48 hrs at 60°C. For quantification ^{35}S-brain paste standards were prepared. Following hybridization slides were dipped in Kodak NTB2 emulsion for autoradiography. Coverslipped slides were digitized and grain densities over the subdivisions of PVN and SON, sampled at 50 µm intervals, were recorded using the Loats Inc. RAS 1000 image analysis system.

The analysis confirmed the increased expression of AVP mRNA in the parvocellular part of the PVN after adrenalectomy revealing a 7 fold increase relative to controls ($p < 0.05$), whereas signals over other areas did not change significantly. Dynorphin mRNA showed a slight increase in the medial parvocellular part, but did not change in magnocellular areas. Present studies are being carried out to quantify the number of mRNA copies for each probe detectable in the different subdivisions and to compare the results to those obtained by solution phase hybridization.

165.5 EFFECTS OF CHRONIC ELECTROCONVULSIVE SHOCK ON VASOPRESSIN mRNA IN THE RAT PARAVENTRICULAR, SUPRAOPTIC AND SUPRACHIASMATIC NUCLEI: A QUANTITATIVE IN SITU HYBRIDIZATION ANALYSIS. J.P. Herman, M.K.-H. Schafer*, E.A. Young and S.J. Watson. Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109.

Specific subpopulations of arginine vasopressin (AVP) neurons are involved in very different types of regulatory processes. In these experiments we analyzed the effect of chronic electroconvulsive shock, a treatment which markedly perturbs function of the pituitary adrenal (PA) axis, on expression of AVP mRNA in the hypothalamic paraventricular (PVN), supraoptic (SON), and suprachiasmatic (SCN) nuclei. Such analysis enables identification of which subtype(s) of AVP neurons respond to changes in PA function, and whether such a stimulus can induce AVP gene expression in parvocellular PVN neurons in a manner similar to that seen following removal of the adrenal glands.
