Six Rambouillet-Columbia sheep fetuses, delivered by cesarian section at 134 to 145 d GA., were perfused with Zamboni's fixative under Bio-Tal anesthesia and their brains processed for localization of CRF using the ABC method. CRF was present within the paraventricular nuclei and the median eminence at all fetal ages. The paraventricular nuclei of the fetal sheep, which are C-shaped structures with their openings directed rostrally, did not display a homogeneous distribution of CRF neurons. In the younger fetuses, CRF cells were located primarily in the dorsal portion of the nucleus. In the later fetal ages CRF neurons were found in both the dorsal and ventral components of the parvocellular portions of the PVN The median eminence contact zone contained a dense plexus of CRF axons even in the youngest fetuses. Yet, the density of terminals of the CRF axons in this area increased in the older fetuses. This suggests that changes in the expression of CRF may reflect critical maturation of this neuroendocrine system prior to parturition Supported by NIH Grants RO-1 HD 18418, PO-1 HD 21350 and RO-1 AM 16166.

PROLACTIN DOES NOT EFFECT POSTNATAL BRAIN DEHYDRATION IN THE PRETERM RABBIT. A.V. Lorenzo, R.M. Beatty*. K.R. Winston* and V.C. Boss Dept of Neurosurgery, Children's, and Brigham and Woman's Hospitals, Boston, MA 02115.

Postnatal dehydration in preterm infants may lead to intracranial hypotension and to germinal matrix (GM) and intraventricular hemorrhage (IVH). Coulter et al. (Pediatr Res 19:1322, 1985) reported that prolactin (prl) reduces postnatal tissue dehydration and the incidence of GM and IVH following hypovolemic hypertension in term newborn beagles. We studied the effect of prl on tissue hydration of preterm rabbits 20% of which exhibit spontaneous GM and IVH. Bromocriptine (bro, 1 mg/kg), fluphenazine (flu, 1 mg/kg), ovine-prl (o-prl, 30.5 IU/kg) or buffer (buf) were administered daily to newborn preterm rabbits for 3 days at which time they were killed. Tissue water and serum prl levels were compared to values of littermates killed on day of birth (dob). Between dob and 3 days, the decline in respective water contents of brain, lung, skin and muscle was similar for all animals, even in those treated with o-prl in which serum prl was 8 times higher than bro, flu or buf treated rabbits. Paradoxically, serum prl levels were similar in pups treated with agents that stimulate (flu), inhibit (bro) or do not effect (buf) pituitary release of prl. We conclude that unlike the effect on term animals changes in serum prl do not alter postnatal tissue dehydration in the preterm animal. (Supported in part by NICHHD Grant 15304 and the Vallely Family Fund.)

SEXUAL DIMORPHISM OF HYPOTHALAMIC PEPTIDE SIGNALING IN REGULATION OF PULSATILE GROWTH HORMONE SECRETION. J.C. Painson* and G.S. Tannenbaum. McGill University-Montreal Children's Hospital Res. Inst., Montreal, Quebec H3H 1P3.

A striking sexual dimorphism exists in the pattern of growth hormone (GH) secretion, however, the role of the CNS in mediating this sex difference is unknown. In the present study, we examined the involvement of the two hypothalamic GH-regulatory peptides, somatostatin (SRIF) and GH-releasing factor (GRF). In freely-moving male rats, the GH response to 1 μg rGRF(1-29)NH_2 iv was significantly greater at peak compared to trough times, the latter due to antagonization by the cyclic increased release of SRIF. In contrast, females failed to exhibit a time-dependent difference in GH responsiveness to GRF suggesting that the pattern of hypothalamic SRIF secretion in females does not follow the male ultradian rhythm. Passive immunization with a specific antibody to rGRF obliterated spontaneous GH pulses in both males and females; moreover, in females anti-rGRF attenuated GH trough levels indicating a physiologic role for GRF in maintaining the elevated GH baseline of females. Hypothalamic immunoreactive GRF content was significantly lower in females compared to males (587.0±26.1 vs. 792.0±79.5 pg/fragment; $P<0.02$). Conclusions: the sexual dimorphism of GH secretion is likely due to different temporal patterning of hypothalamic GRF/SRIF signals to somatotrophes with females exhibiting tonic, rather than episodic, SRIF secretion compared to males.

A ROLE FOR THE ADRENAL IN THE MATURATIONAL PROCESS OF THE LHRH (LH-RELEASING HORMONE) NEURON. A.Barnea, G.Cho* and D.E.Hartter, Depts. OB/GYN and Physiol., Univ. Tx. Southwestern Med. Center, Dallas, TX. 75235, USA.

It is known that androgens regulate the function of the hypothalamic LHRH neuron of the male rat. It appears that the adrenal is the primary source of circulating testosterone in the immature rat and the testis is the primary source in the adult. We have previously established that the sequential exposure of median eminence (ME) explants to copper and prostaglandin E_2 (Cu/PGE) leads to a robust release of LHRH. To ascertain the role of the adrenal and testis in the regulation of the LHRH neuron during maturation, LHRH release in response to Cu/PGE (pg/15 /ME) and LHRH content (ng/ME) were assessed in ME explants of 6 wks (maturing) and 12 wks (adult) male rats 12 days after adrenalectomy (ADX) or castration (TX).

Maturing	Sham	ADX	TX	Adult	Sham	ADX	TX
Release	26.8	14.7	9.5	Release	31.1	31.1	7.9
Content	2.5	2.4	1.1	Content	3.0	2.9	1.3

TX leads to a comparable reduction in LHRH release and content; this occurs in both age groups. ADX leads to a marked reduction in LHRH release but not in LHRH content; and this occurs only in the maturing rat. Thus, the adrenal and testis exert a differential effect on the LHRH neuron. The testis regulates both the secretory and storage functions of the LHRH neuron independently of maturational age. The adrenal regulates the secretory function of the LHRH neuron in an age-dependent manner, suggestive of a change in the profile of steroids secreted by the adrenal and/or a change in the responsiveness of the LHRH neuron to a given steroid.

SEXUAL DIFFERENTIATION OF THE RAT ARCUATE NUCLEUS NEURONAL PLASMA MEMBRANE. L.M. Garcia-Segura[1]*, J. Perez[1]*, P.A. Tranque[1]*, G. Olmos[1]* and F. Naftolin[2]*, (SPON: P. Rakic) (1) Instituto Cajal, C.S.I.C., 28006 Madrid (Spain) and (2) Dept. of Obstetrics/Gynecology, Yale Univ. School of Med., New Haven, CT.

Hypothalamic sexual differentiation is controlled by estrogen. The basis for this appears to be the secretion of testosterone by the testis and its aromatization in the hypothalamus. There is a sex difference in the numerical density of intramembranous protein particles (IMP), which in adults is abolished in concert with increased endocytotic activity during estrogen treatment (J. Ster. Bioch., 29:215, 1988). EXPERIMENT: The number of exo-endocytotic images and the number of IMP in the neuronal membrane were quantitatively assessed in freeze-fracture replicas of arcuate nucleus from birth to adulthood. As before, arcuate neurons from females contained significantly more particles in their plasma membranes than neurons from males. Testosterone treatment of females resulted in an increased number of exo-endocytotic images and in the abolishment of the sex difference in the number of IMP. CONCLUSIONS: Neonatal testosterone treatment induces changes in perikaryal membrane composition. As in adults these changes may reflect an increased endocytotic activity induced by locally formed estrogen that may underlie sex differences in neuronal membrane IMPs. PLASMA TESTOSTERONE DELAYS ONSET OF MATURE BINOCULAR VISION IN HUMAN INFANTS. R. Held, J. Bauer, and J. Gwiazda, MIT Infant Vision Laboratory, Cambridge, MA 02139.

The ages of onset (average 3.5 months) of stereopsis and the fusion-rivalry discrimination measured behaviorally are delayed by several weeks in males compared to females. In contrast, no sex differences are found in the developmental course of grating acuity. This suggests that it is visual mechanisms at the cortical level which suffer delayed maturation in males. Indeed, it is during this period of development when radical changes in neuronal connectivity are occurring in the visual cortex: synaptogenesis is at its peak rate and the segregation of the ocular dominance columns is in progress. Just prior to this period, the average levels of testosterone (T) rise to a peak (about 8 weeks of age) in males and then subside. T-levels in females of this age are almost zero. To assess the role of T in modulating these neuronal developments, serial measures of T-levels were made in 12 male infants from 6-8 weeks of age until the onset of fusion-rivalry discrimination (13.6 weeks, range 9-18 weeks). This discrimination is a precise marker of the onset of mature binocularity. The correlation of the onset age of fusion-rivalry discrimination with T-levels at 8 weeks of age yields a Pearson $R=0.719$ ($p<.01$). Measurements of other steroids showed no significant correlation.

IN VIVO UPTAKE OF ^{3}H-ESTRADIOL BY THE FETAL PRIMATE BRAIN. **R.P. Michael, R.W. Bonsall* and H.D. Rees. Dept. Psychiatry, Emory Univ. School of Medicine, and Georgia Mental Health Inst., 1256 Briarcliff Road NE, Atlanta, GA 30306.**

Neurons in the preoptic area, hypothalamus, and amygdala of fetal macaques have been shown by us to concentrate radioactivity after the in vivo administration of ^{3}H-testosterone, and a major portion of the nuclear radioactivity in these regions is in the form of ^{3}H-estradiol. To study the uptake and binding of estradiol by the fetal brain, 500 uCi ^{3}H-estradiol was administered via the umbilical vein to rhesus and cynomolgus monkeys (2 males and 3 females) on day 122-125 of gestation. The fetus was delivered 1 h later by cesarean section. The brain was frozen for thaw-mount autoradiography and samples of cerebral cortex were used for analysis of radioactivity in nuclear and supernatant fractions by high performance liquid chromatography. There were only a few weakly labeled neurons in the hypothalamus and amygdala of one female, and no labeled cells in the brains of the remaining four fetuses, despite high levels of radioactivity in plasma. ^{3}H-estradiol was more rapidly cleared from fetal blood than from adult blood but was still detectable in plasma 60 min after injection. In supernatant fractions, no ^{3}H-estradiol could be detected, suggesting that the absence of labeled neurons in autoradiograms might have been due both to rapid clearance and an inability to pass from plasma to cytoplasm and, hence, into the nucleus. The mechanisms preventing the entry of estradiol into neuronal nuclei may protect the fetal brain from any deleterious effects of estrogenic hormones during development. (Supported by USPHS Grant MH 40420 and by the Georgia Department of Human Resources.)

DEVELOPMENT OF SEXUALLY DIMORPHIC AXON NUMBERS IN THE LARYNGEAL NERVE OF XENOPUS LAEVIS. Darcy B. Kelley and Jane Dennison*, Department of Biological Sciences, Columbia University, New York, N.Y. 10027

In clawed frogs, male-specific courtship song reflects activity of the more numerous laryngeal motor neurons. We examined the ontogeny of this sex difference by counting motor axons in EM photomicrographs of laryngeal nerves.

Adult males have approximately 100 more laryngeal axons than females (male: 321, female: 225). At tadpole stage 56, axon number is high (614) in both sexes. Axon number then decreases in females until the adult value is reached at 6 months post-metamorphosis. In males, 100 additional axons are added between tadpole stages 59 and 62. Whereas the extent of myelination is the same for both sexes at all stages, the number of degenerating axon profiles is higher in females. The percentage of growth cone-like axonal profiles in males declines between stages 56 to 59 and again between stages 62 to 66.

We conclude that the adult male/female difference in laryngeal nerve axon number is due to the addition of approximately 100 axons between stages 59 and 62 in males and the maintenance of this relative difference thereafter. Morphological evidence indicates (1) less cell death in males than in females and (2) outgrowth of more axons in males. Axon number is dimorphic prior to sexual differentiation of muscle fiber number and may contribute to the additional myogenesis in male larynx (Sassoon and Kelley, Am. J. Anat., 1986). ISOLATING DEVELOPMENTALLY IMPORTANT GENES FROM THE LOBSTER NERVOUS SYSTEM. L.N. Geller*, L. Kobierski*, H. Potter, and E.A. Kravitz. Department of Neurobiology, Harvard Medical School, Boston, MA 02115.

In the lobster, Homarus americanus, dramatic changes in form and behavior occur during development that are paralleled by changes in the nervous system. It is likely that amines and certain peptides play important roles in some of these developmental transitions. In addition, the molting hormone, 20-hydroxyecdysone is released into the circulation of insects and crustaceans before each molt, and contributes to the transition to the next developmental stage. To facilitate the examination of nervous system development, we are attempting to clone two families of lobster genes: one represents direct transcriptional regulators of development; the other consists of proteins likely to be targets of transcriptional regulation. In the first category, we are attempting to clone the gene for the lobster 20-hydroxyecdysone receptor. We are using the zinc finger region of a hormone receptor from Drosophila melanogaster (kindly supplied by W. Seagraves) to probe a genomic library constructed from a partial Mbo 1 digest of lobster DNA cloned into EMBL-4. In the second category, we are using a probe from the active site region of the rabbit tryptophan hydroxylase gene (kindly supplied by S.L.C. Woo). Positive lobster DNA clones have been isolated using both probes and are in the process of being analyzed for comparison with other species and for their pattern of expression during lobster development.

TESTOSTERONE STIMULATES NEUROPEPTIDE Y LEVELS IN SELECTED HYPOTHALAMIC SITES: EFFECTS OF AGING. A. Sahu*, S.P. Kalra, W.R. Crowley and P.S. Kalra (SPON:K.M. HEILMAN). Ob/Gyn UF Col Med, Gainesville, FL and U TN Col Med, Memphis,TN

Neuropeptide Y (NPY) is localized in various hypothalamic (HYP) sites that are innervated by LHRH-containing and gonadal steroid-concentrating neurons. Previous evidence that NPY stimulates LHRH release in steroid-primed rats and castration (CAST) decreases the release and levels of NPY selectively in 3 HYP sites, suggested that, similar to the effects on LHRH, steroids may also influence NPY neurosecretion. To test this hypothesis we examined the effects of testosterone (T) on NPY levels in microdissected HYP sites of young (2-3 mo) and old (15 mo) male rats. Young: Of the 7 sites examined, NPY levels decreased after CAST only in the median eminence (ME), arcuate (ARC) and ventromedial nucleus (VMN). Physiological T replacement immediately after CAST prevented the decrease in these sites. Further, T replacement for 10 days, beginning 2 weeks postCAST when NPY stores were depleted, significantly raised NPY levels selectively in these 3 sites. Aged: Overall NPY concentrations in each of the 7 nuclei examined were lower than those observed in young rats. As in young rats, CAST decreased NPY levels further in ARC and VMN of old rats. However, CAST also led to a decrease in NPY levels in the medial preoptic area (MPOA) and dorsomedial nucleus, but not in the ME of old rats. Also, T replacement was not as effective because the CAST-induced decrease was prevented only in the MPOA of aged rats. Thus, despite the widespread distribution of NPY in the hypothalamus, the facilitatory effects of T on NPY levels are restricted to only those sites that are involved in LHRH secretion and the aging process per se attenuated these T effects. (HD 11362).

DIFFERENTIAL EFFECTS OF ESTROGEN ON SUBSTANCE P mRNA LEVELS IN THE RAT ANTERIOR PITUITARY AND HYPOTHALAMUS. E.R. Brown, R.E. Harlan, & J.E. Krause. Dept. of Anatomy & Neurobiology, Washington University Medical School, St. Louis, MO 63110; Dept. of Anatomy, Tulane University School of Medicine, New Orleans, LA 70112

Gonadal steroids alter substance P (SP) peptide levels in the rat anterior pituitary (AP): Estrogen decreases and androgen increases AP SP in male and female rats. In order to determine whether these steroid effects occur at the level of peptide synthesis, we analyzed preprotachykinin (PPT) mRNA levels in individual AP glands, as well as in hypothalami, from intact rats, as well as castrated males (CAST) and ovariectomized females (OX) which were injected daily with either estradiol benzoate (EB; females), testosterone propionate (TP; males), or oil vehicle, for 10 days following surgery. A nuclease protection assay was used to compare levels of the SP-encoding PPT mRNAs (α, β, and γ) in the different treatment groups, and β-actin mRNA, measured by northern analysis, was used as a control. OX resulted in a 5-fold increase over no-surgery control levels, and EB replacement caused a 7-fold reduction below levels in OX rats, in AP β- and γ- PPT mRNAs. On the other hand, in the hypothalamus EB caused a significant increase in all three PPT mRNAs over OX levels. CAST resulted in a decrease, and TP replacement caused an increase back to control levels, in AP β- and γ- PPT mRNAs; this effect was not significant, however, perhaps due to TP aromatization to estrogen. There were no differences in SP-encoding mRNAs in male hypothalami between any of the groups. The EB-induced decrease in these mRNAs in the AP indicates that the estrogen effect on SP levels is at least in part due to changes in peptide synthesis. Furthermore, this regulation is extended to the hypothalamus, where estrogen alters SP-encoding mRNA levels in a direction opposite to that in the AP. These results support the notion that AP and hypothalamic SP is involved in the regulation of AP function.

TRANSMITTER UPTAKE, STORAGE, SECRETION AND METABOLISM III

RECONSTITUTION OF THE ATP-DEPENDENT GLUTAMATE UPTAKE SYSTEM INTO LIPOSOMES. M. Carlson*, P. Kish* and T. Ueda. Univ. of Michigan Mental Health Res. Inst., Ann Arbor, MI 48109.

We have previously provided evidence for ATP-dependent glutamate uptake into synaptic vesicles, supporting the neurotransmitter role of glutamate. Based upon the unique properties of the vesicular uptake system, we have proposed that the vesicular glutamate translocator plays a crucial role in selecting glutamate for neurotransmission. It is proposed that the vesicular uptake components consist of a glutamate translocator and a proton-pump Mg-ATPase complex. In this study, we have solubilized the vesicular uptake components from brain synaptic vesicles with sodium cholate in the presence of phospholipids and reconstituted the components into phospholipid vesicles (liposomes) by removing the detergent by gel filtration. We demonstrate that the properties of the reconstituted glutamate uptake system are highly similar to those observed in the intact synaptic vesicles, namely ATP-dependency, K_m for glutamate, stimulation by low millimolar concentrations of chloride, sensitivity to electrochemical proton gradient dissipators, and specificity for L-glutamate. The specific uptake activity of the reconstituted system is about 70% higher than that of the native vesicular system. The reconstituted glutamate uptake assay described here represents an initial step toward the separation and purification of the functional proton-pump ATPase complex & the glutamate translocator. (Supported by NSF Grant BNS 8509679.)

INSULIN-LIKE GROWTH FACTOR-I (IGF-I) ENHANCES CATECHOLAMINE SECRETION FROM BOVINE CHROMAFFIN CELLS. M.K. Dahmer* and R.L. Perlman. Depts. of Peds. and Pharmacol. and Physiol. Sci. and Kennedy Mental Retard. Res. Cent., University of Chicago, Chicago, IL 60637.

We have recently reported that bovine chromaffin cells contain IGF-I receptors (M.K. Dahmer and R.L. Perlman, J. Neurochem. 51, 321-323, 1988). We have now studied the effects of IGF-I on catecholamine secretion from these cells. Chromaffin cell cultures were maintained in serum-free medium in the presence or absence of IGF-I (10 nM) and then incubated for 10 min in medium containing 55 mM K^+; catecholamines released from the cells were assayed by liquid chromatography with electrochemical detection. IGF-I did not affect the survival or the catecholamine content of the cells. Cells that were cultured for 4 days in the presence of IGF-I, however, exhibited a 2-3 fold increase in high K^+-evoked catecholamine secretion. The enhancement of catecholamine secretion was dependent on the IGF-I concentration ($EC_{50} \cong 3$ nM). Insulin also enhanced catecholamine secretion, but was much less potent than IGF-I; thus, the action of IGF-I is probably mediated by IGF-I receptors. IGF-I also enhanced the secretion of catecholamines elicited by ionomycin (3 μM), suggesting that it acts at a step distal to Ca^{2+} entry. IGF-I appears to be an important regulator of chromaffin cell function. (Supported by NIH grants HD04583, HL07455 and HL29025).

CHOLINERGIC SYNAPTIC VESICLES CONTAIN TWO ATPASE ACTIVITIES. S.M. Parsons, S.K. Yamagata*, and K. Noremberg. Dept. of Chemistry, University of California, Santa Barbara, California 93106.

A glycoprotein MgATPase has been purified from Torpedo californica electric organ synaptic vesicles and shown to have a native-detergent solubilized M_r of 210,000 ± 9000 composed of 110, 104, 98, and 69 kDal subunits. This ATPase is inhibited by vanadate (K_i 10μM), and it accounts for about 2/3 of the total activity in the vesicles. Acetylcholine active transport is not inhibited by vanadate; rather, it is stimulated by 25 percent. Vanadate-insensitive ATPase activity in the vesicles is inhibited by N-ethylmaleimide (K_i 8 μM) as is acetylcholine active transport. This second activity presumably is due to the vacuolar-type ATPase generally postulated to pump protons into most secretory vesicles. The glycoprotein ATPase purified by us forms a phosphoenzyme intermediate with [γ-^{32}P]ATP, but the ATPase is ouabain insensitive and not stimulated by Ca^{2+}. Other properties are being investigated.

479.4

SODIUM-DEPENDENT UPTAKE OF NUCLEOSIDES BY DISSOCIATED BRAIN CELLS FROM RAT. J.D. Geiger. Dept. of Pharmacol., Univ. of Manitoba, Winnipeg, MB. R3E OW3.

Nucleoside transport was studied using a mixed population of dissociated brain cells from adult rat. Accumulation of [^{3}H]adenosine during brief (15 sec) incubation periods was significantly enhanced by the presence of 110 mM sodium. This occurred at substrate concentrations that ranged from 0.25 to 100 uM. Kinetically, the rapid accumulation of [^{3}H]adenosine was best described by a two-component system. In the presence of sodium, the K_T and Vmax values for the high affinity component were 0.9 uM and 8.9 pmoles/mg protein/15 sec, and for the low affinity component were 313 uM and 3428 pmoles/mg protein/15 sec, respectively. In the absence of Na^+, the $K_{T(high)}$ value was significantly higher; 1.8 uM. [^{3}H]Uridine accumulation was best described kinetically by a one-component system that in the presence of Na^+ had K_T and Vmax values of 1.0 mM and 2.6 nmoles/mg protein/15 sec, respectively. As with [^{3}H]adenosine, in the absence of Na^+, the K_T value was significantly higher; 1.8 mM. Sodium-dependent transport of [^{3}H]adenosine was inhibitable by ouabain and 2,4-dinitrophenol. Nitrobenzylthioinosine demonstrated high affinity and selectivity in blocking the sodium component. Thus, high affinity sodium-dependent nucleoside systems, in addition to facilitated diffusion systems, exist on brain cells from adult rats.

479.5

LOCALIZATION OF THE DOPAMINE UPTAKE SITE IN RAT BRAIN USING [^{3}H]-BTCP. J.K.Wamsley, M.Hunt* and F.Filloux. Dept. of Psychiatry, Univ. of Utah Sch. of Med., S.L.C., UT. 84132.

To date, a number of tritiated ligands have been used for autoradiographic labeling of dopamine(DA) uptake sites in the brain. These include [^{3}H]-mazindol, [^{3}H]-nomifensine, [^{3}H]-methylphenidate and [^{3}H]-GBR12935. None have proven satisfactory thus far. ((Benzo(b)thiophenyl-2)-1-cyclohexyl)N-piperidine (GK-13 or BTCP) has been shown to be a potent inhibitor of DA uptake whose affinity for noradrenergic (NE) sites is substantially less, (Chicheportiche et. al.). We have found [^{3}H]-BTCP binding to 10um coronal sections of rat forebrain to be both reversible and saturable and of comparatively high affinity ($K_D \approx$10 - 15nM). The highest specific binding was achieved using 50mM Tris buffer (pH=7.0) which also contained 120mM NaCl. Under these conditions, nonspecific binding was ≤ 45%. Preliminary autoradiograms demonstrate that specific binding in the forebrain is concentrated in the basal ganglia and olfactory tubercle, while little or no specific binding is present in the cerebral cortex. Specific binding is potently displaced by GBR12909, a selective DA uptake inhibitor. No greater degree of displacement is achieved by mazindol, an agent with greater affinity for the NE sites than for DA uptake sites. These data suggest that [^{3}H]-BTCP should be very useful for autoradiographic studies of the dopamine transport complex.

479.6

"SUBSTANCE M," AN IMIPRAMINE BINDING SITE LIGAND FROM HUMAN URINE. K.G. Walton, T. Hauser*, T. McCorkle*, C. Maclean*, D. Fleshman* and R.K. Wallace. Departments of Chemistry and Physiology, Maharishi International University, Fairfield, IA 52556.

Imipramine and other tricyclic antidepressants inhibit the active uptake of serotonin into neurons and blood platelets. This effect involves high-affinity binding of imipramine to a portion of the uptake site where the inhibitor appears to act allosterically. A reduced number of imipramine binding sites in a subset of depressed patients may reflect differences in serotonergic tone between these patients and normal subjects. The possibility that an unidentified endogenous ligand normally regulates serotonin uptake at this site and may play a modulatory role in the serotonin system is under investigation in our laboratory. We have previously reported an inhibition of imipramine binding by extracts of human urine. This inhibitory activity has now been further purified using TLC on silica plates with a mobile phase of acetone / methylene chloride / water / ammonia (80 / 20 / 2 / 0.2). The activity was first concentrated from the urine using a reversed phase C_{18} extraction column (Baker-10 SPE), eluting with acetonitrile. In a typical urine sample, 50% inhibition of [^{3}H]imipramine binding was achieved with extract from 0.1ml of urine (assay volume = 0.5 ml). Eluates from 3 adjacent regions of the TLC plate had inhibitory activity. Reverse phase HPLC of each of these eluates shows 1-3 major and a small number of minor uv-absorbing species. Complete purification and identification of the active ligand(s) seems near.

479.7

COORDINATE STIMULATED RELEASE OF CALCITONIN GENE-RELATED PEPTIDE (CGRP) AND SUBSTANCE P (SP) FROM DISSOCIATED CULTURES OF NEONATAL RAT VAGAL SENSORY NEURONS. D.B. MacLean, Div. of Endocrinology, Brown University, Rhode Island Hospital, Providence, RI 02902

These studies sought to determine whether in cultures of vagal sensory neurons the stimulated release of two neuropeptides, SP and CGRP, is differentially regulated, as previously demonstrated regarding their content. Jugular-nodose ganglia from neonatal rats were enzyme dispersed and co-cultured with rat atriacytes. Neuropeptide content was measured by RIA in release media (KRB, 1% FBS) from 15-20 min epochs between 2-4 weeks in culture. Both SP and CGRP release were stimulated by capsaicin. 34 mM K+-supplemented KRB stimulated SP and CGRP release 6-10x above basal levels, e.g. SP, 23±4 pg and 168±20 pg/well and CGRP 91±27 pg and 702±202 pg/well, basal vs stimulated, x± SD. Bradykinin (BK), maximal effect at 10 nM, resulted in 3-4x basal release e.g. SP, 64±13 pg and CGRP 290±49 pg/well, but did not further enhance K+ release. Histamine did not raise basal or BK-induced release. Serotonin (0.5 uM) weakly stimulated basal release and enhanced BK-evoked release e.g. CGRP 180±55 vs 473±223 pg, BK vs BK + serotonin, P<.01. Forskolin (10 uM) raised both SP and CGRP media content to 2.5-3.5x basal levels; aminophylline did not enhance basal or BK stimulated release. Conclusion: Both CGRP and SP are released from vagal sensory neurons in response to similar stimuli.

479.8

THE DISTRIBUTION OF HIGH AFFINITY UPTAKE SITES FOR [^{3}H] GABA IN THE HUMAN MYENTERIC PLEXUS. A. Krantis*, A. Khalil and C. Krause, Digestive Diseases Research Group, Dept. of Physiology and Div. of Gastroenterology, Univ. of Ottawa, Ottawa, K1H 8M5, Canada.

GABA is a transmitter of myenteric neurons in the guinea-pig, and is proposed to be an enteric neurotransmitter in the rat, cat and human, where GABA and its metabolic enzymes have been localized in neural elements of the intestine wall (Tanaka 1985, Life Sciences, 37: 2221-2235). However, the disposition of GABAergic neurones in the human enteric nervous system is unknown. Therefore we sought to determine the occurrence and disposition of high affinity uptake sites for [^{3}]GABA (characteristic of GABA nerve cells) in the human large intestine. Autoradiography (after Krantis et al. 1986, Neuroscience 17(4): 1243-1255) was performed on paraffin sections (12-20 μm) of various segments of colon taken at surgery and incubated with 50 Ci/mmole (Amersham) 2,3 [^{3}]GABA, 5.10^{-9} to 10^{-8}M, in the absence or presence of specific inhibitors of high affinity GABA uptake. Radiolabelled GABA was accumulated by a sub-population of myenteric neurones in all segments examined. However, few labelled processes could be seen. These results show that GABA is transported into human myenteric neurones by a high affinity system.

QUINOLINIC ACID FORMATION IN RAT BRAIN IN VIVO AND IN VITRO: EFFECTS OF STRIATAL LESIONS. C. Speciale, U. Ungerstedt* and R. Schwarcz. Maryland Psych. Res. Ctr., Baltimore, MD 21228.

In view of the potential role of the excitotoxic brain metabolite quinolinic acid (QUIN) in neurodegeneration, we have begun to examine mechanisms controlling its synthesis in the brain. Both in vivo (using brain microdialysis in awake rats) and in vitro (in brain slices), local pretreatment with QUIN's putative bioprecursors tryptophan and kynurenine (1 mM) failed to yield QUIN. In contrast, QUIN production was demonstrated after tissue exposure to as little as 10 µM 3-hydroxyanthranilic acid (3HANA). Since 3HANA-oxygenase activity is greatly increased in lesioned brain (Brain Res., 436: 18, 1987), the ibotenate (40 µg)-injected rat striatum was examined for its ability to produce QUIN from 3HANA. One week after surgery, striata of lesioned (IBO) or saline-treated (SAL) rats were perfused with 30 µM 3HANA. Extracellular QUIN, collected hourly, increased more rapidly in IBO (75±10 vs. 28±6 pmoles/50 µl during the 2nd hour; $p<0.01$) than in SAL rats. After in vitro exposure of striatal slices to 30 µM 3HANA (30 min, 37°C), 135±9 vs. 49±2 pmoles QUIN/mg protein, respectively, were detected in the medium after incubation with slices from IBO and SAL rats ($p<0.01$). Increased extracellular levels of QUIN in lesioned tissue may play a role in neurodegenerative processes. (Supported by a Fogarty Fellowship (to C.S) and USPHS grant NS 16102).

KYNURENINE AMINOTRANSFERASE IN HUMAN BRAIN. M. Nakamura, E. Okuno, [1]W.O. Whetsell Jr. and R. Schwarcz. Maryland Psych. Res. Ctr., Baltimore, MD 21228 and [1]Dept. Pathol., Vanderbilt Univ. School Med., Nashville, TN 37232.

The cerebral biosynthesis of the putative neuroprotectant kynurenic acid (KYNA), a constituent of human brain, has as yet not been elucidated. In rat tissue, four enzymes have been identified which can transaminate L-kynurenine to KYNA, and one transaminase has been described in the human liver. Using a conventional spectrophotometric assay (Biochem. J., 189: 581, 1980), we found kynurenine transaminase (KYNT) activity in thawed human brain tissue homogenate. KYNT activity was dependent on α-ketoglutarate (αKG) and pyruvate (PYR) as aminoacceptors. Product formation was confirmed by HPLC analysis. Linearity of the enzymatic reaction was ascertained up to 2 hours of incubation and up to 600 µg protein/assay tube. In the course of our efforts to purify KYNT from human brain, αKG and PYR were used as aminoacceptors in parallel at every purification step. Differences existed with regard to both the yield of activity and specific activity when the results using αKG and PYR were compared, indicating the presence of at least two KYNT proteins in the human brain. Efforts are now under way to further purify and characterize the two enzymes, and to examine their respective roles in the anabolism of neuroactive KYNA.

(Supported by USPHS grants NS 16102 and NS 20509).

479.11

SYNTHESIS OF KYNURENIC ACID FROM ITS BIOPRECURSOR L-KYNURENINE IN RAT BRAIN IN VITRO AND IN VIVO. W.A. Turski, J.B.P. Gramsbergen, C. Speciale, U. Ungerstedt* and R. Schwarcz. Md. Psych. Res. Ctr., Baltimore, MD 21228.

The neuroprotective broad spectrum excitatory amino acid antagonist kynurenic acid (KYNA) has recently been identified in mammalian brain. In the present study, we have examined the synthesis and liberation of KYNA from rat brain in vitro (slices) and in vivo (microdialysis) after exposure of the tissue to L-kynurenine (KYN). After incubation, brain slices produced KYNA in a tissue-, dose (KYN)-, time-, temperature-, oxygen- and glucose-dependent fashion. Under standard conditions (2 h incubation at 37°C using 50 µM KYN in regular, oxygenated Krebs-Ringer buffer), cortical slices produced about 100 pmol KYNA per mg protein. De novo synthesized KYNA was rapidly liberated into the incubation medium, and its production could be blocked by the non-selective transaminase inhibitor, aminooxyacetic acid (IC_{50}: 25 µM). KYNA production and liberation did not depend on the presence of Ca^{2+}-ions and remained unchanged in high Mg^{2+} (20 mM) medium. Experiments with slices derived from ibotenate lesioned striata (40 µg/2 µl; 7 days after surgery) suggest a predominantly glial localization of KYNA production.

After in vivo perfusion with 500 µM KYN, KYNA was detectable in 30 min fractions of striatal dialysates, reaching plateau concentrations after about 3 h.

Supported by USPHS grants NS 16102 and NS 20509.

NEURONAL ACTIVITY AFFECTS KYNURENIC ACID PRODUCTION IN RAT BRAIN SLICES. J.B.P. Gramsbergen, W.A. Turski and R. Schwarcz. Maryland Psych. Res. Ctr., Baltimore, MD 21228.

The endogenous excitatory amino acid antagonist and brain metabolite kynurenic acid (KYNA) may play a role in the prevention of excitotoxic brain damage.

KYNA can be produced by brain slices in vitro upon exposure to its bioprecursor L-kynurenine (KYN; cf. Turski et al., this meeting). The effect of different experimental conditions was assessed by measurement of liberated KYNA in the incubation medium. Blockade of neuronal activity with 1 µM TTX or by incubation in Na^+-free medium gave rise to higher concentrations of KYNA (+23% and 31%, respectively; $p<0.05$), whereas depolarization of the slices by K^+ (50 mM) or veratridine (5 µM) resulted in a substantial decrease (-38% and -68%, respectively; $p<0.001$) of KYNA content in the medium. The effects of both veratridine and high K^+ were blocked in Na^+-free incubation medium. Furthermore, the effect of veratridine was inhibited by TTX and the effect of high K^+ could be attenuated in Ca^{2+}-free medium and was blocked completely by 20 mM Mg^{2+}.

Both high K^+ and veratridine were not effective in experiments performed with slices derived from ibotenate lesioned (40 µg/2 µl; 7 days postsurgery) striata. Taken together, our data show that neuronal activity (and possibly a releasable factor), rather than direct depolarization of glial cells, affects the (glial) production of KYNA.

EXCITATORY AMINO ACIDS X

480.1

ANTAGONIST PHARMACOLOGY OF EXCITATORY AMINO ACID RECEPTORS EXPRESSED IN XENOPUS OOCYTES. T.A. Verdoorn and R. Dingledine. Dept. Pharmacology and Curr. Neurobiol., Univ. North Carolina, Chapel Hill, NC 27599.

Quantitative pharmacological studies of neuronal EAA receptors were done in Xenopus oocytes injected with rat brain mRNA. Inward currents induced by NMDA and kainate were both antagonized by CNQX (FG 9065). The properties of antagonism were different for NMDA and kainate receptors, however. CNQX was a competitive antagonist of the receptor mediating the kainate current as determined by Schild analysis (pA_2 = 6.53 ± 0.02, slope = 1.02 ± 0.02, n=19) up to a dose ratio of approximately 100. The block of NMDA receptors by CNQX was non-competitive since 6 µM and 15 µM CNQX reduced the maximum NMDA current by 49 ± 8% (n=3) and 69 ± 6% (n=3) respectively, and 15 µM CNQX increased the NMDA EC_{50} by no more than 2-fold. CNQX had little or no effect on the oscillating chloride current induced by quisqualate and caused no detectable ionic current by itself. D-APV antagonized currents induced by NMDA and L-aspartate in an apparently competitive manner up to D-APV concentrations of at least 100 µM (approximate dose ratio = 100). The pA_2 of D-APV was 5.85 ± 0.04 (slope = 1.03 ± 0.03, n=9) against NMDA currents and 5.86 (n=2) against L-aspartate currents. D-APV alone caused no ionic current. These data indicate NMDA and L-aspartate currents may be mediated by the same receptor. The non-competitive block of NMDA currents by CNQX further distinguishes NMDA receptors from kainate receptors.

480.2

EXPRESSION OF THE N-METHYL-D-ASPARTATE/PCP RECEPTOR IN XENOPUS OOCYTES INJECTED WITH mRNA FROM NCB-20 CELLS. L. Kushner*, J. Lerma*, M.V.L.Bennett and R.S. Zukin Albert Einstein College of Medicine., Bronx, NY 10461

The N-methyl-D-aspartate (NMDA) receptor complex is a ligand-gated cation channel which contains regulatory binding sites for Mg^{2+}, Zn^{2+} and glycine. Recent evidence suggests that this receptor complex also contains the phencyclidine (PCP) receptor which mediates the psychotomimetic effects of PCP derivatives, σ opioids and the dioxalanes, and that PCP acts as a blocker of the NMDA gated channel. The mouse neuroblastoma-Chinese hamster brain hybrid cell line NCB-20 has a PCP receptor similar to the rat brain receptor based on quantitative receptor assays under equilibrium binding conditions. This site was labelled by the potent phencyclidine derivative N-[1-(2-thienyl)cyclohexyl]piperidine (TCP) with a binding affinity (K_d) of 335 nM and a receptor density (B_{max}) of 9264 fmol/mg protein. In order to investigate the molecular basis of the NMDA/PCP receptor of NCB-20 cells we looked for its expression in Xenopus oocytes injected with NCB-20 cell poly(A^+)RNA (50 ng/cell) Oocytes were voltage clamped and perfused with Mg^{2+}-free amphibian Ringer's solution. Drugs were bath-applied. At a holding potential of -60 mV, NMDA (EC_{50} = 20 µM, with 10 µM glycine) evoked a partially desensitizing inward current that was potentiated by glycine (EC_{50} = 0.1 µM) and inhbited by the competitive antagonist D-(-)-amino-5- phosphonovaleric acid (IC_{50} = 3 µM). NMDA currents were blocked by PCP (0.1 µM) and MK-801 (0.1 µM) in a use dependent manner. There was little or no response to quisqualate (10 µM), kainate (500 µM) and GABA (100 µM). These data indicate that the NCB-20 cells contain mRNA which encodes a NMDA/PCP receptor like that of neurons.

480.3

NMDA, KAINATE AND QUISQUALATE RECEPTORS OF RAT BRAIN EXPRESSED IN XENOPUS OOCYTES: SUMMATION EXPERIMENTS INDICATE THAT EACH GATES SEPARATE CHANNELS. J. Lerma*, L. Kushner*, M.V.L. Bennett, and R.S. Zukin (SPON: E. Masurovsky) Albert Einstein College of Medicine, Bronx, NY 10461.

Rat brain mRNA injected into Xenopus oocytes leads to responsiveness to the glutamate agonists NMDA (N), kainate (K) and quisqualate (Q) (Kushner et al., PNAS 85: 3250, 1988). Sharing of channels by receptors for these agonists has been suggested (Jahr and Stevens, Nature 325: 522, 1987). However, the present study of voltage-clamped oocytes indicate independence: 1) The Hill coefficients differ (c.1.0, 1.5 and 1.9 for N, K and Q, respectively). 2) PCP receptor ligands are channel blockers selective for NMDA receptors. When NMDA channels are blocked by trapped PCP, K and Q currents are unaffected. 3) NMDA and Q currents summate linearly. 4) NMDA and K currents summate with a 10-20% deficit. Part of the deficit is because NMDA is a weak antagonist at K receptors; NMDA in the presence of a sufficient concentration of APV, PCP or Mg to block NMDA responses reduces K currents slightly, whereas APV alone has a lesser effect and PCP or Mg alone has no effect. The remainder of the deficit is ascribable to weak antagonist action of K at NMDA receptors. 5) Q currents are usually much smaller than K currents. Saturating Q slightly facilitates responses to low concentrations of K and reduces responses to high concentrations of K. Plausibly, Q is a partial agonist at K receptors, such that K receptors occupied by 2Q are inactive, QK are partially active and 2K are maximally active. Although specificities of the available drugs are not absolute, these data support the classical concept that NMDA, K and Q act with highest affinity at different binding sites each gating its own channel.

480.4

COMPETITIVE AND NON-COMPETITIVE BLOCK OF NMDA/PCP RECEPTORS EXPRESSED IN XENOPUS OOCYTES. M.V.L Bennett, J. Lerma*, L. Kushner* and R.S. Zukin. Albert Einstein College of Medicine, Bronx, NY 10461

NMDA receptors were expressed in Xenopus oocytes following injection of rat brain mRNA (Kushner et al. PNAS 85: 3205, '88). Glycine is required for responses to bath-applied NMDA. Responses to varying NMDA concentrations (with 10 μM glycine, steady state, partially desensitized) have a Hill coefficient, n=1 and K_d=16 μM. I_{max} increases with glycine concentration, but n and K_d are unaffected, consistent with allosteric potentiation. APV (EC_{50}=3 μM) is a competitive blocker; K_d is shifted to higher concentrations with little effect on n or I_{max}. Block by PCP is non-competitive; I_{max} is reduced without change in K_d or n. PCP appears to be a channel blocker, and block and unblock exhibit use dependence. PCP alone blocks very slowly; block develops rapidly in the presence of NMDA. Rate of onset of block increases with agonist concentrations (when channel open probability is higher), but degree of block depends on PCP and not NMDA concentration (indicating that PCP enters and leaves channels primarily if not exclusively when they are open). Removal of agonist leaves the channel blocked. Recovery is slow in the absence of applied agonist and is speeded by reapplication. Block is voltage dependent in that at more inside positive voltages recovery (in the presence of agonist) is faster. Mg^{2+} shows similar non-competitive and voltage dependent block (ED_{50}=10 μM), but on and off times are too rapid to demonstrate trapping in the channel. Block by Zn^{2+} (EC_{50}=10 μM) is non-competitive but less voltage dependent. These results show further characteristics of the NMDA/PCP receptor expressed in oocytes and strengthen the view that PCP is an open channel blocker.

480.5

7-CHLOROKYNURENIC ACID: A SELECTIVE ANTAGONIST AT THE GLYCINE MODULATORY SITE OF THE NMDA RECEPTOR COMPLEX. A.C. Foster, J.A. Kemp*, P.D. Leeson*, R. Tridgett*, T. Priestley* and G.N. Woodruff*. Merck Sharp and Dohme Research Laboratories, Terlings Park, Eastwick Road, Harlow, Essex, U.K.

Glycine has been shown to markedly potentiate responses in cultured cerebral neurones mediated by N-methyl-D-aspartate (NMDA) receptors (Johnson and Ascher, Nature, 325: 529, 1987). Electrophysiological experiments using isolated outside-out membrane patches (ibid) and radioligand binding studies (Wong et al, Eur. J. Pharmacol. 142: 487, 1987) indicate an allosteric interaction through a strychnine-insensitive glycine recognition site which is part of the NMDA receptor complex. Here we present evidence that 7-chlorokynurenic acid (7-Cl KYNA) inhibits NMDA responses by a selective antagonism of glycine at its modulatory site. In rat cortical slices 7-Cl KYNA (10-100μM) non-competitively inhibited NMDA responses and this effect could be reversed by the addition of glycine (100μM) or D-serine (100μM). Radioligand binding experiments showed that 7-Cl KYNA had a much higher affinity for the strychnine-insensitive [^{3}H]glycine binding site (IC_{50} 0.56μM) than for the NMDA (IC_{50} 169μM), quisqualate (IC_{50} 153μM) or kainate (IC_{50} > 1000μM) recognition sites. Whole cell patch clamp recordings from rat cortical neurones in culture also indicated that the inhibition of NMDA responses by 7-Cl KYNA could be reversed by glycine and in addition basal NMDA responses were abolished, suggesting a negative modulatory effect of 7-Cl KYNA at the glycine site. These findings indicate that the glycine modulatory site of the NMDA receptor is functional in intact tissue and that 7-Cl KYNA may be a useful tool for the study of its involvement in CNS function.

1-HYDROXY-3-AMINOPYRROLIDONE-2 (HA-966) AND KYNURENATE ANTAGONISM OF N-METHYL-D-ASPARTATE (NMDA) RECEPTOR MEDIATED EVENTS IN SLICES OF RAT NEOCORTEX IS REVERSED BY GLYCINE. E.J. Fletcher* and D. Lodge* (SPON: M. Duchen). Dept. Basic Vet. Sci., Royal Vet. Coll, London NW1, U.K.

Glycine potentiated responses evoked by NMDA in patch clamp studies of Johnson & Ascher (Nature, 325:529, 1987), via a strychnine-insensitive site near the NMDA receptor.

On rat cortical wedges, however, we found that glycine (10uM-1mM) did not enhance depolarisations evoked by NMDA. But, when NMDA responses were reduced by either kynurenate or HA-966, glycine reversed the antagonism of NMDA but not that of quisqualate. Thus, 200uM kynurenate reduced NMDA responses to 59 + 2% of control whilst in the presence of 100uM glycine this was only 32 + 5%. 200uM HA-966 alone reduced the response to NMDA by 32 + 0.6% but in the presence of 100uM glycine by only 8 + 4%. NMDA antagonism produced by magnesium, aminophosphonovalerate (AP5), ketamine and dextrorphan was not reversed by glycine.

Spontaneous synaptic activity in cortical wedges bathed in magnesium-free medium was reduced by magnesium, AP5 and kynurenate, but only the latter was reversed by glycine.

These results suggest that glycine tonically facilitates synaptic responses mediated by NMDA receptors and that HA-966 may be useful in characterising this novel modulatory site on the NMDA receptor channel complex.

MULTIPLE CLASSES OF EXCITATORY AMINO ACID RECEPTORS ON CULTURED EMBRYONIC AMPHIBIAN SPINAL NEURONS. S.B. Sands and M.E. Barish, Department of Physiology and Biophysics, University of California, Irvine, CA 92717.

Activation of excitatory amino acid (EAA) receptors has been implicated in mechanisms of CNS synaptic transmission including long term synaptic potentiation. EAA receptors may also play a role in the structural development of the CNS. To address this last question we are investigating the development and characteristics of EAA receptors in cultured embryonic *Xenopus* spinal neurons using the patch clamp technique. The internal solution used for whole cell and outside-out patch recording is primarily CsCl. Drugs are transiently applied to the cell under study with a perfusable extracellular pipette.

Responses to glutamate (GLU) and three GLU agonists, kainate, quisqualate and N-methyl-D-aspartate (NMDA), which define different GLU receptor classes, are present on ~60% of neurons examined within 12 hours of dissociation from late neural plate-stage embryos. A consistent association of GLU with glycine (GLY) responses suggests that these cells are motoneurons. The threshold for GLU response is <1 μM; half maximal concentration is ~20 μM. The GLU response is potentiated by low (<2 μM) concentrations of GLY, and is stereospecific for the L isomer. Responses to application of NMDA (10-100 μM) in Mg-free external solution are rarely observed, but can be exposed by simultaneous application with GLY. Potentiation of NMDA responses by GLY occurs with a half maximal concentration of <1 μM.

The effects of activation of these receptors on neurite outgrowth is currently under investigation.

480.8

DOES QUISQUALATE ACTIVATE A FAST TRANSIENT CURRENT? Cha-Min Tang* Marc Dichter and Martin Morad*(SPON:B Twarog) Dept. of Physiol. and Neurol., U of Pa., Phila.,Pa. 19104

There is no general agreement whether the quisqualate (quis) activated current desensitizes (JP 399;224, NSL 63:225). In cultured hippocampal neurons we find that the speed of drug application and the concentration tested can account for the reported discrepancy. We observe both a fast transient and a non-desensitizing current upon rapid step application fo quis in every neuron tested, supporting the report of Grantyn et al (BR 420:182). The dose response suggests two quis are required to activate each channel mediating the persistent current and activation occurs at low concentrations (half max. at 0.2 uM). The transient current is activated only above 1 uM (K_D~10-20uM). The transient current, however, shows steady state desensitization at the low concentrations that activate the persistent current. The desensitization follows a single exponential (τ~30-40 msec) and is voltage insensitive. Thus in order to observe the transient current quis has to be increased from below the inactivatingto the activating concentrations within 2-3 τ's (<100msec). In about half of the neurons the persistent current showsprominent suppression at quis concentrations above 1 uM (negative cooperativity). It is not known if these current components are mediated by a single receptor/channel complex with multiple agonist binding and allosteric interactions or separate channels.

480.9

PHYSIOLOGICAL REGULATION OF GLUTAMATE RECEPTOR FUNCTION BY DESENSITIZATION. L.O. Trussell & G.D. Fischbach
Dept. Anat. & Neurobiol., Washington U. Sch. of Med., St. Louis MO 63117.

Responses of voltage-clamped cultured chick spinal neurons to prolonged application of glutamate fade with a time course dependent on the receptor type and the method of application. Rapid application of 1 mM glutamate to outside-out membrane patches show that G_2 (APV resistant) currents fade with a $t_{1/2}$ of 5 ms. The concentration dependence of desensitization was studied by whole cell recording. Bath application of 2-100 μM glutamate (with 2-APV) reduced the responses to ionophoretic glutamate pulses applied at receptor hot spots with an ID_{50} of 8 μM. This value is in the range of concentrations that bathe neurons in vivo and in vitro (2-15 μM). Significant reduction was observed with glutamate concentrations that produced little or no receptor activation. Indeed, superfusing cells with fresh, glutamate-free solutions often increased the size of ionophoretic glutamate responses. Evoked and spontaneous excitatory synaptic currents were reduced in amplitude by 48±17% (± S.D., N=4 cells) following application of 10 μM glutamate. These data suggest that receptor desensitization by normal concentrations of glutamate modulate the efficacy of central synaptic transmission. This work was supported by NS #18458 and the ALS Association.

480.10

CHARACTERIZATION OF A RAPIDLY DESENSITIZING GLUTAMATE CURRENT IN CULTURED POSTNATAL HIPPOCAMPAL PYRAMIDAL NEURONS **L.L. Thio, D.B. Clifford, and C.F. Zorumski, Washington University School of Medicine, Departments of Psychiatry and Neurology, St. Louis, MO 63110**

Rapid pressure applications of glutamate evoke a rapidly activating and rapidly decaying inward current in >95% of the cultured neonatal rat hippocampal pyramidal neurons studied with the whole cell patch clamp technique. The decay occurs despite the continued application of glutamate, and is followed by a steady inward current. The fast, transient current is not the product of an electrical, pressure, or enzymatic artifact. While NMDA, kainate, domoate, ibotenate, and D or L-homocysteate do not evoke this rapidly desensitizing current, other structural analogs of glutamate such as quisqualate, AMPA, willardiine, and bromowillardiine do. The quisqualate current has been examined in further detail. Both the transient and steady-state phases have linear IV relationships with reversal potentials near 0mV. The fast, transient and steady-state currents are activated by quisqualate in a dose-dependent manner with K_{ap}'s of 50μM and 3μM, respectively. The fast, transient current evoked by 100μM quisqualate reaches half its peak value in 20ms and decays exponentially to 26% of its peak value with a time constant of 81 ms. The current recovers completely in less than 4s. The percentage of desensitization, the time constant of decay, and the time of recovery are identical at +50mV and -50mV.

480.11

QUISQUALIC ACID INFLUENCES KAINATE-INDUCED RESPONSES IN CULTURED CEREBELLAR GRANULE CELLS: BIOCHEMICAL AND ELECTROPHYSIOLOGICAL STUDIES. V. Gallo+, S.G. Cull-Candy* and M.M. Usowicz*. +Neurobiology Section, Pathophysiology Laboratory, Istituto Superiore di Sanita', 00161 Rome, Italy, and MRC Receptor Mechanisms Group, Pharmacology Dept., University College, London WC1E 6BT, U.K.

Kainic acid (KA) (20-300μM) and quisqualic acid (QUIS) (5-300μM) stimulated the release of preaccumulated ^{3}H-D-aspartate from rat cultured cerebellar granule cells in a dose-dependent manner. This effect of KA, but not that of QUIS, could be antagonized by kynurenic acid (KYN) (50-200μM) or by 2,3-cis-piperidine dicarboxylic acid (200μM). QUIS (10-50μM) inhibited in a dose-dependent manner the ^{3}H-D-aspartate release induced by 50μM KA. Under these conditions, ^{3}H-D-aspartate release induced by KA+QUIS was not antagonized by KYN. However, simultaneous application of ineffective concentrations of KA (10μM) and QUIS (2-5μM) evoked the release of ^{3}H-D-aspartate, and this release could also be blocked by KYN. Moreover, QUIS (2-50μM) or KYN (50-200μM) antagonized KA-induced cGMP formation: half maximal concentrations were 5μM QUIS and 100μM KYN.

These biochemical experiments were extended by complementary electrophysiological studies. Whole-cell voltage clamp recording from cerebellar granule cells showed that currents generated by 30-100μM KA were reversibly diminished by KYN (100-200μM), both at negative and positive holding potentials. Currents produced by KA were also inhibited by 5μM QUIS. This inhibition by QUIS was greater for currents evoked by 100μM KA, than for the smaller currents produced by 30μM KA. Similar observations have been made in retinal horizontal cells (Ishida and Neyton, 1984, P.N.A.S. 82, 1837). The whole-cell experiments suggest that QUIS influences KA-responses in cerebellar granule cells, possibly acting at KA receptors.

480.12

QUISQUALATE EFFECTS IN CULTURED NEURONS FROM THE RAT SUPERIOR COLLICULUS: A PATCH-CLAMP STUDY. M. Perouansky+ and R. Grantyn (SPON: H. Holländer). MPI, 8033 Martinsried, FRG

Cultured neurons from the visual layers of the rat superior colliculus express at least three different receptors for acidic aminoacids (Perouansky and Grantyn, J. Neurosci. 1988). Quisqualate-(QA)-selective components are resistant to NMDA- and kainate-(KA)-receptor antagonists such as D-2-amino-5-phosphonovaleric acid (APV) and kynurenic acid. A QA-receptor-mediated component can therefore be isolated in the compound response of tectal neurons to exogenous L-glutamate (Glu). Binding to QA-receptors produced up to half of the current elicited with 100 uM Glu.

All collicular neurons from E21/P1 rats responded to QA, its EC_{50} ranging from 0.1 to 0.3 uM. Application of QA modifies the response to other Glu-agonists. Testing QA with various concentrations of KA showed that QA acts as a competitive antagonist of KA. The effect of QA on subsequently elicited $I_{(NMDA)}$ is more complex. The initial transient component of $I_{(NMDA)}$ was suppressed, while the persistent component temporarily recovered from its block by APV. These experiments demonstrate, thus, a modulatory action of QA on NMDA-receptors.

QA had a strong effect on GABA-release, even under the condition that voltage-activated Na and Ca currents were fully blocked. QA-induced depolarization of presynaptic terminals and/or liberation of Ca from intracellular stores by activation of second messenger chains may account for this novel effect of QA.

480.13

ACTIONS OF KYNURERIC ACID ON THE NMDA-ACTIVATED CATIONIC CHANNEL: A PATCH CLAMP STUDY.
M.Bertolino, S.Vicini and E. Costa., (SPON: M. Santi). FGIN, Georgetown Univ., Washington D.C. 20007.

N-D-methyl-aspartic acid (NMDA) activates cationic channels in outside-out patches excised by neonatal rat cortical neurons in primary culture. These channels openings are characterized by a mean channel opening duration of 5-6 msec and conductance of 50 pS . D-2-amino-5-phosphonovalerate (APV), an antagonist of the NMDA recognition site on glutamate receptor reduced dramatically the frequency of these opening observed in the outside-out membrane patches exposed to NMDA. Kynurenic acid, a metabolite of tryptophan, produced as well reduction of these openings. Glycine was shown to potentiates NMDA responses increasing the channel opening frequency. APV and kynurenic acid both, counteract this glycine potentiation. APV action is probably due to competition for glutamate binding sites while kynurenic acid seems to have a non competitive action on this site as shown by whole-cell current dose-response to ionophoretically applied NMDA in presence and absence of kynurenic acid and APV. Supramaximal concentration of glycine are able to partially overcome the kynurenic and not the APV induced reduction of channel opening frequency. The interaction between these compounds will be discussed.

481.1

OLEIC ACID INHIBITS SHAM FEEDING WHEN DUODENALLY INFUSED WHILE TRIOLEIN DOES NOT. D. Greenberg, G.P. Smith, and J. Gibbs. Dept. of Psychiatry, New York Hospital-Cornell Medical Center White Plains, NY 10605.

The specific satiety stimulus provided by ingested fats is unknown. A long-chain triglyceride mixture [Intralipid (Kabi Vitrum Inc., CA)] or a single long chain fatty acid (oleic) elicits satiety when infused intraduodenally in sham feeding rats. We compare here the satiating potency of oleic acid with its triglyceride triolein.

Method: Rats were equipped with gastric cannulas for sham feeding and Silastic catheters for duodenal infusions. After 17h food deprivation, rats were permitted to sham feed liquid food (BioServ 40% v:v). Infusions began 12 min after sham feeding began and lasted 26 min. Infusions were 10 ml of oleic acid (6.5 and 13 kcal), 10 ml of triolein (2.5, 5 ,10 and 20 kcal) or 10 ml of 0.15M NaCl.

Results: Oleic acid infusions significantly reduced sham feeding by %58 (6.5 kcal) or %69.5 (13 kcal) [$F(2,6) = 40.8$, $p<.001$] compared to saline infusion. Triolein failed to significantly reduce sham feeding [maximal %17 (10 kcal); $F(3,13) = 1.91$, $p<.1$].

Conclusions: These results suggest that for long-chain fats, fatty acids are more satiating than are triglycerides.

BLOCKADE OF CHOLECYSTOKININ (CCK) SATIETY IN GENETICALLY OBESE ZUCKER RATS. A.J. Strohmayer, D. Greenberg, R. von Heyn*, L. Dornstein* and C. Balkman*, Dept Psychiatry, Cornell Univ Med Coll, Manhasset NY 11030, USA.

The specific CCK receptor antagonist L364,718 was used in the present study to block endogenous CCK satiety in Zucker rats. 6 male fa/fa obese and 6 male Fa/Fa leans were adapted to a 6 hour food deprivation, and IP injections 30 min before a one hour test meal of liquid food. Rats were injected with either L364,718 (0.375 mg/kg) or vehicle. Each rat was tested twice at this dose, the results pooled and significance determined by correlated T-test. Food intake was increased 25% in lean rats following L364,718 (19.6 ml±1.06) compared to vehicle alone (16.1 ml±0.64,T=4.072,p<0.01). Obese Zucker rats did not increase food intake following L364,718 (16.9 ml±1.33) compared to vehicle (15.5 ml±1.55, T=1.493,p>.1). The results suggest that blocked CCK receptors cause over eating in lean rats, while the blockade had no effect on obese rats, suggesting they do not release endogenous CCK. These data support an hypothesis of a failure of CCK satiety in the genetically obese Zucker rat.

481.3

THE EFFECTS OF CCK-8 INFUSION ON INTAKE AND GASTRIC EMPTYING IN NON-OBESE WOMEN. J. Guss*, H.R. Kissileff, R. Pierson* and F.X. Pi-Sunyer*. Obesity Research Center, St. Luke's\Roosevelt Hospital & Columbia University, N.Y., NY 10025.

To test the hypothesis that slowing of gastric emptying mediates the effect of CCK-8 on food intake in women, gastric emptying and intake of a test meal were measured after two doses of CCK-8 (1.125 µg/min .05625 µg/min) and saline given on nonconsecutive days in six women. The infusion began 10 min before the meal and continued for 5 min into the meal. Subjects ate a radiolabeled (technetium-99m-DTPA) soup preload (500 g) 20 min before the test meal. Intake was significantly ($p<.03$, 1-tailed) less on the larger CCK-8 dose (190 g) than on saline (319 g). Although there was no correlation between the amount of soup emptied before the meal and intake of the meal, there was a significant correlation ($r^2 = .93$ high dose CCK, $r^2 = .82$ for low dose CCK-8) between amount eaten in the test meal and amount of soup emptied during the test meal on days when CCK-8 was infused but not on days when saline was infused. Therefore, CCK-8 may faciliate signals of satiety from the stomach, but that stomach fullness per se does not mediate CCK-8's effects on emptying. (Supported by NIH grant #DK36507.)

481.4

COMPARATIVE EFFECTS OF THE CCK ANTAGONIST L364,718 ON FOOD INTAKE AND PANCREATIC EXOCRINE SECRETION IN RATS. R.D. Reidelberger*, M.F. O'Rourke* and T.E. Solomon* (SPON: J. Campbell). Depts. of Physiol. and Med., Univ. Kansas Med. Sch. and V.A. Med. Ctr., Kansas City, MO 64128.

The CCK receptor antagonist L364,718 was used to define the role of CCK in food-stimulated pancreatic secretion and satiety in rats. For pancreatic studies, animals were prepared with gastric, jugular vein, bile-pancreatic duct, and duodenal cannulas. In rats receiving a maximal stimulatory dose of CCK8 (200 pmol/kg-h), L364,718 (0.02, 0.1, 0.5, 1, 2 mg/kg i.v.; Merck Sharp & Dohme) caused dose-related inhibition of amylase output which reached levels > 90% at 0.5 mg/kg and higher. A liquid meal increased amylase output maximally; L364,718 (0.5 mg/kg) abolished the response. In food intake studies, L364,718 (0.01, 0.03, 0.1, 0.3 mg/kg i.p.) caused dose-related reversal of the maximal inhibitory effect of exogenous CCK8 (8 nmol/kg) on liquid food intake; threshold and maximal doses were 0.03 mg/kg and 0.3 mg/kg. L364,718 alone (0.03, 0.1, 0.3, 1 mg/kg) stimulated liquid and solid food intake dose-dependently; threshold dose was 0.1 mg/kg for each diet. Short-term intake (2-3 h) was increased by 16 to 35%; 22-h intake by 7 to 22%. We conclude: 1) L364,718 acts as a long-lasting inhibitor of exogenous CCK8 on pancreatic secretion and food intake; 2) endogenous CCK is important in the physiologic control of food intake and pancreatic exocrine secretion in rats.

481.5

THE EFFECTS OF CHRONIC AND ACUTE TREATMENT WITH THE POTENT PERIPHERAL CHOLECYSTOKININ ANTAGONIST L-364,718 ON FOOD AND WATER INTAKE IN THE RAT. CA Watson*, LH Schneider, ES Corp*, SC Weatherford, R Shindledecker, RB Murphy, GP Smith and J Gibbs. (SPON: SH Ackerman) Dept Psychiatry, NY Hosp-Cornell Med Ctr, White Plains, NY 10605; Dept Chemistry, New York Univ, NY, NY 10003

Cholecystokinin (CCK) released by ingested food may act as a physiological mechanism limiting food intake. To test this hypothesis, we compared the effects of chronic and acute treatments with the potent, highly selective CCK receptor antagonist L-364,718. Rats (male, S-D, 490-550g) were maintained (23 h/d) on a liquid diet under a reversed light/dark cycle. L-364,718 (n=9) or vehicle (n=9) was injected ($i_1p.$) at 1000 h (0.5 $mg\text{-}kg^{-1}$) and at 1400 h (1.0 $mg\text{-}kg^{-1}$). L-364,718 increased food intake both from 1030-1330 h (24%) and over the first 24-h (32%). The magnitude of these increases declined progressively so that by day 7, intake did not differ from controls, and remained so for the rest of the 14-d period. By contrast, 24-h water intake was significantly elevated with respect to controls throughout the experiment. Results from the acute study (n=18) replicated the day 1 results of the chronic study. These findings confirm and extend those of Reidelberger and O'Rourke (1987). They are consistent with an important role for endogenous CCK in the control of food intake. [Supported in part by MH15455 (GPS), MH00149 (GPS), NS24781 (LHS)]

481.6

DOUBLE-LABEL IMMUNOHISTOCHEMICAL LOCALIZATION OF CHOLECYSTOKININ (CCK) AND METHIONIN-ENKEPHALIN (ENK) IN THE RAT NUCLEUS TRACTUS SOLITARIUS (NTS). P.L. Faris*, B.K. Hartman, J.P. Kettinger*, J.N. Howard*, J. Chen[1], A. Nadzan[1] and J.F. McKelvy[1]. (SPON: J. Gottesman) Depts. of Psychiatry and Pathology, Univ. of Minnesota, Mpls, MN 55455 and Abbott Labs, Abbott Park, IL 60064.

Recent attention has focused on the role of the NTS in mediating peptidergic influences on food intake and nociception. CCK and ENK have been shown to have opposite effects on these behavioral parameters although the exact anatomical loci underlying this physiological antagonism is not known in many cases. This study investigated interactions between CCK and ENK immunolabeled neurons in the NTS at the level of area postrema (AP). CCK and ENK were visualized by incubating sections in a mouse monoclonal antibody against CCK-8 sulfate plus a polyclonal rabbit antiserum against ENK followed by anti-rabbit (goat)-texas red and anti-mouse (goat) FITC. Mis-matching the secondary antibodies resulted in abolition of staining.

At the caudal extent of AP, Enk-ergic soma were present in the NTS with processes extending dorsally towards AP and ventromedially to the Dorsal Motor Nucleus (DMN). At this anatomic level, only scattered CCK-containing soma were observed abutting AP. CCK fibers were also localized to the DMN, and several fibers appear to contain both peptides. CCK and ENK fibers were numerous in the transitional area between the medial NTS and the most rostral extent of nucleus gracilus. The number of CCK-soma increased dramatically at the rostal extent of AP and were juxtapositioned between ENK-soma. Interestingly, fibers labeled for one peptide often appeared to encircle soma containing the other peptide. Supported by NS-12311 (BKH), RSDA MH-00595 (PLF).

VAGOTOMY BLOCKS INSULIN SPIKE THAT PRECEDES MEAL INITIATION. L.A. Campfield, F.J. Smith, D.W. Driscoll* and N. Spirt*. Neurobiology and Obesity Research, Hoffmann-La Roche, Nutley, NJ 07110.

We have previously reported a small, transient rise in plasma insulin (I) prior to the transient decline in blood glucose (TDBG) that precedes meal initiation (MI) in free-feeding rats. We have also shown that following vagotomy, TDBG are not always followed by MI. In order to further characterize the role of I in MI, plasma I and meal pattern were monitored in chronically cannulated, weight matched, male Wistar rats with sham (S) or total subdiaphragmatic vagotomy (V). Blood was continuously withdrawn (25 µl/min for up to 100 min) from lightly heparinized awake rats and pooled over 4 min intervals. In experiments without MI, no significant changes in plasma I were observed over the sampling period in both S and V rats. In experiments (n=6) with MI in S rats, I rose to a peak (60%) then declined to a minimum level at 26 and 8 min prior to MI respectively. In contrast, in V rats I did not rise but instead gradually fell to a plateau prior to MI (n=6). These data demonstrate that a vagally dependent I spike is not necessary for MI. Since we observed an increased frequency of small TDBG that were just at or below threshold for normal MI in V rats, these data suggest that V may have two effects that result in less than faithful coupling of MI and BG: 1) denervation of peripheral glucoreceptors and 2) absence of I spike that may enhance the magnitude of TDBG.

481.8

REVERSAL OF THE ANORECTIC EFFECTS OF CHLOROCITRIC ACID BY SUBDIAPHRAGMATIC VAGOTOMY. W.B. Laughton, D. Driscoll*, and J. Rossi*. Neurobiology and Obesity, Hoffmann-La Roche Inc., Nutley, NJ 07110.

It has been reported that the anorectic effect of the putative satiety agent cholecystokinin (CCK-8) is critically dependent upon the integrity of abdominal vagal sensory fibers. This has been interpreted as evidence for a peripheral site of action of CCK-8.

The present experiment evaluated the role of the vagus nerve in mediating the anorectic effect of chlorocitric acid, another inhibitor of food intake which has been postulated to act at a peripheral site.

Male Sprague-Dawley rats (230-250 g) were subjected to either total subdiaphragmatic vagotomy or sham surgery. Following recovery, animals were food deprived for 17 h (overnight). At 9 a.m., animals were administered either chlorocitric acid (100 mg/kg in dH20 by gavage), or citric acid (same dose) as a control. Thirty-minute food intake was suppressed by 40% in the sham-operated rats ($P < 0.05$); this effect was totally abolished in the vagotomized animals (4% suppression; NS). The effect of 8 µg/kg (IP) CCK-8 (46% suppression) was also totally reversed by vagotomy (1.6% suppression).

These data support the idea that the appetite suppressant effect of chlorocitric acid is a phenomenon of peripheral origin which is relayed to the CNS via the subdiaphragmatic vagus nerve.

481.9

VAGOTOMY ATTENUATES SUPPRESSION OF SHAM FEEDING INDUCED BY INTESTINAL NUTRIENTS. Daniel P. Yox, H. Stokesberry* and R.C. Ritter. Dept. of VCAPP, College of Veterinary Medicine, Washington State University, Pullman, Wa. 99164.

We examined the participation of the subdiaphragmatic vagus nerve in the suppression of sham feeding induced by intraintestinal (IIN) nutrient infusions or by intraperitoneal (IP) injection of CCK-8. Infusions or injections were made while rats were allowed to feed with an open gastric fistula. Results are as follows:

	% Suppression of Sham Feeding (±SE)	
IIN or IP	Sham Vagotomy	Vagotomy
CCK-8 (2 ug/kg)	51.2±7.2	10.0±3.5
maltose (0.13 kcal/ml)	27.9±9.4	-4.7±9.0
oleate "	63.2±9.6	1.9±10.3
L-phe "	55.2±4.6	21.7±8.0.

Our results indicate that the subdiaphragmatic vagus nerve is the predominant neural substrate mediating the suppression of sham feeding induced by IP CCK-8 or by IIN maltose or oleic acid. Nonvagal as well as vagal subtrates are involved in suppression of food intake by L-phenylalanine. These results extend our previous findings using the neurotoxin capsaicin and suggest that small unmyelinated vagal sensory neurons mediate the suppression of feeding by intestinal chemical stimuli.

481.10

LOW CAPSAICIN DOSES THAT SELECTIVELY ATTENUATE CHOLECYSTOKININ-SATIETY CAUSE SELECTIVE DEGENERATION OF VAGAL SENSORY TERMINALS. E.H. South, R.C. Ritter, T. Dinh* and S. Ritter. WOI Regional Program in Vet. Med., Univ. of Idaho, Moscow ID 83843 and Dept. of VCAPP, Washington State Univ., Pullman, WA 99164

High doses of capsaicin cause degeneration of primary sensory teminals in the nucleus of the solitary tract (NST) and the spinal nucleus of the trigeminal (SP5). The NST degeneration is associated with attenuation of vagally mediated cholecystokinin (CCK)-satiety. SP5 degeneration is associated with loss of trigeminally mediated corneal chemosensation. To attain more selective behavioral effects of capsaicin on food intake and to attain a better appreciation of the anatomical distribution of CCK-responsive vagal sensory neurons, we compared effects of low capsaicin doses (LCD) (20-25mg/kg) and high capsaicin doses (HCD) (225mg/kg) on the corneal chemosensory response and the suppression of food intake by CCK. Both LCD and HCD attenuated CCK-induced suppression of food intake. LCD but not HCD-treated rats retained corneal chemosensitivity. Rats sacrificed immediately after LCD exhibited a more circumscribed degeneration pattern in the NST than that observed in HCD rats and little or no degeneration in SP5. HCD rats exhibited extensive degeneration in SP5. These data indicate that low intraperitoneal capsaicin doses are relatively selective for destruction of abdominal vagal sensory neurons such as those which mediate suppression of feeding by CCK.

481.11

INTRAGASTRIC (IG) ASPARTAME DOES NOT INFLUENCE SHORT-TERM FOOD INTAKE (FI) OR SELECTION WHEN ADMINISTERED WITH A CARBOHYDRATE (CHO) LOAD. R.J. Bialik, E.T.S. Li and G.H. Anderson. Dept. of Nutritional Sciences, University of Toronto, Toronto, Ontario M5S 1A8.

High doses of aspartame (the methyl ester of phenylalanine and aspartate) have been reported to alter post-absorptive events associated with ingestion of CHO. The present study investigated whether aspartame would alter the normal feeding responses (i.e. FI suppression, diet selection) observed following a CHO load. Rats were adapted to a 12 h (1800-0600) feeding schedule, with a choice of low (5%) and high (55%) protein diets available only during the dark. On different days, rats received either CHO or CHO plus aspartame by gavage. The CHO load (pure cornstarch, 4 ml/kg of a 37.5 g/dl solution) reduced total FI (by 36%) and consumption from the low protein diet (by 43%) in the first hour, without affecting 2 or 12 hr FI. Addition of aspartame (0, 50, 200 or 500 mg/kg) to the CHO load failed to alter FI compared to CHO alone. We conclude that the reduction in total FI and the selective suppression of a low protein diet following a CHO load are unaltered by large doses of aspartame.

A GLUCOSE INDEPENDENT PROBE UNCOUPLES MEAL INITIATION FROM BLOOD GLUCOSE DYNAMICS. F.J. Smith, D. Driscoll* and L.A. Campfield. Neurobiology and Obesity Res., Hoffmann-La Roche, Nutley, NJ 07110.

A role for peripheral and central glucose receptive neurons in the control of meal initiation (MI) has been proposed. We have previously shown that exogenous glucose infused during a transient decline in blood glucose (BG) delays MI. Glucose and glucose analogs such as 2-buten-4-olide(2B40) have been reported to decrease the firing rate of both hepatic vagal afferents and glucose sensitive neurons. The ability of 2B40 to block MI was assessed in free-feeding female Wistar rats chronically implanted with cardiac and femoral cannulas. BG and meal pattern were continuously recorded (up to 150 min) following a 2 min IV infusion of 10, 20, 40 or 80 µM of 2B40. During intermeal intervals, changes in BG were not observed following administration of 10, 20 and 40 µM (<5%) but increased by 30% following 80 µM; feeding was not observed in any of these 24 trials. When 2B40 was superimposed on transient declines in BG, MI was reliably blocked following 20 and 40 µM and only partially (33%) blocked following 10 µM. In contrast to glucose, application of 2B40 (10-40 µM) did not alter the shape of the decline in BG, suggesting that uncoupling of MI from BG occurred at the level of detection by glucose sensitive neurons. We conclude that 2B40 uncouples MI from BG at low doses by blocking the detection of declines in BG and at higher concentrations by also altering BG dynamics.

482.1

EVIDENCE THAT THE CELLULAR SOURCE FOR RETINAL REGENERATION IN GOLDFISH IS WITHIN THE DIFFERENTIATED RETINA. P.A. Raymond. Dept. Anat. & Cell Biol. and Neurosci. Prog., Univ. Michigan, Ann Arbor, MI 48109.

The neural retina in fish and amphibians can regenerate following surgical or neurotoxic destruction. We have proposed that rod precursors are the source of new cells for retinal regeneration in goldfish. Rod precursors are proliferating cells within the differentiated retina that normally produce only rods. Other proliferating pools that are potentially involved in regeneration include the circumferential retinal germinal zone (GZ) and the retinal pigmented epithelium (RPE). To determine whether cells from the GZ disperse and migrate centrally to colonize degenerated regions, a cocktail of ^{3}H-thymidine (which labels mitotic cells in the GZ) and ouabain (which destroys differentiated retinal neurons) was injected into the right eye (RE), and ^{3}H-thymidine alone was injected into the left (LE). One month later both eyes were prepared for autoradiography. In the LE, a wedge of heavily labeled cells separated the original retina from the peripheral annulus of new retina added at the GZ by normal growth. In the RE, a diffuse wedge of weakly labeled cells was at the boundary between central, degenerated (now regenerating) retina and a peripheral annulus of new retina. The weak label reflected increased proliferative activity in the GZ of the RE, but the extra cells contributed to peripheral growth, not central regeneration: the annulus of new retina added by the GZ was about 220 µm wider in the RE. The degenerated (central) retina had collapsed, however, so overall retinal length was about 400 µm less in the RE. In amphibians it is thought that central retina regenerates from RPE following retinal degeneration induced by devascularization. We have used ouabain to destroy retinal neurons, which might account for the difference in results. I report here that in devascularized goldfish eyes, there is no evidence for RPE involvement in regeneration; instead the process is similar to that described previously for ouabain-treated retinas. These results provide further evidence that neither GZ nor RPE is responsible for retinal regeneration in fish.

482.2

RABBBIT RETINAL GANGLION CELLS SURVIVE OPTIC NERVE TRANSECTION. C. Rosario*[1], K. Fry[2], and R. Madison[1]. (SPON: B. Seckel). Departments of Neuropathology and Neuroscience, Harvard Medical School and Children's Hospital, Boston, MA.[1], and Center for Biotechnology, Baylor College of Medicine, The Woodlands, TX.[2]

Several recent reports have suggested that under certain conditions rabbit retinal ganglion cells will survive optic nerve transection (Lavie et al., Brain Research, 419, 166-172, 1987). For the past several years this laboratory has been investigating the applicability of various "nerve guide tubes" to effect nerve regeneration in the peripheral nervous system (see Abstracts by Arichibald and Madison, and Krarup et al. this volume). The current study assess the usefullness of such nerve guide tubes to effect repair of the central nervous system, the rabbit optic nerve.

Six adult male New Zealand rabbits received transection of the left optic nerve intra-orbitally, immediately distal to the papilla. A collagen based nerve guide tube (1 cm) was sutured onto the short proximal nerve stump, and the tube was filled with Type I collagen (Vitrogen) containing 1000 units/ml acidic fibroblast growth factor with heparin (gift of Dr. P. D'Amore). Eight to 10 weeks following surgery, animals were processed for either frozen section immunocytochemistry with the AB5 antibody which is specific for retinal ganglion cells (Fry et al., Brain Research, 338, 360-365, 1985) or plastic embedding. Histological results indicate that under these conditions, although many ganglion cells have apparently died, there is a distinct population of AB5 positive cells which continue to remain in the retina. Supported by NS22404 to RM.

482.3

A NOVEL TREATMENT CAUSES REGENERATION OF AXONS AMONG ASTROCYTIC PROCESSES WITHIN THE ADULT RABBIT OPTIC NERVE. M. Schwartz, M. Belkin*, A. Solomon*, V. Lavie, S. Ben-Bassat*, M. Murray[1], M. Rosner*, A. Harel* and S. Rumlet*, Weizmann Institute of Science, Rehovot, Israel and [1]Medical College of Pennsylvania, Philadelphia, PA

Degenerating CNS tissue is apparently inhospitable to growing axons. Our results suggest, however, that it can be amenable to activation to become supportive for regeneration. Regenerating fish optic nerves can provide activators, which caused a marked increase in laminin immunoreactive sites in treated injured rabbit optic nerves. However, it is not sufficient to bring regeneration to completion. To get a better growth, we have combined the application of the activators with low energy He-Ne laser irradiation, which had a delaying effect on injury-induced degeneration. Such treatment has resulted in the appearance of abundant newly growing unmyelinated axons, which traversed the site of injury and extended into the distal nerve stump. These axons were seen adjacent to astrocytes. About 4000 axons were counted in the treated nerves, six weeks after injury. These axons appeared in a compartment (4.8% of the total cross-section area), consisting of 47.9% of unmyelinated axons and 41.9% of myelinated axons. In contrast, in non-treated nerves six weeks after injury no axons could be observed, though the lesions were comparable. Identification of these cells (now supporting growth) using specific markers for glial cells at various stages of differentiation is currently under way.

482.4

PATHWAY SELECTION BY REGENERATING MAUTHNER AXONS OF THE ADULT GOLDFISH. S.J. Zottoli, M.A. Agostini*, P.D. Danielson*, E.J. Lee*, T.L. Laidley*, E.A. Markstein* and T.L. Scalise*. Dept. of Biology, Williams College, Williamstown, MA 01267.

Injury to the spinal cord of adult goldfish results in the loss of function caudal to the wound. Although functional recovery of swimming is known to occur, the sound-evoked C-bend initiated by the Mauthner cell (M-cell) does not return for at least 6 months. In an attempt to determine the morphological basis for the lack of this functional recovery we have severed the M-axon by spinal cord crushes or cuts and studied the pathways taken by its sprouts. M-axons were filled with Lucifer yellow and studied in brain wholemounts 30 and 60 days postoperatively (22°C). Eighty-five percent of the filled M-axons regenerated and 52% of those axons sent sprouts caudally as well as rostrally. The longest sprouts extended 3.0mm rostrally and 3.6mm caudally from the retraction bulb. Some of the caudal projections extended past the wound site for up to 3.0mm and the majority of these sprouts extended ventral and lateral to the previous location of the M-axon in the spinal cord. Since none of these fish displayed sound evoked C-bends, we hypothesize that regenerating M-axons follow pathways in the spinal cord that are inappropriate for functional regeneration. Supported by NSF grant BNS 86-06607 and CSI 86-50488.

Functional regeneration demonstrated in the adult spinal cord of the lamprey. A.H. Cohen, M.T. Baker*, T.A. Dobrov*.Section of Neurobiology and Behavior, Cornell University, Ithaca NY 14853.

It is known that there can be functional regeneration in larval lampreys (Cohen et al., PNAS.83:2763-2766,1986). We now show that adults with spinal lesions share this capacity for regeneration, but incompletely.

Partial lesions of either lateral or medial tracts were made in young feeding adult lampreys (*Petromyzon marinus* and *Ichthyomyzon unicuspis*). After 8-10 months, the animals were tested for functional regeneration. The spinal cord was dissected out with the notochord and superfused with curare (15mg/l) and D-glutamate (0.25-0.50 mM) to activate fictive swimming. The activity of two motor nerves, one rostral and one caudal to the lesioned segment, were monitored. When stable and coordinated, the bursting was recorded. The tracts which had formerly been spared were cut in the lesioned segment and bursting again observed. 200 consecutive bursts of the most stable coordinated bursting were recorded and analyzed and the phase lags between the two segments were measured. Plots of the phase lags over time and phase histograms were made. The non-randomness of the histograms was assessed by a Chi-square test with 19 degrees of freedom (distributing the phase lags over 20 equal bins). After the experiment was completed the cords were examined histologically to assure that the fibers remaining in the lesioned segment all had the typical regenerated appearance. Of the medially lesioned animals 3 of 5 showed non-random distributions of phase lags during fictive swimming (Chi-square 23.7-116.8; $p<<0.001=38.6$). 3 of 5 laterally lesioned also showed non-random phase delays (Chi-square 19.1-296.7). Thus, many questions remain, but it can be said with certainty that adult lamprey spinal cords retain some capacity for functional restoration of fibers which can sustain intersegmental coordination during drug induced fictive swimming even in the absence of sensory, mechanical and descending factors. Supported by NIH grant No. NS16803 and AFOSR contract No.F49620-87-C-0013.

REGROWTH OF AXONS INTO AN EXTENDED CELLULAR MATRIX FOLLOWING INJURY OF THE DORSAL COLUMN OF THE ADULT RAT SPINAL CORD BY A METHOD OF CONTROLLED FREEZING. N.R. West and G.H. Collins. Departments of Pathology and Anatomy, SUNY Health Science Center, Syracuse, New York.

With a proper matrix it is known that axons of mature mammalian central nervous system regenerate. It has been more difficult to demonstrate that such a matrix can develop from supporting elements of central nervous tissue. We were able to demonstrate regrowth of axons into a matrix 2.5-3.0 mm in length following cryogenic injury to the dorsal column of mature rat spinal cord (Collins, West, et. al. J Neuropathol Exp Neurol 45:742, 1986). Recently, we demonstrated the feasibility of producing, by this method, a lesion 1.0 cm in length within which a similar matrix develops (West and Collins, Neuroscience Abstracts, 1987). The purpose of this report is to demonstrate that axonal regrowth will occur through a matrix which is 5-10 mm in length. These results are based upon the study of 5 animals subjected to cryogenic injury of the dorsal column at T7-T9, using cryodes 4.0-7.0 mm in length. Fifteen days following injury animals have lesions 5-10 mm in length. Macrophages are sequestered into identifiable areas, around which a cellular matrix containing myelinated and unmyelinated axons is seen. The axons which diminish in the proximo-distal (caudal-rostral) direction, represent a regrowth distance of 5.0-10.0 mm.

482.7

INDUCED REGENERATION OF CUT DORSAL ROOT FIBERS INTO ADULT RAT SPINAL CORD. J.D. Siegal* , M. Kliot, G.M. Smith*, S. Tyrrell*, J. Silver (SPON: E. Housepian). Neuroscience Center, CWRU Medical School, Cleve., OH 44106.

Glial scar formation and inhibition by white matter are thought to impede sensory axons from regenerating across the dorsal root entry zone (DREZ) into the adult rat spinal cord. In order to assess the relative roles of these barriers, we unilaterally transected lumbar dorsal roots (L4-L6) and implanted the distal portion of L4 medially into the white matter of the dorsal columns or laterally just superficial to the gray matter of the dorsal horn. After 3 weeks, anterograde labelling with HRP demonstrated that many axons entered the spinal cord from laterally-implanted roots. A significant population of these axons entered the gray matter and formed terminal fields with synaptic boutons. Other axons extended into the white matter of the dorsal columns for variable distances. The placement of a specially designed Millipore filter, coated with embryonic astrocytes, just medial to the implanted root increased regeneration into the gray matter. Successful regeneration of axons was associated with a localized and limited inflammatory response near the sites of ingrowth. We, therefore, believe that axonal regeneration is enhanced by the lateral placement of a transected sensory root, the use of an astrocyte-coated polymer, and the presence of a limited inflammatory response. NEI-EY05952.

482.8

ENHANCED DORSAL ROOT AXONAL REGENERATION IN ADULT RAT SPINAL CORD FOLLOWING ENTRY ZONE IRRADIATION. F.J. Liuzzi, Dept. of Anatomy and Cell Biology, Eastern Virginia Med. Sch., Norfolk, VA 23501.

After dorsal root crush the majority of regenerating axons are stopped at the root-cord interface where they encounter the CNS environment of the cord. EM of this region reveals tightly interwoven astrocytic processes and numerous astrocytic somata. Although many of the regenerating axons terminate among the astrocytic processes to form stable axo-glial endings (Liuzzi and Lasek, Science 237:642, 1987), HRP anterograde injury-filling reveals that a small number of these regenerating axons breach the entry zone to gain access to the spinal gray matter (Liuzzi and Lasek, Soc. Neurosci. Abst. 13:395, 1987).

I have begun to study the use of post-crush irradiation of the dorsal root entry zone as a way of modifying the glia of the region with the intention of enhancing the regeneration of axons into the cord. In 3 of 4 animals examined to date, there has been an apparent enhancement of axonal growth into the cord as compared to that in non-irradiated animals. HRP labelling of regenerating dorsal root axons revealed a variable reinnervation of the spinal gray matter. EM of labelled axons in one animal revealed Schwann cell myelination in the white matter and identifable HRP-labelled synaptic terminals in the gray matter. This work is supported by grants from the SCRF and NINCDS.

DORSAL ROOT IMPLANTS IN PREDEGENERATED RAT SPINAL CORD. A. Bignami, H. Mansour* B. Labkovsky* and D. Dahl Spon: J. Bossom. Harvard Medical School and VA Medical Center, Boston, MA 02132.

Glial hyaluronate binding protein (GHAP) is a brain specific protein localized in white matter astrocytes and showing structural similarity (up to 89%) with the hyaluronate binding region of cartilage proteins (see Perides et al., this meeting). GHAP disappears from reactive astrocytes in long-standing Wallerian degeneration. Extensive dorsal rhizotomy was performed in rats at the thoracolumbar level. One month after operation, 2 dorsal roots (not previously transected) were implanted into the degenerated dorsal columns. The rats were examined at varying intervals after the second operation. In 3 rats, the implanted roots were found within the degenerated dorsal columns. Double staining experiments showed that regenerated axons crossed the boundary between laminin-positive PNS and laminin-negative CNS. Furthermore, the periphery of the implant was strongly positive with both laminin and GFAP antibodies, thus indicating invasion by reactive astrocytes. Regenerated axons followed an irregular course in the severely gliosed tissue surrounding the implant. No growth was observed in the degenerated dorsal columns above the zone of implantation. The findings suggest that normal astrocytes rather than reactive astrocytes form a barrier to axonal growth. Supported by NS 13034 and by the VA.

EVIDENCE FOR REINNERVATION OF SKELETAL MUSCLE BY MOTONEURONS VIA VENTRAL ROOT IMPLANTS INTO THE SPINAL CORD OF THE CAT. T. Carlstedt , S. Cullheim*, H. Lindå*, M. Risling* and B. Ulfhake* Dept of Handsurgery, Dept of Anatomy, Karolinska Institutet, Box 60400, S-10401 Stockholm, Sweden.

We have previously shown that cat lumbar motoneurons may reinnervate ventral roots after division of their axons in the spinal cord (Risling et al., Brain Res. 280:15, 1983). This unexpected regenerative capacity of the motoneuron has been further explored in cats after implantation of avulsed ventral roots into the spinal cord.

The left ventral roots L6-S1 were avulsed from the surface of the cord. The L6 root or rostral L7 rootlets were immediately inserted into the ventrolateral part of the L7 segment. After 11-12 months, spinal neurons responding antidromically to stimulation of implanted roots were injected intracellularly with horseradish peroxidase and were studied light and electron microscopically.

Morphological and physiological analysis of the studied neurons revealed that alpha and probably also gamma motoneurons were able to reinnervate ventral root implants. Such neurons could be excited or inhibited by segmental reflex activity and their axons could conduct nerve impulses. The character of muscle twitch responses, elicited by electrical stimulation of implanted roots, strongly indicated that denervated muscles were reinnervated by new motor axons via the transplant.

REGENERATION OF CENTRAL AXONS INTO PERIPHERAL NERVE GRAFTS Keith Carson, J.K.Terzis,D.Spurrier*,T. Liberson*, C.Peffley* Microsurgical Research Center,E.V.M.S, Norfolk, VA 23507

At present, the possibility of surgical intervention to restore lower limb function in the paraplegic patient has been limited. The major limitation to restoring motor function has been the absence of a suitable motor neuron pool that can be tapped in order to replace motor neurons located caudal to the site of spinal injury. We wish to address the question of whether central neurons, other than those of the ventral horn, can contribute regenerating axons to denervated peripheral musculature. To study this problem, we used peripheral nerve grafts to connect the spinal cord to a denervated distal muscle (the gastrocnemius) in the rat. The left sciatic nerve is dissected out as a free nerve graft and the distal end inserted into the corticospinal tract through an incision in the dorsal column and the proximal end is coapted with the contralateral sciatic nerve at the sciatic notch. Following a six month survival period, the origins of the CNS neurons sending axons into the peripheral nerve graft are determined by using HRP as a retrograde tracer. The purposes of this experiment include: 1) to confirm whether central neurons can regenerate new axons into peripheral nerve grafts inserted into the spinal cord; 2) to confirm that at least some of these axons can re-establish functional contacts with peripheral targets; 3) to determine the central origins of fibers that invade the PNS grafts; and 4) to examine the morphological, physiological and behavioral extent to which motor function of reinnervated muscles is restored. Preliminary light microscopy through the distal region of the graft shows hundreds of myelinated axons. Currently HRP transport studies are in progress to trace the cells origin of the axons.

CELLULAR ORIGIN OF THE REGENERATIVE PLACODE DURING LATERAL LINE REGENERATION IN THE AXOLOTL. J. E. Jones* and J. T. Corwin. (SPON: H. Gillary) Békésy Lab. of Neurobiology, Univ. of Hawaii, Honolulu, HI 96822

Neuromast organs in lateral line systems contain sensory hair cells and supporting cells that are similar to their counterparts in the ear. Partial tail amputation in the axolotl (Ambystoma mexicanum) results in regeneration of the lost portion and replacement of the neuromasts removed. Previous work showed that an undifferentiated cellular mass, the regenerative placode, originates from the distalmost neuromast remaining after amputation and gives rise to the new neuromasts. We identified the type of cell that initially seeds the placode, and determined how the placode advances during regeneration. DIC microscopy, combined with time-lapse videorecording, documented that cells on the posterior margin of the deepest layer of supporting cells in the last neuromast remaining after a tail cut became mitotically active at about the time the placode normally appears. Cell divisions were frequent in the placode itself, once seeded by these basal layer supporting cells. The production of new cells must account for some part of the placode's extension, but its cells also became motile, as evidenced by membrane ruffling. Ruffling is usually a result of lamellipodia-mediated cell migration. During wound healing in mammals, ruffling is seen at the leading edge of the advancing epithelial sheet. The process differed here in that all cells within a given area were involved. Macrophages were found to be present and active at the regeneration site. In other systems these cells have been shown to secrete specific mitogens, suggesting the possibility of such a role here. (Supported by grants from NINCDS to J. T. Corwin.)

REGIONAL APPEARANCE OF MYELIN CONSTITUENTS IN THE DEVELOPING RAT SPINAL CORD. M.E. Schwab and T. Savio. Brain Research Institute, Univ. of Zurich, August-Forel-Str. 1, CH-8029 Zurich, Switzerland.

The regulation of oligodendrocyte differentiation and myelin formation is poorly understood at present. On the other hand, oligodendrocytes contain specific membrane proteins able to inhibit nerve fiber growth (Caroni and Schwab, '88). Studying the appearance of myelin specific glycolipids (GalC) and of MBP in the rat cervical spinal cord we found that the time of expression of these components is highly specific for a given structure. It starts in the ventral funiculus (P1) and dorsal ascending tracts (P2-P4). Pyramidal tract (P11) and gray matter regions (patchy appearance!) myelinate late. - Frozen sections of spinal cords were used as substrates for cultured neuroblastoma cells and neurons. On adult and P13 tissue white matter areas were strongly inhibitory for cell adhesion and neurite growth. In contrast, all regions of P0 spinal cord were good substrates. When oligodendrocytes were suppressed P13 spinal cords did not exhibit inhibitory substrate properties. These results suggest that local signals in fiber tracts crucially influence oligodendrocyte differentiation, and that the expression of inhibitory substrates could locally influence nerve fiber growth.

CHANGES IN PROTEASE NEXIN I (PNI) DURING C_2 MUSCLE CELL DEVELOPMENT. B.W. Festoff, C. Maben*, and J.S. Rao*. Neurobiol. Res. Lab (151), V.A. Med. Ctr., Kansas City, MO 64128.

PNI inhibits the activity of serine proteases and also mediates their binding, internalization and degradation by cells. PNI is identical to glial derived nexin (GDN), a neurite outgrowth promotor found in rat and human glial cells. Our results show the increased production of PNI in post-fusional myotubes compared with myoblasts. The increased production of PNI was characterized quantitatively by ELISA and immunoprecipitation. ELISA shows that PNI production increases at day 4 after fusion. ^{35}S-labeled myoblast and myotube media and cell layer extracts were passed through a heparin-Sepharose column, the eluate was precipitated with anti-PNI and characterized by SDS-PAGE. In peak 1 (0.2M NaCl), 43 Kd protein was increased at day 4, while in peak 2 (0.45M NaCl), 48 Kd was increased at day 4. These results show the increased production of two different molecular forms of the serpin, PNI, during myogenesis in vitro.

ELECTRON-HISTOCHEMICAL OBSERVATION OF 5'-NUCLEOTIDASE IN PRIMARY CHICK EMBRYONIC NEURAL CULTURES H.C.LUDWIG,P.E.SPOERRI*and E.MARKAKIS.Department of Neurosurgery,Georg-August-University,Robert-Koch-Str.40,D-3400 Goettingen,Federal Republic Of Germany

5'-nucleotidase has shown in several investigations to be an ubiquitous enzyme present in neuro nal and nonneuronal particularly glial plasma membranes(Kreutzberg et al.,Brain Res.158,1978;247). The ectoenzyme may play an important role in neural-glial interactions in which glial cells are providing adenosine to the neurons and therefore facilitate neuronal growth,development and differentiation.Presently,the expression of 5'-nucleotidase was examined in reaggregating neurons and glial cells,isolated from 8 day old embryonic chick brain,spinal cord and retina grown in monolayer culture systems.By modification of known cytochemical methods for EM demonstration of 5'-nucleotidase we were able to localize the enzyme on the plasma membranes of glial flat cells.Special interest was directed towards the heterogeneity of the membranes of retinal Mueller cells grown in histotypically oriented rosettes.In these rosettes the degree of heterogenious expression of 5'-nucleotidase coincides with developing neurons and retinal receptors.

OMEGA-3 FATTY ACIDS IN THE DEVELOPING PHOTORECEPTOR CELL. N. G. Bazan, F. Cai* and B. L. Scott*. LSU Eye Center, New Orleans, LA 70112

The omega-3 essential fatty acid family comprises a major acyl group of retinal photoreceptor membranes and synaptic membranes of brain and retina. Docosahexaenoic acid (22:6w3) represents nearly 50% of the fatty acyl groups in the disk membrane of photoreceptors although its function is not well understood. We are studying the omega-3 fatty acid family in the developing mouse pup and find that the major omega-3 fatty acid supplied to pups in mother's milk is linolenic acid (18:3w3). In addition we have studied the accumulation of 22:6 in developing photoreceptor cells and brain of mice at different postnatal ages and have examined the ability of these animals to synthesize 22:6 from 18:3.

We find that the content of 22:6 in photoreceptor cells increased 3- to 4-fold in the various phospholipid classes as the cells synthesize the adult complement of rod outer segment disk membranes. Furthermore, studies of the synthesis of $[^{14}C]$22:6 from intraperitoneally-injected $[^{14}C]$18:3 indicate that the liver is the major site of this conversion in the developing pups, and that omega-3 fatty acid is presented to the growing photoreceptor cells and to brain primarily in the 22:6 form. A similar model is postulated also to occur during the differentiation of synaptic membranes. Supported by EY04428 and the Edward G. Schlieder Educational Foundation.

EXPRESSION OF A 35-kDa SUBSTRATE FOR THE EGF RECEPTOR KINASE IN A MIDLINE RAPHE OF THE FLOOR PLATE PRIOR TO THE ARRIVAL OF DECUSSATING FIBERS IN RAT EMBRYOS. James A. McKanna* (SPON: J.A. Pulliam), Dept. of Cell Biology, Vanderbilt Univ., Nashville, TN 37232

A 35-kDa protein (p35), purified by Fava and Cohen (JBC 259:2636) as a preferential substrate for the tyrosine kinase activity of the EGF receptor, is developmentally regulated in embryos and is presumed to play a role in morphogenesis. In rat embryos of 11 days gestation (E11), p35 is expressed in a ventral midline raphe of primitive glial ependymal cells that run from the lumen of the neural tube to the pial surface. The p35 staining is first apparent in the rostral hindbrain, but by day E14 the raphe runs the length of the floor plate from the caudal edge of the midbrain to the tip of the spinal cord. Thus, p35 is expressed in glial cells at the future ventral commissure prior to the arrival of decussating axons, and it may serve gradient, guide or gate functions. The p35 immunoreactivity disappears from the CNS by postnatal day 3; however, because silver stains show that the raphe cells persist through adulthood, we prefer to avoid the term "radial glia" which refers to cells that purportedly differentiate. In addition to serving as a tyrosine kinase substrate in the mediation of growth factor effects, p35 binds calcium and phospholipids, indicating that it may influence the cytoskeleton. Supported by CA43720.

BASIC FIBROBLAST GROWTH FACTOR STIMULATES SURVIVAL OF NON NEURONAL CELLS DEVELOPING FROM TRUNK NEURAL CREST. C. Kalcheim Dept. of Anat.& Embryol. Hebrew Univ. Hadassah Med.School-Jerusalem 91010-Israel.

Our study characterizes the early influence of the CNS on survival of neural crest (NC) cells. We find that basic fibroblast growth factor (ß FGF), synthesized in the CNS, stimulates survival of HNK-1 immunoreactive NC cells separated from the neural tube by a silastic membrane impregnated in 100 ng/ml ß FGF. Rescued cells were then observed for over 30 hr. after grafting in 12 out of 16 chick embryos. In contrast, no surviving cells could be found in any of 10 control embryos. ß FGF was also tested on trunk NC cells cultured with somite cells. FGF promoted a dose dependent increase in the number of HNK-1 positive non neuronal cells in 1-4 day old cultures (1.8 to 8.2 fold over controls using FGF at 10 pg/ml to 1ng/ml). Similar increase in the number of non neuronal cells was attained when FGF was added to pure NC cultures. FGF had no mitogenic effect on the NC-derived non neuronal cells but found to increase the incorporation of (3H) Thymidine into acid insoluble material in somite cultures devoid of NC by 3.3 - 8.4 fold over control. Our results demonstrate a direct effect of FGF on survival and/or differentiation of the NC-derived non neuronal cell population. Sponsored by the MDA and The Israel Acad. of Sciences.

DIFFERENTIAL EXPRESSION OF THE CHICKEN NERVE GROWTH FACTOR RECEPTOR GENE DURING DEVELOPMENT. E Escandon* and M Chao*.(SPON:L. Schleifer). Dept. Cell Biol. and Anatomy, Cornell University Med. College, New York, NY 10021.

A genomic chicken library was screened with human nerve growth factor (NGF) receptor cDNA probes at moderately high stringency. Four positive bacteriophage clones were isolated and characterized by restriction mapping and Southern blot analysis. A 5.5 kb Hind III fragment was isolated by virtue of homology with the 5' end of the human cDNA sequence. The region of homolgy was further localized, analyzed by DNA sequencing and found to correspond to the extracellular domain of the NGF receptor. Northern blot analysis of poly (A)+ RNA from embryonic chicken brain detected a unique and specific mRNA of 3.9 Kb in length, similar to the size seen in human melanoma cells, rat PC12 and Schwann cells. The same mRNA could also be detected in chick spinal cord and dorsal root ganglia. S1 nuclease protection analysis indicated that NGF receptor mRNA is expressed in the various brain vesicles and their derivatives, substantially decreasing at later embryonic stages. The differential appearance of receptor mRNA and the presence of NGF in selective brain regions suggests a role for NGF and its receptor during chicken brain development.

GABA AND $GABA_A$/BENZODIAZEPINE RECEPTOR-LIKE IMMUNOREACTIVITY IN THE DEVELOPING RAT CEREBELLUM. D.L. Meinecke, and P. Rakic. Section of Neuroanatomy, Yale School of Medicine, New Haven, CT 06510

To explore the possibility that the development of local neuronal circuits may be related to the expression of neurotransmitters and their receptors, we have studied the ontogeny of GABA and $GABA_A$ receptors in cells which form GABAergic inhibitory connections in the rat cerebellum. Cerebella from rat pups ages 0 days to 21 days post-natal were immunostained with GABA antisera (Immunonuclear) and E9 monoclonal antibodies directed against the $GABA_A$/benzodiazepine receptor complex (Sweetnam et al., Mol. Brain Res. '87). Immunolabeled tissue was examined with light and electron microscopy.

The cerebellum of new born animals contains only pre-natally generated Purkinje and Golgi II neurons. At this early stage, both cell types could be immunolabeled with GABA and E9 antibodies. The other cells of the cerebellar cortex arise post-natally from a germinal external granular layer which is present from about 2 to 21 days. Cells of the external granular layer and descending migrating neurons were not labeled with either GABA or E9 antibodies at any age. However, after arriving in the granular layer, maturing granule cells and their growing dendritic processes were E9 positive. Like granule cells, basket and stellate cells in the molecular layer do not appear to immunoreact with either antibody during their bipolar stage, and express E9 and GABA only after they develop dendrites and axons. These results indicate that cells which participate in GABAergic cerebellar circuits express GABA receptors only after they attain their final position and begin elaborating dendrites involved in synaptogenesis.

TRISOMY 16 MOUSE MODEL OF DOWN'S SYNDROME: 210KDALTON NEUROFILAMENT SUBUNIT REGULATION BY INTERFERON; CENTRAL NERVOUS SYSTEM ELECTRON MICROSCOPIC OBSERVATIONS A. V. Plioplys. Surrey Place Centre and Div. Neurology, Hospital for Sick Children and Univ. Toronto, Ont. M5S 2C2

The trisomy 16 mouse is an excellent model for the human Down's syndrome (DS). It is postulated that sensitivity to interferon may underly defects in neuronal formation in DS (J Neuro Sci 1987, 79:91). When applied to CNS cultures taken from normal fetal mice, interferon increases the immunohistochemical expression of the 210K neurofilament subunit. This effect can be block by the application of oxyphenbutazone which inhibits interferon-mediated metabolic pathways. CNS cultures taken from trisomy 16 fetal mice express greater intensity of the 210K neurofilament subunit immunohistochemical staining than do normals. Application of oxyphenbutazone normalizes trisomy 16 CNS neurofilament expression.***EM observations were made of the cortical plate within the developing telencephalic vesicle at E17. The results included: 1. neuronal microtubular profiles which were more coiled and curved in the trisomic condition than in normals; 2. increased neuronal membrane fragility in trisomy 16; 3. increased nuclear contour irregularity in trisomic neurons; 4. significant decrease in the cross-sectional area of neuronal nuclei in trisomy 16 ($p<0.01$). The observations concerning nuclear morphologic differences in trisomy 16 may be related to the reported differences in nuclear histone expression in Alzheimer's disease.

A BEHAVIORAL AND ANATOMICAL INNER EAR MUTANT GENERATED BY INSERTIONAL MUTAGENESIS IN TRANSGENIC MICE. E.B. Crenshaw III*, [1,4], A.F. Ryan[2,3], and M.G. Rosenfeld*[4,5]. (SPON: R. Emeson) Depts. of [1]Biology, [2]Surgery/Otolaryngology and [3]Neurosciences, and the [4]Eukaryotic Regulatory Biology Program, UCSD School of Medicine, and [5]Howard Hughes Medical Institute, La Jolla, CA 92093.

Transgenic mice were generated by microinjection of a chimeric gene consisting of the 5' flanking region of the human vasopressin gene fused to the v-src gene. While most of these animals exhibited normal behavior, one of fourteen lines showed circling, hyperactivity and head tossing similar to that seen in some labyrinthine mutants. The mutant integration event in this strain cosegregates with phenotype.

Anatomical examination of the mutant's inner ear showed disorganization of the vestibular membranous labyrinth. Most vestibular epithelia were absent. The saccular macula was reduced in size, but relatively normal in cellular structure. Its otolithic membrane was overgrown with epithelium or characterized by amorphic, enlarged otoconial remnants. The vestibular ganglion appeared to be normal in size, and afferent fibers entered the vestibule in near normal numbers. However, they projected in apparently random directions. The cochlea of the mutant was largely normal in appearance, though loss of spiral ganglion cells in the apical turn varied from slight to a virtually complete loss of neurons in the upper one third of the cochlea.

The ability to clone the gene from this mutant will allow the exact characterization of mutational events, as well as identification of the normal gene involved in those aspects of inner ear development that have been altered in the transgenic mouse.

Supported by the Howard Hughes Medical Institute, by grant NS14945 from NIH/NINCDS, and by the Research Service of the VA.

483.11

PROLIFERATION OF TREMBLER MOUSE SCHWANN CELLS IN CULTURE AND DURING WALLERIAN DEGENERATION. H.L. Koenig*,N.A. Do Thi* and B. Ferzaz* (SPON : D. Fambrough).Lab. Neurobiologie Development, Univ. Bordeaux I, 33405 TALENCE, France.

Schwann cells (SC),which do not divide in vivo, proliferate in cell cultures when mitogenic signals,such as neurite or myelin breakdown products are present.In Trembler mutation,characterized by hypomyelination and basal lamina excess,the Schwann cells proliferate continually.The increase of SC is regular in the peripheral nerve from 3 day-old mice(+25%) to adult (x6).We were interested to analyse the proliferation capacities of Trembler and control SC when they are deprived of neural influence and after they are re-associated with nervous tissue.In cell cultures, SC from 1 and 4 days animals had a similar nuclei labeling index at each time tested (1 to 9 days in culture).By contrast,when Schwann cells are plated from 15 days old mice, Trembler cells proliferate less than control cells.Similarly, in wallerian degenerating sciatic nerve, the proliferation of Schwann cells is approximatly 5 times higher in control than in Trembler.

When the tibial nerve is sutured to the degenerated distal stump, the SC proliferation is stimulated anew, less in Trembler than in control. In culture, Trembler and control nerve extracts,added respectively to control and Trembler SC stimulate similarly their proliferation at a very high level.

The Trembler mutation affecting primarly the SC provides a good model system to analyse the cellular origin and molecular nature of in vitro and in vivo mitogenic signals.

484.1

DIFFERENT DISTRIBUTION OF SLOW AND FAST K CHANNELS IN RAT MYELINATED NERVE. J.R. Schwarz* and J. Röper* (SPON: Europ. Neurosc. Assoc.). Inst. of Physiol., UKE, D-2000 Hamburg 20, FRG.

Single myelinated rat nerve fibers were dissected and voltage clamped to study the properties of their K channels. K currents were recorded in the intact node of Ranvier and after acute paranodal demyelination with lysolecithin and pronase. Results: 1. The analysis of tail currents recorded in isotonic KCl solution revealed that K channels with slow gating kinetics were located in the nodal membrane whereas those with fast kinetics were located in the paranode. The conductance of the fast K channels increased linearly with the increase in the axonal area which had been demyelinated. 2. The sigmoidal steady state activation curve of the slow K channels had an inflection point at -70 mV, i.e. 50% of these channels were in the open state at the resting potential. At negative potentials they showed an inward rectification which could be reduced by addition of $BaCl_2$. 3. The paranodal fast K channels were activated at more positive potentials and were selectively blocked by 1 mM 4-aminopyridine. Conclusion: Myelination in rat nerve is accompanied by a local segregation of slow and fast K channels.

TWO LARGE CONDUCTANCE K^+ CHANNELS IN THE SOMATIC AND DENDRITIC REGION OF CEREBELLAR PURKINJE NEURONS. D.L. Gruol, T. Jacquin * and A.J. Yool. Div. Preclin. Neurosci., Res. Inst. Scripps Clinic, La Jolla, CA 92037.

We have previously identified several types of voltage-sensitive K^+ channels in cell-attached recordings from the somatic and dendritic region of cerebellar Purkinje neurons in culture. In the present series of experiments, we have focused on the characteristics of two of these channel types when studied in outside-out and inside-out membrane patches. Using saline solutions mimicking physiological conditions, the single channel conductances were 90 and 75 pS. Both channel types were active at potentials depolarized to the normal resting membrane potential of these neurons (-60 mV) and had extrapolated reversal potentials around -65 mV. Changing the equilibrium potential for Cl^- by ion substitution did not alter the reversal potential for the unitary events; changing the equilibrium potential for K^+ did, demonstrating that the channels were K^+ selective. Both channel types were sensitive to low concentrations of extracellular TEA, channel activity being significantly reduced by 1 mM concentrations. The activity of both channel types was also reduced by 10 mM extracellular Ba^{++}. Thus, the two K^+ channel types are similar in conductance and pharmacological sensitivity. The main characteristic that distinguishes the channel types is voltage sensitivity. The 75 pS channel type is most active at potentials hyperpolarized to 0 mV; the frequency of opening and the duration of the open state increases as the membrane potential is hyperpolarized. In contrast, the 90 pS channel is active at potentials depolarized to 0 mV; the frequency of channel opening and the duration of the open state increases as the membrane potential is depolarized. This difference in voltage-sensitivity suggests that the two channel types play different roles in controlling the excitability of Purkinje neurons. Supported by NS 21777 and training grant AA07456.

SINGLE POTASSIUM CHANNELS IN CULTURED RAT HYPOTHALAMIC NEURONS. J. G. McLarnon, Dept. of Pharmacology & Therapeutics, The University of B. C., Vancouver, B. C., V6T1W5, Canada.

The properties of voltage-dependent potassium channels in cultured rat hypothalamic neurons have been studied using the patch clamp technique. With the inside-out mode and 140 mM K^+ in the bath and 5 mM K^+ in the pipette a channel with conductance of 52 pS is commonly observed after depolarization steps. This channel is selective for K^+ since the extrapolated reversal potential is close to that predicted for K^+ and shifts to a value of zero when the bath solution contains 5 mM K^+; the channel was non-conducting when the solution contained 140 mM Cs^+. Single exponential fits were adequate to describe the histograms of open times for the K^+ channels with membrane depolarization acting to increase the channel open time. The distributions of closed times required two-component fits reflecting short closed sojourns during open events and longer closed periods between openings. A concentration of 10 mM TEA, applied to the outside of the cell membrane (outside-out mode), blocked the 52 pS channel. In the cell-attached mode with no TTX in the solutions, outward K^+ currents were associated with the after-hyperpolarization phase of the capacitively recorded action potential. The properties of the K^+ channels studied are consistent with those associated with the delayed rectifier K^+ conductance and would serve to mediate electrical excitability in hypothalamic neurons.

484.4

REPETITIVE FIRING IN HIPPOCAMPAL NEURONS IS MODULATED BY THE MEMBRANE POTENTIAL PRIOR TO ACTIVATION, THROUGH THE ACTION OF A SLOWLY INACTIVATING POTASSIUM CURRENT, I_D. J. F. Storm, Institute of Neurophysiology, University of Oslo, Oslo 1, Norway.

In hippocampal neurons, the firing frequency in response to depolarizing current is regulated by spike-activated K currents (I_{AHP}, I_C, I_M). In addition to this "feedback" discharge control, there may be a "feed-forward" control by the membrane potential prior to activation of the cell (MP). Thus, both I_A and I_M are expected to modulate the initial firing, in ways which depend on their degree of activation (I_M) or inactivation (I_A) at rest. Here I report evidence that a third potassium current, I_D, mediates a particularly long-lasting influence by the MP on subsequent discharge. Voltage clamp measurements indicate that I_D inactivates more slowly and is more sensitive to 4-aminopyridine (4-AP) than I_A, but it activates faster than I_M or I_K (Storm, 1988, Biophys. J. 53: 148A).

CA1 pyramidal cells (n=36) in rat hippocampal slices, were impaled with KCl-filled micro-electrodes, at 31-35°C. Repetitive firing was elicited by injecting long depolarizing current pulses (1-10 s). The MP was controlled by steady current injection. At MPs close to the normal resting potential, there was often a 200-800ms delay to the onset of firing, while the cell depolarized slowly, forming a "ramp". The ramp and delay appeared to reflect inactivation of I_D because: (1) the input resistance increased during the ramp; (2) the ramp was blocked by 50 µM 4-AP; (3) hyperpolarization of the MP (to enhance I_D) increased the delay (up to 10s); whereas (4) depolarization (which inactivates I_D) abolished it. I_D also appeared to counteract the spike frequency adaptation, which was reduced by hyperpolarization and enhanced by depolarization. Plots of firing frequency against current intensity (f/I-plots), normally show a low-gain range ("primary range") for small intensities. This range was increased by hyperpolarization and abolished by depolarization of the MP, suggesting that I_D is essential for this low-gain part of the f/I relation.

PHENCYCLIDINE BLOCKADE OF VOLTAGE-DEPENDENT POTASSIUM AND CALCIUM CURRENTS IN ISOLATED HIPPOCAMPAL NEURONS: PHARMACOLOGY AND VOLTAGE-DEPENDENCY. J.M.H. ffrench-Mullen, M.A. Rogawski and J.L. Barker, Laboratory of Neurophysiology and Medical Neurology Branch, NINCDS, NIH, Bethesda, MD 20892.

Using whole-cell voltage clamp recording techniques, we previously observed that phencyclidine (PCP) produces a selective block of the sustained, voltage-dependent K^+ current (I_K) in hippocampal neurons (*Neurosci. Lett.*, in press). In the present study, we compared the K^+ channel blocking activity of PCP with that of a series of PCP and *sigma* recognition site ligands. In addition, we examined the effect of these compounds on Ca^{2+} currents. The IC_{50}'s (*uM*) for blockade of I_K were: PCP, 36; dexoxadrol, 73; levoxadrol, 260; (+)-SKF-10,047, >300; (-)-SKF-10,047, >300; (+)-3-PPP, >300. In contrast, the IC_{50}'s for blockade of the transient K^+ current (I_A) were: PCP, 330; dexoxadrol, 285; levoxadrol, 285. The blockade of I_K by PCP was voltage-dependent so that the fractional block decreased as the cell was depolarized. Assuming that PCP blocks I_K by entering the channel pore, calculations according to the method of Woodhull suggested that the binding site is about 5-10% into the electrostatic field. These experiments confirm that PCP (and also dexoxadrol/levoxadrol) selectively block I_K; I_A is only affected at very high concentrations of the drugs. Blockade of I_K by PCP occurs at a site that is pharmacologically similar to the "low affinity PCP" ([^{3}H]PCP-3-OH) binding site, but dissimilar to "high affinity PCP" or *sigma* binding sites (Itzhak, *Life. Sci.* 42:745-752, 1988). PCP also reduced Ca^{2+} current in these cells (IC_{50}, 10 *uM*) whereas (+)-SKF-10,047 and (+)-3-PPP were inactive (10 *uM*), suggesting that blockade of I_K and I_{Ca} may occur at pharmacologically similar sites.

CATION AND ANION PERMEABILITY DURING THE EXCITATORY RESPONSE TO ATP IN CHICK SKELETAL MUSCLE. S. A. Thomas and R. I. Hume. Dept. of Biology, Univ. of Michigan, Ann Arbor, MI 48109

Adenosine 5'-triphosphate (ATP) has recently been shown to elicit two distinct currents in embryonic chick skeletal muscle (Hume and Thomas, Soc Neurosci Abstr 13:790); a rapidly activating, desensitizing current which has a reversal potential near -15 mV, and a more slowly activating current that reverses at the potassium equilibrium potential. The late current is due to an increase in the permeability to potassium, but the early current might result from an increase in the permeability to various combinations of cations or anions. We performed ion substitution experiments to determine the ions that are permeable during the early response to ATP. We found that ATP increases membrane permeablility to anions as well as monovalent and some divalent cations, but not to larger ions like tetraethylammonium or glucuronate.

We determined the reversal potential of the early response to ATP in different external solutions, and used the Goldman equation to calculate permeability ratios. There was little difference in the permeability to the monovalent cations sodium, potassium and cesium. On the other hand, larger cations like tetraethylammonium were much less permeable. In addition, the divalent cations magnesium, calcium, and barium (but not cobalt) were significantly permeable. However, isotonic concentrations of these divalent cations, and much lower (5 mM) concentrations of manganese, zinc, and cadmium blocked the response to ATP. Finally, two independent lines of evidence indicated that small anions such as chloride and acetate were also permeable, while the larger anion glucuronate was much less so. We are now testing the possibility that the cation and anion permeability may be through a single charge nonselective ion channel activated by ATP.

A CALCIUM-DEPENDENT, VOLTAGE SENSITIVE CHLORIDE CURRENT IN CHICK SKELETAL MUSCLE. R. I. Hume and S. A. Thomas. Dept. of Biology, Univ. of Michigan, Ann Arbor, MI 48109

Skeletal muscle of many species is known to possess regenerative sodium and calcium spikes. Unlike several other species, however, developing chick skeletal muscle also possesses a long-lasting afterdepolarization (AD). We have confirmed reports that the AD is the result of a chloride current, and demonstrate that activation of this current is calcium-dependent and voltage sensitive.

A large positive shift in the peak potential of the AD occurred when external chloride was replaced by glucuronate. However, the AD disappeared when external calcium was lowered from 1 to 0.1 mM. Replacing external calcium with barium resulted in barium spikes following depolarization, but no AD. When cobalt replaced calcium, no regenerative responses were present. In these experiments, the sodium spike was blocked with tetrodotoxin. With external cobalt but no calcium, the AD could often be restored by including 20 mM calcium in the 3 M KCl recording electrode. This effect could not be mimicked with magnesium.

Whole cell patch clamp recordings were made from myoblasts under conditions in which chloride was the only plausible charge carrier. Large currents were observed following depolarization in approximately half the cells when internal calcium was buffered at 10^{-6} M, but currents were absent or greatly attenuated at 10^{-8} M. The reversal potential for these currents depended on E_{Cl} and activation and inactivation were both voltage sensitive.

THREE TYPES OF CHLORIDE CHANNELS IN CULTURED RAT HIPPOCAMPAL NEURONS

D.G. Owen*, N.L. Harrison and J.L. Barker (SPON: A.P. Mariani)
Laboratory of Neurophysiology, NINCDS, NIH, Bethesda, MD 20892 and *Dept. of Pharmacology, University College London, London WC1, U.K.

We have recorded from inside-out patches of somatic membrane from cultured hippocampal neurons, in order to isolate ion channels that might underlie slow depolarization-activated macroscopic tail currents recorded from these cells. We initially recorded from patches using asymmetric NaCl solutions in order to detect both cation and anion channels. Reversal potentials were determined using voltage ramps applied to the patch. Ca^{2+}-activated channels were sought by applying Ca^{2+} (10nM - 10μM) to the cytosolic face of patches. Cation-selective channels proved extremely rare, whereas anion-selective channels were observed frequently. Solutions containing the impermeant cation N-methyl D-glucamine (NMG) and Cl^- ions were used to isolate anion channels. Improved seals (250 GΩ) and reduced background noise were obtained under these conditions, and it was possible to resolve three types of anion channels quite readily, none of which was identical with GABA-activated anion channels: (1) a "big" voltage-activated channel (B_{Cl}), activated at about -25mV by depolarizing ramps from -50mV (whole cell convention). The B_{Cl} channel was only slightly selective for Cl^- over Na^+ or NMG^+, and exhibited a main conductance state of ~300pS. (2) A Ca^{2+}-activated channel (Cl_{Ca}; ~20pS) seen at $[Ca^{2+}]_i > 0.5\mu M$, which was voltage-insensitive. (3) A 'leak' channel (Cl_L; ~8-12pS), which was Ca^{2+}- and voltage-insensitive. Both Cl_L and Cl_{Ca} channels were highly selective for Cl^- over Na^+ or NMG^+. The macroscopic current generated by Cl_L channels may be a factor in the resting conductance of these cells. The relationship between B_{Cl} and Cl_{Ca} and whole cell currents awaits further investigation.

THE VOLTAGE DEPENDENCE OF ACTIVATION BY CALCIUM OF CHLORIDE CHANNELS IN XENOPUS OOCYTES. E.M. Landau, B. Gillo and T. M. Moriarity. Depts. of Psychiatry and Pharmacology, Mt. Sinai School of Medicine and the Bronx VA Medical Center, New York, NY.

The voltage sensitivity of the calcium-dependent chloride channels in the oocyte derives from the voltage dependence of the plasma membrane calcium channels. We now report that the voltage sensitivity of chloride channel activation was altered dramatically when intracellular calcium was increased independently of changes in the membrane potential. This was achieved by treating the cells with cadmium (0.2-0.4 mM), by injecting them with inositol-trisphosphate (0.2-0.4 pmol) or by exposing them to the calcium ionophore A23187 in the presence of calcium. Under these circumstances the chloride current occurred at voltages between -100 and +100 mV and the conductance increased ten-fold per 150-210 mV depolarization in the range of -100 to -10 mV. At more positive voltages the conductance appeared to saturate. It is concluded that intracellular calcium activates the chloride channel by acting on a site located part of the way through the membrane thickness.

CHIRAL CLOFIBRIC ACID ANALOGS: R-(+) OPEN, AND S-(-) BLOCK CHLORIDE CHANNELS IN RAT SKELETAL MUSCLE. D.Conte-Camerino*, S.H.Bryant, M.Mambrini*, A.DeLuca*, D.Tricarico*, V.Tortorella*, and G.Bettoni*. Med. Chem. and Pharmacobiology Departments, University of Bari, 70126-Bari, Italy and Department of Pharmacology and Cell Biophysics, University of Cincinnati, Cincinnati, OH 45267.

Enantiomeric pairs of four 2-(p-chlorophenoxy)isobutyric acid (clofibric acid or CPIB) analogs were synthesized, resolved and the absolute configurations determined. The analogs used were the methyl, phenyl, propyl and hexyl substitutions on the chiral alpha carbon. Measurements of chloride conductance, membrane potentials and membrane excitability were made on rat extensor digitorum fibers in vitro at 30°C with standard two microelectrode methodology. The S-(-) isomers of each analog produced only a block of chloride conductance with increasing concentrations until 100% block. The R-(+) isomers, on the other hand, increased chloride conductance by as much as 17% to 39% at low concentrations, but at higher concentrations decreased chloride conductance, but never by more than 25% of the control value. Racemic mixtures produced only a chloride conductance block. The conductance increase effect is antagonized by the S-(-) isomers. The actions of the enantiomeric pairs to either produce or inhibit myotonic excitability paralleled their ability to block or increase chloride conductance, respectively. (Supported by NIH Grant NS-03178 and an MDA Grant-in-aid.)

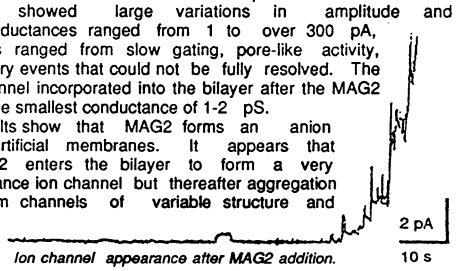
MAGAININ 2, AN ANTIBIOTIC FROM THE AFRICAN CLAWED FROG INDUCES SINGLE CHANNEL ACTIVITY IN ARTIFICIAL MEMBRANES. R.A. Cruciani[1]*, J.L. Barker[1], M. Zasloff[2]* and E.F. Stanley[3], [1]LNP and [3]LB, NINCDS; [2]HG, NICHD, NIH. Bethesda MD 20892.

Magainin 2 (MAG2), a 23 amino acid peptide from the skin of *Xenopus Laevis*, exhibits antimicrobial activity against a broad range of microorganisms (Zasloff, PNAS 84:5449). We have previously shown that MAG2 increases the anion conductance of artificial lipid bilayers (Cruciani et al., Bioph. J. 53:9a). In this study we have examined the single channel activity of MAG2.

Lipid bilayers of PS-PC in n-decane were formed on the tip of 3 to 8 μm micropipettes in a symmetrical 600 mM KCl solution. Increases in bilayer conductance were observed after addition of MAG2 to the external solution. This conductance was composed of discrete current steps that showed large variations in amplitude and kinetics. Conductances ranged from 1 to over 300 pA, and kinetics ranged from slow gating, pore-like activity, to fast flickery events that could not be fully resolved. The first ion channel incorporated into the bilayer after the MAG2 addition had the smallest conductance of 1-2 pS.

These results show that MAG2 forms an anion channel in artificial membranes. It appears that initially MAG2 enters the bilayer to form a very small conductance ion channel but thereafter aggregation occurs to form channels of variable structure and stability.



Ion channel appearance after MAG2 addition.

485.1

TWO DIFFERENT G-PROTEINS MAY MEDIATE RECEPTOR-STIMULATED PHOSPHOLIPID BREAKDOWN IN CULTURED RAT SENSORY NEURONS, Teresa M. Perney* and Richard J. Miller (SPON: M.E. Gurney). Dept. of Pharmacol. & Physiol. Sci., Univ. of Chicago, Chicago, IL 60637.

Recent evidence has suggested that the metabolism of phosphatidyl inositol 4,5,-bisphosphate (PIP_2) is regulated by a G-protein. However, the identity of the G-protein involved is still uncertain. We investigated the ability of neuropeptide Y (NPY) and bradykinin (BK) to stimulate the hydrolysis of PIP_2 in cultured dorsal root ganglion (DRG) neurons and the sensitivity of both responses to pertussis toxin (PTx) and cholera toxin (CTx). We observed that both NPY and BK stimulated a transient release of [^{3}H]inositol trisphosphate ([^{3}H]IP_3) from [^{3}H]inositol prelabeled DRG neurons. NPY (EC_{50} = 5 nM) stimulated a 2-5 fold increase in [^{3}H]IP_3 levels which peaked at 30 sec, while BK (EC_{50} = 2 nM) produced a 10-15 fold increase in [^{3}H]IP_3 within 15 sec. The effects of BK and NPY on [^{3}H]IP_3 are additive. In addition, both NPY and BK stimulated [^{3}H]IP_3 formation were subject to negative feedback inhibition by short-term treatment with phorbol esters. When DRG neurons are pretreated with PTx (350 ng/ml) the ability of NPY to stimulate [^{3}H]IP_3 production was abolished, while the response to BK was unaffected. Furthermore, pretreatment of DRG neurons with CTx (2 μg/ml) enhanced only the NPY stimulated formation of [^{3}H]IP_3. Microspectrofluorometric measurements demonstrated that both NPY and BK were able to increase $[Ca^{2+}]_i$ in the same fura-2 loaded neuron. The increase occured in Ca^{2+}-free media indicating that the IP_3 produced was able to release intracellular Ca^{2+} stores. These results suggest that different G-proteins can mediate receptor-stimulated PIP_2 hydrolysis and Ca^{2+} mobilization in the same cell.

THE EFFECTS OF KINASE C ACTIVATING AND INHIBITING AGENTS ON MEMBRANE PROPERTIES OF RAT HIPPOCAMPUS IN VITRO. N. AGOPYAN and K. KRNJEVIC, Depts. Physiol. and Anaesthesia Research, McGill University, Montréal, Québec, Canada.

In previous experiments on hippocampus in situ both activation [by phorbol diacetate (PDAc)] and inhibition [by 1-2-methylpiperazine dihydrochloride (H-7)] of kinase C resulted in enhancement of population spikes (Agopyan and Krnjević 1987, Soc. Neurosci. Abst. 13:64). We have now studied the effects of PDAc and H-7 in vitro.

Hippocampal slices were maintained in an interface chamber and intracellular recordings were made from the cell bodies of CA1 pyramidal cells.

Iontophoretic application of PDAc increased the amplitude of both EPSPs and IPSPs, reduced the number of spikes evoked by depolarizing pulses and the membrane resistance, without affecting the membrane potential. Iontophoresis of H-7 on the other hand increased the amplitude and the number of action potentials induced by both orthodromic and antidromic stimulation, and reduced IPSPs and the membrane resistance.

These results, in keeping with those obtained in situ, suggest that kinase C activation enhances both EPSPs and IPSPs, whereas inhibition of kinase C leads to depression of IPSPs.

MUSCARINIC ACTIVATION OF IP_3 MEDIATED CHLORIDE CURRENT IS INHIBITED BY THE βγ-SUBUNITS OF G-PROTEINS. T.M. Moriarty*, B. Gillo*, D. Carty*, R. Premont*, R. Iyengar* and E.M. Landau (SPON: J. Thornborough). Depts. of Psychiatry and Pharmacology, Mt. Sinai School of Medicine and Bronx V.A. Medical Center, New York, N.Y.

The Xenopus oocyte has a muscarinic (MAch) activated Cl- current which is mediated by IP3 and is probably transduced by a G-protein. This study examines the mechanism of G-protein coupling of receptors to IP3 production. The MAch response was examined in two-electrode voltage clamped oocytes in a superfusion apparatus. Modulation of the MAch evoked Cl- current was examined in oocytes microinjected with resolved G-protein subunits purified from bovine brain and human RBC. The presence of a G-protein in oocytes was shown by pertussis toxin (PTX) labeling of a 40 kDa band from oocyte membranes. A 36 kDa band was labeled by an antiserum specific for the β-subunit. PTX treatment uncoupled the MAch receptors from activation of the Cl- current. Cells microinjected with 1.5 ng of βγ showed a 95% reduction in the MAch activated Cl- current. Cells injected with equal volumes of βγ storage buffer showed no change in response. Cells injected with boiled βγ, bovine serum albumin or resolved α-subunits also showed no reduction in response. Cells injected with varying concentrations of βγ showed a dose-response relationship with half-maximal inhibition of MAch activated Cl- current at about 1 nM. Cells injected with 1.5 ng βγ could not response to bath applied agonist, but could generate the Cl- current on intracellular injection of IP3. These results suggest that there is a G-protein responsible for MAch receptor mediated signal transduction through IP3, that it is an αβγ heterotrimer and that its mode of action is similar to that of the hormone activated adenylyl cyclase.

MOLECULAR ISOLATION OF A PUTATIVE PHOTORECEPTOR-SPECIFIC PHOSPHOLIPASE C GENE OF DROSOPHILA, norpA, AND ITS ROLE IN PHOTOTRANSDUCTION. **B.T. Bloomquist*, R. Shortridge*, S. Schneuwly*, M. Perdew*, and W.L. Pak. Dept. of Biological Sciences, Purdue Univ., W. Lafayette, IN 47907**

Severe norpA mutations of Drosophila eliminate the photoreceptor potential. Evidence suggests that the norpA gene encodes a protein involved in an intermediate step of phototransduction. Inoue et al. (1985) and Selinger and Minke (1988) have reported that norpA mutations affect the phospholipase C (PLC) activity in the eye. We obtained from C. Montell, H. Steller, and G. Rubin two cosmids containing DNA from the region between the distal breakpoints of two gamma-ray induced deficiencies, Df(1)rb4 and Df(1)biD2, which define the location of the norpA gene. To prove that the gene is contained in the cloned DNA and to localize it, we isolated in transposon mutagenesis a norpA allele which contains a hobo element in the same region as that cloned into the cosmids. Northern hybridizations show that the putative norpA transcript is approx. 7 kb in length and expressed only in the adult head. In situ hybridizations of a cDNA corresponding to this region to adult tissue sections show heaviest labels in photoreceptors. Conceptual translation of an open reading frame contained in cDNAs corresponding to this region generates a large protein with extensive sequence similarity to the only published eukaryotic PLC sequence (Stahl et al., 1988). We conclude: (1) the norpA gene encodes a PLC; (2) the PLC is a critical component of phototransduction machinery in Drosophila.

CHARACTERIZATION OF THE SOLUBILIZED $INSP_4$ BINDING SITE IN RAT CEREBELLUM. P.B. Sklar, A.B. Theibert* S. Supattapone, R. Mourey*and S.H. Snyder. The Johns Hopkins University Sch. of Med., Dept. of Neuroscience, Baltimore, MD 21205.

Inositol 1,3,4,5-tetrakisphosphate ($InsP_4$) is produced rapidly and transiently upon stimulation of the phosphoinositide system. In several reported studies microinjection of $InsP_4$ in conjunction with inositol 1,4,5-trisphosphate ($InsP_3$) mimicked receptor activation, suggesting a role for $InsP_4$ as a second messenger in signal transduction.

We have demonstrated specific binding sites for [^{3}H]$InsP_4$ in rat cerebellar membranes. Recently we have detergent solubilized and partially purified this cerebellar $InsP_4$ binding site. Specific activity of binding is increased approximately 100-fold over homogenates. The binding site is separated, during the purification, from the $InsP_3$ receptor, the $InsP_3$/$InsP_4$ 5-phosphatase, and the $InsP_3$ 3-kinase. Characterization of this [^{3}H]$InsP_4$ binding reveals an IC_{50} for $InsP_4$ of 80 nM. $InsP_3$ and $InsP_2$ are much weaker at competing binding, both showing IC_{50}'s > 1 μM. Binding is potently inhibited by heparin and calmodulin. Finally, solubilized [^{3}H]$InsP_4$ binding is observed in several peripheral tissues, including those of the immune system.

485.6

MOLECULAR ANALYSIS OF REGULATORY SUBUNITS OF cAMP-DEPENDENT PROTEIN KINASE (PKA) IN *APLYSIA* NEURONS. P.J. Bergold, S. Beushausen, S. Sturner*, H. Bayley, and J. H. Schwartz. Center for Neurobiology and Behavior and Howard Hughes Medical Institute, Columbia University, 722 W. 168th St., New York, NY 10032 and Worcester Foundation for Experimental Biology, 222 Maple Ave., Shrewsbury, MA 01545

cAMP, through activation of PKA, is a critical mediator of the changes in *Aplysia* neurons that occur during both short- and long-term sensitization. It has been proposed that a sustained increase in the activity of PKA is an essential difference between short- and long-term sensitized cells. Changes in the ratio of the two types of PKA subunits is one mechanism for altering the activity of the enzyme. We have previously shown that the level of the regulatory subunits (R) decrease as compared to the catalytic subunit (C) during long-term sensitization as measured with the cAMP-photoaffinity reagent, [^{32}P] 8-N_3-cAMP. To study the specific roles the neuronal isoforms of PKA have in mediating synaptic plasticity, we have isolated genomic and cDNA clones encoding R subunits. Partial sequence analysis of a genomic clone isolated by low stringency hybridization to a bovine R_I cDNA (provided by Dr. G. S. McKnight, U. of Washington) revealed two exons with greater than 90% predicted amino acid identity with bovine R_I. An oligonucleotide probe derived from the sequence of one of these exons was used to screen an *Aplysia* neuronal cDNA library. One positive phage was isolated from approximately 3 X 10^6 recombinants. The 3.5 kb insert of this clone contained sequence encoding the C-terminal 234 amino acids of R_I including the translation terminator. The sequence predicts a protein with greater than 80% amino acid identity with bovine R_I. Using the *Aplysia* R_I probe, a rare transcript of 8 kb was detected on Northern blots of neuronal polyA+ RNA. Several polyclonal antisera were prepared against a peptide predicted by the genomic DNA sequence to be part of the *Aplysia* R_I cAMP-binding domain. One of these antisera reacted strongly with a M_r 54,000 neuronal protein on Western blots. We can now measure the changes in PKA that occur in *Aplysia* sensory neurons during the induction of long-term sensitization with these reagents for R together with those for C described by Beushausen et. al., (These Abstracts).

485.7

TWO ISOFORMS OF THE cAMP- DEPENDENT PROTEIN KINASE (PKA) CATALYTIC SUBUNIT IN APLYSIA NEURONS ARISE THROUGH ALTERNATIVE SPLICING S. Beushausen, P. J. Bergold, S. Sturner*, A. Elste*, V. Roytenberg*, J. H. Schwartz and H. P. Bayley. Howard Hughes Medical Institute, Center for Neurobiology and Behavior, Columbia University, 722 W 168th St., NY, NY, 10032. Worcester Foundation for Experimental Biology, 222 Maple Ave, Shrewsbury, MA 01545.

Studies in Aplysia have implicated cAMP-dependent protein kinase in several instances of synaptic plasticity including short and long term facilitation in sensory neurons. To assist in the analyses of these processes we have isolated genomic and cDNA clones encoding catalytic (C) subunits of the enzyme.

A randomly primed Aplysia neural cDNA library was screened with a mouse Cα cDNA (provided by G.S. McKnight). Nucleic acid sequence analysis of the clones revealed two different classes of cDNA encoding putative C isoforms. Both contained open reading frames 1056 nucleotides in length, but differed at 39 positions between residues 423-549. The inferred amino acid sequences indicated that the isoforms were 97% identical, differing at 10/42 positions between residues 142-183. The Aplysia amino acid sequences were 83-85% identical to murine and bovine Cα and Cβ, and 83% identical to the Drosophila subunit. Sequence analysis of an Aplysia genomic DNA fragment and S1 nuclease mapping of cellular RNA confirmed that this variation arises through alternative splicing of two mutually exclusive exon cassettes with homology and equal length to exon 6 of the mouse Cα gene. In contrast, S1 analysis of mouse brain and liver RNA using a Cα probe failed to show alternative splicing in this region. Although not strictly tissue specific, the Aplysia transcripts were expressed at different relative levels in different tissues. For example, the major transcript in neurons was present at relatively low levels in ovotestis.

Recently, clones for the regulatory (R) subunits of the kinase have been obtained (Bergold et al., These Abstracts). Next, we intend to use nucleic acid and immunologic probes to investigate how combinatorial expression of R and C isoforms might be involved in synaptic plasticity.

485.8

G_S ACTIVATES ADENYLATE CYCLASE IN NEOSTRIATAL PRESYNAPTIC TERMINALS. N. Aronin. Department of Medicine, University of Massachusetts Medical School, Worcester, MA 01655

G_S is a GTP-binding protein which mediates receptor activation of adenylate cyclase. Here the presynaptic activation of adenylate cyclase by G_S was examined in rat neostriatal synaptosomes. First, since $G_S\alpha$ is ribosylated specifically by cholera toxin (CT), neostriatal synaptosomes were incubated in a medium containing ^{32}P-NAD and activated CT (10 µg/ml). ^{32}P-ribosylated proteins were then separated by 10% SDS-polyacrylamide gel electrophoresis. Second, synaptosomes were treated with activators of $G_S\alpha$, NaFl (10mM) and CT (10 µg/ml), and the generated cAMP was measured by radioimmunoassay. Results: After ^{32}P-NAD ribosylation of synaptosomal proteins by CT, two major bands were identified, at 45k and 52k, consistent with previously reported molecular weights of $G_S\alpha$. Labeling of proteins was absent in the synaptosomes when CT was omitted. Cholera toxin and NaFl increased cAMP generation in the synaptosomes by 200% and 400%, respectively. By electron microsopic examination, the synaptosomal preparation reproducibly contained about 90% synaptosomes without postsynaptic elements. These findings indicate that in the synaptosomes $G_S\alpha$ is linked to adenylate cyclase activation. Since axoaxonal synapses are rare in the neostriatum and G_S is generally thought to transduce signals of membrane-bound receptors, these results point to paracrine, autocrine or hormonal regulation of adenylate cyclase activity in presynaptic terminals in the mammalian neostriatum.

485.9

EVIDENCE THAT LIPOXYGENASE METABOLITES LINK DOPAMINE D2 RECEPTORS TO POTASSIUM S-CHANNELS IN APLYSIA SENSORY NEURONS. Y. Yaari. Howard Hughes Med. Inst., Columbia Univ. Col. of Phys & Surg., New York, NY 10032.

Dopamine (DA) is a putative inhibitory transmitter in some synapses in Aplysia. When applied onto Alysia pleural sensory neurons in culture, it produced membrane hyperpolarization and conductance increase by activating the potassium S-current. While acting through distinct D2-like receptors (as indicated by the effects of selective D1 and D2 agonists and antagonists), DA mimicked the inhibitory action of the peptide transmitter FMRFamide, which is thought to be mediated by the production of lipoxygenase metabolites of arachidonic acid. DA may stimulate the same cascade, as (i) inhibition of phospholipase activity with p-bromophenacyl-bromide prevented the actions of DA and FMRFamide; (ii) blockage of the lipoxygenase pathway with nordihydroguaiaretic acid markedly reduced the actions of both transmitters, while (iii) blockage of the cycloxygenase pathway with indomethacin had no effect; (iv) DA exerted its action in neurons loaded with cyclic-AMP analogues, indicating that it does not act by inhibiting adenylate cyclase.

Thus D2-like receptors mediating inhibition in Aplysia sensory neurons may be linked to potassium S-channels by lipoxygenase metabolites of arachidonic acid.

485.10

FORMATION OF THE 12-LIPOXYGENASE PRODUCT 12-KETO-EICOSATETRAENOIC ACID (12-KETE), A POSSIBLE SECOND MESSENGER IN APLYSIA NEURONS. D. Piomelli, E. Shapiro, S. Feinmark* and J.H. Schwartz, HHMI and Dept. of Pharmacology, Columbia Univ. Col. of Phys. & Surg., New York, NY 10032.

The 12-lipoxygenase product 12(S)-hydroperoxy-5,8,10,14-eicosatetraenoic acid (12-HPETE) mimics synaptic responses produced by histamine and Phe-Met-Arg-Phe-amide (FMRF) in identified neurons of the marine mollusk, Aplysia. Since 12-HPETE is known to be metabolized further in other animals, we investigated whether these actions might require conversion of 12-HPETE to other active products. Here we report the identification of 12-keto-5,8,10,14-eicosatetraenoic acid (12-KETE), a metabolite of 12-HPETE formed by Aplysia nervous tissue. Release of [^{3}H]12-KETE occurs when the nervous tissue is labeled by incubation with [^{3}H]- arachidonic acid and then stimulated with histamine. In L14 cells, a cluster of identified motor neurons that produce inking, application of 12-HPETE elicits a change in membrane potential similar to that evoked by histamine. A similar effect is produced by 12-KETE provided by A.R. Brash (Vanderbilt U) but not by 12(S)-hydroxy-5,8,10,14-eicosatetraenoic acid (12-HETE), another metabolite of 12-HPETE, suggesting that 12-HPETE and its metabolite 12-KETE participate in the transduction of histamine responses in Aplysia neurons.

485.11

CALCIUM DEPENDENT EFFECTS OF MAITOTOXIN ON PHOSPHOINOSITIDE BREAKDOWN AND ON CYCLIC AMP ACCUMULATION IN PC12 AND NCB-20 CELLS. Fabian Gusovsky, Takeshi Yasumoto* and John W. Daly. LBC, NIDDK, NIH, Bethesda, MD 20892.

The marine dinoflagellate toxin maitotoxin (MTX) stimulates phosphoinositide breakdown in pheochromocytoma PC12 cells and in neuroblastoma hybrid NCB-20 cells in a calcium dependent, calcium channel blocker resistant fashion. In PC12 cells the maximal stimulation of phosphoinositide breakdown occurs at 1.5 mM $[Ca^{2+}]_o$, whereas in NCB-20 cells the maximal stimulation is observed at 2.5-4.5 mM $[Ca^{2+}]_o$. Phosphoinositide breakdown leads to both inositol phosphates and to diacylglycerides. The latter through stimulation of protein kinase C would, like phorbol esters, be expected to augment cyclic AMP accumulation in PC12 cells and to inhibit receptor-mediated cyclic AMP accumulation in NCB-20 cells. MTX did potentiate forskolin-induced accumulation of cyclic AMP in PC12 cells and did inhibit prostaglandin E_2-induced accumulation of cyclic AMP in NCB-20 cells. The effects of MTX on accumulation of cyclic AMP were calcium-dependent and the concentrations of calcium required for maximal responses were the same as the ones required for maximal stimulation of phosphoinositide breakdown. The results confirm previous studies on the heterogeneous input of protein kinase C to cyclic AMP-generating systems performed with phorbol esters and demonstrate the utility of MTX as a unique tool for studies of systems that involve second messengers generated through stimulation of phosphoinositide breakdown.

485.12

PHOSPHATIDYLCHOLINE TURNOVER AS A REPORTER FOR THE ACTIVATION OF DISTINCT CELLULAR SIGNALLING PATHWAYS: IMPLICATIONS FOR THE ACTION OF NGF AND CAPSAICIN. S.I. Patterson+,* A. Gatti* and M.R. Hanley . +Dept Neurobiology, Stanford University School of Medicine, Stanford, Ca 94305, USA and MRC Molecular Neurobiology, Hills Rd, Cambridge CB2 2QH, UK.

Turnover of membrane phosphatidylcholine (PC) shows both constitutive and pharmacologically-stimulated components in a neuronal cell line NG115-401L which can be followed by the extracellular release of radioactive choline metabolites. Although independently regulated, both constitutive and stimulated release occur through phospholipase D, releasing ^{3}H-choline into the medium. The basal release is reduced by agents that raise intracellular calcium, and by cAMP stimulants or mimetics. These agents do not influence a second class of stimulated PC turnover effects which are sensitive to protein kinase C activators, and can be down-regulated by persistent exposure to phorbol diesters. Moreover, the detailed pharmacology of the stimulated component indicates that NGF and capsaicin may be additional and independent stimulants as they are additive with phorbol diester stimulation of turnover. These results suggest that both NGF and capsaicin may activate novel or known kinases early in their signalling pathways. The hormone bradykinin, which causes both intracellular calcium mobilization and PKC activation in these cells, shows simultaneous regulation of these two distinct processes.

TIME COURSE OF FUSION PORE CONDUCTANCE DURING EXOCYTOSIS OF MAST CELL SECRETORY VESICLES. A. Spruce,* L. Breckenridge,* W. Almers, Dept. Physiol., U. Washington, Seattle, WA 98195

Exocytosis begins with the opening of a fusion pore that connects vesicle lumen with cell exterior (Breckenridge & Almers, Nature 328:814). When the pore first opens, a transient outward current through it (trace I) equalizes the potentials across vesicle (E_V) and cell membranes (E_C). ($E_C - E_V$) is obtained by subtracting the time integral of I from its final value and then dividing by the vesicle capacitance. The pore conductance (trace G) is given by $I/(E_C - E_V)$. G rises abruptly to a value G_o (arrow); the rise time (102±45 μs SD at 10 kHz) is not well resolved. Later, G grows more gradually as the pore dilates. Sometimes (12% of cases) the slow phase is too rapid to be distinguished from the fast. The histogram of G_o is skewed (range 80-800 pS, peak 220 pS, median 270 pS, 195 transients). The abrupt opening of the pore, faster than in gap junction channels (Neyton & Trautman, J Exp Biol 124:93; Veenstra & deHaan, Am J Physiol 254:H170), is reminiscent of the abrupt opening of single ion channels. NIH grants AR17803 and GM 39520.

TIME COURSE OF TRANSMITTER RELEASE AND CALCIUM CHANNELS AT THE MOUSE MOTOR NERVE TERMINAL. A. I. Bain* and D. M. J. Quastel. Dept of Pharmacology & Therapeutics, Univ. of British Columbia, Vancouver, B. C., Canada V6T 1W5

Following nerve stimulation the quantal components of EPPs are sharply focused in time with most appearing in a period of about 0.4 ms. Using a computer to locate each quantum and minEPP, we find that changes in release rate and latency produced by repetitive stimulation in the presence of Ba are consistent with a fixed underlying time course of intracellular Ca/Ba at release sites, with time constants of about 0.5 ms for the rising and falling phases. Brief submaximal focal depolarizations of nerve terminals (NTDs) elicit quanta with a more dispersed latency. The effectiveness of NTD trains to produce rise of minEPP frequency in the presence of Ba provides a method for assessing the relative extent of Ca-channel opening by pulses; results show no substantial channel inactivation up to at least 100 ms and no inhibition of ion entry except by pulses much larger than those causing maximal activation. By extrapolation from results with varied Ca/Ba it appears that a component of the EPP should persist even in the absence of ion entry and, with 'buffered' Ca or with ion entry inhibited by bekanamycin there indeed occur small EPPs that grow with high frequency stimulation, in proportion to minEPP frequency. Thus, nerve impulses influence release by a mechanism(s) other than Ca channel gating.

ROLES OF PRESYNAPTIC CALCIUM AND POTENTIAL IN RELEASING NEUROTRANSMITTER. R.S. Zucker and P.G. Haydon. Physiol.-Anat. Dept., Univ. Calif., Berkeley, CA 94720 and Zool. Dept., Iowa State Univ., Ames, IA 50011.

We have examined the roles of presynaptic membrane potential and intracellular calcium activity in triggering the release of acetylcholine at an inhibitory synapse formed between two isolated somata from the snail Helisoma trivolvis. Buccal ganglion neurons B5 and B19 were co-cultured under conditions which suppress neurite outgrowth and permit formation of a soma-soma synapse. Synaptic transmission was monitored as miniature inhibitory postsynaptic currents in cell B19 recorded using whole cell patch clamp. Presynaptic membrane potential was controlled by simultaneous whole cell patch clamp of neuron B5. Presynaptic internal calcium concentration was controlled by internal perfusion of B5 with the photodynamic chelator Nitr-5, 75% loaded with calcium. We observed: 1) Depolarization of B5 to above +15 mV releases transmitter in a normal-calcium medium. 2) Voltage-induced transmitter release is reduced by presynaptic introduction of Nitr-5, and abolished in a zero-calcium medium. 3) Photolysing Nitr-5 to raise presynaptic free calcium from 240 nM to over 1.5 μM elicited transmitter release. Release increased to about the rate caused by normal action potentials as calcium concentration rose to 10 μM, which is near the level occuring at release sites during action potentials. 4) Transmitter release was independent of presynaptic potential in the range -120 to +40 mV, when internal calcium was elevated by Nitr-5 photolysis and external calcium was eliminated. We conclude that action potentials normally release transmitter solely by admitting external calcium to release sites, with no direct effect on secretion. Supported by NIH Grants NS 15114 and NS 24233.

DIFFERENT FUNCTIONAL ROLES FOR TWO COMPONENTS OF CALCIUM CURRENT IN APLYSIA SENSORY NEURONS. B.W. Edmonds, E.R. Kandel and M. Klein*, Ctr. Neurobiol. & Behav., Columbia Univ., HHMI, New York, NY 10032.

Calcium current was recorded in isolated Aplysia sensory cells using the whole-cell version of the patch-clamp technique. Currents obtained over a range of test voltages suggest the presence of two distinct components: a largely non-inactivating current which begins to activate around -20 mV and an inactivating current which is recruited at higher voltages (> 0 mV). A pharmacological separation has been achieved with nifedipine and FMRFamide. Nifedipine selectively antagonizes the non-inactivating component of current, whereas FMRFamide selectively reduces the inactivating component. Because FMRFamide is a transmitter mediating presynaptic inhibition in sensory cells, selective modulation of the inactivating component of calcium current may be important (in addition to enhancement of K^+ conductance) for the expression of this form of plasticity. Unlike FMRFamide, nifedipine does not inhibit transmitter release. Taken together, the data are consistent with the idea that of the two components of current, only the inactivating component is important for transmitter release and for at least one form of synaptic plasticity.

DOES FMRFamide-STIMULATED RELEASE OF ARACHIDONIC ACID DEPEND ON Na/H EXCHANGE OR INTERNAL CALCIUM? H. Blumenfeld*, B. Bug, N. Buttner*, J.D. Sweatt* and S.A. Siegelbaum. Ctr. for Neurobiol. & Behav., HHMI, Columbia Univ., New York, NY 10032

FMRFamide increases the S K^+ current in Aplysia sensory neurons through lipoxygenase metabolites of arachidonic acid (A.A.). Two mechanisms proposed to control release of A.A. through stimulation of phospholipase A_2 are an increase in Ca_i or an increase in pH_i due to Na/H exchange. Here we study possible roles for Ca_i or pH_i in the response to FMRFamide.

FMRFamide had no effect on resting Ca_i (100 nM), as determined by fluorescence ratios with fura-2 in the soma or growth cone. However, FMRFamide did decrease the Ca_i transient in response to action potentials in both cell body (23%) and growth cone (58%), consistent with its role in presynaptic inhibition. Next, the role of Na/H exchange was studied by replacing external Na with N-methyl-d-glucamine. Na removal reduced the S current response to FMRFamide by 66% but did not effect the response to A.A. Thus, the Na-sensitivity lies at a stage leading to A.A. release. However, pH_i (7.0) measured with BCEF showed no change in response to FMRFamide. FMRFamide also did not speed recovery from acidification following exposure to NH_3, arguing against marked stimulation of Na/H exchange. The inhibition of the FMRFamide response in Na-free medium could be related to a decrease of 0.3 pH_i units we see upon Na removal. Thus, the FMRFamide-mediated release of A.A. does not require an increase in Ca_i or pH_i.

PRESYNAPTIC CALCIUM AT MOTOR NERVE TERMINALS DURING POST-TETANIC POTENTIATION. K.R. Delaney*, D.W. Tank and R.S. Zucker (SPON: A. Dearry). Physiol.-Anat. Dept., Univ. Calif., Berkeley, CA 94720 and Molec. Biophys. Dept., AT&T Bell Labs., Murray Hill, NJ 07974.

We have measured calcium levels in individual presynaptic terminals of the excitor axon to the crayfish claw opener muscle while recording excitatory junctional potentials (EJPs). Fura-2 (17 mM in 100 mM KCl) was iontophoretically injected (15-20 nA for 30-60 min) into the preterminal axon, which was then stimulated extracellularly while EJPs were recorded in proximal fibers. Terminals (2-7 um dia.) filled with fura-2 on the same or an adjacent muscle fiber were imaged during stimulation using a cooled charge-coupled device camera attached to an upright microscope with a 40X objective. Long-lasting facilitation of the EJP was observed following tetanic stimulation of the excitor axon (9 of 10 preparations with 7-10 min 20-33 Hz tetani). Presynaptic free calcium concentration increased rapidly after the onset of stimulation and rose further during the tetanus, as did the EJP. Increased presynaptic calcium was closely correlated with potentiation of the EJP (tested at 1 Hz) during the first 5-10 min after the tetanus. In 5 of 7 preparations, a measureable enhancement of the EJP was observed more than 20 min after the tetanus, although calcium had returned to pre-stimulus levels. The results are consistent with a rise in presynaptic calcium contributing only to the early phase of post-tetanic potentiation. Supported by NIH Grant NS 15114 and Bell Labs.

POTENTIATION OF SYNAPTIC TRANSMISSION AT AN IDENTIFIED SYNAPSE IN THE CEREBRAL GANGLION OF APLYSIA. S.M. Fredman. Dept. of Physiology, Meharry Medical College, Nashville, TN 37208.

The excitatory monosynaptic connection between A and B neurons in the cerebral ganglion of Aplysia exhibits homosynaptic potentiation following high frequency stimulation. Two A and two B neurons were impaled in ganglia bathed in 5x Ca^{2+}, 3x Mg^{2+} SW to suppress polysynaptic pathways. One A neuron was driven at 0.004-0.01 Hz, producing a decrement of its EPSPs in the B neurons. An interposed stimulation of the A neuron with a 2 sec 10-30 Hz train potentiated the EPSPs in both B neurons. The amplitude of the subsequent test EPSPs slowly increased to 150% of their initial (pre-decrement) levels, with the peak increase occurring 5-6 min after the high frequency train. A single 2 sec stimulation produced potentiation lasting longer than 20 min. Stimulating either B neuron or the second A neuron at 30 Hz was without significant effect on the EPSPs evoked by the first A neuron. This suggests a primarily presynaptic mechanism for the potentiation. This work was supported by NIH grant NS20846 and RCMI grant RR03032.

486.8

A NOVEL MOLECULAR MECHANISM FOR PRESYNAPTIC INHIBITION: THE ARACHIDONIC DERIVATIVE HEPOXILIN-A DIRECTLY ACTS ON THE SEROTONIN-SENSITIVE "S" K^+-CHANNEL TO INCREASE ITS OPENING IN APLYSIA SENSORY NEURONS. F. Belardetti, W. Campbell*, P. Chabert*@, J.R. Falck*, C. Mioskowski*@, and M. Rosolowsky*. Depts. Pharmacology and Molecular Genetics, UT Southwestern Med. Ctr., Dallas, TX 75235 and @Lab. De Chimie Bio-Organique, Universite' L. Pasteur, Strasbourg, France 67408.

FMRFamide increases, through the release and transformation of arachidonic acid to 12-hydroperoxy-eicosatetraenoic acid (12-HPETE), the opening (P_O) of the S channel in Aplysia sensory neurons (SNs), but 12-HPETE applied to inside-out SN patches does not increase this P_O. 12-HPETE to act might need to be re-arranged to Hepoxilins A and Hepoxilin B. To test this idea, SNs were incubated with clotrimazole (5 μm), an inhibitor of the re-arrangement. The FMRFamide response was abolished (4/6 cells). Next, 12-HPETE (~160 nM) was applied to inside-out patches in the presence of hematin (1 μM), to catalyze the re-arrangement. Under these conditions, 12-HPETE now produced a sharp and transient, 10-fold increase of the S channel P_O (4/6 patches). In separate experiments without hematin, Hepoxilin A applied to inside-out patches (250-500 nM) produced a similar large increase of P_O (3/5 patches). Vehicle application (N=3) was without effect. Since no GTP or ATP was added, this action on the channel does not involve a G-protein, cGMP, cAMP or a phosphorylation reaction, but appears direct.

CA^{++}-CHANNELS SUFFICIENT FOR QUANTAL RELEASE FROM CHICK CILIARY GANGLION NEURONS. J.T. Hackett and J.B. Tuttle. Depts of Physiol. and Neurosci., Univ of Virginia School of Medicine, Charlottesvl., Va 22908

Recordings of Ca^{++}-channels involved in quantal release have not been reported. However, synaptic Ca^{++} channel properties must include: low voltage activation, slow or no inactivation, block by Mn^{++} but not dihyrdropyridine, and close proximity to the release site. To record synaptic Ca^{++}-currents, muscle was grown on 1 mm spots of collagen and ciliary ganglion neurons added after myotube formation. This restricts neurite length and the available realm of synaptic interaction. Neurons were whole-cell patch clamped with the pipet containing 150mM CsCl, 10mM EGTA-CsOH, 1 mM $MgCl_2$ and buffered to pH 7.4. The bath had 10 mM $CaCl_2$ and 2 uM tetrodotoxin. Quantal postsynaptic potentials were detected using microeletrodes placed in the muscle cells. In simultaneous recording from nerve and muscle pairs, three conditions were obtained: non-transmitting junctions with only non-synaptic Ca^{++}-channels; low probability release evoked solely by non-synaptic Ca^{++}-channels; one-to-one transmission with synaptic Ca^{++} channels that did not inactivate. These results indicate that intracellular Ca^{++} can trigger release independent of the Ca^{++} channel source. We conclude that synaptic Ca^{++} channels impart strong transmission to these synapses because response characteristics, density and location give a more exclusive linkage to the release mechanism. SYNAPTIC AND CELLULAR MECHANISMS OF CARBACHOL-INDUCED HIPPOCAMPAL RHYTHMIC SLOW WAVE (THETA). F.W.Y. Tse and B.A. MacVicar, Dept. of Medical Physiology, University of Calgary, Calgary, Alberta, T2N 4N1, Canada.

We recorded intracellularly from CA3 pyramidal neurons in hippocampal slices of 21-28 days old rats. Carbachol (20-60μM) induced 5-10 Hz depolarizations (theta) which occurred synchronously in CA3 neurons and increased in amplitude with membrane hyperpolarization.

Carbachol-induced theta was blocked by atropine, TTX, kyurenic acid (an excitatory amino-acid blocker), or Ca^{++} channel blockers (Cd^{++}, Co^{++} or Mn^{++}); but it was not blocked by bicuculline, 5-7mM external Ca^{++} (which blocks polysynaptic transmission), blockers of NMDA receptors, or removal of the dentate gyrus. Activation of C kinase by a phorbol ester or inhibition of C kinase by preincubation in H-7 neither activated theta nor blocked carbachol-induced theta. However, bath application of inhibitors of intracellular Ca^{++} release (TMB-8 or Ba^{++}) blocked carbachol-induced theta.

We postulate that hippocampal theta involves muscarinic enhancement of a non-NMDA monosynaptic excitation of CA3 neurons by amino-acid releasing interneurons with widespread connections in the CA3 region. Intracellular Ca^{++} mobilization but not C kinase activation is critical in carbachol-induced theta.

DYNAMIC PROPERTIES OF CHEMICAL TRANSMISSION IN THE CRAB T-FIBER SYNAPSE. J.-W. Lin and R. Llinás. Dept. Physio. & Biophysics., NYU School of Medicine, New York, NY 10016

The crab T-fiber synapse is a tonically transmitting junction with a non-spiking presynaptic element. It is one of the few synapses that allows simultaneous pre- and postsynaptic recordings at the junctional site (Blight and Llinas, Phil. Trans. Roy. Soc., 1980).

Two electrodes were used presynaptically and one postsynaptically. EPSPs were evoked by 50 mV, 3-5 ms presynaptic pulses. A double pulse paradigm revealed a brief facilitation that was followed by a longer lasting depression. The former declined within 150 ms, the latter within a second. Repetitive stimulation with comparable inter-pulse intervals (0.1 to 40Hz) showed mainly depression, i.e. EPSP amplitude was inversely related to stimulus frequency. By contrast, prolonged (300 ms) conditioning pulses (CP), with an amplitude range of 20 to 140 mV, potentiated the test EPSPs up to 6 fold. The potentiation decayed with a time constant of 3.1 sec ($\pm$0.67, n=4). The magnitude and duration of the potentiation increased with larger CPs. As the CP approached the supression level (+80mV), the potentiation was reduced. This result indicates that the potentiation is triggered by the CP-activated calcium influx. Furthermore, the potentiation behaved as a saturable process, since repeated CP (which activated near maximal potentiation if applied individually) had little effect on the magnitude and time course of the potentiation that followed. ONGOING ELECTRICAL ACTIVITY OF SUPERIOR CERVICAL GANGLION CELLS IN MAMMALS OF DIFFERENT SIZE. D. Purves and A. Ivanov, Dept. Anatomy & Neurobiology, Washington Univ. School of Medicine, St. Louis, MO 63110 and Bogomoletz Inst. of Physiology, Kiev, U.S.S.R.

Studies of the organization of the peripheral sympathetic system have demonstrated systematic differences in the form and innervation of superior cervical ganglion cells among closely related mammals that differ primarily in size (Purves et al., J. Neurosci. 6: 158-163, 1986). Ganglion cells in progressively larger mammals have more elaborate dendritic arbors and receive a greater number of preganglionic inputs. In the present study we asked how these structural and functional differences might affect the ongoing pattern of synaptic activity among individual neurons. Accordingly, we used intracellular recording to monitor ongoing postsynaptic activity from ganglion cells in anesthetized but otherwise intact mice, hamsters, rats, guinea pigs and rabbits.

The proportion of ganglion cells exhibiting postsynaptic activity during a standard period of observation (5 minutes) under urethane anesthesia was least in a small mammal like the mouse (30%), intermediate in animals of intermediate size such as the hamster and rat (48% and 45%, respectively), and greatest in the neurons of the largest animals in the series, the guinea pig (89%) and rabbit (95%). We found, moreover, that the frequency of synaptic activation was also proportional to animal size. The amplitudes of the postsynaptic responses, however, were inversely related to body weight, being largest in the mouse and least in the rabbit.

These differences in activity patterns are presumably related to the functional requirements of animals of different bulk, and raise the interesting question of whether normal activity in other parts of the mammalian nervous system also varies in parallel with animal size.

INFLUENCE OF PERIPHERAL TARGET SIZE ON NORMAL PATTERNS OF SYNAPTIC ACTIVITY OF RAT SUPERIOR CERVICAL GANGLION CELLS. J. T. Voyvodic and A. Ivanov*, Washington Univ. Sch. of Med., St. Louis, Mo. 63110 and Bogomeltz Inst. of Physiology, Kiev, U.S.S.R.

The dendritic complexity of sympathetic ganglion cells can be regulated by changing the relative size of peripheral axonal targets (Voyvodic, Soc. Neur. Abstr., 13:574, 1987). Thus, increasing (or decreasing) the amount of target tissue available to neurons in the rat superior cervical ganglion increases (or decreases) the number and length of ganglion cell dendrites. Here, we have examined whether changes in target size and dendritic geometry are associated with changes in synaptic activation of ganglion cells by preganglionic innervation. The relative target size of neurons innervating the submandibular gland was increased by partially denervating the gland at birth, causing the death of many ganglion cells and an increase in size of the dendritic arbor of the remaining neurons. Patterns of tonic synaptic activity were subsequently measured in adult rats for cells innervating either control or partially denervated submandibular glands.

In control rats, only 11% of the ganglion cells innervating the gland (N=95) exhibited ongoing synaptic activity under urethane anesthesia during a 5 minute period of observation. Experimentally increasing the relative size of the target increased the number of active neurons from 11% to 42% (N=60). Moreover, these cells showed an increased frequency of synaptic activity compared to controls, with superthreshold responses increasing from 0.1 to 0.3/s, and subthreshold EPSPs increasing from 0.1 to 1.5/s.

Therefore, increasing the size of the dendritic arbor by increasing the relative size of the peripheral target is associated with a higher rate of ongoing synaptic activity. We suggest that the increase in ongoing synaptic activity is due to increased preganglionic convergence onto the more complex ganglion cells produced by target enlargement.

ACTIVITY-DEPENDENT DIFFERENCES IN THE NUMBERS OF SYNAPTIC VARICOSITIES AT CRAYFISH MOTOR TERMINALS REVEALED BY LIGHT MICROSCOPY. G.A. Lnenicka and S. LePage*. Dept. Biol. Sci., SUNY, Albany, NY 12222.

Differences in the morphology of phasically and tonically active motor terminals were examined in the closer muscle of the crayfish claw. Lucifer Yellow or HRP was injected into the axon of the phasically active fast closer excitor (FCE), and the tonically active slow closer excitor (SCE). The terminals were subsequently viewed with the light microscope. The SCE terminals had a greater total number of synaptic varicosities, as well as more synaptic varicosities per muscle fiber compared to the FCE terminals. These results are consistent with an earlier serial section EM examination of short lengths of terminal, which demonstrated that the SCE had more synaptic varicosities per terminal length than the FCE. This difference in synaptic varicosities appears to be activity-dependent since the previous study also demonstrated that tonic *in vivo* stimulation of the FCE resulted in an increase in the number of varicosities per terminal length (J. Neurosci. 6: 2252). In this system, the number of synaptic varicosities is correlated with the amount of transmitter released during repetitive stimulation (J. Neurosci. 5: 459). An examination of the time-course of the activity-dependent formation of synaptic varicosities is in progress.

EFFECTS OF EXPANDED MOTOR UNIT SIZE ON SYNAPTIC EFFICACY AT FROG NEUROMUSCULAR JUNCTIONS. M. Regnier and A.A. Herrera, Dept. Biological Sci., Univ. of Southern California, Los Angeles, CA 90089.

To study mechanisms regulating synaptic efficacy we expanded motor unit sizes in sartorius muscles of adult frogs by crushing the nerve and reducing the number of motor axons reinnervating the muscle.

Synaptic safety margins, measured as the sensitivity of nerve-evoked twitching to lowered $[Ca^{2+}]$, were lower in reinnervated muscles with expanded motor units than in control reinnervated muscles. Low safety margins can be partially explained by low transmitter release from nerve terminals. Intracellular recording revealed that both evoked and spontaneous release of transmitter were lower in muscles with expanded motor units. Nerve terminal lengths did not differ between reinnervated muscles with expanded motor units and control muscles suggesting that transmitter release per unit nerve terminal length was lower in expanded motor units. These results suggest that release and synaptic efficacy are inversely related to experimentally altered peripheral field sizes of motor axons. We are currently investigating whether changes in release or postsynaptic properties from expanded motor units are different at short and long postoperative times. This may provide evidence for mechanisms regulating synaptic effectiveness. Supported by MDA and NSF.

EFFECTS OF REDUCING MOTOR UNIT SIZE ON THE LEVEL OF POLYNEURONAL INNERVATION IN REINNERVATED ADULT FROG SARTORIUS MUSCLES. M.J. Werle and A.A. Herrera. Biol. Sci. Dept., Univ. of Southern California, Los Angeles, CA 90089-0371.

Motor unit size in reinnervated adult frog (Rana pipiens) sartorius muscles was surgically reduced by excising half the muscle fibers and allowing all sartorius motoneurons to reinnervate the remaining fibers. At varying postoperative times (12 days to 2 years), the muscles were removed, and the level of focal polyneuronal innervation (PI) surveyed using intracellular recording. At all times studied, reinnervated muscles with reduced motor units had a consistently lower level of PI than reinnervated muscles with larger motor units. Since physiological estimates of PI may not be accurate at the earliest stages of reinnervation (6-14 days after nerve crush), we are using histology to estimate PI at these times. In this way, we hope to determine if the consistent difference in the level of PI results from an difference in the rate of synapse elimination at these early times or if the initial level of PI formed in muscles with reduced motor units is smaller.

We have also made histological observations of synaptic structure for all muscles from which intracellular recordings were made. Our findings may offer insight into the relationship between motor unit size and competition for synaptic connections. Funded by NSF and MDA.

DYNAMIC STRUCTURAL REARRANGEMENTS AT THE GROWING AND ADULT MOUSE NEUROMUSCULAR JUNCTION. R. Hill* & N. Robbins (SPON: R. Lederman) Div. Neuroscience, Case Western Reserve Sch. Med., Cleveland, OH 44106.

In order to establish the extent to which adult nerve terminals engage in remodelling, nerve terminal growth in relation to postsynaptic growth was repeatedly observed in both growing and mature identified mouse neuromuscular junctions (NMJ).

Twenty NMJ's from adult (5-6 mo) and 10 from young (3-4 week) CB6F-1 mouse pectineus muscles were observed. The nerve terminals (NT) were stained in situ with the nontoxic binding fragment of tetanus toxin conjugated to texas red (TTcTR) and the postsynaptic AChR's with bungarotoxin-FITC. The animal was then placed on the microscope stage where a 100x objective, SIT camera and frame grabber boards generate and record the image of the NMJ. Three observations were made of each NMJ: on days 0, 4 and 8 in young mice, and on days 0, 35 and 90 in adults.

The predominant form of growth at immature NMJ's consisted of NT extension followed (within a maximum of 8 days) by extension of the corresponding AChR. NT retractions were infrequent. At the mature NMJ, gross structure did not change appreciably over time (Lichtman, 1987), but many adjustments of morphology did occur. Approximately 50% of the NMJ's exhibited lengthenings of both NT and AChR complexes while approximately 50% showed shortenings. Further, 50% of the junctions showed swinging or "floating" of existing NT-AChR complexes of at least one branch.

Our data indicate that immature NMJ's increase in size and complexity by net outgrowth of NT and subsequently, AChR's. The data argue against the notion that the adult NMJ is structurally inflexible. Rather, the adult structure results from both movement of branches and a dynamic equilibrium between ongoing expansive and retractive events. (Support, NIH AG06641 and AG00105).

NEUROMUSCULAR JUNCTIONS SHRINK AND EXPAND AS MUSCLE FIBERS CHANGE SIZE: STUDIES IN AN ANDROGEN SENSITIVE MUSCLE. S. M. Breedlove, R. J. Balice-Gordon, and J. W. Lichtman, Dept. Psych., Univ. of Calif., Berkeley and Dept. Anat. and Neurobiol., Washington Univ. Sch. Med., St. Louis, MO 63110.

After the first postnatal month, neuromuscular junctions in the mouse sternomastoid are not substantially remodeled, but rather enlarge by simple elongation of existing branches as muscle fibers grow (Balice-Gordon and Lichtman, in prep.). These observations are consistent with the idea that growth of junctions is an essentially passive phenomenon related to growth of postsynaptic muscle fibers. To directly test this, we have used 4-Di-2-ASP staining of nerve terminals and fluorescent bungarotoxin labeling of acetylcholine receptors to repeatedly examine the same junctions in the bulbocavernosus (BC) muscle of sexually mature male mice from 3 to 6 months of age. The BC is involved in copulatory behavior and is sensitive to androgens; castration results in a decrease in muscle mass which can be reversed with testosterone.

As in the sternomastoid muscle, BC junctions enlarge in proportion to muscle fiber growth but are otherwise remarkably stable in their configuration over the several month interval examined. Visual inspection of the BC muscle and surrounding structures 2-4 weeks after castration indicated a decrease in muscle size. Revisualization of junctions showed that many, if not all, nerve terminal branches and receptor sites were still present. However, the size of junctions determined by total area and by branch lengths had declined. Thus, junctions in the BC do not remodel in response to a decrease in muscle fiber size by the retraction of branches, but their overall size is altered in proportion to changing postsynaptic cell size. To reverse this effect, we have administered testosterone after shrinkage and are examining junction morphology as muscle fibers are enlarged.

PRE- AND POSTSYNAPTIC REMODELING IN ADULT MOUSE MUSCLE INDUCED BY BOTULINUM TOXIN. C.G. Reiness and J.W. Lichtman, Dept. of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110

Botulinum toxin blocks neuromuscular transmission, which is restored following extensive neuronal sprouting. Using fluorescent stains that mark both nerve terminals and acetycholine receptors (AChRs), we have observed identified botulinum-poisoned synapses over time in adult mice to determine the fate of original synaptic sites during the recovery from intoxication.

The left sternomastoid muscle of adult (20-25g) mice was exposed, stained with rhodaminated alpha-bungarotoxin to label AChRs and with 4-(4-diethylaminostyryl)-N-methylpyridinium iodide to label nerve terminals (Lichtman et al, J. Neurosci. 7:1215, 1987). Both terminals and AChRs were viewed, then botulinum toxin A (Sigma, 0.4 ng in 0.4 ul) was applied to the endplate zone. One to 13 weeks later, muscles were restained as above and reviewed.

Following a 2-3 week period of muscle atrophy, nerve sprouts are detectable over the fibers, and the original endplates appear shrunken but otherwise unchanged. Subsequently the fibers enlarge, and at this time small AChR clusters can often be found in association with the sprouts. The original AChR sites are generally unaltered, but the overlying nerve terminals are spotty and disordered, suggesting that they are retracting. The original endplates then disintegrate, losing nerve terminals and underlying AChRs. Newly forming synapses are frequently detectable nearby on the same fibers. These new sites often have abnormal morphologies and they persist, with minor additions or deletions, throughout the period we have observed.

These results demonstrate that establishment of new synaptic contacts on muscle fibers induces the rapid elimination of the preexisting synaptic sites.

DISCREPANCIES BETWEEN HISTOLOGICAL AND IN VIVO OBSERVATIONS OF MOTOR NERVE TERMINAL REMODELLING. A.A. Herrera, L.R. Banner*, and N. Nagaya*, Dept. Biological Sci., Univ. of Southern California, Los Angeles, CA 90089.

Until recently, synaptic remodelling at neuromuscular junctions could only be inferred from histological images representing single time points. Repeated observations of junctions in living frogs have now revealed that remodelling commonly occurs even under normal conditions in adults (Soc. Neurosci. Abstr. 13, 1665; 1987).

Analysis of these in vivo images suggests that some of the previous histological results must be re-interpreted: 1) Histology supports the view that terminal sprouts are ephemeral. They either differentiate into mature terminals or retract. We find that terminal sprouts are rather stable, neither growing nor retracting for months. 2) Empty, cholinesterase (ChE)-stained postsynaptic folds are taken as histological evidence of terminal retraction. Indeed, we observe that most retracting branches leave behind ChE-stained folds. However, we also see such folds beyond the distal tips of branches that have grown, suggesting that growth can be followed by partial retraction or that postsynaptic differentiation can precede terminal growth. 3) It was anticipated that remodelling may be more pronounced at polyneuronally innervated junctions, since synapse elimination is prolonged in frogs. Over periods longer than a year, growth is indeed substantial, but multiple inputs are apparently not eliminated. Supported by NIH.

DIRECT VISUALIZATION OF SYNAPTIC REMODELING IN GASTROCNEMIUS MUSCLES OF LIVING ADULT MICE. D.J. Wigston. Department of Physiology, Emory University School of Medicine, Atlanta, GA 30322.

Dynamic rearrangements of synaptic connections can be observed directly in muscles of living animals, although different muscles may vary considerably in the extent of NMJ remodeling. NMJs in the mouse sternomastoid, a fast-twitch muscle, appear to be remarkably stable (Lichtman et al.,1987; J. Neurosci. 7:1215), whereas about 50% of NMJs in the slow-twitch soleus exhibit some reorganization over 6 months (Wigston, 1987; Soc. Neurosci. Abstr. 13:1007). To explore the possibility that the difference between sternomastoid and soleus in the extent of NMJ remodeling reflects their different physiological type, I examined NMJs in another fast-twitch muscle, lateral gastrocnemius (LG). I labeled acetylcholine receptors at LG NMJs in anesthetized animals with rhodamineα-Bungarotoxin and presynaptic terminals with the fluorescent dye 4-Di-2-ASP (Lichtman et al.,1987). Using low levels of illumination I obtained images of superficial NMJs with a SIT camera and digital image processor. Three months later I restained and examined the same NMJs. Remodeling, in the form of additions and deletions of branches, was evident at some NMJs but less frequently than I observed in soleus muscles monitored over the same time. The extent of remodeling at mammalian NMJs might thus depend on the amount or frequency of their activation.

NEURON/GLIAL RELATIONSHIPS OBSERVED IN LIVING MICE. S.L. Pomeroy and D. Purves, Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

The relationship of salivary duct ganglion neurons and their associated glia was assessed by videomicroscopy in anesthetized but otherwise intact mice. Adult males (CF1 strain; 25-30g) were placed on the stage of a modified microscope and the salivary duct ganglia were exposed as previously described (Purves et.al., Science 238: 1122-1126, 1987). Video images were obtained using a 100X water immersion objective.

The arrangement of particular neurons and the 1-3 glia associated with them was assessed by filling single glial cells with 5(6)-carboxyfluorescein after impalement with a microelectrode. In all cases (n=75), the entire neuron was enveloped by a glial sheath stained with fluorescent dye. This result indicates that each glial cell is associated with a single neuron, and that when more than one glial cell is associated with a neuron it is strongly dye coupled to the other glia investing that cell. The stability of the neuron/glia relationship was determined by repeated examination of cells over intervals up to 130 days. While no changes were noted after 6 hours, an increasing percentage of neurons showed change in number and/or location of associated glial nuclei over progressively longer intervals. After 110-130 days, 80% of the neurons showed change in these parameters.

Finally, examination of electron micrographs of 192 salivary duct neurons revealed that preganglionic nerve terminals are much more prevalent in the vicinity of glial nuclei than elsewhere on the neuronal surface. This association of nerve terminals and glial nuclei, which in turn change in number and/or location over time, is in agreement with the recent observation that preganglionic terminals are gradually remodelled. This association also suggests that glia play a part in ongoing synaptic rearrangement. Supported by USPHS grants NS 18629, 11699 and 07027.

DYNAMIC RELATIONSHIP BETWEEN SYNAPTIC EXTRACELLULAR MATRIX AND MOTOR NERVE TERMINALS IN LIVING FROGS. L. Chen* & C.-P. Ko (SPON: J.H. Caldwell). Dept. Biol. Sci., Univ. Southern California, Los Angeles, CA 90089.

Rhodamine-labelled peanut agglutinin (PNA) specifically stains the synaptic extracellular matrix at living frog neuromuscular junctions (NMJs). To examine the remodeling of synaptic matrix and its dynamic relationship with nerve terminals in identified NMJs of living adult frogs (R. pipiens), sartorius muscles were stained with 4-di-2-Asp, a fluorescent dye for motor nerve terminals (10uM, 3 min), followed by PNA (50ug/ml, 30 min). NMJs were observed in anesthetized frogs in situ with fluorescence microscopy and videotaped with a SIT camera. After about 2 mos., the same muscles were restained and identified NMJs reexamined. Preliminary results show changes in synaptic matrix and/or nerve terminals in more than half of NMJs observed. Some NMJs increase or decrease equally in both matrix and terminal length. In others, either the terminal extends while the matrix retracts, or the terminal retracts while the matrix is unchanged. In one junction viewed 3 times, an extension (30 um) of both matrix and terminal was observed after 2.5 months. A third imaging done 6 weeks later revealed a decrease (24 um) in the terminal but a slight increase in the matrix length.

Results suggest that remodeling occurs in nerve terminals and synaptic matrix in adult frog NMJs. Also, changes in nerve terminal length and synaptic matrix do not necessarily correspond.

PRIMATE SELECTIVE BRAIN RETENTION OF TC99M-ECD: A NEW CEREBRAL PERFUSION AGENT. R. C. Walovitch, M. Watson*, M. Ganey*, and S. J. Williams*. E.I. DuPont de Nemours & Co., (Inc.), N. Billerica, MA 01862.

Tc99m-ethyl cysteinate dimer (ECD) is a neutral, lipophilic complex which rapidly crosses the blood brain barrier. It is presently being evaluated clinically as a marker of regional cerebral perfusion. Multispecies pharmacological evaluation of Tc99m-ECD show the compound to be efficacious as a brain perfusion agent only in primates. The brain pharmacokinetics of Tc99m-ECD are similar in humans and in non-human primates. Rapid brain uptake (initial 5% injected dose) was observed in both species, as was prolonged retention in a cerebral perfusion pattern (Neurology 38:363,1988). Results in humans and nonhuman primates suggest that the brain retention and extensive renal clearance of Tc99m-ECD are due to its rapid metabolism via ester hydrolysis. Subcellular distribution studies in monkey brain one hour post Tc99m-ECD administration demonstrate that more than 70% of the activity is localized in the cytosolic fraction and is primarily in the form of single polar metabolite. When this metabolite was injected into a monkey it failed to cross the blood brain barrier. These results support the hypothesis that Tc99m-ECD is metabolized rapidly in the brain of primates by a specific enzymatic pathway to a polar complex which is trapped.

CORTICAL CEREBRAL BLOOD FLOW (CBF) IS INCREASED BY ELECTRICAL STIMULATION OF THE BASAL FOREBRAIN (BF): MODULATION BY CHOLINERGIC MECHANISMS. S.P. Arnerić. Dept. of Pharmacol., Southern IL Univ. Sch. Med., Springfield, IL

We sought to determine: 1) Does electrical stimulation of the BF alter cortical CBF? 2) If so, are cholinergic receptors involved? Rats were anesthetized (chloralose), paralyzed, artificially ventilated and arterial blood gasses controlled. A craniotomy was performed over the parietal cortex and microvascular perfusion, an index of CBF, measured continuously with laser-doppler flowmetry. Electrical stimulation of the BF with a bipolar concentric electrode elicited remarkable increases in cortical CBF (up to 250% of resting CBF) that were frequency (2.5-100 Hz) and intensity (25-150 μA) dependent; but independent of heart rate or arterial pressure (N=7). A nicotinic antagonist, mecamylamine (4 mg/kg, i.v., 20 min prior) significantly attenuated by 52±8% the BF-elicited increase ($p<0.05$; N=4). In contrast, the response was enhanced by 40±15% ($p<0.05$; N=3) with a cholinesterase inhibitor, physostigmine (50 μg/kg, i.v.). Surprisingly, a muscarinic antagonist, atropine (1 mg/kg, i.v.) also enhanced the effect similarly. CONCLUSIONS: 1) Cortical CBF is profoundly increased by electrical stimulation of neurons originating in or passing through the BF; 2) cholinergic neurons, possibly those in the BF, participate in this response; and 3) nicotinic receptors facilitate, while muscarinic receptors inhibit this dilator pathway (Supported by American Health Assistance Foundation).

488.3

STATE-DEPENDENT DIFFERENCES IN CEREBRAL BLOOD FLOW DURING CORTICAL SPREADING DEPRESSION IN RAT. R. B. Duckrow. Department of Medicine, Division of Neurology, The Pennsylvania State University, Hershey, PA 17033.

Cortical spreading depression (SD) is a reversible phenomenon that may occur during complicated and classic migraine headache. In anesthetized rats regional cerebral blood flow (rCBF) increases dramatically as SD advances through the neocortex. However, hyperemia has not been measured in the cortex of awake humans during migraine. The hypothesis that these flow differences are state-dependent was tested by measuring rCBF in awake and anesthetized rats during SD. Using pentobarbital anesthesia a bipolar electrode was placed on the lateral convexity of the left hemisphere and secured with dental acrylic. Two days later rats were prepared under halothane/nitrous oxide anesthesia, restrained with a plaster hip-cast and allowed a one hour recovery period. SD was induced by a 5 mA direct current lasting 5 seconds and confirmed by recording electrocortical activity. Two minutes later rCBF was measured using 14C-iodoantipyrine in regions isolated by gross dissection. In rats reanesthetized with pentobarbital, rCBF in the hemisphere with SD increased by 40%. In awake rats rCBF decreased by 30% in the SD hemisphere and increased by 50% in the contralateral hemisphere. These state-dependent differences in rCBF during SD are consistent with the presence of an intrinsic neural system regulating blood flow in the brain. BLOOD FLOW IN NEURAL GRAFTS. S.C. Jones, E. Korfali*, W.D. Knowles, S.M. Chou*, J.R. Little*. Cerebrovascular Research Lab., Cleveland Clinic Foundation, Cleveland, OH 44195.

The extent and amount of blood flow and tissue perfusion in neural grafts is important in the evaluation of neural grafts for the treatment of Parkinson's and Alzheimer's disease and for cerebral ischemia.

Nine Sprague Dawley rats weighing 180-200 g were prepared with a 2x3 mm cavity for transplantation. Two weeks later, embryonic septal tissue from 15-16 day old embryos was placed in five of these animals. Four were not grafted. All surgical procedures were performed under barbiturate anesthesia (Nembutal 40-50 mg/kg, i.p.). Five months after transplantation (body weight ± SEM = 480 ± 8 g), cerebral (and graft) blood flow (CBF) was determined using quantitative autoradiography (Sakurada et al., Am. J. Physiol. 234:H59, 1978) under physiologically controlled and stable conditions of mean arterial blood pressure (83 ± 7 mmHg), $PaCO_2$ (34.8 ± 0.7 mmHg), PaO_2 (170 ± 6 mmHg), and pH (7.422 ± 0.012). Grafts were differentiated from host tissue in Nissl stained sections.

CBF ± SEM for parietal cortex of all animals were 66 ± 5 ml/min/100 g, normal for pentobarbital anesthetized rats. Graft and contralateral-to-graft flows were 37 ± 3 and 51 ± 6 ($p < 0.1$), compared to contralateral-to-graft site in the non-graft animals of 64 ± 11.

Grafted animals had normal CBFs in adjacent-to-graft cortex, whereas grafted tissue had blood flows that were lower than normal brain except for one animal. Grafted tissue appears to develop perfusion that provides lower blood flow than normal brain.

LOCAL SYMPATHETIC CONTROL OF THE CEREBRAL CIRCULATION: AN AUTORADIOGRAPHIC STUDY. U.I. Tuor. Division of Biomedical Research, Hospital for Sick Children, 555 University Avenue, Toronto, Canada M5G 1X8

The present study examined the effect of sympathetic stimulation on the local cerebral circulation. Changes in local cerebral blood flow were measured in anesthetized rats during unilateral stimulation of the superior cervical ganglion using ^{14}C-iodoantipyrine autoradiography. Stimulation parameters were chosen on the basis of preliminary studies in 10 rats, which demonstrated that stimulation of the ganglion at 15 Hz, 3 msec and 10 V produced a 1-2 mm Hg reduction in cerebral venous (sagittal sinus) pressure indicating an overall reduction in cerebral blood volume and/or flow. In sham control animals (n=4), changes in local cerebral blood flow with respect to the contralateral hemisphere were less than 2% in all regions examined. During unilateral stimulation of the sympathetic ganglion (n=5), blood flow in temporal muscle was reduced by 70±12% (mean±SEM) whereas there were less marked reductions in local cerebral blood flow. For example, blood flow in the cerebellar cortex was similar in both hemispheres. Blood flow in the parietal cortex and the caudate nucleus were reduced ipsilateral to the stimulation by 9.3±2.8% and by 11.0±5.4%, respectively. Reductions in flow were unevenly distributed within these regions possibly corresponding to a differential regional density of sympathetic innervation of the cerebrovasculature. Further experiments and analysis are required to map in detail the influence of sympathetic stimulation on the cerebral circulation.

488.6

CHANGES IN REGIONAL CEREBRAL BLOOD FLOW AND SUCROSE SPACE AFTER 3-4 WEEKS OF HYPOBARIC HYPOXIA(0.5ATM). J.C. LaManna, K.A. McCracken*, and K.P. Strohl*. Depts. Neurology, Medicine and Physiol./Biophys., Case Western Reserve University Cleveland, OH 44106, U.S.A.

Chronic hypoxia results in increased ventilatory rate and hematocrit, with decreased PaCO2, which have important consequences for cerebral vascular function. In this study, adult Wistar rats were kept in a hypobaric chamber for 3-4 weeks at 0.5ATM. Rats were studied either 4 or 24 hours after removal from the chamber. Regional cerebral blood flow (BF) and sucrose space (SS) were measured by the dual-label single pass indicator fractionation method using 14C-butanol and 3H-sucrose in cerebral and cerebellar cortex, hippocampus, and striatum. Rats were anesthetized with chloral hydrate (400mg/kg, i.p.) for placement of arterial and venous cannulae, and allowed to recover. 4 hrs after being returned to normobaric normoxia, arterial CO2 was still decreased, arterial pH was acidic and hematocrit was elevated. BF in all regions was about 3 times control. SS in these rats was depressed but, when considered with the rise in hematocrit, indicated that regional blood volume was probably not altered. BF and SS at 24 hrs were the same as control rats. Thus, hypoperfusion due to hyperventilation does not occur in chronic hypoxia. The cerebrovascular effects of chronic hypoxia persist for some hours after return to normoxia. We conclude that there must be long-term changes in the control mechanism of the cerebral vasculature during acclimatization to hypoxia.

488.7

REGIONAL VARIATION IN BRAIN GLYCOGEN CONCENTRATION AND CATABOLISM IN SUCKLING RABBITS, R.S.Rust* (SPON: M. Noetzel) Depts. of Neurol. and Pediatr., Washington Univ. Sch. of Med., St. Louis, MO 63110.

Histological studies have identified brainstem and deep cortical radial glial cells as important loci for deposition of glycogen during early neural development, but regional variation in concentration and utilization of this glycogen has not been well characterized. Nine five day old rabbit pups were killed either by direct immersion in liquid nitrogen or by rapid freezing of heads at 30 or 120 second intervals after decapitation in order to assess changes in glucose, glycogen, G6P, ATP, and lactate in ten brain regions, measured by standard enzymatic methods after appropriate extraction of excised tissues. Glycogen concentration in parietal cortex (2.0±0.41mM/kg) was similar to that found throughout mature rabbit brain. Significantly greater concentrations ($p \leq 0.001$) were found in subiculum (3.89±0.58), midbrain (5.95±0.85), cerebellum (7.65±1.12), medulla (9.86±0.67) and cervical spinal cord (12.71±1.24). Total ischemia resulted in 25-44% reduction in glycogen concentration in midbrain, pons, medulla, and cord, but little if any change in cortical or cerebellar regions. Regional rates of glucose, PCr, and ATP and for accumulation of lactate roughly paralleled glycogen utilization. These results suggest that glycogen enrichment in certain functionally critical areas of developing brain may provide a rapidly mobilizable energy reserve during total ischemia.

TOTAL OR PARTIAL BRAIN ISCHEMIA: A NEW RAT MODEL. J.C. de la Torre, T. Fortin* and J. Thakar. Univ. of Ottawa Health Sciences, Ottawa, Ont.

Experimental stroke models using the rat have been developed to produce partial or total arrest of blood flow to brain but no model offers both options. The four-vessel total ischemia model and several modifications of it, hinges on the fact that rats remain symptomless if fewer than 3 vessels to the brain are occluded (e.g., both vertebral arteries). This model was difficult to reproduce because vertebral artery electrocautery through the alar foramina often resulted in brain tissue damage or undesirable bleeding despite direct visualization of the vessel. The present model was developed because the rat offers many advantages over other animal models. Rat is anesthetized with diazepam-somnotol and xylocaine is sprayed orally to reduce gag reflex. Rat is intubated with a PE 190 catheter and ventilated mechanically. After a mid-thoracic incision, a hemostat is used to clamp the left costo-sternal attachments from just above the xiphoid process to just below the first rib. An electrocoagulating incision is made between sternum and hemostat to expose the heart. The aortic arch great vessels are identified and the left and right subclavian arteries are occluded with microvascular clips. The chest wall is closed with sutures and 2 ligatures are looped around both common carotid arteries then threaded externally via catheters. After rat fully recovers, one or both carotid ligatures are pulled and released for varying periods of time. This procedure results in either partial or total cerebral ischemia compunded by reperfusion damage. Pilot studies show that this 3 or 4 vessel occlusion model can be easily and reliably set-up to study morphologic, physiologic and chemical brain pathology under moderate or severe circulatory parameters.

Recovery of Impaired Endothelium - Dependent Relaxation Following Concussive Brain Injury. M.D. Ellison*, D.E. Erb*, J.T. Povlishock (Spon. J. Astruc) Dept. of Anat., VA Commonwealth Univ., Richmond, VA 23298

Endothelium dependent relaxing factors (EDRF) are agents of undetermined chemical identity, produced by normal endothelium, which effect vasodilation in response to certain agonists. Recently, it has been shown that feline pial microvessels produce an EDRF when exposed to topically-applied Ach and that such a response is abolished immediately following experimental fluid percussion brain injury. Whether the post-traumatic impairment of endothelial dependent relaxation (EDR) is reversible, over time, has not been determined and was examined in the present study. Aseptically, anesthetized cats were each equipped with a cranial window and subjected to a moderate level of brain injury. Pial arteriolar EDR following Ach exposure was assessed prior to injury and at 30 minutes, 4, 8 and 12 hours post-trauma. At each assessment, vascular diameters were measured before and after Ach application. At 30 minutes post-injury, normal Ach-induced EDR was converted to vasoconstriction, most notably in small caliber vessels (<100μm). At 4 hours, recovery of EDR was observed in a number of vessels, and by 12 hours the majority of vessels exhibited a normal response, although some remained dysfunctional. Small arterioles recovered sooner than large ones. The findings suggest that, in the absence of secondary insults, mechanisms underlying early posttraumatic loss of cerebral EDR do not persist and do not, for the most part induce irreversible changes which prevent recovery of EDR. Those vessels, which fail to demonstrate EDR at 12 hours post-trauma, however, may require more time for recovery or may be irreversibly damaged. Supported by NIH Grant NS 12587

ANTIPSYCHOTIC DRUGS INCREASE NEUROTENSIN CONCENTRATIONS AFTER DESTRUCTION OF DOPAMINE NEURONS BY 6-HYDROXYDOPAMINE. C. Bissette, K. Dole, M. Johnson*, D. Knight* and C.B. Nemeroff. Depts. of Psychiat. & Pharmacol., Duke Univ. Med. Ctr., Durham, NC 27710.

The chronic administration of clinically effective antipsychotic drugs increases the concentration of neurotensin (NT) in the anterior caudate nucleus and nucleus accumbens of rat brain. Because neuroleptic drugs block the dopamine (DA) receptors that are found in these regions containing terminal projections of mesencephalic DA neurons, we sought to determine whether the presynaptic DA neurons were essential for this neuroleptic-induced increase in neurotensin concentration. Adult, male, Sprague-Dawley rats were pretreated with desmethylimipramine (30 mg/kg, IP) one hour before intracisternal injection of either 6-hydroxydopamine (6-OHDA, 200 μg) or 0.1% ascorbic acid vehicle. This procedure was repeated after seven days and results in a greater than 90% depletion of DA in the caudate nucleus. One week after the last 6-OHDA injection, some animals from both groups were injected daily with either haloperidol (1 mg/kg, IP) or 0.3% tartaric acid vehicle for three weeks. Rats were decapitated and the following brain regions dissected for radioimmunoassay of NT: frontal cortex, olfactory tubercles, nucleus accumbens, anterior caudate, septum, pre-optic/diagonal band, hypothalamus, amygdala, hippocampus, ventral tegmental area/substantia nigra and cerebellum.

Both the 6-OHDA treated group and vehicle controls receiving haloperidol had significant ($p<0.001$, ANOVA) increases in NT concentrations in the nucleus accumbens and anterior caudate nucleus compared to the groups that did not receive haloperidol. Thus, while the postsynaptic dopamine receptor is needed for the neuroleptic-induced increase in NT concentrations in these regions, the dopamine neuron is not primarily involved. Supported by NIMH MH-35415 and a grant from the Schizophrenia Research Foundation.

ASYMMETRICAL DISTRIBUTION OF NEUROTENSIN (NT)-IMMUNOREACTIVITY FOLLOWING UNILATERAL INJECTION OF 6-HYDROXYDOPAMINE IN RAT VENTRAL TEGMENTAL AREA (VTA). S.N. Johnson* and D.S. Zahm. (SPON:R.Walsh) Dept. of Anat. and Neurobiol., St. Louis Univ. Sch. of Med., St. Louis, MO 63104.

It has been shown that IP administration of haloperidol (HAL) is followed within 24 hours by increases in the numbers of NT-IR neurons selectively in the ventral striatum (Eggerman and Zahm, Neuropeptides 11(3):125-32, '88). We now report a similar but more dramatic response following unilateral 6-hydroxydopamine (6OHDA) injections in the VTA. One week following such injections, NT-IR neurons were 10- to 50-fold more numerous in striatal districts on the lesioned as compared to unlesioned sides of the brains. In contrast to conditions following DA receptor blockade, the distribution of NT-IR neurons extended to include dorsal striatal territories after 6OHDA lesions. The extreme dorsolateral quadrant, however, always remained devoid of NT-IR neurons. The moderate expansion of the NT-IR pallidal districts observed after HAL treatment was more pronounced after 6OHDA. The NT-IR territory of the globus pallidus on the lesioned side was 1.5-2.5 times larger that its counterpart on the unlesioned side. The dorsolateral ventral pallidal district that normally exhibits sparse NT-IR and gives rise to projections terminating in the substantia nigra and subthalamic nucleus (see Zahm and Johnson, this volume) displayed intense NT-IR following the chemical lesion. Support: NIH NS-23805 and the American Parkinson Disease Association.

489.3

NEUROTENSIN INNERVATION OF DOPAMINE NEURONS IN RAT VENTRAL TEGMENTUM. J. Woulfe* and A. Beaudet. Montreal Neurological Institute, Montreal, Canada, H3A 2B4.

Several lines of evidence advocate a functional interaction between neurotensin (NT) and dopamine (DA) neurons in the brain. Among these is the selective association of NT high affinity binding sites with DA neurons in the substantia nigra, pars compacta (SNC) and ventral tegmental area (VTA) of the rat. To further examine the morphological substrate underlying NT-DA interactions in the ventral midbrain, we have employed a light and electron microscopic sequential double antigen localization technique for simultaneous visualization of NT (using 3'3 diaminobenzidine as the chromogen) and the dopamine biosynthetic enzyme tyrosine hydroxylase (TH, using benzidine dihydrochloride as the chromogen). At the light microscopic level, NT-immunoreactive terminals were densely distributed throughout the VTA and SNC in close proximity to TH-immunoreactive somata and dendrites. On electron microscopic examination, direct axosomatic and axodendritic synaptic connections were identified between NT-immunoreactive axon terminals and TH-immunoreactive perikarya and dendrites. The present results provide morphological evidence for a direct NT innervation of DA neurons in the VTA and SNC. This is consistent with a neural influence imparted by NT on the activity of DA systems arising from these areas. Supported by MRC.

ENHANCEMENT OF DOPAMINE METABOLITES IN THE NUCLEUS ACCUMBENS USING MICRODIALYSIS PERFUSION AFTER INJECTION OF NEUROTENSIN AND CHOLECYSTOKININ INTO THE VENTRAL TEGMENTAL AREA. Ph. De Witte(1), J. Crawley(2) and I. Mefford(3). (1) Lab. Psychobiology, Univ. Louvain, B-1348 Louvain-la-Neuve, Belgium; (2) Lab. Behav. Neuroscience and (3) Lab. Biochemistry, National Institutes of Mental Health, Bethesda, MA 20817, USA.

High densities of neurotensin-cholecystikinin-and dopamine-containing perikarya were found in the ventral tegmental area (VTA). Coexistence between these peptides and dopamine in the fibers of the mesolimbic pathways originating from the VTA and projecting to the nucleus accumbens suggested a neuromodulation on the dopaminergic transmission by these peptides. The aim of the present study was to estimate the level of concentration of the extracellular metabolites of dopamine, i.e. DOPAC and HVA, and serotonine, i.e. 5HIAA, in the nucleus accumbens after microinjection of neurotensin of cholecystokinin (10 pmodes and 10 nmoles) into the VTA. The concentration of these metabolites was estimated using high pressure liquid chromatography with electrochemical detection. Our results show that the injection of distilled water and the low dosage (10 pmoles) of neurotensin or cholecystokinin remain without effect. The injection of saline gave rise to transient increase in DOPAC while 10 nmoles of both peptides induced a larger and longer increase in the extracellular DOPAC and HVA while 5-HIAA never changed from the baseline level, in the nucleus accumbens after their VTA microinjections.

CHOLECYSTOKININ REVERSES A NEUROTENSIN-INDUCED INCREASE IN DOPAMINE RELEASE IN THE NUCLEUS ACCUMBENS: AN IN VIVO ANALYSIS. A.G. Phillips[1], A. Lesage[1], C.D. Blaha[1,2], and H.C. Fibiger[2], Depts. of Psychology[1] and Psychiatry[2], Univ. of British Columbia, Vancouver, BC, Canada, V6T 1Y7.

The neuropeptides cholecystokinin (CCK8-S), neurotensin (NT) and the catecholamine dopamine (DA) have been shown to be colocalized in mesotelencephalic neurons. Using in vivo chronoamperometry (60s pulse rate), we have shown previously that intracerebroventricular (icv) injection of NT (0.1-10 ug/10 ul) induced an immediate dose-dependant increase in DA release in the nucleus accumbens. In contrast icv administration of CCK8-S (5-100 ng) inhibited DA release in this region of the rat brain. In vivo microdialysis (1 ul/min;10-12 min dialysates) in combination with microbore HPLC-EC permitted the measurement of DA and its major metabolites in the nucleus accumbens. These analyses confirmed a significant increase in extracellular DA levels after icv administration of comparable doses of NT. Chronoamperometric studies also revealed an immediate reversal of the NT-induced increase in the DA signal when CCK8-S was administered 60 min after NT. Parallel studies with microdialysis are presently ongoing to confirm the antagonistic effect of CCK8-S on NT modulation of DA neurotransmission.

489.6

OPIOID INHIBITION OF AMINO ACID ELICITED CATECHOLAMINE RELEASE FROM HIPPOCAMPAL AND STRIATAL SLICES OF RAT BRAIN. L.L. Werling, P.N. McMahon* and B.M. Cox. Dept. of Pharm., Uniformed Services University, Bethesda, MD 20814-4799.

We have previously reported that the potassium (K^+)-stimulated release of [^{3}H]NE from slices of rat hippocampus can be inhibited in a dose-dependent manner by opioid agonists which act through the mu receptor, but not by those acting through delta or kappa receptors. In contrast, K^+-stimulated release of [^{3}H]DA from striatal slices can be inhibited by kappa opioid agonists, but not by mu or delta agonists. We now report that release of these catecholamines can be stimulated by glutamate and N-methyl-D-aspartate (NMDA) in a dose-dependent manner. Quisqualate and kainate were much less effective in stimulating release. Release stimulated by 100 μM NMDA could be blocked by the antagonist 2-amino-5-phosphono-valeric acid (APV, 50 μM) or by the inclusion of Mg^{+2} in the incubation medium. Consistent with the pharmacological profile for inhibition of K^+-stimulated release, the mu-opioid agonist Tyr-D-Ala-Gly-NMePhe-Gly-ol inhibited NMDA-stimulated [^{3}H]NE release from hippocampal slices, while the kappa agonist U-50,488H inhibited NMDA-stimulated [^{3}H]DA release from striatal slices over concentration ranges equivalent to those required for inhibition of K^+-stimulated release. Taken together, these data suggest that amino acids which interact with NMDA receptors, and opioids, acting through mu or kappa receptors, may participate in local regulation of catecholaminergic pathways in rat brain.

489.7

CHRONIC STRESS IN MICE ALTERS DOPAMINERGIC FUNCTIONING IN MESOLIMBIC SYSTEM THROUGH ENDOGENOUS OPIOIDS. S. Puglisi-Allegra, S. Cabib*and A. Oliverio* Istituto di Psicobiologia e Psicofarmacologia, C.N.R., via Reno 1, 00198 Roma, Italy

Repeated exposure (10 days) to immobilization (2 h) produces a change in sensitivity to the effects of apomorphine on stereotypic climbing behavior in mice tested 24 h after the last stressful experience. This effect was prevented when naltrexone was administered before each stress session, indicating that alteration of dopamine (DA) functioning induced by chronic stress is mediated through endogenous opioid system.

Biochemical analysis of DA systems response to 2 h immobilization revealed an increase of DOPAC/DA and HVA/DA ratios and a decrease of 3MT/DA ratio in the nucleus accumbens (NAS) and the caudatus-putamen (CP). An increase of HVA/DA ratio was also found in the frontal cortex (FC). Naltrexone administered before immobilization antagonized the decrease of 3MT/DA ratio in NAS but not in CP. Moreover, apomorphine administered in chronically stressed animals was shown to produce stronger effects on DA metabolites in NAS while no significant difference was observed in CP and FC. These results show that immobilization stress inhibits DA release in NAS through endogenous opioids. Moreover, they suggest that repeated stressful experiences alter DA receptor sensitivity in mesolimbic system.

NEUROTRANSMITTER INTERACTIONS IN THE DORSAL STRIATUM OF THE RAT STUDIED BY IN VIVO MICRODIALYSIS. G.Damsma, H.C.Fibiger, A.S.Horn and B.H.C.Westerink. (SPON: S.R.Vincent). Div. of Neurological Sciences, Univ. of Britisch Columbia, Vancouver, B.C., Canada, V6T 1W5 and Dept. Medicinal Chemistry, Univ. of Groningen, A.Deusinglaan 2, 9713 AW Groningen, The Netherlands.

Neuronal interactions in the striatum of freely moving rats have been studied using a microdialysis sampling technique. On-line connection of the dialysis outlet to sensitive HPLC equipment enabled us to determine directly the dialysate concentrations of dopamine and acetylcholine which are most likely representing the release of these neurotransmitters (Westerink, B.H.C., et al., Life Sci., 41:1763, 1987).

Rats received various drugs, e.g. dopaminergic agonists, neuroleptics, cholinomimetics, anticholinergics, and anesthetics. The results indicate that there is neither a muscarinic modulation of the dopamine release nor a dopaminergic modulation of cholinergic release. These data challenge the well-established hypothesis of a mutual interaction between dopaminergic nigro-striatal terminals and cholinergic striatal interneurons.

CENTRAL CHOLINERGIC INNERVATION OF THE DOPAMINERGIC AND SEROTONERGIC SYSTEMS. B.K. Hartman, P.L. Faris*, S.J. Kalmbach*1, C. Cozzari*2, A. Berod*3. Dept. Psychiatry, Univ. of Minn, Mpls. MN 55455, Wash. U. Sch. Med. St. Louis MO, Inst. Biol. Cell., Rome, It., Inserm U-171, Lyon, Fr.

Double label immunohistochemistry was used for the simultaneous visualization of choline acetyltransferase (CAT) and tyrosine hydroxylase (TH) or serotonin (5-HT) to investigate the interactions between the pontomesencephalic cholinergic group of neurons (PMCG) and the dopamine and 5HT systems in rat brain. First, CAT was localized using the PAP technique with nickel-cobalt enhanced DAB. Sections were then processed for either TH or 5-HT localization using PAP with alpha-napthol as substrate and differentiated with the dye pyronin-B. The jet-black CAT positive cells and processes contrasted well with the bright magenta staining of the TH or 5-HT positive structures, making evaluation of interactions feasible at the light microscopic level.

The ventral-rostral part of the PMCG extended to the caudal limit of the dopaminergic neurons of the substantia nigra. CAT-positive axon fibers were observed to enter the nigra where they formed numerous bouton-like contacts with TH-positive dendrites and soma. Interactions were restricted to the caudal half of the nigra and the ventral tegmental dopamine neurons. The dorsal part of the PMCG was observed to send axon fibers medially and rostrally into the dorsal raphe where a small number of interactions with 5-HT-positive neurons occured. CAT-positive axons then turned ventrally to enter the midline raphe, again making contact.

On the basis of these results and previously reported interactions between this cholinergic group and the noradrenergic neurons, it is hypothesized that an important function of the PMCG is to coordinate the functions of the three biogenic amines. Supported by NS-12311 (BKH), RSDA MH-00595 (PLF).

EVIDENCE FOR A FUNCTIONAL INTERACTION BETWEEN THE SEROTONIN (5-HT) REUPTAKE PROCESS AND α_2-ADRENERGIC RECEPTORS LOCATED ON 5-HT TERMINALS IN THE RAT HYPOTHALAMUS. P. Blier, A.M. Galzin* and S.Z. Langer. Laboratoires d'Etudes et de Recherches Synthélabo (L.E.R.S.), 58, rue de la Glacière, 75013 Paris, France

The efficacy of presynaptic α_2 receptor agonists to inhibit the electrically-evoked release of [^{3}H]-monoamines from preloaded brain slices was shown to be attenuated in the presence of reuptake blockade for the 5-HT and the noradrenaline (NA) systems. There is controversy, however, as to the involvement of a functional link between the presynaptic receptors and the reuptake carriers or of a competition between the exogenous agonist and the neurotransmitter for the receptor sites. In order to verify the concept that such a functional interaction could exist, we undertook to study the α_2-adrenergic-mediated inhibition of electrically-evoked [^{3}H]-5-HT release from preloaded slices of the rat hypothalamus, a model in which endogenous NA does not reach the NA heteroreceptors located on 5-HT terminals. Two periods of electrical stimulation were applied 60 min (S_1) and 104 min (S_2) after the onset of superfusion. Drugs were added 20 min before S_1 or S_2. The NA reuptake blocker desipramine (0.3 µM) did not alter the electrically-evoked release of [^{3}H]-5-HT or the inhibition produced by UK 14.304 (0.001-10 µM), an α_2-adrenergic agonist. The 5-HT reuptake blockers citalopram (0.01-1 µM) and paroxetine (1 µM), which by themselves did not modify [^{3}H]-5-HT release, decreased the inhibition of [^{3}H]-5-HT release produced by UK 14.304. The effect of exogenous NA (0.1-1 µM) on [^{3}H]-5-HT release was also attenuated in the presence of citalopram. In contrast, citalopram modified neither the electrically-evoked release of [^{3}H]-NA nor the UK 14.304-mediated inhibition of [^{3}H]-NA release. The interaction was also present in slices obtained from rats with depleted endogenous stores of 5-HT. Activation of either protein kinase C or of adenylate cyclase together with phosphodiesterase inhibition, which attenuate the UK 14.304-inhibition of [^{3}H]-5-HT release, did not hamper the interaction between UK 14.304 and citalopram. In conclusion, the presynaptic NA heteroreceptor and the 5-HT reuptake carrier appear to be functionally linked. This interaction cannot be attributed to an increased synaptic availability of either NA or 5-HT or to an activation of either the phosphatidylinositol cycle or the adenylate cyclase system.

DEVELOPMENT OF DEPOLARIZATION INDUCED GLUTAMATE RELEASE AND ITS MODULATION BY SEROTONIN IN CORTICAL NEURONS. L. Sikich and R. D. Todd. (SPON: E. Robins) Department of Psychiatry, Washington University School of Medicine, St. Louis, MO 63110.

Glutamate has been postulated to play roles in both normal developmental processes such as synaptogenesis and in pathological processes such as perinatal neuronal death from asphyxia. However, the developmental time course of glutamate release and of its modulation by other neurotransmitters has not been well characterized. In adults, glutamate release is elicited by depolarization and is inhibited by serotonin (5HT). In the cerebellum, depolarization induced glutamate release can not be demonstrated until the granule cells begin to mature at PND 14-20. Neurons in the cortex mature much earlier and might develop glutamate release during embryonic life. However, this has not been examined. Likewise, the development of sensitivity to 5HT has not been examined. This work addresses both questions in a dissociated cell culture system.

Cortices from E13 to E22.5 fetal rats were dissected, triturated and plated. The cultures were loaded with 100 nM ^{3}H glutamate, washed extensively and depolarized with a high K^+ solution. The cultures were electrophysiologically healthy and cells survived the experimental manipulations. Glutamate release was minimal from E13 to E17, then increased rapidly to a peak level ~two-fold greater than baseline at E19.5, and finally fell to minimal levels by E22.5. The effect of 5HT on glutamate release was tested by exposing cultures to 100 nM 5HT immediately before treatment with the high K^+ solution. Under these conditions, 5HT did not influence depolarization induced glutamate release. This work demonstrates that depolarization induced glutamate release is present prenatally and can be studied in a culture system of living, embryonic, cortical cells. Serotonin modulation of glutamate release was not detected.

THE EFFECT OF TRYPTOPHAN HYDROXYLASE INHIBITION ON SUBSTANCE P mRNA DEVELOPMENT IN THE MEDULLARY RAPHE NUCLEI. P.D. Walker, L. Ni*, T.L. Green*, S. Schotland*, R.P. Hart, and G.M. Jonakait. Dept. of Biol. Sci., Rutgers University, Newark, NJ 07102.

Substance P is co-localized with serotonin (5-HT) in almost all of the neurons developing in medullary raphe nuclei, B1 and B2 (Ni and Jonakait, Soc. Neurosci. Abst., 1987). Factors regulating co-localized neurotransmitter molecules during development are ill-defined. We sought to determine possible changes in SP mRNA levels following inhibition of tryptophan hydroxylase (TPH), the rate-limiting enzyme in 5-HT biosynthesis.

Pregnant rats received Alzet minipump implants containing *p*-chlorophenylalanine (*p*CPA) on day 8 of gestation (E8). Each pump contained an amount of *p*CPA sufficient to deliver 100 mg/kg/day for 14 days. In addition, a 300 mg/kg s.c. injection was given at the time of implantation. Control animals received sham surgery with no pump implantation. As measured by radioenzymatic assay, TPH activity in dorsal raphe nuclei from *p*CPA-treated litters was inhibited by 60-70% from E14 to post-natal day 3 (PND3) returning to control levels at PND 8. Total RNA isolated from medullary raphe nuclei of control and *p*CPA-treated litters was subjected to Northern blot analysis using a radioactive RNA probe for rat preprotachykinin (subclone from pGem 2-31-1, kindly provided by J. Krause, Washington University, St. Louis, MO) In contrast to TPH activity, SP mRNA levels were down to 7% of control at E14 and steadily increased to equal control levels from E19 to birth. At PND1, SP mRNA levels were increased four-fold and then fell to control levels by PND8.

These results suggest that inhibition of 5-HT biosynthesis has regulatory consequences for co-localized peptide neurotransmitters. (Supported by NS 23687. GMJ and RPH are Johnson & Johnson Discovery Research Fellows.)

DOPAMINE (DA) SYSTEM RESPONSES IN THE AMYGDALA (AM) AND CAUDATE-PUTAMEN (CP) TO ACUTE VS. REPEATED REMOXIPRIDE TREATMENT IN THE RAT. E.C. Essig* and I.C. Kilpatrick* (SPON: P. Dean). Dept. of Pharmacology, Medical School, University Walk, Bristol BS8 1TD, England.

Current data suggest that an action of neuroleptic drugs on DA systems in non-CP loci may confer their anti-psychotic activity. Here, we report the influence of an atypical neuroleptic, remoxipride (RMX) on DA utilisation in AM and CP after both acute and chronic treatments.

RMX (2.1 mg/kg i.p.) or its vehicle was given to male Wistar rats (n=10-12 per group) as either single (acute) or repeated injections once daily for 10 days. Food and water were freely available. Two hours after the last dose, AM and CP were assayed for DA and its two major metabolites, DOPAC and HVA by an HPLC-EC method.

Acutely, RMX evoked large elevations in DA utilisation in both AM (DOPAC +59%, $p<0.001$; HVA +163%, $p<0.01$) and CP (DOPAC +232%, $p<0.01$; HVA +236%, $p<0.01$). After 10 days RMX treatment, these changes were less pronounced in CP (DOPAC +43%, $p<0.001$; HVA +75%, $p<0.01$). In the AM, the relative increase in HVA concentration was almost halved (+71%, $p<0.05$). A small elevation in DOPAC remained (+14%) but this was no longer significant.

These data suggest that the profound neurochemical 'tolerance' of DA systems seen in CP to repeated dosing with RMX can also be seen to a lesser degree in AM. In view of the report that meso-amygdaloid DA neurones do not appear to possess autoreceptors that regulate DA synthesis (Kilts et al., J. Neurosci. 7, 3961-3975), the present data may reflect an RMX-specific action.

We thank Astra Alab (Sweden) for supplies of RMX.

EFFECTS OF RISPERIDONE (RIS), A NEW NEUROLEPTIC, ON NIGRAL-STRIATAL DOPAMINERGIC (DA) NEURONS. P.S. Blum and C.B. Davis*. Department of Biological Research, Janssen, Research Foundation, Spring House, PA 19477.

RIS was compared to haloperidol (HAL) on DA neurons using two methods. A) apomorphine (APO)-induced inhibition of DOPA synthesis, and B) activity of DA neurons in the substantia nigra (SN). To measure DOPA synthesis, rats were treated with gamma-butyrolactone to block activity of SN neurons, and NSD-1015 to block DOPA decarboxylase. After treatment, striatal DOPA levels were 22.4+0.9 pmol/gm, about 10 times the levels in untreated animals (2.8+0.2 pmol/gm). DOPA levels were reduced 51% by APO pretreatment (1 mg/kg i.p.). Both RIS (ED_{50}=0.32 mg/kg i.v.) and HAL (ED_{50}=0.06 mg/kg i.v.) blocked APO-induced inhibition of DOPA synthesis. These data suggest that RIS, like HAL, is a presynaptic D-2 antagonist at the terminals of DA neurons. In separate experiments, recordings were made from DA neurons in the SN of chloral hydrate anesthetized rats. APO inhibited activity in these neurons (ED_{50}= 12+2 µg/kg i.v.), and HAL blocked this inhibition with a threshold dose of 20 µg/kg i.v. RIS, however, did not consistently block APO-induced inhibition of neural activity. Rather, RIS either had no effect (to 80 µg/kg i.v.) or produced an abrupt cessation of neural activity (between 80 and 320 µg/kg i.v.). Unlike HAL, and unlike the effect of RIS at the nerve terminal, RIS had no detectable effect at D-2 receptors in the SN.

EFFECTS OF CHRONIC HALOPERIDOL ADMINISTRATION ON POPULATIONS OF DOPAMINE NEURONS INNERVATING THE AMYGDALOID NUCLEAR COMPLEX AND BED NUCLEUS OF THE STRIA TERMINALIS (BNST). T. Ely*, C. Anderson*, C. Kilts*. (SPON:M. McMilian). Duke Univ. Med. Center, Durham, NC 27710.

The present study mapped the biochemically estimated response to chronic haloperidol administration of populations of dopamine (DA) neurons innervating discrete projection fields within the limbic system. Animals sacrificed 24 hr following the last of 28 daily haloperidol (HAL) treatments (0.3mg/kg, i.p.) exhibited a significant decrease in the HVA and DOPAC concentration of selective brain nuclei (e.g. olfactory tubercle, cingulate cortex). Acute HAL administration significantly increased the HVA and DOPAC concentration of all brain nuclei examined, particularly the ventral and dorsal subdivisions of the BNST. Upon accounting for the residual effect of chronic HAL administration on DA metabolism, a significant attenuation of the biochemically estimated response to HAL following chronic HAL administration was noted in only a minority of brain nuclei. DA neurons projecting to the central and lateral amygdaloid nuclei exhibited the greatest degree of tolerance development while the response to HAL of neurons projecting to the intercalated cell groups and cortical amygdaloid nucleus was not influenced by chronic drug administration. These data further reinforce the pharmacological heterogeneity of mesoamygdaloid DA neurons and suggest their inequivalent role in the mechanism of antipsychotic drug action. (NIMH MH 39967).

HALOPERIDOL FORMS MOLECULAR COMPLEXES WITH DOPAMINE IN VIVO. T. A. Patterson* and J. O. Schenk. Dept. of Chemistry and Programs of Biochemistry and Pharmacology/Toxicology, Washington State University, Pullman, WA 99164-4630.

A previous report from this laboratory suggested that the dopamine (DA) antagonist haloperidol (HAL) forms molecular complexes with DA in vitro (see Neurosci Abst. 13: 134.8, 1987). Herein we report that in vivo voltammetric studies suggest that these complexes also form in vivo.

Experiments were conducted using 300 um diameter carbon paste sensing electrodes in order to obtain optimal voltammetric peak shapes. An injection syringe was placed ca. 1 mm from the sensing electrode and the electrode assembly placed in the striatum of a chloral hydrate anaesthetized rat. Analysis was made by linear potential sweep voltammograms run every 10 minutes from 0.00V to 0.50V, scan rate = 10 mV/sec. A baseline oxidation potential was established for DA by direct injection of dopamine, 6.65 pmole of HAL was injected and the oxidation peak was again monitored every 10 minutes for at least 70 minutes. The injection of HAL results in a shift of the DA oxidation potential to higher values, indicating that a complexation reaction has occurred. This shift also occurs following a systemic injection of HAL (2 mg/kg). Supported by: MH42759 and the State of WA.

DIFFERENTIAL REGULATION OF MESOTELENCEPHALIC DOPAMINE NEURONS BY THE SEROTONERGIC AGONIST 8-HYDROXY-DPAT. A. M. Rasmusson, R. H. Roth, and A. Y. Deutch. Depts. of Pharmacology and Psychiatry, Yale University School of Medicine, New Haven, CT 06510.

The selective stress-evoked activation of the dopamine (DA) neurons innervating the prefrontal cortex (PFC) does not appear attributable to a lack of impulse-modulating autoreceptors on these neurons: other DA neurons which also lack these autoreceptors are not activated by mild footshock stress. These data suggest that extrinsic controls over DA neurons may be critical to the regulation of central DA systems. The serotonin innervation of the midbrain DA neurons may be such a control system. We have examined the effects of the serotonin agonist 8-hydroxy-DPAT, which at low doses is an autoreceptor agonist, on both basal activity and stress-evoked activation of the mesotelencephalic DA systems. DA turnover, as reflected by DOPAC/DA, was significantly increased in the PFC by 225 ug (but not 75 ug) 8-OH-DPAT; DA turnover was not altered in the nuc. accumbens or striatum. The stress-induced activation of mesoprefrontal DA neurons was essentially unaltered by 8-OH-DPAT. However, the high dose of 8-OH-DPAT resulted in a stress-induced increase in NAS DA turnover. These data suggest that 5-HT mechanisms may differentially regulate the mesotelencephalic DA subsystems.

DOPAMINE METABOLISM IS SELECTIVELY ALTERED IN PREGNANCY. R.E.A. Craig* and C.E. Greenwood. Dept. Nutr. Sci., Fac. Med., Univ. of Toronto, Toronto, Ontario, Canada. M5S 1A8.

The relationship between acute administration of precursor amino acids (AA) and monoamine (MA) metabolism has been well elucidated in adult rats. However, the effect of chronic AA administration on NT metabolism in altered physiological states is less well understood. Therefore, to examine the effect of AA supplementation on MA metabolism during pregnancy, 20% casein diets, enriched with 5% L-phenylalanine (PHE) or equimolar tyrosine (TYR), were fed to pregnant (PREG) rats from G12-G20 and to nonpregnant (NPREG) rats for 9 days. Of the MAs, only dopamine (DA) metabolism was altered during pregnancy. Despite similar brain TYR levels, steady-state levels of DOPAC, the major metabolite of DA, were reduced during pregnancy in striatum (1608±75 vs 1118±43 ng/g; X±SEM for NPREG and PREG rats) and remaining hemispheres (110±7 vs 85±4 ng/g). Hypothalamic DA was lowered (401±40 vs 277±16 ng/g) in PREG rats; DOPAC remained unchanged. Similar effects of pregnancy were seen when DA and metabolites were measured following haloperidol injection (2 mg/kg, i.p.) and when DA synthesis was estimated using NSD 1015 (100 mg/kg, i.p.). Feeding precursor AA elevated DA in PREG rats to NPREG levels. No effect of pregnancy on steady-state levels of either norepinephrine or serotonin and its metabolite 5HIAA was observed. The results indicate that DA metabolism is decreased in pregnancy, and that this effect can be alleviated by dietary AA supplementation. (NSERC).

490.7

REGIONAL AND SIDE DEPENDENT EFFECTS ON DOPAMINE UTILIZATION INDUCED BY DIFFERENT DURATIONS OF RESTRAINT STRESS. J.N. Carlson, S.D. Glick and J.L. Baird*. Department of Pharmacology and Toxicology, Albany Medical College, Albany, N.Y. 12208.

We have studied the effects of restraint (immobilization) stress on dopamine (DA) utilization in projection areas of the mesocortical (prefrontal cortex - PFC), mesolimbic (nucleus accumben -NAS), and nigrostriatal (striatum - STR) systems. Female Long-Evans rats were restrained in Plexiglas cylindrical tubes for 15 minutes, 30 minutes or 60 minutes, and then immediately decapitated. Bilateral samples of the above brain regions were removed and assayed for DA, DOPAC and HVA content by HPLC with electrochemical detection. At 15 minutes, DA utilization, as indicated by HVA/DA and DOPAC/DA was elevated in the left PFC. At 30 minutes these measures were elevated on both sides of the PFC with the left side being greater; at 60 minutes, these measures declined bilaterally, although the left side was still higher than the right. The NAS was bilaterally elevated at 30 minutes and at 60 minutes. There was little effect of any duration of restraint in the striata. The data suggest that, as stress is prolonged, different DA systems, as well as different sides of the PFC, are sequentially activated. (Supported by NIDA grant DA03817 to S.D.G.).

490.8

EFFECTS OF DOPAMINE DEPLETION OF THE PREFRONTAL CORTEX ON STRESS-INDUCED CHANGES IN MESOLIMBIC AND STRIATAL DOPAMINE FUNCTION. W. A. Clark, R. H. Roth, and A. Y. Deutch. Depts. of Pharmacology and Psychiatry, Yale Univ. School of Medicine, New Haven, CT 06510.

Mild footshock stress and conditioned fear selectively increase dopamine (DA) metabolism in the prefrontal cortex (PFC); more severe stress recruits other DA neurons, such as those projecting to the nucleus accumbens (NAS). It is unclear whether DA release in the PFC is a permissive event (initiator) allowing other catecholamine neurons to respond, or whether PFC DA release is part of a coping response. Previous data indicating that DA autoreceptor-selective doses of apomorphine are anxiolytic favor an initiator role for PFC DA release. We have therefore examined the effects of stress on DA systems in the rat NAS and striatum (CP) after 6-hydroxydopamine lesions of the PFC. A stress-evoked increase in the DA metabolite DOPAC was observed in the NAS, but not CP. Lesions of the DA innervation of the PFC blocked the stress-induced increase in DA metabolism in the NAS, but did not significantly alter DOPAC levels in the CP. These data suggest that the preferential activation of mesoprefrontal DA neurons evoked by stress may be necessary for the subsequent involvement of other catecholamine neurons which contribute to means of coping with stress.

490.9

TURNOVER OF CENTRAL BIOGENIC AMINES IN THE RAT DURING ACUTE AND CHRONIC COLD EXPOSURE. A.Y-C. Shum*, C-F. Chen* F-Y. Liao* and J-Y. Wang (SPON: H-S. Yin). Dept. of Pharmacology, National Yang-Ming Medical College, and Dept. of Physiology, National Defense Medical Center, Taipei, Taiwan, R.O.C.

Turnover rates provide valid indices of neuronal activities. A non-isotopic, non-steady state method for estimating amines turnover was applied to the investigation of the possible involvement of monoaminergic neurons during cold exposure and adaptation in the rat, a homeotherm. Male Sprague-Dawley rats were cold exposed (4°C) for 30 mins, 24 hrs, 1 and 6 weeks respectively and the turnover of catecholamines and serotonin in different brain regions estimated from the acumulation of the intermediates dihydroxyphenylalanine (DOPA) and 5-hydroxytryptophan (5HTP) after inhibition of the common synthesizing enzyme l-aromatic acid decarboxylase. Increased metabolism, as reflected by increase in oxygen consumption, was observed after 1 and 6 weeks of exposure. Proliferation of mitochondria in the interscapular fad pad, thereby turning it from white to brown, was also observed. These observations indicated the shifting of mode of thermogenesis from shivering to nonshivering. Coinciding with these changes, increased turnovers of serotonin and catecholamines were also observed in the anterior hypothalamus, midbrain-pons, and medulla oblongata. These observations suugest strongly of physiological involvement of central monoaminergic neurons in cold acclimation.

EFFECTS OF MAO-B INHIBITOR ON DOPAMINE SYSTEMS IN MPTP TREATED MICE. B.K. Gupta and M. Gupta, Department of Anatomical Sciences and Neurobiology, School of Medicine, Univ. of Louisville, Louisville, KY 40292

Our previous studies have shown that treatment of mice with MPTP decreases dopamine levels in the striatum as well the number of fluorescent cell bodies in the substantia nigra pars compacta (SN). Furthermore MPTP neurotoxicity can be prevented by pre-treatment with MAO-B inhibitor. MAO-B activity in the brain increases with age which leads to decreased catecholamines. The present studies were undertaken to investigate if treatment of MPTP lesioned mice with MAO-B inhibitor, deprenyl, prevents further deterioration of the nigrostriatal dopamine system and other systems in the brain. Male C57BL/6 mice at 18 months of age were divided into four groups: (a) control, (b) MPTP treated at 60 mg/kg given in multiple injections over two days, (c) MPTP followed by deprenyl three days later, (d) deprenyl alone (0.035 mg/5ml in drinking water for upto 10 days. All the four groups of animals were sacrificed by decapitation, brains were quickly dissected out and frozen on dry ice. 16 um thick frozen sections were cut using a cryostat and processed for fluorescence histochemistry using the SPG method. Our results show a decreased number of fluorescent neurons in the SN with MPTP treatment as compared to the controls and were quantitated in the four groups. Results of these studies will be presented in details. Supported by USPHS grant R29 NS 24291 to MG.

490.11

DOPAMINE AND TYROSINE HYDROXYLASE LEVELS IN THE CORTICAL AND SUBCORTICAL AREAS IN THE MPTP-PARKINSONIAN MONKEYS. I.J.Kopin, A.Zuddas, V.Weise*,R.J.Plunkett*, E.H.Oldfield* and K.S.Bankiewicz,(SPON:R. Fox) NIH, NINCDS, Bethesda, MD, 20892

Dopamine (DA) and tyrosine hydroxylase (TH) were measured in brain areas of one full parkinsonian, three hemiparkinsonian (HPD) and two normal monkeys. Cortical areas of interest were: prefrontal cortex, medial frontal gyrus, frontal eye field, motor cortex, superior temporal sulcus, parietal sulcus, parietal gyrus, occipital gyrus, cingulate gyrus. Subcortical areas were: dorsal and ventral caudate nucleus, dorsal and ventral putamen, head of caudate nucleus, nucleus accumbens, superior colliculus and inferior olive. DA and TH in cortex of hemiparkinsonian monkeys were similar on both the MPTP infused and contralateral sides and not significantly different from controls. However, the full parkinsonian animal showed elevated cortical levels of dopamine. DA and TH in the caudate and putamen in HPD on the MPTP treated side and in the full parkinsonian monkey were decreased >95% when compared to non-treated side in HPD or control monkeys. Caudate and putamen in the non-MPTP treated side in HPD did not differ from controls. Other subcortical areas showed some decrease in DA and TH levels in the full parkinsonian animal and on the MPTP treated side in HPD monkeys. These results further support the specificity of the effects of MPTP on dopaminergic neurons in the nigrostriatal pathway and indicate that the delays in initiation of motion are not due to deficit in cortical dopamine.

490.12

THE ROLE OF THE DOPAMINE TRANSPORT SYSTEM IN MPTP-INDUCED MITOCHONDRIAL DAMAGE. S. Ofori*, R.E. Heikkila and W.J. Nicklas. Dept. of Neurology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854.

The administration of MPTP or MPTP analogs, such as 2'CH_3-MPTP, to experimental animals leads to the destruction of dopaminergic neurons of the nigrostriatal pathway. Neurotoxicity is dependent upon the monoamine oxidase catalyzed formation of the pyridinium species (MPP^+ or 2'CH_3-MPP^+) from the tetrahydropyridine, and selective uptake of the pyridinium species into dopamine (DA) neurons by the DA transport system. Pretreatment with inhibitors of DA uptake protect against neurotoxicity. In experiments with neostriatal slices, the pyridinium ions formed from MPTP and 2'CH_3-MPTP inhibited complex 1 of mitochondrial electron transport, and thereby increased lactate (LAC) production. DA uptake inhibitors (i.e. Win 35,428, Mazindol and McN 5908) reduced 10μM 2'CH_3-MPTP-induced LAC formation by 57%, 45% and 34% respectively. Win 35,428 lowered 5μM-induced LAC accumulation by 82%, and that due to 50μM MPTP by 45%. Correlations will be made between the capacity of uptake inhibitors to decrease the tissue content of the pyridinium species, and LAC formation. These results are consistent with the concept that toxic effects of MPTP and 2'CH_3-MPTP are due to uptake of the pyridinium species into the DA neuron, and subsequent mitochondrial damage.

490.13

DEVELOPMENT OF THE DOPAMINERGIC NIGROSTRIATAL PATHWAY IN MALE SWISS-WEBSTER MICE: RELATIONSHIP TO MPTP-INDUCED NEUROTOXICITY. L. Manzino, D. Tonzola*, P.K. Sonsalla, B.A. Sieber*, A. Giovanni, and R.E. Heikkila. Dept. of Neurology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854.

MPTP-induced dopaminergic neurotoxicity depends on 1) the monoamine oxidase (MAO) B dependent formation of the pyridinium species MPP^+ and 2) the uptake of MPP+ by the dopamine (DA) transport system. Aged animals are known to be more sensitive to MPTP than young adults whereas immature animals are less sensitive. One possible explanation for these sensitivity differences is that brain MAO-B activity increases during aging. In developing mice, we have measured neostriatal levels of MAO-B and MAO-A as well as biochemical markers of dopaminergic activity (tyrosine hydroxylase activity, ^{3}H-DA uptake, DA content). The development of MAO-A activity was considerably more rapid than that of MAO-B activity. The development of neostriatal dopaminergic markers paralleled that of MAO-B. Since MPTP-induced toxicity is dependent on MAO-B and the DA transport system, any differential effects of MPTP during development might be due to either parameter. We will discuss relationships between: 1) MPTP-induced toxicity, 2) toxicity produced by 2'ethyl-MPTP (which is bioactivated by MAO-A and 3) the development of MAO activity and the nigrostriatal dopaminergic pathway.

490.14

EFFECTS OF MPTP, 2'ETHYL-MPTP AND THEIR PYRIDINIUM SPECIES ON CULTURED PC-12 CELLS. A. Basma*, H. Geller and R.E. Heikkila. Depts. of Neurology and Pharmacology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854.

The dopaminergic neurotoxicity of MPTP is dependent upon the monoamine oxidase-B (MAO-B) catalyzed oxidation of MPTP to a dihydropyridinium intermediate which in turn is oxidized to the pyridinium species MPP^+. In the present study PC-12 cells ($50x10^3$) were exposed to varying concentrations of MPTP, 2'ethyl-MPTP or their pyridinium species for periods of 1-14 days. Toxicity was assessed by resuspending live cells and counting aliquots. The PC-12 cell line contains high levels of dopamine and MAO-A, but relatively little MAO-B. The MPTP analog, 2'ethyl-MPTP, which is considerably better than MPTP as a substrate for MAO-A, was much more toxic than MPTP in PC-12 cells. Both the toxicity of MPTP and 2'ethyl-MPTP and the formation of their corresponding pyridinium species were largely attenuated by the MAO inhibitor pargyline. The pyridinium species themselves, MPP^+ and 2'ethyl-MPP^+, were relatively equipotent and quite toxic to PC-12 cells. These data suggest that the MAO-A catalyzed formation of pyridinium species from MPTP and 2'ethyl-MPTP plays an important role in the toxicity to PC-12 cells. This cell line represents an excellent model system with which to study the mechanism of action of MPTP.

DIFFERENTIAL EFFECTS OF MPTP IN THE RAT AND MOUSE. A. Giovanni, P.K. Sonsalla and R.E. Heikkila. Dept. of Neurology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854.

MPTP administration causes a degeneration of the nigrostriatal dopaminergic pathway in mice. In contrast, rats are considerably less sensitive. In the present study, we administered MPTP to male Sprague-Dawley rats (Charles River) and male Swiss-Webster mice (Taconic Farms) and measured brain levels of MPTP and its major metabolite 1-methyl-4-phenylpyridinium (MPP^+). In contrast to what is generally accepted, we found similar levels of MPP^+ in the brains of rats and mice over a 2 hour time period after a single s.c. injection of 40 mg/kg of MPTP. In parallel experiments, MPTP administration caused a dopamine depletion of approximately 70% in the mouse neostriatum but had no significant effect in the rat neostriatum. These data suggest that the differential sensitivity of rats and mice to MPTP is due to more than simply the brain level of MPP^+. We have devised different dosing regimens in an attempt to maintain high brain levels of MPTP and MPP^+ for extended time periods. Experimental variables included: the dose of MPTP, the number of injections, and the interval between injections. By altering the above variables we have been able to obtain a substantial depletion of neostriatal DA in the rat. Reasons for the differential effects of MPTP in the rat and the mouse will be discussed.

490.16

(+)MK-801 PROTECTS AGAINST METHAMPHETAMINE (METH)-INDUCED, BUT NOT MPTP-INDUCED, NEUROTOXICITY IN MICE. P.K. Sonsalla, W.J. Nicklas and R.E. Heikkila. Dept. of Neurology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854.

METH or MPTP administration to mice damages nigrostriatal dopaminergic neurons. Toxicity induced by METH appears to depend on DA, whereas that induced by MPTP depends on formation of its metabolite, MPP^+. Although the exact cellular mechanisms responsible for cell death by METH or MPTP are unknown, oxidative stress has been implicated for both. It has been suggested that oxidative stress associated with massive release of excitatory amino acids (EAAs), i.e. glutamate, might underlie reperfusion or postischemic neurodegeneration. Reperfusion damage can be prevented by (+)MK-801, a non-competitive antagonist of the N-methyl-D-aspartate receptor. In the present studies, we found that (+)MK-801 prevented METH-induced, but not MPTP-induced, dopaminergic neurotoxicity. In mice treated with METH, neostriatal DA content and tyrosine hydroxylase activity were approximately 50% of control values; administration of (+)MK-801 prior to and after METH prevented these decrements. These results suggest that oxidative stress mediated by EAAs may play a role in the neurotoxic actions of METH, but not those of MPTP. These observations may have implications for several neurodegenerative disorders where oxidative stress might be involved in pathogenesis of the disease.

NEUROTOXICITY IV

491.1

MPP^+ IS NEUROTOXIC TO CEREBELLAR GRANULE CELLS. A. Marini*, T. S. Nowak, Jr. and I. Kopin (SPON: K. M. Newrock) CNB and LNNS, NINCDS, NIH, Bethesda, MD 20892

We have developed a neuronal culture system to study the neurotoxicity of MPP^+. Cerebellar granule cells are susceptible to the neurotoxic effects of MPP^+ at 50-100uM, evident as a loss of neuronal processes and disintegration within several days. In contrast, MPTP is not toxic. In cocultures of cerebellar astrocytes and granule cells MPTP is selectively neurotoxic to the granule cells, and this toxicity is prevented by the addition of the MAO inhibitor pargyline. Preliminary results in pure granule cell cultures indicate that MPP^+ at 30 uM or more results in a striking reduction of phosphocreatine (PCr) in the absence of significant ATP loss. The decrease in PCr was evident within 3 h after addition of MPP^+, and preceded any morphological evidence of neurotoxicity. Our results suggest that these culture systems are suitable for studying several aspects of the neurotoxic effects of MPTP and MPP^+, including components of uptake and metabolic conversion. The biochemical evidence that PCr levels fall prior to any effect on ATP levels or overt cell death is perhaps consistent with reports of mitochondrial dysfunction following exposure to MPP^+ in vitro. Future studies may be expected to further define mechanisms by which MPP^+ affects neuronal energy metabolism and to determine the relevance of such effects to its neurotoxicity.

491.2

ASTROCYTES INVOLVEMENT IN N-METHYL-4-PHENYL-1,2,3,6 TETRAHYDROPYRIDINE NEUROTOXICITY. G. Cappelletti*, G. Malanca*, A. Vescovi* and E.A.Parati.Inst. Neurol. "C.Besta" Milan, Italy, 20133.

Neuroglial cells seem to be involved in toxic mechanism of the potent drug N-Methyl-4-phenyl-1,2,3,6 tetrahydropyridine (MPTP). MPTP toxicity is probably mediated by its toxic metabolite MPP+, through the action of monoamine oxidase B (MAO-B). In the brain, MAO-B is contained predominantly in glial cells. Moreover the "in vitro" study directly showed that pure cultures of mammalian astrocytes are capable of converting MPTP to MPP+. In order to better understand the glial cells role in promoting neuronal degeneration we studied the correlation between the metabolic properties of cultured rat cerebellum astrocytes and the survival of cultured PC12 cells,considered as a model of dopaminergic neurons. We exposed astrocytes to different MPTP concentrations (0.1-1 μM), evaluated cell viability and collected the conditioned media at several incubation time. Preliminary data showed the conditioned medium of MPTP-treated astrocytes seems to be more toxic on PC12 cells than non-conditioned medium containing similar MPTP and MPP+ concentrations. We discuss these data in terms of astrocytes involvement in MPTP neurotoxicity.

491.3

DIETHYLDITHIOCARBAMIC ACID ENHANCES THE NEUROTOXICITY OF 1-METHYL-4-PHENYL-1,2,3,6-TETRAHYDROPYRIDINE IN THE CD-1 MOUSE. D.B. Miller, J.P. O'Callaghan and J.F. Reinhard, Jr.[1] Health Effects Rsch. Lab., U.S. EPA and [1]Wellcome Rsch. Labs., Burroughs Wellcome Co., RTP, NC 27711.

1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) is a catecholaminergic (CA) neurotoxicant in man, nonhuman primates and certain mouse strains. Diethyldithiocarbamic acid (DDC) increases CA depletion and the glial response in C57Bl/6 mice. Here we report on DDC (400 mg/kg i. p.) and MPTP (5, 10 or 20 mg/kg i. p. X 4 every 2 hrs) in female CD-1 mice, a nonsensitive strain. To be neurotoxic MPTP must be metabolized to 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridinium (MPP+). To partially eliminate kinetic and metabolic factors the effect of DDC after ICV MPP+ (10 or 20 ug) and on bovine adrenal medullary (BAM) cells in culture (0.3 mM MPP+ and 0.3 - 3.0 mM DDC) was also examined. DDC increased the general toxicity of MPTP and increased CA depletions at both 5 and 10 mg/kg MPTP. DDC also increased the toxicity of MPP+ in BAM cells as evidenced by decreased CA levels and increased total protein. ICV MPP+ toxicity was also increased. It appears DDC can enhance the neurotoxicity of MPTP and MPP+ in nonsensitive mouse strains.

491.4

CHARACTERIZATION OF MPP+ TOXICITY FOR RAT DOPAMINERGIC NEURONS IN CULTURE. P.P. Michel*, H. Zawadcka*, M. Goldstein, J. Sanchez-Ramos, W.L. Strauss and F. Hefti. Depts. Neurology and Pharmacology, Univ. of Miami, Miami, FL 33101, and Neurochemistry Research Unit, NYU Medical Center, New York, NY 10016.

In cultures of dissociated fetal rat mesencephalic neurons, MPP+ and its analog 2'-methyl-MPP+ selectively affect dopaminergic neurons. 10μM MPP+ during 48 hours reduced the number of tyrosine hydroxylase (TH)-positive neurons by 90% but failed to reduce the number of TH-negative cells. The number of TH-positive neurons declined further, when sister cultures were kept after treatment for up to 6 days in MPP+-free medium. 10μM MPP+ for 48 hours reduced the uptake of 3H-dopamine by 95%. There was no recovery when cultures were kept in MPP+ free medium for another 6 days after the treatment. These findings, together with earlier morphological observations, strongly suggest that MPP+ results in morphological destruction of the cultured rat dopaminergic neurons. Using Northern blotting and in situ hybridization techniques, we presently are investigating the effects of MPP+ treatment on levels of mRNA[TH].

491.5

MPP+ RESISTANT PC12 MUTANTS CREATED BY RETROVIRAL INSERTION. M.J. Kadan and M.M.S. Lo. NIDA,ARC, Baltimore, MD 21224.

The catecholaminergic cell line, PC12, provides a useful model system in which to study the mechanism of 1-methyl-4-phenylpyridinium (MPP^+) neurotoxicity. Infection of PC12 cells by retroviruses creates random mutations throughout the genome. MPP^+ resistant mutants resulting from retroviral insertion can be used to identify the genes involved in MPP^+ neurotoxicity.

We have infected PC12 cells (10^8) with a recombinant retrovirus pZIPNEOSV(X). These infected cells were selected for expression of virus and resistance to 500μM MPP^+. We have determined independently 1) frequency of infection ($1x10^{-4}$), and 2) frequency of spontaneous mutations resulting in MPP^+ resistance ($1.4x10^{-4}$). The number of virally infected MPP^+ resistant colonies we obtained ($1x10^{-6}$) is approximately 100 times greater than the number predicted if these events (viral infection and MPP^+ resistance) are unrelated. This shows a significant correlation between viral intergration within the selected mutants and induction of a mutation resulting in resistance to MPP^+. We have obtained a large library of MPP^+ resistant clones. Analysis of the proviral positions within these mutants will allow us to identify and characterize the gene targets involved in MPP^+ neurotoxicity.

Supported in part by a grant from Johns Hopkins C.A.A.T.

491.6

CHRONIC TWO-FOLD VITAMIN E (VE) SUPPLEMENTATION ANTAGONIZES MPTP-INDUCED NEUROLOGICAL AND NEUROCHEMICAL DEFICITS IN CATS. J.S.Althaus*, M.A.Travis, E.D.Hall and P.F.VonVoigtlander. CNS Diseases Research Unit, The Upjohn Company, Kalamazoo, MI 49001

The effects of a two-fold increase in dietary VE (from 35 to 70 I.U./lb of dry food) for 12 weeks were examined on the dopaminergic neurotoxicity of N-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) in cats. Neurological dysfunction was quantified by blinded evaluators using a 6-parameter scale and dopamine (DA) and homovanillic acid (HVA) were measured in the ventral limbic, tegmental and caudate regions via HPLC with electrochemical detection. Cats were treated with 0.9% saline or MPTP (5 mg/kg) i.p. once daily for 3 days and neurological and neurochemical evaluation carried out on the first post-treatment day. Control saline-treated, normal VE cats (n=5) had a mean neurological assessment score (maximum = 14) of 12.1 ± 0.5 (x ± S.E.M.) while normal VE cats treated with MPTP (n=4) had a score of only 6.5 ± 0.7. In contrast, MPTP treated, VE supplemented animals (n=13) had a mean score that was significantly improved to 9.9 ± 0.4. Correlated with the neurological dysfunction, the normal VE, MPTP-treated cats showed significant depletions of DA in all three brain regions examined, whereas in the VE supplemented, MPTP-treated cats, significantly higher levels were measured in the caudate and ventral limbic areas. These results show a clear protective effect of the anti-oxidant VE against MPTP neurotoxicity.

491.7

1-METHYL-4-PHENYL-1,2,3,6-TETRAHYDROPYRIDINE (MPTP) SELECTIVELY DEPRESSES BRAIN BUFARALOL HYDROXYLASE ACTIVITY IN C57 BL/6J MICE. G.S. Shahi*, N.P. Das+*, E.J.D. Lee°* and S.M. Moochhala°†SPON: P.T-H. Wong) Depts of Physiology, +Biochemistry and °Pharmacology, Faculty of Med., National Univ. of S'pore, Singapore 0511.

MPTP is a neurotoxin which causes an irreversible parkinsonian syndrome clinically indistinguishable from idiopathic Parkinson's disease. It can be detoxified by metabolism via the cytochrome P-450 enzyme system (Weissman et al, J.Med.Chem., 28:997-1001, 1985). Bufaralol hydroxylase (buf) is thought to be the cytochrome P-450 enzyme activity capable of detoxifying MPTP in the brain (Fonne-Pfisher et al, Biochem. Biophys. Res. Commun, 148: 1144-1150, 1987).

We have studied the in vivo effects of MPTP on buf and aryl hydrocarbon hydroxylase (AHH) activities in mouse brain. We found that MPTP (given i.p.) inhibited buf and AHH activities in a dose-dependent manner. MPTP appears to selectively depress buf activity and is about 2300 times more potent in depressing buf activity compared to AHH activity (ID_{50} for buf $1x10^{-4}$mg/kg and ID_{50} for AHH $2.3x10^{-1}$ mg/kg). In vitro studies were also carried out.

The possible clinical implications of our findings with respect to Parkinson's disease will be discussed.

491.8

RETINAL DOPAMINE SENSITIVITY TO MPP^+ TOXICITY. C Harnois, T Di Paolo, G Marcotte* & M Daigle*. Centre Hospitalier de l'Université Laval, Département d'ophtalmologie et École de pharmacie, Université Laval, Québec, PQ, Canada.

1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) is not metabolized into active 1-methyl-4-phenylpyridinium (MPP^+) in the eye[1], and does not decrease retinal dopamine content in monkeys[2]. MPP^+ was injected into the vitreous of rabbit eyes; one eye received doses of either 7, 70 or 700 μg, the other being used as control. Electroretinograms (ERG) and oscillatory potentials (POS) were recorded. DA and its metabolites were analyzed by HPLC-EC.

Two eyes treated with 700 μg presented extinguished ERG and POS from day 1 to day 44 and a decreased retinal DA concentration (15% of control on day 1 and 40% on day 31). Injection of 7 μg of MPP^+ had no effect on the ERG, the POS or the retinal DA concentration. The eyes treated with 70 μg showed different results. On day 1, the b-wave of the ERG was selectively decreased (15% of the control) and the a-wave was not affected, suggesting retinal drug toxicity. On day 21, the ERG and POS were about 40% of that of the control eye. On the other hand, DA concentration was 80% on day 1 and 114% on day 21. Fundus photographs and fluorescein angiographies revealed that eyes treated with either 700 or 70 μg of MPP^+ presented generalized retinal pigment epithelium modifications.

These data suggest that intravitreal injection of MPP^+ results in an unspecific retinal toxicity, and that it cannot be used to study the physiological role of retinal DA.

Supported by the Medical Research Council of Canada grants to CH and TDP.

491.9

MPTP DOSE-DEPENDENT LOSS OF MOUSE DOPAMINERGIC AMACRINES. W. Tatton, M. Kwan*, M. Verrier, N. Seniuk* and E. Theriault. Playfair Neuroscience Unit, The Toronto Hospital and Department of Physiology, University of Toronto, Toronto, Canada M5T 2S8.

MPTP produces dose dependent loss of neurons in substantia nigra compacta (SNC), locus coeruleus (LC), A13 hypothalamus and ventral tegmental area of 8-10 week old C57 black mice (Seniuk and Tatton, 1986). To investigate possible cell loss in retinae, C57 mice were given intraperitoneal MPTP according to two schedules: 30 mg/kg/day for 10 days (300 mg/kg total) or 30 mg/kg twice in one day (60 mg/kg total). Twenty days after the last dose the retinae were incubated with antiserum to tyrosine hydroxylase (TH) or choline acetyltransferase (CHAT) as whole mounts or serial sections. Normal retinae revealed TH and CHAT amacrines (AMs) in regular arrangements with respective mean densities of 43.8 ± 6.4 and 832 ± 20.3 cells/mm^2. The AM somas and terminal locations corresponded to those previously described for rabbit retinae (Famiglietti and Tumosa, 1986; Dowling and Ehinger, 1978). MPTP reduced TH AM densities to 7.4 ± 6.2 and 17.4 ± 8.1 for 300 and 60 mg/kg total doses. AMs in MPTP retinae did not show decreased TH staining intensities relative to normals and were randomly lost with no predilection for the central or peripheral retinae. TH AM loss was relatively greater for low MPTP doses than that for SNC and LC neurons. The alterations in visual contrast sensitivity (Bodis-Wollner et al., 1987) and PERGs (Nightengale et al., 1986) in Parkinsonian humans and the PERG abnormalities in MPTP-treated monkeys (Onofrj et al., 1986) may be at least partially explained by a reduction in dopaminergic amacrines' contributions to retinal processing (see Jensen and Daw, 1988). Supported by MRC grant MT5218.

491.10

NON-PARKINSONIAN TOXICITY OF 1-METHYL-4-PHENYL-1,2,5,6-TETRAHYDROPYRIDINE (MPTP): GASTRIC AND DUODENAL ULCERS. A. KESHAVARZIAN*, A. WIBOWO*, J.H. GORDON AND J.Z. FIELDS (SPON: I. Held). Dept. Med., Loyola Univ. Med. Sch., Maywood, IL 60153, and Med. & Res. Svces., Hines VA Hosp., Hines, IL 60141.

Although MPTP causes dopaminergic damage with subsequent development of parkinsonism, in rodents it also affects other neurotransmitter systems and produces other toxicity, namely, duodenal (DU) and gastric (GU) ulcers; the ulcerogenic mechanism is unknown. Since gender and age influence the metabolism of both neurotransmitters and toxins, we evaluated their influence on MPTP toxicity. MPTP-HCl [MPTP] sc, tid, was given to rats for 4 days and ulcers were checked on day 5. In 3 mo old female rats MPTP up to 15mg/kg/injection caused few ulcers [<30%]. Doses of 24 to 36 mg caused > 90% DU but > 50% mortality. MPTP at 20 mg/kg produced > 90% DU, 61% GU with < 20% mortality. Aging increased both mortality and the incidence of DU but not GU in female rats: [MPTP=15 mg, 3 mo=25% DU, 78% GU; 6 mo=33% DU, 100% GU; 12 mo=60% DU, 66% GU; 18 mo=66% DU, 66% GU]. Females had more DU (but not GU) than males. This difference disappeared after ovariectomy (OVX) [MPTP=20 mg, female=92% DU, 62% GU; male=42% DU, 58% GU; OVX=67% DU, 70% GU]. These observations suggest that both age and sex hormones are important in MPTP toxicity and may be due to their effects on MPTP metabolism to toxic metabolites (e.g. MPP+).

Temporal Changes in Dopamine in Rats with MPTP induced Motor Deficits. M.E. Melnick and M.K. Shellenberger. Dept of Physical Therapy Education and Dept of Pharmacology. University of Kansas Medical Center, Kansas City, Ks 66103

We have previously reported changes in locomotor activity and gait patterns following treatment with MPTP in rats. The alterations in gait included a shortening of the stride, an increase in width and an increased tendency to walk with a flat-footed gait. The purpose of this project was to investigate the changes in dopamine (DA), norepinephrine (NE) and serotonin (5HT) concentrations in frontal cortex, striatum and substantia nigra 30, 60 and 90 days after injection of MPTP or solvent. Year-old rats were injected with MPTP or solvent (20 mg/kg,ip) for 7 days. Brains were removed 30, 60 or 90 days after the last MPTP injection and quickly frozen. Subsequently the brains were regionally dissected and prepared for chemical analysis using HPLC with electrochemical dissection. At 30 days post-injection DA levels in the striatum were 45% of control; at 60 days, 65% of control and at 90 days 72% of control. DA levels in the substanta nigra were not significantly reduced at any of the time periods investigated. These data indicate that there is some recovery of DA levels in the striatum with time following chronic administration of MPTP in the rat. Recovery of gait abnormalities lags behind the recovery of DA levels. We are presently evaluating the extent of gait abnormality with DA levels to determine the correlation between the behavior and neurochemical changes. (USPHS Grant NS 22124)

DOPAMINERGIC NEURONS IN THE SUBSTANTIA NIGRA IN MPTP LESIONED YOUNG AND AGED MICE. M. Gupta, Dept. of Anatomical Sciences and Neurobiology, University of Louisville, School of Medicine, Louisville, KY 40292.

Our previous studies have shown that young adult mice treated with MPTP demonstrate a reduced number of fluorescent neurons in the substantia nigra pars compacta (SN). Furthermore, aged mice treated with MPTP show marked physical symptoms of motor dysfunction followed by decreased number of fluorescent cell bodies in the SN. The present studies were undertaken to investigate if these severe physical symptoms seen in the MPTP treated aged mice are due to a more severe damage to the nigrostriatal system as compared to the young adult group. 3 and 21 months old male C57BL/6 mice were given multiple injections of MPTP (total dose 60-90mg/kg body weight) over a two day period. Three days after the last injection, control and treated animals were anesthetized with chloropent and perfused intracardially with saline followed by 4% paraformaldehyde. Brains were dissected out, frozen 40um thick serial sections were cut and alternate sections stained immunocytochemically for tyrosine hydroxylase (TH). Our results show a significant decrease in the number of TH-positive neurons in both the MPTP treated groups compared to their controls. Whether the TH-positive neurons are more significantly decreased in aged mice will be presented in details. Supported by R29 USPHS grant NS24291.

491.13

THE EFFECT OF MPTP ON BRAIN CHOLECYSTOKININ CONCENTRATION IN THE MOUSE. C.A. DeSalvo*, W.A. Bauman*, H. Sershen*, A. Hashim* (SPON: G. Lehrer). Veterans Administration Medical Center, Bronx NY and Center for Neurochemistry, Ward's Island, NY.

Cholecystokinin octapeptide (CCK-8) and dopamine (DA) have been shown to colocalize in meso-limbic neurons. To determine the effect of MPTP (DA neurotoxin) on brain CCK-8 and DA concentrations, Balb/cBY mice were subcutaneously injected with MPTP (30 mg/kg at time 0 and 6 hrs) or vehicle, then on day 5 sacrificed. Striatum (S) and olfactory tubercle (OT) were dissected and stored at -50°C until extraction and assay (radioimmunoassay for CCK-8 and HPLC with electrochemical detection for DA). Results (mean±SEM):

	Section	CCK-8	DA	DOPAC+HVA/DA
Control	OT	1.2±0.1	117± 2‡	0.16±.01
MPTP	OT	1.2±0.1	38±14‡	0.24±.06°
Control	S	1.0±0.1	153±16‡	0.17±.01°
MPTP	S	0.9±0.1	10± 2‡	0.87±.02°

All concentrations: ng/mg protein. HVA=homovanylic acid, DOPAC=dihydroxyphenylacetic acid. $^{\ddagger}p<0.02$, $^{\ddagger}p<0.01$, $^{\circ}p<.001$

Conclusions: (1) MPTP markedly reduced DA concentration in S and OT (2) increased DOPAC+HVA/DA in S suggests a compensatory up regulation of surviving DA terminals (3) MPTP does not decrease CCK-8 concentration in S and OT, possibly because of neuronal differences in uptake and/or metabolism of this neurotoxin.

491.14

IN VIVO DOPAMINERGIC NEUROTOXICITY OF MPP^+ ANALOGS STUDIED BY MICRODIALYSIS OF DOPAMINE AND LACTATE IN RAT STRIATUM. H.Rollema*[1], R.G.Booth* and N.Castagnoli Jr.* (SPON: R.B.Mailman). Division of Toxicology, School of Pharmacy, University of California, San Francisco, CA 94143 and Dept. of Medicinal Chemistry, School of Pharmacy, State University Groningen, 9713 AW The Netherlands[1].

In vivo microdialysis in rat striatum has previously been used to study the effects of MPP^+ on DA-ergic nerve terminals. Changes in the dialysate levels of DA and metabolites indicate the profound and irreversible effects of a 10 min intrastriatal perfusion with 10 mM MPP^+ (Rollema, H. et al., Eur. J. Pharmacol. 126: 345, 1986), while the simultaneous increase in striatal lactate formation reflects the inhibition of mitochondrial respiration by MPP^+ (Rollema, H. et al., J.Pharm.Exp.Therap. in press, 1988). Measurement of these parameters allows the assessment of the in vivo neurotoxicity of analogs of MPP^+, which as charged ammonium species do not enter the brain after systemic administration. The study of such a series of compounds, including substituted phenylpyridiniums, alkylpyridiniums, tricyclic ions and potential endogenous compounds such as (iso)quinoliniums and beta-carboliniums, showed that a number of analogs have MPP^+-like neurotoxic effects after intrastriatal administration. The activities of the compounds range from virtually equipotent to 100-fold less potent than MPP^+ itself. From these data structure-activity-relationships can be studied, which will be discussed in view of the current hypotheses on the mechanism of action of MPP^+. (Supported by NIH Grant NS 23066 and a NATO Science Fellowship to H.R.).

NEUROTOXICITY V

492.1

ENHANCED UPTAKE OF A HEAVY METAL (SILVER) AFTER SURGICAL DISRUPTION OF THE BLOOD-BRAIN BARRIER IN RATS AND MONKEYS. G.F. Alheid, and C.L. Haselton*. Dept. Behavioral Medicine and Psychiatry, Univ. of Virginia, Charlottesville 22908

Single, peripheral injections of silver protein, result in a reliable pattern of labeled neurons in the forebrain and brainstem of rats (Rungby and Danscher, Acta Neurol. Pathol. 60:92,'83), and in the hypothalamus and brainstem of monkeys (Alheid, Anat. Rec. 220:8A,'88), that may be visualized with physical development. In the course of experiments in which animals injected with peripheral silver were subsequently injected intracranially with neuroanatomical tract-tracers, an unusual pattern of neuronal labeling was observed, suggesting that blood-brain barrier disruption incidental to tracer injection resulted in neuronal accumulation of silver, either directly, or possibly after retrograde transport from the area of damaged parenchyma. In the rat, silver labeling of cells (not normally labeled by peripheral injections) included the ventral anterior thalamus, while in the monkey (marmoset) neurons were labeled in substantia innominata, dorsal raphe, and locus coeruleus. In silver injected, but unoperated monkeys, these areas do not contain labeled neurons. In both the monkey and rat dense silver labeling was observed in the cortex at the site of damage incidental to the tracer injections, while in rats and monkeys which received tracer injections but no prior peripheral silver injection, no silver labeling was observed. We are currently examining material from additional monkeys to determine the generality of these observations and to identify any additional areas with "increased" labeling compared to intact controls, and in rats we are testing the possibility that the topography of uptake by neurons may vary with the particular site of blood-brain barrier disruption. Supported by NINCDS 17743 and the Virginia Center on Aging.

492.2

EARLY ESTABLISHMENT OF CHARACTERISTIC METABOLIC ABNORMALITIES AFTER PORTACAVAL SHUNTING. A.M. Mans, M.R. DeJoseph*, D.W. Davis, J.R. Vina*, and R.A. Hawkins. Dept. Anesthesia, Milton S. Hershey Medical Center, Hershey, PA 17033

Portacaval shunting in rats causes many changes in concentrations of brain and plasma metabolites, as well as in glucose use, blood-brain barrier transport, liver-to-body weight ratio and behavior. However, the etiology of the abnormal brain function remains obscure. The time course of these abnormalities after shunting is largely unknown; such knowledge may show correlations between the development of encephalopathy and biochemical alterations.

We have measured the following variables at six time points between 1 day and 60 days after portacaval shunting or sham-operation: brain content of neurotransmitters, amino acids, glucose and ammonia; plasma concentrations of amino acids, glucose, ammonia and lactate; indices of brain glucose use and tryptophan transport across the blood-brain barrier; liver and body weight. All these variables were measured in the same rats. The results showed that many of the changes that occurred after shunting were already apparent as early as 1 day after surgery and nearly all were present after 2 days. With some exceptions the new values were maintained relatively constant throughout the period studied, and therefore had apparently reached new steady-state levels.

Supported in part by NIH Grant NS 16389.

492.3

CEREBELLAR BLOOD-BRAIN BARRIER (BBB) IS DAMAGED BY INGESTED PROTEIN IN BILE DUCT-LIGATED RATS. J.Neiman[1]*, P.A.Stewart,[2] C.R.Farrell[2]*, P.L.Carlen[1,3], and H.Orrego[1,3]*. Addiction Research Foundation[1], 33 Russell St., Toronto, Ontario, and Departments of Anatomy[2] and Medicine[3], University of Toronto., Toronto, Ontario, Canada, M5S 1A8.

Cerebellar damage and liver disease are frequently seen in alcoholics. Furthermore, patients with hepatic encephalopathy can become comatose after ingesting high levels of protein. The pathogenesis of these effects probably includes changes in the composition of the brain extracellular fluid. We questioned whether blood-brain barrier breakdown plays a role in these phenomena. Hepatic cirrhosis was produced in rats by ligating the common bile duct. After 3-4 weeks, half of the experimental and half of the sham-operated rats were force-fed 1.5 g/kg casein hydrolysate. Two hours after feeding the operated rats were stuporous, but unfed operated and all sham-operated rats appeared normal. The integrity of the BBB was evaluated using an intracardiac injection of horseradish peroxidase (HRP). 30 seconds after injection, the rats were decapitated and the brains removed and examined for HRP leakage. Within the cerebral cortex the BBB appeared to be intact in all animals, however in animals with both bile duct ligation and casein feeding, multiple, large leakage spots were found in the cerebellum, primarily in white matter. The BBB damage in the cerebellum suggests that liver disease and dietary proteins may play a role in the cerebellar damage seen in alcoholic patients.

DOXORUBICIN MYOTOXICITY AND NEUROTOXICITY: INJECTION INTO THE ORBICULARIS OCULI. L.K. McLoon and J. Wirtschafter. Dept. of Ophthalmology, University of Minnesota, Minneapolis, MN 55455.

Doxorubicin is a fluorescent retrogradely transported neurotoxin that has the capability of chemodenervation and chemomyectomy. The effect of injection of doxorubicin on the orbicularis oculi and its motor neurons was examined in monkeys and rabbits. Two mg of doxorubicin in sterile saline was injected into the right lower lids of two cynomolgus monkeys and nine rabbits. The animals were sacrificed four or 64 days after doxorubicin injection. Skin ulceration and necrosis occurred in some of the experimental animals, and when present was completely healed in two to three weeks. The injected muscles showed extensive evidence of degeneration at the injection site with cytoplasmic vacuolization, edema and myofibrillar disorganization. There was little evidence of myotoxic effects in portions of the muscle distant from the injection site. By 64 days after injection, the orbicularis oculi was greatly reduced in muscle mass, with few muscle fibers remaining at the injection site. Counts of the facial motor neurons 64 days after doxorubicin injection indicated there was only a 15% loss of neurons on the injected side. The neurons on the injected side appeared to have a decrease in cell body area, although this was not quantified. Thus, doxorubicin appeared to have a more myotoxic than neurotoxic effect when injected into this muscle system. Its clinical application in the treatment of various muscle spasm diseases will be discussed.

DIFFERENTIAL EFFECTS OF BUTHIONINE SULFOXIMINE ON GLUTATHIONE LEVELS IN NEUROCHEMICALLY DEFINED REGIONS OF THE MOUSE BRAIN. N. Harary and T.H. McNeill. Dept. of Neurology, University of Rochester, Rochester, NY 14642.

Glutathione (GSH) plays an important role in the protective mechanisms of cells. This study evaluated the effects of butathione sulfoximine (BSO), an inhibitor of GSH synthesis, on GSH levels in the striatum, substantia nigra and locus coeruleus in young and aged mice. All tissues were analyzed using the HPLC system. GSH values in the striatum, substantia nigra and locus coeruleus of the young control animal were 2.14, 1.47 and 1.32 mmol/kg respectively. BSO induced a dose dependent effect on GSH levels in animals injected with 1.5 to 6.0 mM concentrations of the drug. GSH was significantly reduced in the three areas within 5 hours following repetitive injections of 4.5 mM BSO, and remained depressed for 24 hours. However, a return to control values occurred in all tissues after 72 hours. Comparison between young and old controls showed that a 15% decrease occurred in GSH concentrations in the striatum and substantia nigra, while the difference between young and old animals in the locus coeruleus was over 40%. The effect on GSH levels of old mice injected with 3.0 mM BSO was comparable to the effect observed in young animals from the same drug exposure. It is presently unknown whether the further decrement in GSH levels from BSO treatment in aged mice has a critical effect on catecholamine neurotransmitter systems. AFFERENT FIBER DYSFUNCTION IN VINCRISTINE NEUROPATHY. EFFECT OF GANGLIOSIDE TREATMENT. F. Di Gregorio*, G. Favaro* and M.G. Fiori. Fidia Research Laboratories, 35031 Abano Terme (PD), Italy.

A reproducible model of vincristine (VCR)-induced neuropathy has been obtained by i.v. administration of 0.25 mg/kg VCR in rabbits, once a week for 5 consecutive weeks. Morphological evidence of axon degeneration was accompanied by reduction of sciatic nerve compound action potential (CAP) amplitude, area and conduction velocity (CV). Extracellular recording of single fiber action potential from teased ventral and dorsal roots demonstrated a generalized decrease of CV, involving α and γ motoneurons as well as primary and secondary afferent fibers. Ganglioside (GA) treatment (50 mg/kg/day, i.v.) during the period of VCR administration limited CAP amplitude and area decrease, and corrected single fiber CV pattern. In particular, the percentage of sensory fibers conducting at high speed (>64 m/s) was larger in GA-treated (26%) than in saline-treated animals (16%). The position sensitivity (i.e. rate of firing as a function of muscle stretch) of both primary and secondary afferents from muscle spindles was reduced by VCR administration. In addition, many fibers required an abnormally high degree of stretching to initiate firing. The possibility that GA treatment could protect spindle function, in addition to impulse conduction along sensory fibers, is currently under investigation.

AXOPLASMIC PROTEIN TRANSPORT DEFICIENCES FOLLOWING CHRONIC EXPOSURE TO ACRYLAMIDE (ACR) AND 2,5-HEXANEDIONE (HD). D.W. Sickles* (SPON: G. Standage) Department of Anatomy, Medical College of Georgia, Augusta GA. 30912-2000

Single injections of acrylamide (ACR) and 2,5-hexanedione (HD) decrease the rate and quantity of protein transport in rat sciatic nerve (Sickles, Toxicologist 8: 43, 1988). These studies (segmental analysis of sciatic nerve radioactivity after 3H-leucine DRG injection) have been extended to determine the overall effect of the neuropathy-producing intoxication schedule upon protein supply to the axon. Over the 24 hour period following a single injection of 50 mg/kg ACR and 4mmoles/kg HD, the rate was equally reduced 6.1% and 8.7%, respectively. Multiple injections (2-10) of ACR or HD produced a flat 7.8% and 13.1% reduction, respectively. The quantity of protein transported was decreased 45% following 1 injection of 50 mg/kg ACR and slowly returned to, but never attained, control levels (-13% at 24 hours). HD (4mmoles/kg) produced a biphasic decrease in capacity of transport. At 1, 16 and 20 hours, a 36, 32 and 33% reduction was observed, but at 8 hours and 24 hours only 9.4 and 2.9% reductions were observed. Two to ten exposures to ACR and HD produced reductions of 49-56% and 51-61%, respectively. Therefore, each toxicant caused a total deficit in protein delivery of 28-30% over the ten day exposure schedule. (Support by NIH OH02020 and MCGRI)

492.8

TOXICOKINETICS OF LINDANE, PICROTOXIN AND Ro5-4864 COMPARED. **D.E. Woolley and H.L. Drummer. Dept. of Animal Physiol., Univ. of Calif., Davis, CA 95616.**

The in vivo effects of lindane (5, 10 and 20 mg/kg), Ro5-4864 (5, 10 and 20 mg/kg) and picrotoxin (PTX; 0.5, 1 and 2 mg/kg) administered i.p. in DMSO (0.5 ml/kg) in the rat were compared because of in vitro evidence that each binds to the picrotoxinin site of the $GABA_A$-activated chloride channel. All 3 drugs produced similar types of seizure activity, hypothermia with peak effect at 1 hr, and hypophagia. However, PTX was the most potent of the three in producing seizures and hypothermia and the least effective in reducing food intake. The time course of seizures, hypothermia and hypophagia produced by the same doses of lindane and Ro5-4864 was strikingly similar. However, Ro5-4864 was more effective in producing hypothermia at the highest dose and less effective at the lowest dose. Male rats were more sensitive than females to the effects, including lethal effects, of lindane, whereas the reverse was true for PTX. (The effects of Ro5-4864 were not compared in both males and females.) Thus, though the 3 drugs shared a similar profile of effects in vivo, some differences in the time course and relative effectiveness on the various measurements could be demonstrated.

DIFFERENTIAL SUSCEPTIBILITY OF SHORT- AND LONG-SLEEP MICE TO BRAIN WEIGHT DEFICITS FOLLOWING PRENATAL ALCOHOL EXPOSURE. C.R. Goodlett, D. M. Gilliam, J.M. Nichols and J.R. West, University of Iowa, Iowa City, IA 52242.

The long-sleep (LS) and short-sleep (SS) lines of mice have been selectively bred for high and low sensitivity as adults to the hypnotic effects of alcohol. The two lines may also differ during development to the neurotoxic effects of prenatal alcohol exposure. Evidence from behavioral studies following prenatal alcohol exposure suggests that LS mice are more susceptible to developmental behavioral deficits than SS mice. The present study examined brain size in adult mice of the two lines given gestational treatment with alcohol. LS and SS dams were treated from gestational days 7-18 with alcohol (either 3.0, 4.0 or 4.5 g/kg twice a day), with an isocaloric control solution (sucrose or maltose-dextrin), or served as unintubated controls. For the LS offspring, there was significant, dose-dependent reduction of brain and body size in adults prenatally exposed to alcohol. For the SS offspring, prenatal alcohol exposure had no significant effects on adult brain and body size. Interestingly, the use of sugar solutions as controls resulted in significant reductions in brain size in the SS (but not LS) lines, compared to unintubated controls. The severity of fetal alcohol effects on the developing CNS may depend in part on genetically determined differences influencing sensitivity to alcohol of the adult CNS. 492.10

IN VITRO NEUROTOXICITY OF METHYL IODIDE AND METABOLITES: GLUTATHIONE ATTENUATION. C.J. Davenport, D.A. Neptun* and K.T. Morgan*. Experimental Pathology and Toxicology, CIIT, Research Triangle Park, NC 27709.

Following oral administration, methyl iodide (MeI;a human neurotoxin) is metabolized to S-methylglutathione and further hydrolyzed to S-methyl-cysteine, glutamate (GM) and glycine (Johnson, J. Biochem.,98:30,1966). The purpose of the present work was to determine whether MeI neurotoxicity could be induced in vitro by the parent compound or selected metabolites, and whether addition of glutathione inhibited neurotoxicity. Mature (15-21 days in vitro) dissociated murine (CD-1 strain) neocortical cultures were exposed to a range of MeI concentrations (0.1-100mM) for 5 min or 1 day; cytotoxicity was assayed 24-36 hr later. Cell death was dependent upon exposure concentration and duration, with a neuronal ED50 of 5mM and <1mM MeI for 5 min and 24 hr exposures, respectively. Although GM was the only metabolic product to induce neuronal injury, MeI toxicity was not believed to be GM-mediated since: (a) The neuronal ED50 for a 5 min exposure to GM is 50-100μM (Choi et al., J. Neurosci.,7:357,1987), (b) The glutamate antagonist DL-2-amino-5-phosphonovaleric acid did not protect against MeI induced injury and (c) Cytotoxicity to MeI but not to GM was reduced by simultaneous addition of reduced glutathione. These results indicate that MeI neurotoxicity probably results from interaction of the parent compound (or unknown metabolites) with protein sulfhydryl groups in brain tissue.

492.11

TYPE II BUT NOT TYPE I PYRETHROIDS ALTER AMYGDALOID KINDLING IN THE RAT. ME Gilbert, CM Mack*, S Acheson*. Northrop Environmental Sciences, RTP, NC 27709.

Type I and Type II pyrethroids both increase sodium channel conductance; Type I's (e.g. cismethrin, CSM) leading to enhanced nerve excitability and repetitive firing, Type IIs (e.g. deltamethrin, DLT) producing nerve inexcitability via a depolarization block. Type II pyrethroids have also been reported to decrease inhibition by antagonism of GABA function. The functional impact of pyrethroids on the CNS may depend on the relative contribution of these contrasting actions. Electrical kindling of the amygdala in rats was assessed in an attempt to dissociate the net effect of these mixed actions. CSM (15 mg/kg, po) or DLT (6 and 10 mg/kg, po) were administered 2 hours prior to daily kindling stimulation (60 Hz, 1-s train biphasic squarewaves at 200 μa) and the rate of development of generalized seizures was compared with controls receiving the corn oil vehicle. DLT (10 mg/kg) facilitated the development of kindled seizures. Additionally, in the absence of stimulation, 3 of 14 animals were observed to experience spontaneous seizures following the 3rd-5th administration of DLT. Subjects treated with CSM did not differ from controls. These data stand in contrast to a previous report in which both Type I and II pyrethroids decreased CD-50 for PTZ (Devaud et al, 1986). DLT may enhance amygdaloid kindling through an antagonism of GABA-mediated inhibition.

492.12

SUPEROXIDE DISMUTASE ACTIVITY IN BRAIN BY STEADY-STATE KINETIC ANALYSIS. Jayasimha Narayanamurthy* & S.P. Mahadik, Div. Neuroscience, NYS Psychiatric Inst., Depts. of Psychiatry, and Biochemistry & Molecular Biophysics, Physicians & Surgeons, Columbia U., New York.

Superoxide dismutase (SOD) levels in CNS are critical in protecting neural function from free radical toxicity after CNS injury (mechanical, ischemic, neurotoxic or metabolic). SOD is often assayed by procedures which involve enzymatic or non-enzymatic generation of superoxide radicals (O_2^-) and their interaction with the suitable detector. We report a procedure in which non-enzymatic generation of steady-state levels of O_2^- is achieved by the interaction of phenazine methosulfate (PMS) with NADH generated by the alcohol dehydrogenase system. The O_2^- generation was monitored (540nm) as nitroblue formazan formation. The reaction was linear over 5min and showed a stoichiometric relationship with NADH production, O_2^- generation and NBT reduction. Under these conditions saturation level of O_2^- was maintained with 1-6U of SOD (bovine erythrocyte) and used for calculation. This rapid & reproducible method determines 0.1U of SOD (2mg wet wt of tissue) using a linear rate of reaction. SOD was determined in extracts (0.1M PO4 buffer, pH 7.8) obtained from different anatomical regions of rat brain. The levels correlated with the regional catecholamine turnover consistent with the possible free radical formation during neuronal activity.

TIME COURSE OF QUINOLINIC ACID-INDUCED NADPH-DIAPHORASE-CONTAINING NEURON CELL DEATH IN RAT STRIATUM. C.M. Wray* and R.J. Boegman (SPON: C. Romero-Sierra). Department of Pharmacology and Toxicology, Queen's University, Kingston, Ontario, Canada, K7L 3N6.

Previous studies have shown that intrastriatal injections of excitotoxins destroy NADPH-diaphorase-containing neurons. We sought to establish the time course and dose-response relationship of neuronal cell death following intrastriatal injections of quinolinic acid (QUIN). Diaphorase-positive neurons appeared swollen and sometimes showed markedly varicosed dendrites three and six hours after an intrastriatal injection (QUIN, 120 nmol/μl). At nine hours, a few swollen cells without dendrites were observed, and by 12 hours post injection, a full lesion had developed with no diaphorase-positive neurons in the core injection area. A dose-response relationship was established by injecting different doses of QUIN into the striatum and determining the number of diaphorase-positive neurons. Injections of 2.5 nmol/μl resulted in a diaphorase cell survival rate of 78.6%, while with 7.5 nmol/μl only 13% remained diaphorase-positive. Our results clearly indicate that in the core injection area which most closely represents the area of the striatum exposed to the injected dose of excitotoxin, NADPH-diaphorase-containing neurons are very sensitive to the neurotoxic action of QUIN.

QUINOLINIC ACID STRIATAL LESIONS DIFFERENTIALLY AFFECT MALE AND FEMALE RATS. E.M. Zubrycki, A.B. Norman, M.T. Shipley, and P.R. Sanberg. Laboratory of Behavioral Neuroscience, Depts. of Psychiatry, Psychololgy, Physiology, Anatomy, and Neurosurgery, University of Cincinnati College of Medicine, Cincinnati, OH 45267.

Excitotoxic lesions of the striatum in male rats result in temporary marked weight loss resembling the lateral hypothalamic syndrome (1). Conversely, it was reported that striatal kainic acid lesions in female rats led to increases in weight and consummatory behavior and further, that decreases in dopamine density were predictive of the resulting weight gain (2). The present study utilized the excitotoxin, quinolinic acid, to lesion the intrinsic neurons of the striatum of male, female, and ovariectomized rats.

Sprague-Dawley rats (n=41) received bilateral injections of 150 nml quinolinic acid or vehicle (1 ul). Body weights were monitored daily and tabulated as percent of original weight. It was found that male rats suffered more dramatic and extended weight losses as compared to females. Although females recovered more rapidly, they did not demonstrate increased weight gain as compared to controls. Ovariectomized rats showed a pattern of weight loss that was a compromise between male and female, but did not differ from either group. Weight gain observed in control groups did not significantly differ.

These results confirm a differential response to excitotoxin lesions between sexes.

POSSIBLE MECHANISM FOR NEUROTOXICITY OF FLUOROACETATE AND FLUOROCITRATE. C. S. Hornfeldt, A. A. Larson. Department of Veterinary Biology, University of Minnesota, St. Paul, MN, 55108.

The mechanism by which fluoroacetate (FA) and fluorocitrate (FC) exert their neurotoxic effects is unknown. It is known that FA is metabolized to FC, a Krebs Cycle inhibitor which causes the accumulation of citrate. Chelation of calcium by accumulated citrate in FA-poisoned animals has been proposed to be responsible for some of the peripheral effects of FA toxicity. To examine the effects of FA and FC in the CNS, and determine whether chelation of calcium is responsible for the convulsant effects of FA, we injected FC intrathecally (IT) in mice. Seizures occurred almost immediately after either FA or FC at the upper end of the dose-response curve. Intracerebroventricular injection of FC also produced seizures but required higher doses and occurred only after a latent period of greater than 40 min. This confirms previous work in the cat and rat suggesting that the spinal cord is the site of action of FA- and FC-induced seizures. While it has been previously demonstrated that cat spinal cord is 300-400 times more sensitive to FC than FA, we found FC to be 2500 times more toxic than FA when injected IT in mice. To determine whether chelation of cations is capable of producing similar actions to those observed after FA and FC, we injected mice IT with citrate, EGTA and EDTA. Each agent produced behavioral effects similar to those seen after FA and FC, both in onset and in molar potency. Coadministration of IT calcium or magnesium with FC or EDTA delayed the onset of seizures after FC and increased the dose of EDTA required to elicit seizures. These results suggest that these agents exert their CNS toxicity by decreasing the concentration of ionized cations in the spinal area. (Supported by Grants DA04090, DA00124 and DA04190)

DEPTH OF CHLORAL HYDRATE ANESTHESIA AS A FUNCTION OF PIGMENTATION AND STRAIN DIFFERENCES IN RATS. D.F. Sisson* and J. Siegel. School of Life and Health Sciences, Univ. Delaware, Newark, DE 19716 and I.S. Westenberg. Glendale College, Glendale, AZ 85302.

In a previous study we used EEG power spectrum analysis as an indicator of depth of chloral hydrate anesthesia and as a predictor of changes of visual evoked potentials (VEPs) in Wistar (W) albino rats. We are now concerned with the generalizability of our findings. The current report investigates differences in power spectra, depth of anesthesia and VEPs as a function of albinism vs. pigmentation and strain differences. Five Long-Evans (LE) rats, 3 pigmented and 2 albino, were compared to each other and to 12 albino W rats. Using EEG power spectral analysis as an indicator of anesthetic depth, it was found that W albino rats are much more sensitive to chloral hydrate anesthetic: 30-40 mg i.v. produced a deep level of anesthesia for 30 min and a moderate level for about 30 min more. In contrast, all LE rats were less sensitive to chloral hydrate: both pigmented and albino rats went deep for only 5-10 min with a 40-90 mg i.v. dose and the subsequent moderate state lasted only 20-25 min. VEPs in both strains were about the same. We conclude that strain difference (W vs. LE) is important in determining sensitivity to chloral hydrate anesthesia and albinism vs. pigmentation is not relevant. This work was supported in part by ARO Contracts DAAG 2980K0015 and DAAL 0388K0043.

EARLY ACTIVITY DECREMENTS IN GROUPED AND ISOLATED MICE AFTER EXPOSURE TO IONIZING RADIATION. H.D. Davis*, D.M. Maier*, and M.R. Landauer* (SPON: B.M. Rabin). Behavioral Sciences Department, Armed Forces Radiobiology Research Institute, Bethesda, MD 20814-5145.

The effect of gamma photon irradiation on locomotor activity was examined in male Swiss-Webster mice that had been pre-housed individually or in groups of 10 for 4 wk prior to radiation exposure. Mice in each pre-housing condition received 10 Gy cobalt-60 radiation (1 Gy/min) or a sham irradiation procedure, forming 4 groups (isolated-sham, grouped-sham, isolated-irradiated, and grouped-irradiated) (N=12/group). Locomotor activity (ambulation, rearing) was monitored individually for 12 hr postirradiation (PR). Radiation produced significant activity decrements from 45 min to 8 hr PR in both grouped and isolated animals. At 4-6 hr PR, activity in the irradiated groups was only 25% of sham irradiated groups (the largest decrement observed). The percent decrease in the activity of irradiated animals (compared to control groups) was similar in both grouped and isolated mice, however, the absolute amount of the activity decrement produced by radiation was smaller in grouped mice than isolated mice due to the lower activity of the grouped control subjects (40-60% of isolated controls 2-7 hr PR).

ALZHEIMER'S DISEASE: TRANSMITTERS

493.1

CEREBRAL CORTICAL CHOLINERGIC REDUCTION IN DOMINANTLY-INHERITED OLIVOPONTOCEREBELLAR ATROPHY (OPCA): IMPLICATIONS FOR THE CHOLINERGIC HYPOTHESIS OF DEMENTIA. S.Kish*, Y.Robitaille*, M.Freedman*, M.El-Awar*, L.Schut*, L.Chang*, and M.Rebbetoy*. (SPON: R. Harrison). Human Brain Lab, Clarke Inst. Psychiat., Toronto, Ontario, Canada M5T 1R8.

Much circumstantial evidence suggests that a brain cholinergic reduction may underlie the dementia of Alzheimer's disease (AD). We measured the behaviour of the cholinergic marker enzyme cholineacetyltransferase (ChAT) throughout the brain of four patients from one OPCA family. ChAT activities were markedly reduced (-50 to -80%) in all (n=27) examined cerebral cortical subdivisions. However, in contrast with observations in AD brain, ChAT levels in amygdala and hippocampus were generally normal or only mildly reduced. Neuropathological analysis revealed a severe loss (-70%) of cholinergic cell bodies throughout the nucleus basalis but with an absence of senile plaques and tangles. Since our OPCA patients had only mild cognitive impairment we conclude that a severe cortical cholinergic loss alone is not sufficient to produce the cognitive deterioration of advanced AD. OPCA may represent a non-AD patient group having a distinctly different pattern of brain cholinergic disturbance which may be useful for studies of behavioural consequences of a more selective cholinergic lesion. (Sup. by MRC of Canada).

493.2

REDUCTION IN SOMATOSTATIN AND CHOLINE ACETYLTRANSFERASE IN RAT BRAIN FOLLOWING QUINOLINIC ACID ADMINISTRATION INTO THE LATERAL VENTRICLE K. Maeda, S. Kuo*, H. Kaneda*, T.N. Chase, C.A. Tamminga NINCDS, NIH, Bethesda, MD 20892, Maryland Psychiatric Research Center, University of Maryland, Balto., MD 21228

Recent evidence suggests that certain neurodegenerative diseases like Alzheimer's disease (AD) may be mediated by the neurotoxic action of excitatory amino acids (EAA). In the present study, we have examined the effect of QA administration in rats into the lateral ventricle on SRIF contents and CAT activities. Daily injections of 10 ug QA for 7 days and a continuous infusion of 80 ug in 14 days were the two administration techniques compared. The repeated manual injection of QA for 7 days did not alter either SRIF content or CAT activity in brain. The QA infusion, however, resulted in a significant reduction in CAT activity in the R hippocampus (0.187 $\pm$ 0.020 nmol/min/mg tissues vs 0.301 $\pm$ 0.038, $p<0.05$) and the R striatum (0.955 $\pm$ 0.072 vs 1.238 $\pm$ 0.074, $p<0.05$), compared to the controls. A reduction in SRIF content was obtained in the R anterior cortex (0.391 $\pm$ 0.060 pg/ug prot vs 0.636 $\pm$ 0.070, $p<0.05$) and the R striatum (0.270 $\pm$ 0.030 vs 0.548 $\pm$ 0.050, $p<0.05$). We also observed a reduction in the SRIF content in the right hippocampus, although the difference was not statistically significant ($p<0.06$). SRIF content in the tissues from the left side (non-cannulated) were not significantly affected by the administration of QA. These data suggest that a heuristic animal model of AD could be developed by the technique of continuous QA infusion into the ventricular system.

ALZHEIMER'S DISEASE: SELECTIVE LOSS OF M1 RECEPTORS IN HIPPOCAMPUS AND INCREASES IN M1 AND M2 RECEPTORS IN STRIATUM AND NUCLEUS BASALIS

N. Lexow*, S. Rosenzweig*, A. Winokur and J. N. Joyce, Departments of Psychiatry and Pharmacology, University Pennsylvania School of Medicine, Philadelphia, PA

We have employed quantitative autoradiography to examine the pre- and postsynaptic elements of the muscarinic cholinergic system in several regions of postmortem brain tissue from 4 Alzheimer's cases and age-matched controls. The density of M1 receptors ([^{3}H]pirenzepine) was decreased in hippocampus (35%), whereas the density of M2 receptors ([^{3}H]N-methylscopolamine with excess pirenzepine) was not changed. No changes in the density of either subtype were apparent in cortical regions. In striatum both M1 (>100%) and M2 (66%) receptors were significantly increased in density as compared to controls. Patches of very dense binding of M1 and M2 receptors were observed within the nucleus basalis of Meyert in the Alzheimer's cases. The density of choline uptake sites ([3H]hemicholinium-3) was decreased in both hippocampus and striatum, suggesting that a cholinergic deficits in Alzheimer's disease are not restricted to the cholinergic system of the hippocampus. Analysis of dopaminergic and serotoninergic systems is currently being pursued.

CHANGES IN NICOTINIC RECEPTORS IN HUMAN AND RAT CNS. E. Giacobini, P. DeSarno,* B. Clark, M. McIlhany. Southern Illinois Univ. Sch. Med., Dept. Pharm., Springfield, IL 62794-9230.

Among the severe deficits seen in the cholinergic system in Alzheimer's disease (AD), a significant decrease in high affinity nicotinic binding sites has been observed. The effect of cholinominetic therapy with cholinesterase inhibitors or cholinergic agonists may be influenced by presynaptic nicotinic receptor function and acetylcholine (ACh) release. We have examined the effect of long- lasting intracerebroventricular (i.c.v) administration of physostigmine (4 ug, twice daily under 13 days) on ^{3}H-ACh release, nicotinic receptor binding and AChE in various brain regions (cortex, striatum and hippocampus) of the rat. We have also compared nicotinic receptor binding in both bioptic and autoptic samples of human frontal cortex of AD patients and controls. Biochemical findings have been correlated to clinical and pathological diagnoses. Nicotinic receptors were characterized by means of three ligands (nicotine, alpha-bungarotoxin and K-bungarotoxin). Comparable decreases in nicotinic binding were observed in both autoptic and bioptic tissue which were closely correlated to clinical and pathological findings. Our studies suggest that frontal cortex biopsy may constitute a useful complement to clinical and pathological examinations in AD. (Supported in part by National Institute of Aging AG05416).

ALTERATIONS IN NERVE GROWTH FACTOR RECEPTOR IMMUNOREACTIVE PROFILES IN THE BASAL FOREBRAIN OF ALZHEIMER'S AND PARKINSON'S PATIENTS. E.J. Mufson[1], D.M. Gash[2], M.A. Bothwell[3], L.B. Hersh[4] and J.H. Kordower[2]. [1]Institute For Biogerontology Research, Sun City, AZ 85351, [2]Dept. of Neurobiol. and Anatomy, Univ. Rochester Sch. Med., Rochester, N.Y. 14642, [3]Dept. Psysiol. & Biophysics, Univ. Washington, [4]Dept. Biochem. Univ. Texas Health Sci. Ctr.

Previous studies of basal forebrain (Ch1-Ch4) neuronal dysfunction in Alzheimer's (AD) and Parkinson's (PD) disease have been performed using Nissl or acetylcholinesterase stains. In the present investigation pathology associated with basal forebrain neurons expressing nerve growth factor receptor (NGFR) was evaluated using a monoclonal antibody directed against human NGFR. Brain slabs were obtained from seven AD (68-78 yrs), one demented PD (74 yrs), one non-demented PD (88 yrs) and four neurologically normal (68-78 yrs) cases. Tissue was fixed for 24 hr in 4% paraformaldehyde and processed immunohistochemically for the localization of NGFR singly or dually for choline acetyltransferase (ChAT). AD and PD was confirmed postmortem using Thioflavin-S and Bielschowsky methods or by the demonstration of cell loss and Lewy bodies in the substantia nigra using H&E. Aged control brains revealed a continuum of NGFR immunoreactive neurons extending throughout the basal forebrain (Ch1-Ch4) with an average of 190,000 positive perikarya per hemisphere. NGFR neurons ranged in shape from small oval cells located within the medial septum (Ch1) to multipolar magnocellular perikarya within Ch4. In AD, subsectors of the basal forebrain exhibited neuronal loss, shrinkage, dystrophic fibers as well as normal appearing NGFR neurons. Cell counts revealed the greatest reduction in NGFR positive neurons (48-83%) primarily within Ch4 as compared to Ch2. There was no consistent pattern to the cell loss observed in AD. Within the Ch subfields NGFR and ChAT colocalized indicating that the NGF receptor does not deccuple from cholinergic neurons in AD. NGFR and ChAT stained basal forebrain sections counterstained with Thioflavin-S revealed numerous ghost NFTs as well as positive tangle bearing neurons. In AD, there was a striking reduction in NGFR immunoreactive fibers within the external capsule enroute to cortex. In PD cases, there was a severe loss of nucleus basalis NGFR positive neurons primarily in Ch4p in the non-demented and no loss in the demented patient. There were virtually no neuritic plaques in any cortical region in the PD cases. These findings indicate that NGFR positive basal forebrain cells are severely affected in AD and also in PD.

NERVE GROWTH FACTOR RECEPTOR IMMUNOREACTIVITY IN THE HUMAN AND MONKEY BRAIN: DISTRIBUTION AND COLOCALIZATION WITH CHOLINERGIC ENZYMES. J.H. Kordower[1], D.M. Gash[1], M.A. Bothwell[2], L.B. Hersh[3], and E.J. Mufson[4]. [1]Dept. of Neurobiology and Anatomy, Univ. Rochester Sch. Med., Rochester N.Y. 14642, [2]Dept. Psysiol & Biophysics, Univ. Washington, [3]Dept. Biochem., Univ. Texas Health Sci. Ctr., [4]Institute For Biogerontology Research, Sun City, AZ 85351.

Brains from four normal aged humans (68-78 yrs) and six Cebus apella monkeys (3-13 yrs) were fixed with 4% paraformaldehyde and processed for the localization of nerve growth factor receptor (NGFR), either alone or in combination with choline acetyltransferase (ChAT), and acetylcholinesterase (AChE) via immuno-histochemical and immunofluorescence procedures. In both species, NGFR containing neurons were found almost exclusively within the basal forebrain (Ch1-4). In the monkey, occasional NGFR positive neurons were also observed in the putamen. Far fewer NGFR immunoreactive neurons were observed within the medial septum (Ch1) of the human, as compared to the monkey. In both species, NGFR positive neurons were seen within the vertical limb of the diagonal band (Ch2) and a few small fusiform NGFR-immunoreactive neurons corresponding to the horizontal limb of the diagonal band (Ch3) were observed near the base of the brain. NGFR-immunoreactive magnocellular and parvicellar neurons were observed throughout the nucleus basalis (Ch4) including the anteromedial, anterolateral, intermediodorsal, intermedioventral and posterior subdivisions. NGFR fibers from these neurons coursed within the external capsule and temporal limb of the anterior commissure to reach the cortex and amygdala. Scattered NGFR positive fibers were also seen in the putamen. While many NGFR containing neurons were observed within the medullary laminae of the globus pallidus and within the internal capsule in monkey, far fewer were seen in these regions in human brain. In both monkey and human, numerous NGFR containing neurons were observed within the bed nucleus of the stria terminalis and a few were seen lodged within the NGFR fibers of the dorsal columns of the fornix. In all of these regions, NGFR colocalized with ChAT or AChE (<95%) in both species. Except for NGFR immunoreactive neurons within the monkey mesencephalic nucleus of the trigeminal nerve, NGFR-immunoreactivity was not observed in other brain regions including Ch5 and Ch6. These findings demonstrate that the NFG receptor is an excellent marker for cholinergic basal forebrain neurons in primates making it a valuable tool for assessing the integrity of the primate basal forebrain in age, disease, or experimental manipulation.

NEUROPLASTIC POTENTIAL OF CHOLINERGIC NEURONS THAT PROJECT TO THE BASOLATERAL AMYGDALA. G.R. Stewart, M.E.Mueller*, M.T. Price and J.W. Olney. Dept. of Psychiatry, Washington University Sch. of Med., St. Louis, MO 63110.

Degeneration of the basal forebrain cholinergic (BFC) system in Alzheimer's disease (AD) does not appear to entail any recovery either because this system lacks such potential, or the disease process overcomes this potential. Here we have studied the rat basolateral amygdala (BLA) to determine whether cholinergic reinnervation occurs in this nucleus after excitotoxic destruction of BFC neurons that project to it. Adult male rats received unilateral injections of the excitotoxin N-methyl-aspartic acid (50 nmol in 0.4 µl) into the ventral pallidum. Following survival times of 10, 30, 60, 120 or 240 days, animals were either decapitated and their brains frozen for biochemical measurements or were transcardially perfused with an aldehyde fixative and the brains sectioned (50 µm, coronal) on a Microslicer and stained for acetylcholinesterase-histochemistry (AchE-HC). Lesions were well confined to a portion of the ventral pallidum which, from retrograde tracer studies, is known to contain most of the BFC neurons that project to the BLA. The status of cholinergic innervation of the BLA was evaluated by AchE and cholineacetyltransferase assay in microdissected samples of BLA and by AchE-HC videodensitometry which we have found to be a reliable method for monitoring cholinergic innervation of BLA. At 10 days post-lesion, there was a 50% loss of staining/enzyme activity (ipsi versus contralateral BLA compared) which persisted through the 30 and 60 day interval then diminished to 42 and 35% loss at 120 and 240 days respectively. Thus, at 4 and 8 months post-lesion there was evidence for gradual cholinergic reinnervation of BLA . Therefore, this system may have some reinnervation potential, but in the context of AD it would probably be insufficient to compensate for the progressive loss of BFC neurons that occurs as a function of the disease process. GALANIN HYPERINNERVATES SURVIVING NEURONS OF THE HUMAN BASAL NUCLEUS OF MEYNERT IN DEMENTIAS OF ALZHEIMER'S AND PARKINSON'S DISEASE. V. Chan-Palay, The Neurology Clinic, University Hospital, CH-8091 Zürich, Switzerland.

The aim of this study is to find the similarities and differences in Galanin innervation of the cholinergic basal nucleus neurons in these dementing disorders as compared to the controls. Immunocytochemistry with antibodies against galanin peptide and against choline-acetyltransferase is applied on perfused brain preparations. Galanin peptide is present in the basal nucleus of Meynert neuron networks in the normal human brain; in local circuit neurons and a number of galanin/cholinergic neurons. In SDAT, there is a loss of cholinergic neurons. Galanin networks demonstrate an inverse relationship to the cholinergic cell loss. Galanin axons hypertrophy and hyperinnervate the remaining cholinergic neurons. In Parkinson's disease the loss of cholinergic neurons accentuated in dementia and the hypertrophy of the galanin axonal networks on cholinergic neurons is dramatic in Parkinson's with dementia and exuberant in the atypical cases of dementia non-responsive to L-Dopa. These findings suggest that the present therapy of cholinergic enhancement as a means to retard intellectual deterioration can have little effect. The activity of galanin peptide needs to be reduced, e.g. by galanin peptide antagonists or small organic molecules that interact with the galanin receptors.

EVIDENCE FOR TRANS-SYNAPTIC DEGENERATION OF CHOLINERGIC AFFERENTS TO THE LOCUS CERULEUS IN ALZHEIMER'S BRAIN. R. Strong,* J.S. Huang,* S.S. Huang,* H.D. Chung,* C. Hale,* M.A. Moore* and W.J. Burke* (SPON: F.A. Mithen). Ger. Res. Ed. and Clin. Ctr., VA Med. Ctr.; St. Louis Univ. Sch. of Med., St. Louis, MO 63125.

Increasing evidence suggests that much of the subcortical pathology of Alzheimer's disease (AD) may be due to trans-synaptic retrograde degeneration of neurons projecting to affected cortical areas. The same may be true of neurons projecting to affected subcortical nuclei. We measured neuron density in the locus ceruleus (LC) of autopsied brains of neurologically normal individuals and AD patients. Neuron density in the LC of AD cases was significantly reduced to approximately 50%. We assayed choline acetyltransferase (ChAT) activity as a marker of cholinergic LC afferents. ChAT activity was reduced by about 50% in AD cases. Significantly, the loss of LC neurons was highly correlated with loss of presynaptic ChAT activity. We measured the effect of LC extracts on mitogen activity in 3T3 cells as a nonspecific measure of trophic factors. Mitogen activity was significantly reduced (50%) in the AD group. Mitogen activity was significantly correlated with ChAT activity and the density of neurons in the LC in all cases. These data are consistent with the hypothesis that trans-synaptic retrograde degeneration of cholinergic projections to the LC occurs in AD.

TETRAHYDROBIOPTERIN AND BIOGENIC AMINE METABOLISM IN ALZHEIMER'S AND OTHER NEUROPSYCHIATRIC DISEASES. R.A. Levine, P.A. LeWitt*[1], N. Pamara*, D. Gurevich*, and M. Stanley, Lafayette Clinic and Wayne State Univ. Sch. of Med., Detroit, MI 48207, and [1]Sinai Hospital of Detroit, Detroit, MI.

Tetrahydrobiopterin (BH_4), as cofactor for phenylalanine, tyrosine, and tryptophan hydroxylases, plays an important role in regulating the synthesis of dopamine and serotonin in the central nervous system, and altered BH_4 metabolism has been associated with certain neurological disorders. In BH_4 biosynthesis, GTP cyclohydrolase (CH) converts GTP to dihydroneopterin triphosphate (NH_2TP); NH_2TP is converted to 6-pyruvoyl-tetrahydropterin (6-PPH_4) by 6-PPH_4 synthase; 6-PPH_4 is converted by one or two enzymes to BH_4, the last enzyme being sepiapterin reductase (SR). NH_2 and neopterin appear only in primate fluids due to intracellular dephosphorylation of NH_2TP.

We have measured the content of BH_4 and neopterin in CSF from a variety of neuropsychiatric patients. In Alzheimer's disease, BH_4 content was decreased by 40%, suggesting that altered BH_4 metabolism may be involved in Alzheimer's disease. CSF neopterin levels were unchanged. BH_4 was well correlated with both homovanillic acid (HVA) and 5-hydroxyindoleacetic acid (5-HIAA) in CSF, which supports the importance of BH_4 as a regulator of biogenic amine synthesis. Studies are underway to measure certain markers of BH_4 metabolism in various areas of Alzheimer brain tissue.

493.11

CORTICAL β-ADRENERGIC BINDING SITES INCREASE IN ALZHEIMER'S DISEASE. P.J. Whitehouse, M. Tabaton*, R.N. Kalaria and J.R. Unnerstall. Departments of Neurology and Pathology, Case Western Reserve University Sch/Med, Cleveland, OH 44106.

In a sample of six Alzheimer Disease (AD) cases and six age-matched controls, we have determined the extent of neuronal pathology in the locus coeruleus (LC) and compared differences between diseased and control tissues with regard to pathology and changes in β-adrenergic binding sites in the frontal cortex. In the AD cases, neuronal density in the LC was reduced by 30-50%. In the frontal cortex, a 20-30% decrease in neuronal density was observed. Using receptor autoradiographic techniques, we found significant increases in the density of cortical β-adrenergic binding sites in the AD cases. Using drugs that selectively mask either the β_1- or β_2-receptor subtypes, significant increases in the density of both β_1- and β_2-adrenergic receptors were seen. The increase in β_1 binding was localized to the deeper cortical lamina, while the increases in β_2 binding were more generally observed throughout the cortex. In a larger sample, these findings were confirmed by homogenate binding. Since these increases in β-adrenergic binding were seen in both homogenate and autoradiographic experiments, and changes in receptor subtype were regionally selective, these changes indicate that the cortex can still exhibit a plastic response to noradrenergic denervation in AD.

LOCUS COERULEUS CELL LOSS IN ALZHEIMER'S AND PARKINSON'S DISEASE: PATTERN ANALYSIS. K.F. Manaye, W.K. Smith, E. Weidmer-Mikhail*, C.L. White*, D.J. Woodward and D.C. German. Depts. of Psychiat., Physiol., Cell Biol. and Pathol., UT Southwestern Med. Cntr., Dallas, TX 75235.

Several studies indicate that there is extensive loss of locus coeruleus (LC) cells in Alzheimer's (AD) and Parkinson's disease (PD). We wished to test the hypothesis that the pattern of cell loss is different in the two disease conditions. Using computer imaging techniques and neuromelanin as the cell marker, we examined the bilateral distribution of cells in 5 PD, 5 AD and 4 normal brains (mean ages of 69, 76 and 67, respectively). Cell locations from 16 sections, 0.8 mm apart, were entered into a computer. There was a greater total loss of LC cells in PD (64%) than in AD (52%). The rostral-caudal distribution of cell numbers differed in the AD and PD brains with the greatest disparity occurring in the middle to caudal third of the LC. There was no right-left asymmetry in LC cell number in the normals or either disease condition. The 3-dimensional pattern of cell loss will be analyzed further for both diseases. NORADRENALINE IN POST-MORTEM BRAIN IN DOWN'S SYNDROME AND ALZHEIMER'S DISEASE. H.Karlinsky,* S.Kish,* Y.Robitaille,* L.Becker,* J.Gilbert,* K.Shannak,* O.Hornykiewicz. (SPON: P.Li). Clarke Institute of Psychiatry, 250 College Street, Toronto, Ontario, Canada M5T 1R8.

We measured the concentration of the neurotransmitter noradrenaline(NE) in autopsied brain of ten infant children(aged 3 months to 12 years) and four adults(aged 22 to 59 years) with Down's Syndrome(DS). This study was prompted by evidence demonstrating 1) markedly increased risk for the early development in DS of the brain neuropathological and clinical changes of Alzheimer's disease (AD) and 2) reduced levels of NE in AD cerebral cortex and hypothalamus. Brain histological analyses revealed the typical changes of AD(plaques,neurofibrillary tangles) in the three oldest DS individuals(43,55 and 59 years). When compared with age-matched controls, NE levels were markedly reduced(-50 to -80%)in the cerebral cortex of the three oldest DS cases. The magnitude of this reduction was similar to that observed in AD brain. Mean NE levels in young DS cerebral and cerebellar cortex,limbic brain and basal ganglia (aged 3 months to 12 years) were not significantly different from age-matched controls. Our biochemical data suggests that DS individuals do not begin life with an AD-type brain NE reduction, but that such changes are age-dependent.

CYTOPATHOLOGY OF PEPTIDERGIC NEURONS IN ALZHEIMER'S DISEASE AMYGDALA. P.B. Cipolloni B.J. Quigley Jr.*, and N.W. Kowall. Dept. Anatomy, Boston Univ., ENR Memorial VA Hosp., Bedford MA 01730 and Neurology Service, Mass.General Hospital, Boston MA 02114.

The amygdala often has the highest density of Senile plaques (SP) in Alzheimer's disease (AD) brain but the relationship of SP distribution to defined neurons in the amygdala is not well understood. We used immunoperoxidase methods to examine somatostatin (SS), neuropeptide Y (NPY), cholecystokinin (CCK), and substance P neurons in the amygdala of 6 AD patients and 6 age-matched controls. SP were defined with Thioflavine S and the silver method of S.K. Campbell et al. (Soc Neurosci Abs 13:678). SP are distributed in all nuclei of the amygdala without a clear mediolateral gradient. The ventral region and paralaminar nucleus are relatively spared. SS and NPY neurons are present in the dorsal part of the lateral (L), accessory basal (AB), and lateral central (Cl) nucleus and the periamygdaloid cortex (PAC). Morphologically these neurons are aspiny stellate cells (Class II). In AD perikaryal density is not visibly altered but fiber density is reduced and neurites in SP are seen with much greater frequency in the cortical and superficial AB nucleus. CCK neurons are found in substantial numbers in the AB and PAC where they contribute heavily to SP formation. Substance P neurons are present in AB, Cl, PAC and dorsal basal magnocellular nucleus where they infrequently contribute to SP. Despite the occurrence of SP throughout the amygdala only SP in medial regions contain peptidergic fibers. This differential incorporation of defined fibers into SP may reflect differences in the structure of SP in different regions of the amygdala.

[^{3}H]INOSITOL 1,4,5-TRISPHOSPHATE BINDING IN NORMAL AND ALZHEIMER DISEASED BRAIN. L.T. Young*, P.P. Li, S.J. Kish*, A.S. Chiu* and J.J. Warsh (SPON: Y. Israel). Clarke Institute of Psychiatry, Toronto, Ontario, CANADA M5T 1R8.

The phosphatidylinositide generated second messengers, especially inositol 1,4,5-trisphosphate (IP_3), are important in neuronal transmembrane signal transduction. IP_3 regulates brain calcium metabolism by binding to endoplasmic reticulum and plasma membrane to mobilize calcium stores. Binding sites for [^{3}H]IP_3 have recently been demonstrated in membranes prepared from rat brain which likely represent putative physiologically significant IP_3 receptors. In view of the importance of IP_3 in CNS calcium metabolism and neuronal function, it is of interest to examine [^{3}H]IP_3 binding sites in the normal and diseased human brain.

Membranes were prepared from autopsied cerebral cortices obtained from six subjects who were free from psychiatric or neurological disease. [^{3}H]IP_3 was found to bind with an affinity of 27 ± 8 nM (mean ± SEM); capacity (B_{max}) of 1.09 ± 0.18 pmol/mg protein and was reversible in the presence of an excess of unlabelled IP_3. This is the first demonstration of specific, saturable, and reversible binding of [^{3}H]IP_3 to membranes prepared from human brain. These [^{3}H]IP_3 binding sites are likely to be physiologically significant receptors. Data on brain regional distribution in subjects with Alzheimer's disease and age matched controls will also be presented.

Supported by the MRC, OMHF and OMH.

TETRAHYDROAMINOACRIDINE IS CONCENTRATED IN BRAIN FOLLOWING INTRAPERITONEAL ADMINISTRATION. D. Liston, L. Russo*, E.E. Mena and I. Williams*, Pfizer Central Research, Groton, CT 06340.

THA is a cholinesterase inhibitor that is currently undergoing clinical trials for use in Alzheimer's Disease. We have examined some properties of THA *in vitro* and *in vivo* to define the mechanism by which THA produces its therapeutic effects. *In vitro*, THA inhibits acetylcholinesterase (AChE) from rat brain and human erythrocytes with an IC50 of 220 nM. The kinetics of enzyme inhibition are best fitted by a model incorporating mixed competitive and non-competitive inhibition, with a K_{ii}=246 nM a K_{is}= 145 nM. THA is considerably more potent at inhibiting butyrylcholinesterase, with an IC50=9 nM. We examined the ability of THA to displace a number of ligands from rat brain membranes. Binding to cholinergic receptors was weak, with 50% displacement of ^{3}H-QNB (muscarinic) at 5.2 uM, ^{3}H-AFDX-116 (M2) at 1.7 uM, ^{3}H-telenzepine (M1) at 10 uM and ^{3}H-nicotine at >10 uM. THA displaces ^{3}H-prazosin (a_1 adrenergic) with an IC50 of 3.3 uM and ^{3}H-mepyramine (H1 histamine) with an IC50 of 5 uM. Monoamine oxidase from brain or liver was not significantly inhibited by THA below 100 uM. *In vivo*, THA exhibited an unusual distribution. Following 3.2 mg/kg i.p., a dose active in mouse passive avoidance, THA was 10-fold higher in brain than in plasma from 20-120 min, with the highest brain concentration (at 20 min) of 2.4 uM. At 120 min, brain THA was 0.34 uM, well above the IC50 for inhibition of AChE. A monohydroxylated metabolite of THA was observed in brain and plasma; this metabolite was a weak inhibitor of AChE. We conclude that the inhibition of brain AChE by THA is sufficient to explain its therapeutic action in Alzheimer's Disease.

493.17

THA INCREASES ACTION POTENTIAL DURATION OF CENTRAL HISTAMINE NEURONS IN VITRO. P.B. Reiner and E.G. McGeer. Kinsmen Laboratory, Dept. Psychiatry, Univ. of British Columbia, Vancouver, BC Canada V6T 1W5.

THA (9-amino-1,2,3,4-tetrahydroacridine) has been reported to produce marked clinical improvement in patients suffering from Alzheimer's disease (AD). THA has anticholinesterase activity and so might alleviate the well-documented deficit in cortical cholinergic innervation in AD. However, THA appears to be clinically more effective than other anti-cholinesterase agents, and thus other mechanisms might play a role in its therapeutic efficacy.

Intracellular recordings were obtained from histaminergic tuberomammillary neurons recorded in vitro. THA in concentrations as low as 1 μM increased the duration of the action potential, and this effect was not mimicked by physostigmine. The many similarities between hypothalamic histamine neurons and other central aminergic neurons suggest that THA may have similar effects upon these neurons as well. By its effect upon action potential duration, THA may increase release of amines upon the cortical targets of aminergic neurons which degenerate in AD. Thus, the therapeutic efficacy of THA may derive from a combination of its anticholinesterase activity and its effects upon the duration of action potentials of aminergic neurons.

493.18

ALTERATIONS IN RESPONSE TO ETHANOL BY TACRINE AND PHYSOSTIGMINE A. Rashtis*, S. Childres*, K. Tachiki*, C. Melchior, A. Steinberg*, & R. F. Ritzmann. Sepulveda & Brentwood VAMC, & Olive View/UCLA MC & CSU Northridge. LA, CA 91343.

Tacrine (THA), a less potent inhibitor of AChE than physostigmine (PHY), has been reported to be more effective in treating Alzheimer's disease. This suggests a pharmacokenetic difference or a different mechanism of action. Rats were injected with THA (3mg/kg) and 2 hrs later various brain regions were isolated and THA and amine levels were determined. In mice, THA and PHY (0.125mg/kg) were injected 1 hr prior to an injection of ethanol (3.2 g/kg, ETOH) and sleep time was measured. The results indicate that THA, depending on brain region, is present in concentrations 50 to 500 times lower than the reported IC50 level for inhibiting AChE. While PHY lowers the duration of ETOH-induced sleep time, THA significantly increased sleep time. This suggests that THA is acting by some other mechanism. Preliminary results indicate that THA produced alterations in brain amines and their metabolites in specific brain regions. 5-HT and dopamine increased, depending on the brain region, as much as 200%. Norepinepherine in cortex decreased by 17%. (Funded by Vet. Admin.)

INFLUENCE OF FRONTAL CORTEX LESION BY IBOTENIC ACID ON DISCRIMINATION AVOIDANCE LEARNING IN RATS. C. Hara, N. Ogawa and T. Naruo*. Dept. Pharmacol., Ehime Univ. Sch. of Med., Ehime-ken 791-02, Japan.

The memory dysfunction of alzheimer disease has been associated with a cortical cholinergic deficiency. In the rat, the ibotenic acid lesion of the nucleus basalis magnocelluralis (NBM) reduces choline-acetyltransferase activity in the dorsolateral frontal cortex (DFC), medial prefrontal cortex (MPC) and parieto-temporal cortex. The present study examined influence of ibotenic acid lesion of DFC, MPC or NBM on retention of discrimination avoidance learning (DAL). Male Wistar strain rats(8 weeks old) were housed in an air-conditioned room (23±1°C) with 12: 12 LD cycle (lights on at 0700) under free access to food and water. In the conditioning, two pure tones with 800 Hz for positive conditioned stimulus (CS) and 400 Hz for negative CS, and visa versa, were used in the two compartment shuttle box. Bilateral DFC and MPC, and unilateral NBM were lesioned by isotenic acid (5 μg/μl for 2 min) under pentobarbital anesthesia (45 mg/kg, i.p.). The retention of DAL was examined on 7, 10, 14 and 21 days after the surgery. The DFC lesion impaired the retention accompanied with increased negative response (NR) without affecting positive response(PR). The MPC lesion elicited the impairment of DAL with increased NR and decreased PR similar to NBM lesion. These results suggest that local dysfunction of cortex region related with NBM elicits impairment of learning behavior.

REGULATION OF SYNAPTIC EFFICACY IN THE HIPPOCAMPUS BY PHOSPHOETHANOLAMINE. G. Barrionuevo, J.E. Bradler*, D. McKeag* and J.W. Pettegrew*. Depts. of Behavioral Neuroscience & Psychiatry & WPIC, University of Pittsburgh, Pittsburgh, PA 15260.

The phosphomonoester phosphoethanolamine (PEA), a key intermediate in the biosynthesis of membrane phospholipids, is released spontaneously and in a stimulus (high K^+ or kainate) dependent manner from the in vivo hippocampus. In addition, ^{31}P NMR spectra demonstrated elevated levels of PEA in Alzheimer's diseased brains. To investigate the effects of PEA on synaptic efficacy, extracellular recordings were made from rat hippocampal slices (3 month old Fischer 344). The amplitude of population EPSPs evoked by stimulating the Schaffer collateral/commissural input to CA1 neurons was monitored prior to and during a 30 min bath application of varying concentrations of PEA. At both 1 mM and 5 mM, PEA induced a substantial depression of population EPSP amplitudes (45% +/- 21 % depression, n=8). This depression was only partially reversible following extended wash periods (87% +/- 21 % of baseline at 30 min, n=8). ^{31}P NMR spectra from freeze-clamped hippocampal slices revealed no effect of PEA on high-energy phosphate or membrane phospholipid metabolism. We are currently studying this regulation with intracellular recordings. Supported by R01-AG05657, AG-05133-01A1, and R01-MH4158 to J.W.P., and an RCDA (NS01196) to G.B.

REGIONAL GLUCOSE METABOLISM ALTERATIONS WITH INTRAVENTRICULAR QUINOLINIC ACID ADMINISTRATION

S. Kuo*, K. Maeda, H. Kaneda*, T.N. Chase, C.A. Tamminga
Experimental Therapeutics Branch, NINCDS, and MPRC, University of Maryland, Balto., MD, 21228

Neurodegenerative disorders may involve neurotoxic EAA transmitters like quinolinic acid (QA). In an attempt to develop an animal model of Alzheimer's disease, we have evaluated two different administration techniques, chronic intraventricular injection (7 days) and intraventricular infusion (14 days) in the rat, to test brain metabolic changes and its similarity to Alzheimer metabolism. QA was introduced into the right lateral ventricle using either daily injection of 10 ug QA via chronic intracerebroventricular cannula for 7 days, or continuous infusion of QA using osmotic minipump (Alzet 2002) for 14 days with a total delivery of 400 ug QA/rat. Local cerebral glucose utilization (LCGU) was measured in 55 different brain areas using the quantitative [^{14}C]-2-deoxyglucose (2DG) autoradiographic method (Sokoloff et al., 1977), as umol glucose/100 gm brain tissue/min. Statistical analysis was done with multivariate analysis of variance. No remarkable alterations in LCGU were noted in the daily QA injection animals. Animals with the 14 day QA infusion demonstrated LCGU in a number of cortical brain areas and increases in LCGU in selected sensory processing areas.

(N=4)	Saline	QA
Frontal Cortex	83.6 ± 5.1	65.6 ± 1.9*
Cingulate Cortex	96.9 ± 6.1	78.2 ± 2.7*

We will compare alterations in glucose metabolism in this rat model with metabolic alterations seen in Alzheimer patients.

493.22

[^{3}]MK-801 BINDING SITES IN ALZHEIMER'S DISEASE.

MM Mouradian, PC Contreras, JB Monahan, TN Chase. Experimental Therapeutics Branch, NINCDS, Bethesda, MD 20892 and Central Nervous Disease Research, Searle & Co., Chesterfield, MO 63198.

Excitatory amino acids and their receptors, particularly the NMDA/PCP complex, have been implicated in the pathogenesis of Alzheimer's disease. In an attempt to further study this receptor complex, postmortem brain tissue homogenates from 22 Alzheimer patients were compared to 21 age-matched controls for binding sites of [^{3}]MK-801, a noncompetative antagonist of PCP binding to the NMDA receptor associated ionophore. Seven brain regions were studied: Brodmann areas A-4, A-9, A-39, A-22, A-38, A-17, and hippocampus. Binding studies were performed with Tris buffer using filtration method. There were no consistent differences between patients and controls in either binding density or affinity constants in any of the areas studied. Hippocampal binding sites correlated positively with symptom duration (r=.963) and age at death (r=.619) in Alzheimer subjects. Loss of perforant pathway afferents to the hippocampus in Alzheimer's disease might result in denervation supersensitivity. Although lack of changes in binding densities of the NMDA/PCP complex in Alzheimer's disease in this study may be due to methodological discrepencies, since the use of homogenized tissue might mask changes limited to microscopic elements seen with autoradiography, nevertheless, these findings lend no support to the view that cortical NMDA receptor-bearing neurons are preferentially affected in this disorder. However, the possibility that the presence of these receptors is a necessary, but hardly sufficient, basis for cell death cannot be excluded.

LEARNING AND MEMORY: ANATOMY III

494.1

LEARNING AND MEMORY DEFICITS AFTER LESIONS OF NUCLEUS BASALIS IN TURTLES.

A. S. Powers, A. Blau*, & M. Petrillo*. Dept. of Psychology, St. John's University, Jamaica, NY 11439.

The basal forebrain of turtles contains a nucleus basalis, a group of cholinergic cells that project to the dorsal cortex. The dorsal cortex is a three-layered cortex on the surface of the telencephalon. We compared the effects of lesions of nucleus basalis and dorsal cortex on pattern discrimination acquisition and reversal and on retention of maze learning. Lesions of the dorsal cortex were made by suction; those in nucleus basalis were made by injections of ibotenic acid. Compared to sham-lesioned controls, both lesions produced an impairment on acquisition and reversal of a horizontal-vertical discrimination. There was no significant difference between the two lesioned groups on either acquisition or reversal. Maze retention was also impaired by both lesions, but there was a suggestion that the impairment was greater in the nucleus basalis group. These results suggest that the nucleus basalis of mammals is a phylogenetically ancient structure that participated in learning and memory in the reptilian ancestors of mammals.

494.2

MAGNETIC RESONANCE IMAGING OF THE RHESUS MONKEY BRAIN: I. STEREOTAXIC LOCALIZATION OF THE BASAL FOREBRAIN.

T.G. Aigner, R.C. Saunders, and J.A. Frank. Laboratory of Neuropsychology, NIMH and Department of Radiology, NIH, Bethesda, MD 20892.

Subcortical neurosurgery in nonhuman primates has traditionally used stereotaxic atlases, x-ray radiography, or electrophysiological recording to locate targeted structures. In an attempt to improve on these sometimes unreliable methods, we used magnetic resonance imaging (MRI) in combination with a specially designed nonmagnetic stereotaxic instrument (SI) to locate the nucleus basalis of Meynert and the medial septum/diagonal band nuclei. These basal forebrain nuclei were chosen to validate the MRI/SI method because their irregular shape makes them especially difficult targets as judged by results with other methods. Monkeys were anesthetized, positioned in the SI, and then scanned in a General Electric Signa 1.5 Tesla MRI unit. Stereotaxic coordinates were derived using standard software routines on the MRI unit. For surgery, each animal was re-positioned in the SI and ibotenic acid was then injected into 14 basal forebrain sites. The animal was re-scanned within 2 weeks to visualize the lesion. Histological analysis confirmed the precision of the technique; 35 out of 42 injections in 3 hemispheres were direct hits and 7 were within 0.5 mm of their intended targets. MRI/SI appears to provide a level of accuracy and reliability surpassing that obtained with earlier methods.

494.3

MAGNETIC RESONANCE IMAGING OF THE RHESUS MONKEY BRAIN: II. RECONSTRUCTION OF EXPERIMENTAL LESIONS.

R.C. Saunders, T.G. Aigner and J.A. Frank*. (SPON: M. Haenlein) Dept. Radiology, NIH and Laboratory of Neuropsychology, NIMH, Bethesda, MD 20892.

The importance of a neural region in a particular psychological function (e.g. memory) can be inferred after psychometric analysis is directly related to the underlying neuropathology. In monkeys, because of their high financial and training costs, this is often delayed until extensive investment in experimental testing is completed. We used magnetic resonance imaging (MRI) to determine the limits of experimental lesions in the rhesus monkey brain. MRI is uniquely suited for visualizing the brain in vivo due to its soft tissue contrast and the abilty to obtain images in three dimensions. Monkeys were appropriately anesthetized, positioned in a specially developed nonmagnetic stereotaxic instrument, and centered in a GE 1.5 Tesla MRI unit. Monkeys were scanned both pre- and post-operatively. The lesions were made by aspiration or by the excitatory neurotoxin ibotenic acid at subcortical and cortical sites. Histological analysis confirmed that both aspiration and neurotoxin lesions can be precisely delineated from MR images. This technique has the added advantages over classic histological assessment in that it allows the lesion to be visualized in any plane and it permits a non-invasive means for evidential histological analysis.

DIFFERENTIAL ANATOMICAL PROJECTIONS BETWEEN FRONTAL CORTICES AND THE BASAL FOREBRAIN IN THE RAT.

D.R. Beers*, R.P. Kesner (SPON: J.R. Baringer). Departments of Anatomy and Psychology, University of Utah, Salt Lake City, Utah 84112.

Neural connections of the rat's basal forebrain and frontal cortices were studied using the retrogradely transported fluorescent tracer bis-Benzimide combined with acetylcholinesterase (AChE) histochemistry. Bis-Benzimide injections in the nucleus basalis magnocellularis labeled neurons in the dorsolateral frontal cortex. In contrast, injections in the horizontal nucleus of the diagonal band labeled neurons in the medial prefrontal cortex. Conversely, when bis-Benzimide was injected in the medial prefrontal or dorsolateral frontal cortices, labeled neurons were seen in the horizontal nucleus of the diagonal band or the nucleus basalis magnocellularis, respectively. Identification of these basal forebrain areas was confirmed by the AChE stain. These results indicate that the basal forebrain of the rat receives reciprocal differential anatomical projections from frontal cortices and this suggests that these connections may mediate differential behavioral functions.

494.5

NUCLEUS BASALIS MAGNOCELLULARIS IS INVOLVED IN TASTE AVERSION LEARNING IN RATS. R. Tardif*, R.P. Kesner, & R.F. Berman. (SPON: S.W. Miller). Departments of Psychology, University of Utah, Salt Lake City, Utah 84112 and Wayne State University, Detroit, Michigan 48202.

It has been shown that the basolateral amygdala plays an important role in mediating taste aversion learning. Other studies suggest that the nucleus basalis magnocellularis (NBM) provides critical cholinergic input pathways to the basolateral amygdala.

Long-Evans rats received either ibotenic acid lesions of the NBM, vehicle control injections, electrolytic lesions of the basolateral amygdala, or served as nonoperated controls. Nonoperated controls, vehicle injected controls, and unilateral NBM lesioned animals all displayed taste aversion learning. Animals with bilateral lesions of the NBM or basolateral amygdala exhibited a disruption in taste aversion learning. Additional analysis of ChAT content in amygdala revealed that there was a significant negative correlation between the degree of disruption of taste aversion learning and levels of ChAT in amygdala. These data suggest that even though NBM lesions produce a taste aversion learning deficit that parallels impairments seen in animals with basolateral amygdala lesions, this deficit does not appear to be mediated by cholinergic projections to the amygdala. It is suggested that NBM lesions might have damaged other cholinergic systems or that some other neural transmitter projecting to amygdala might be involved.

494.6

BEHAVIORAL EFFECTS OF ELECTROLYTIC VERSUS IBOTENATE LESIONS OF NUCLEUS BASALIS IN RESPONSE TO GANGLIOSIDE TREATMENT. B.S. Bitran*, L. Lescaudron*, and D.G. Stein. (SPON: M. Wilson). Brain Research Lab., Clark University, Worcester, MA 01610.

Lesions of the nucleus basalis magnocellularis (NBM) deplete cortical acetylcholine levels and produce memory impairments in rats, while GM_1 ganglioside treatment stimulates the recovery of those levels after lesions of the NBM (Florian et al. *Neurosci. Lett.* 75: 313-316, 1987). In the present study, electrolytic but not ibotenate lesions of the NBM produced deficits in the Morris Water Maze; GM_1-treated rats were not significantly different from saline-treated rats on this task. Both electrolytic and ibotenate lesions impaired acquisition of a passive avoidance task; however, GM_1 treatment facilitated performance of ibotenate-lesioned rats only. Locomotor activity, measured in an open field, was not affected by NBM lesions or by GM_1 administration. Although the two lesion types did not differ in terms of the number of NBM cells destroyed, the electrolytic lesions produced greater damage to adjacent structures. GM_1 treatment did not affect cell survival in the NBM after electrolytic or ibotenate lesions. Further correlations between behavioral and neuroanatomical data will be reported.

DIFFERENTIAL EFFECTS OF QUISQUALATE OR IBOTENATE INJECTED INTO NUCLEUS BASALIS MAGNOCELLULARIS (NBM) ON BEHAVIOR AND NEUROCHEMISTRY. G.L. Wenk, A. Markowska* and D.S. Olton. Dept. of Psychology, The Johns Hopkins University, Baltimore, MD 21218.

Lesions of the NBM induced by either quisqualic (QUIS) or ibotenic (IBO) acid produced different effects on behavior and neurochemistry in rats. IBO injections decreased choline acetyltransferase (ChAT) activity (48%) and [^{3}H]Neurotensin binding (45%) in frontal cortex and impaired performance in T-maze alternation. QUIS injections decreased ChAT activity (78%) but did not alter [^{3}H]Neurotensin binding or impair performance. Therefore, non-cholinergic cells that are in the NBM, project to cortex, and have presynaptic [^{3}H]Neurotensin binding sites may be involved in the performance of this task. These data have implications for the effects of loss of NBM cells and provide new information about the neural organization of cells in the NBM and the mechanisms responsible for their degeneration in Alzheimer's Disease.

494.8

NUCLEUS BASALIS LESIONS AND PAVLOVIAN CONDITIONING IN THE RABBIT. S.R. Ginn and D.A. Powell. Dorn VA Hospital and University of South Carolina, Columbia, SC, 29201.

Ibotenic acid (IA) lesions of the nBM were made prior to classical conditioning in rabbits; other rabbits were subjected to sham lesions of the nBM, served as unoperated controls, or received pseudoconditioning (viz., random shocks/tones). Eyeblink (EB) and heart rate (HR) conditioned responses (CRs) were assessed. Lesions of the nBM had no effect on acquisition of the EB CR, but the HR CR of the lesioned animals was attenuated compared to the control groups. IA lesions of the nBM reduced cortical CAT concentrations by 50% compared to control animals. In a second experiment, rabbits received sham or nBM lesions after conditioning training was completed, but prior to retention testing. There were no differences between the groups for the HR or EB CRs during either phase of this experiment, even though IA lesions reduced cortical CAT concentrations by 80%.

These results suggest that the nBM may be part of a cortical-subcortical pathway that modulates Pavlovian autonomic conditioning. The effects of the lesions of the nBM were most apparent early in conditioning, suggesting that the nBM affects attention/stimulus registration processes during learning.

494.9

THE ROLE OF THE CENTRAL NUCLEUS OF THE AMYGDALA AND ITS EFFERENT PATHWAY TO THE BRAINSTEM IN SHOCK SENSITIZATION OF THE STARTLE REFLEX. J.M. Hitchcock, C.B. Sananes & M. Davis. Dept. of Psychiatry, Yale Univ., Ribicoff Res. Fac., Conn. Mental Health Ctr., New Haven, CT, 06508.

The amplitude of the acoustic startle reflex can be markedly increased during the 5-40 minutes following presentation of ten 0.6 mA footshocks (shock sensitization). This facilitation represents an unconditioned effect of shock on startle. A consistent literature indicates that the amygdala plays an important role in unconditioned as well as conditioned responding to fear-producing stimuli.

Lesions of the central nucleus of the amygdala, but not of the immediately adjacent lateral nucleus, blocked shock sensitization. Central nucleus lesions also decreased reactivity to shock (jumping and flinching). However, this did not account for the blockade of shock sensitization, because when a higher shock intensity was used, producing equivalent reactivity to that of controls at the lower intensity, central nucleus lesions still blocked shock sensitization.

A follow-up study was conducted to determine the central nucleus efferent pathway that might be involved in the mediation of shock sensitization of startle. Lesions of the rostral part of the ventral amygdalofugal pathway (VAF), which carries efferents to the forebrain, had no effect on shock sensitization of startle. In contrast, lesions of the caudal part of the VAF, a branch of which projects directly to the startle circuit, blocked shock sensitization of startle.

These findings, along with previous results, lead us to hypothesize that activation of the central nucleus of the amygdala increases startle through its projection to the startle pathway, and this mediates the unconditioned effects of shock on startle, as well as the conditioned effects of stimuli paired with shock on startle.

494.10

LESIONS OF THE BASOLATERAL AMYGDALA AND OF THE PYRIFORM CORTEX IMPAIR ACQUISITION OF A CONDITIONED ODOR PREFERENCE. N. Beaulieu*, R. Morris* and M. Petrides. (SPON: D. N. Pandya). Dept. of Psychology, McGill University, Montreal, Quebec, Canada, H3A 1B1.

Previous research demonstrated that lesions of the basolateral amygdala (BLA) and of the pyriform cortex (PC) impaired the acquisition of a conditioned odor aversion (Beaulieu et al., Soc. Neurosci. Abstr., 1987). The present study investigated the effects of similar lesions on the acquisition of a conditioned odor preference.

Testing was carried out in a chamber with a drinking spout at each end of it. Water-deprived rats were exposed simultaneously to 2 distinct odors (chocolate and almond) for 15 min./day for 10 consecutive days. One of the odors (S+) was present in the shavings surrounding one of the spouts from which a 15% sucrose solution was delivered, while the other odor (S-) surrounded an empty spout. Pairing conditions and side of presentation of the odors were counterbalanced. On day 11, the rats were again exposed to the odors but now water was available from both spouts. Normal animals drank more water from the spout on the side with the S+ odor, demonstrating a preference for that odor. Both groups of operated animals drank similar amounts of water from both spouts, indicating a lack of odor preference.

These results show that, with the present testing procedures, lesions of both the BLA and the PC impair formation of a preference for an odor. However, the contribution of these 2 structures may not be of the same nature.

494.11

The amygdala is involved in the expression of conditional analgesia. F.J. Helmstetter, R.N. Leaton, M.S. Fanselow*, & D.J. Calcagnetti* Psychology Department, Dartmouth College, Hanover, N.H. 03755

The amygdala seems to play an important role in the acquisition and performance of conditional fear as reflected in a number of preparations. We wished to determine if this structure is involved in the analgesia displayed by rats in the presence of shock associated stimuli. Relative to controls, animals with electrolytic lesions involving portions of the central, lateral, and basolateral amygdaloid nuclei spent less time freezing and were less analgesic as indexed by the formalin test. Bilateral microinjection of diazepam (30µg /1µl x2) into the amygdala produced a similar pattern of results. These data are consistent with the position that conditional analgesia is a response to a central fear-like motivational process.

SUBCORTICAL AFFERENT CONNECTIONS OF THE AMYGDALOID CENTRAL NUCLEUS IN RABBITS. C.G. Gentile*, C.G. Markgraf, P.M. McCabe, D.R. Liskowsky, R.W. Winters*, & N. Schneiderman (SPON: M.D. Gellman). Dept. of Psychology, Univ. of Miami, Coral Gables, FL 33124.

The amygdaloid central nucleus (ACE) is known to play an important role in classically conditioned heart rate responses to acoustic stimuli in the rabbit (Kapp *et al.*, 1979; Gentile *et al.*, 1986). While the efferent projections of this nucleus to various cardioregulatory structures have been examined extensively in this and other species, afferent projections to the ACE have been described in one study in the rabbit (Kapp et al., 1984). The present study examined subcortical afferent projections to the ACE and other amygdaloid nuclei, with a focus upon inputs from auditory nuclei.

New Zealand rabbits received injections of the retrograde fluorescent tracer Fluoro-gold (4% in saline, 20nl) in ACE. Two to three weeks later, the animals were perfused and sections were examined, using fluorescent microscopy, for the presence of retrogradely labelled cells in subcortical structures. Labelled neurons were located primarily ipsilaterally, in several areas including substantia innominata, midline thalamic nuclei, ventromedial and paraventricular hypothalamus, dorsal and ventral periacqueductal gray region, medial parabrachial nucleus, substantia nigra, locus coeruleus, and nucleus tractus solitarius. Of particular interest were labelled neurons in the magnocellular region of the medial geniculate nucleus and in the ventrolateral parabrachial region bordering on the intermediate nucleus of the lateral lemniscus. Both groups of cells may relay auditory or multi-modal sensory information to the ACE. Supported by NIH grants NS 24874, HL 07426, and HL 36588.

PROJECTIONS FROM THE ACOUSTIC THALAMUS TERMINATE IN THE LATERAL BUT NOT CENTRAL AMYGDALA. *C.F. Farb, D.A. Ruggiero and J.E. LeDoux* Div. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

Acoustic stimuli are transformed into symbols of danger by way of projections from the acoustic thalamus to the amygdala. The relay to the amygdala should, therefore, originate in thalamic areas that are within the projection field of the inferior colliculus (IC). In the present study we determined whether the central (CA) and/or lateral (LA) amygdaloid nuclei receive inputs from neurons that receive afferents from the IC. WGA-HRP was delivered iontophoretically to CA (n=8) or LA (n=10). Injections confined to LA resulted in transport to cells in the posterior intralaminar nucleus (PIN) and medial division of the medial geniculate body (MGM). Following injections in CA labelled neurons were located in the posterior thalamic region (PT) between the MGM/PIN and the anterior pretectal nucleus. Injection of WGA-HRP into the MGM/PIN (n=2) resulted in retrograde transport to cells in the shell regions of IC and anterograde transport to LA. Injections in PT (n=4) failed to label cells in IC, but did produce anterograde transport to the CA. Injections of IC (n=5) produced anterograde transport to the MGM/PIN, but not to PT. These observations demonstrate that neurons in the MGM/PIN receive inputs from the IC and project to LA. In contrast, CA does not appear to receive a direct input from the acoustic thalamus. The projection to LA may, therefore, be a critical relay in emotional learning. (Supported by MH38774).

SHORT LATENCY ORTHODROMIC ACTION POTENTIALS EVOKED IN AMYGDALA AND CAUDATE-PUTAMEN BY STIMULATION OF THE MEDIAL GENICULATE BODY. *C. Clugnet, J.E. LeDoux, S.F. Morrison and D.J. Reis* Div. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

Anatomical tracing studies indicate that the medial geniculate body (MGB) projects to areas of the amygdala and caudate-putamen, as well as to the auditory cortex. Responses of single neurons to electrical stimulation of the MGB were examined in those subcortical areas that receive direct anatomical projections from the MGB. Recordings were made in rats (n=20) anesthetized with chloral hydrate (7%, ip). Units in the caudate-putamen and lateral amygdala were excited by short pulses (twin shocks, 60 µsec each, 200 µsec apart, 500 µA, 0.1 Hz). Mean latencies were 3.7±1.7 msec in the lateral caudate-putamen (n=61), 5.3±2.2 msec. in the medial caudate- putamen (n=46), and 7.2±2.6 msec. in the lateral amygdala (n=35). Units in other amygdaloid regions required longer, higher frequency pulses (single shock, 500µsec, 500 µA in the central amygdala and 1.3 mA in the basolateral/basomedial amygdala, with frequencies varying from 0.2 to 1 Hz). Mean latencies were 9.9±2.6 msec in the central amygdala (n=38) and 13.3±3.7 msec in the basal amygdala (n=50). In the latter regions, responses followed a caudo-rostral gradient, with cells responding to MGB stimulation being more numerous caudally. These data are consistent with anatomical findings demonstrating direct projections to the lateral amygdala and caudate-putamen. The longer latency and higher threshold responses in the central and basal amygdaloid nuclei may be accounted for by multisynaptic projections to these areas, perhaps from one of the regions receiving direct MGB projections. Supported by NYHA and MH38774.

494.15

CONTEXTUAL MODULATION OF EMOTIONAL PLASTICITY. *A.E. Xagoraris, L.M. Romanski, B.T. Volpe and J.E. LeDoux*. Div. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

When rats experience an acoustic or visual stimulus in the presence of footshock, the acoustic or visual stimulus becomes a conditioned emotional stimulus (CS) capable of eliciting learned fear responses. We have found that the pairing of one CS (CS1) with a footshock unconditioned stimulus (US) prevents the subsequent development of conditioned responses to a second CS (CS2) paired with the same US one week later in the same apparatus. Conditioning with CS2 is also interfered with if CS1 is presented in a random relation to the US or if only the US is given during the first training session. However, conditioning to CS2 is unaffected when CS1 and CS2 are paired with the US in physically unique conditioning chambers. These findings suggest that once the rat is shocked in a given apparatus, the apparatus becomes a contextual CS and that novel stimuli subsequently paired with the US in that particular environment are ignored. This phenomenon is similar to "blocking", where prior training with CS1 interferes with subsequent training with a compound CS consisting of CS1 and CS2. However, in the present case the blocking effect is not due to the prior pairing of CS1 with the US but to a relation that develops between the US and environmental context in which it first appears. Context also affects the expression of fear, since the magnitude of the fear response elicited by CS1 is smaller when tested in a novel chamber than in the conditioning apparatus. (Supported by MH38774).

494.16

DESTRUCTION OF PERIRHINAL AND NEOCORTICAL PROJECTION TARGETS OF THE ACOUSTIC THALAMUS DOES NOT DISRUPT FEAR CONDITIONING. *L.M. Romanski, A.E. Xagoraris, D.J. Reis and J.E. LeDoux*. Div. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

Destruction of the medial geniculate body (MGB), but not its neocortical projection field, disrupts the classical conditioning of autonomic activity (increases in arterial pressure, AP) and emotional behavior ("freezing", F) to a pure tone paired with footshock. However, cortical areas along the rhinal fissure, which were spared in previous lesion studies, also receive inputs from MGB. In the present study we therefore examined whether combined removal of perirhinal and neocortical projection areas would affect emotional (fear) conditioning. Rats were lesioned, allowed to recover for 2-3 weeks, subjected to fear conditioning, and tested. Conditioned responses did not differ in controls (AP, 16±2; F, 117±2; n=7) and in rats with cortical ablations (AP, 13±1; F, 98±16; n=6). In contrast, conditioned responses were significantly reduced by lesions of MGB (AP, 4±1, $p<.01$; F, 0; $p<.01$; n=7). Conditioned responses were similar in animals with MGB lesions to responses in controls given random presentations of tone and shock (AP, 4±1.5, ns; F, 4±3, ns; n=7). These data demonstrate that fear conditioning does not depend upon any cortical area receiving inputs from the MGB. Since the MGB is necessary for the formation of the association between the tone and shock, its subcortical projections, which originate in the medial MGB and posterior intralaminar nucleus, must be essential components of the fear conditioning circuitry. (Supported by MH38774).

494.17

ANIMALS WITH ISCHEMIC OR IBOTENIC ACID HIPPOCAMPAL INJURY DISPLAY SPATIAL MEMORY IMPAIRMENT. Bruce T. Volpe, Beverly Waczek*, P. Colombo, H.P.Davis. Dept. of Neurology, Cornell Univ. Med. Ctr., White Plains, NY 10605, Univ. of Col., Col. Springs, Col.

Animals exposed to ischemia by the four vessel occlusion method (post ischemic, PI animals) reproducibly develop severe injury to the CA1 hippocampus and dl caudate, and have a spatial working memory impairment on radial 8, 12 and modified T-mazes. We tested whether ischemic hippocampal injury was sufficient to cause a spatial working memory impairment by comparing the performance of PI animals and animals exposed to high (hi-IBO,16-24 mcg) and low dose (lo-IBO,6-12 mcg) ibotenic acid injections into the dorsal hippocampus. We used a split stem T-maze to measure memory for invariant, trial independent information (reference), and memory for variable trial dependent information (working). Reference performance required the animals to choose either the rough or smooth surfaced alleyway on the stem. Correct working performance required that the animal alternate choice of goal arm for a food reward. Animals were trained for 20 trials, exposed to ischemia or ibotenic acid and returned for 30 post operative trials. Results showed no difference in pre-operative performance ($p>.5$) among all groups. On post operative trials there was no difference among groups on reference memory performance ($p>.1$). Lo-IBO animals performed the working memory task comparably with IBO controls ($p>.1$). However, both PI and hi-IBO animals performed the working memory task worse than controls ($p<.01$). This data suggests that hippocampal ischemic injury may be sufficient to cause the spatial working memory impairment in PI rats, and, further, suggests that this deficit may be a function of the amount of hippocampal injury.

494.18

EFFECTS OF DORSAL CAUDATE DAMAGE ON MEMORY FOR INVARIANT SPATIAL AND TACTILE INFORMATION. P.J. Colombo, H.P. Davis, B.T. Volpe. Dept. Psychology, Univ. Colorado at Colorado Springs, 80933, Dept. Neurology Cornell Univ. Med. Ctr., White Plains, NY 10605.

Electrical stimulation or lesions to the caudate impairs acquisition and retention in a variety of tasks that have an invariant rule based component (Phillips & Carr, Cand. J. Neurol. Sci., 14, 1987). Rats were pretrained on a 12-arm radial maze with 7 of 12 arms baited for either 36 or 80 daily trials, subjected to bilateral radiofrequency lesion of the dorsal caudate, allowed to recover, and then tested. Working performance, remembering which arms have been entered on a particular trial, was not impaired in rats given either 36 or 80 pretraining trials. However, the invariant reference aspect of radial maze performance was impaired in rats pretrained for 36 trials ($p<.01$). Reference performance was not impaired in animals given 80 pretraining trials ($p>.20$). Rats with caudate damage were also tested in a split stem T-maze that required the animal to make a tactile and spatial discrimination. The tactile discrimination did not vary across trials whereas the spatial discrimination varied from trial to trial. Caudate and control rats demonstrated similar performance on both the tactile and spatial discrimination. The results indicate that the dorsal caudate is initially required for normal reference performance in a spatial task. After extensive pretraining the caudate is not necessary for accurate reference performance in the radial maze.

494.19

PREOPERATIVE TRAINING EFFECTS ON RADIAL MAZE PERFORMANCE IN ANIMALS WITH ISCHEMIC OR IBOTENIC ACID HIPPOCAMPAL INJURY. H.P. Davis, P.J. Colombo, B.T. Volpe. Dept. Psychology, Univ. Colorado at Colorado Springs, 80933, Dept. Neurology, Cornell Univ. Med. Ctr., White Plains, NY 10605.

Rats with severe damage to the CA1 hippocampus following 30 minutes of ischemia by the 4 vessel occlusion method are impaired on the working memory aspect of a radial maze, but not on the reference aspect. Pretraining effects on working and reference performance were examined by training animals for either 36 or 80 trials prior to ischemic insult on a radial maze with 7 of 12 arms baited. Postoperative reference performance, as indicated by not entering unbaited arms, was not impaired in post ischemic rats given 36 or 80 pretraining trials. Working performance, reentering arms, was impaired in post ischemic rats given 36 pretraining trials ($p<.01$), but not in animals given 80 pretraining trials. Pretraining effects and task difficulty were further investigated in animals with ibotenic acid induced hippocampal damage by assessing working performance after 0, 30, or 60 pretraining trials on either a 4-, 8-, or 12-arm radial maze with all arms baited. Rats with hippocampal damage given 0 pretraining trials and tested on either a 4-, 8-, or 12-arm maze were impaired ($p<.05$). Rats given 30 pretraining trials demonstrated impaired working performance only on the 12-arm maze ($p<.05$). Rats pretrained for 60 trials demonstrated normal postoperative working performance. These findings show that pretraining and task difficulty significantly effect memory performance of animals with ischemic or ibotenic acid induced hippocampal damage.

494.20

OPPOSITE EFFECTS OF LEARNING AND RELEARNING OF A MAZE ON [^{3}H]2-DEOXYGLUCOSE UPTAKE: LIMITATIONS OF THE RELATIVE OPTICAL DENSITY MEASURE. M. Sarter (SPON: W.Kehr). Dept. Neuropsychopharmacology, Schering AG, D-1000 Berlin 65, F.R.G.

Rats were trained either in a 6-arm radial maze, or they were allowed to explore an alley maze with similar extensions or only the center of the maze. Following 8 acquisition sessions, a 5 day-break was followed by implantation of catheters into the jugular vein. Two days later, 2-deoxyglucose was injected 5 minutes before the test session. Controls were again tested in the maze center, the other two groups explored the 6-arm radial configuration. Rats which previously learned this configuration (relearners) showed clear evidence of memory compared to rats which experienced this configuration for the first time (learners). Glucose uptake was measured using the relative optical density measure. Compared to controls, relearners showed a general decrease of glucose uptake, whereas learners showed an increase of glucose uptake in limbic cortical and subcortical areas. Since relative optical densities vary considerably with subtle changes in white matter optical density, results based on the relative optical density measure may not be valid.

494.21

AFFERENT CONNECTIONS OF MAGNOCELLULAR REGION OF THE MEDIAL GENICULATE NUCLEUS IN THE RABBIT. P.M. McCabe, C.G. Markgraf, J.A. Quetel*, D.R. Liskowsky, R.W. Winters*, and N. Schneiderman. Dept. of Psychology, Univ. of Miami, Coral Gables, FL 33124.

The magnocellular region of medial geniculate nucleus (mMGN) has been demonstrated to be an important region for the acquisition and retention of classically conditioned cardiovascular and behavioral responses to aversive stimuli. Neurons in mMGN exhibit broad tuning curves, receive multi-modal sensory input, and show learning related changes in electrophysiological activity. Although the afferent connections of this region have been examined in other species (e.g. Ledoux *et al.*, 1985), inputs to mMGN have not been described in the rabbit. The present study sought to advance our understanding of the neural substrates of conditioning by assessing the afferent anatomical connections of mMGN in rabbits.

Pressure injections of the retrograde fluorescent tracer Fluoro-gold were made via a micropipette into mMGN or nearby control sites. Two weeks later the animals were perfused and sections were examined using fluorescence microscopy. Cell bodies were localized in several ipsilateral auditory structures including deep layers of the auditory cortex, the external nucleus of inferior colliculus (IC), the ventral portion of central nucleus of IC, the dorsal nucleus of the lateral lemniscus (NLL), and the ventral NLL. Dense labeling was also observed in the reticular nucleus of the thalamus, and more sparce labeling was seen in the deep layers of superior colliculus and in the spinal trigeminal nucleus. The mMGN connections we observed in rabbits are consistent with those found in rats. Supported by NIH grants NS 24874, HL 07426, and HL 36588.

494.22

THALAMIC INPUT TO MEDIAL PREFRONTAL CORTEX IN MACAQUES. X.-C.M. Lu*, J. Bachevalier, D. Kowalska*, and L.G. Ungerleider (SPON: B.M. Slotnick). Lab. Neuropsychology, NIMH, Bethesda, MD 20892.

To determine the source of thalamic inputs to the medial aspect of the prefrontal cortex, we injected retrograde tracers (WGA-HRP, nuclear yellow, and/or bisbenzimide) into 8 medial prefrontal sites and tritiated amino acids into 6 thalamic sites, in a total of 9 rhesus monkeys. Two of the thalamic injections were confined to the magnocellular portion of the medial dorsal nucleus (MDmc), two were centered in MDmc but also included the midline nuclei, one was confined to the anterior nuclei (AN), and one was centered in AN but also included dorsal MDmc and dorsal MDpc (the parvocellular portion of MD). The results indicated that precallosal cortical areas 14, 25, and 32 all receive projections largely from dorsal MDmc. In the most anterior portions of areas 14 and 32 and in area 10, the projections arise from dorsal MDpc. Sub- and supracallosal area 24 receives its major thalamic input from AN (mostly the anterior medial nucleus). Projections from AN extend to large portions of medial limbic cortex, including, in addition to area 24, areas 23, 25, and retrosplenial and entorhinal cortex. Combining these results with prior data, we conclude that precallosal regions have access to amygdalar information via MDmc, while sub- and supracallosal regions have access to hippocampal information via AN.

494.23

VISUAL DISCRIMINATION LEARNING BY MONKEYS WITH MEDIAL THALAMIC LESIONS. S. Jacobson, N. Butters and E.C. Gower. VA Medical Center, Boston, MA 02130.

In a previous experiment, monkeys (M. fascicularis) with medial thalamic lesions were found to exhibit an acquisition deficit for a visual pattern discrimination task (A+ B-). The possibility that this deficit could be due to difficulty in reversing the rule which had been practiced in an immediately preceeding series of non-matching tasks (win/shift, with respect to the sample stimulus) was assessed by presenting 3 additional sets of discrimination problems. Each set was composed of 8 problems learned in succession to a criterion of 90% correct in 30 trials. Practice with associative problems did not reduce the performance decrement of the experimental monkeys, and it was apparent that they were retarded in developing a learning set. A transfer task (A+ C-, D+ B-) was also presented, in which the elements A+ and B- had been learned as a pair and maintained the original reward assignments as members of new pairs. Monkeys with lesions were not able to maintain the learned response choice as well as normal monkeys, when the context provided novel stimuli which were differentially rewarded. These results suggest that the deficit sustained by monkeys with medial thalamic lesions is related to the acquisition and maintainance of the stimulus/reinforcement association, and is affected by the amount of within-problem interference. (Supported by VA Medical Research funds.)

THE EFFECTS OF VENTRAL THALAMIC LESIONS ON COGNITIVE AND MOTOR COMPONENTS OF LEARNING IN THE RAT. R. Shen* and D. Asdourian. Dept. of Psych., Wayne state Univ., Detroit, MI 48202.

Recent evidence suggests that the ventromedial and ventrolateral nuclei of the thalamus(VM-VL) are important both in helping to maintain motor responses initiated from the motor cortex and in gathering critical subcortical information from the cerebellum and basal ganglia(BG) which it then sends to the cerebral cortex. The VM-VL is important because it is the only place through which subcortical information from BG and the cerebellum can be sent back to the cerebral cortex. Evidence also shows that the caudate-putamen(Cd-Pt) of the BG as well as the cerebellum play important roles in learning. Cd-Pt is found to be involved in visual and spatial discrimination learning and different paradigms of maze learning. The purpose of this study is to investigate the general neurological deficits and learning deficits produced by the electrolytic lesions of the VM-VL. A 15 item neurological test and 3 learning tasks: T-maze spatial reversal, T-maze brightness discrimination, and complex maze, were used in this study. No deficits were observed on any of the neurological test items following the VM-VL lesions. Lesions affected performance on the T-maze spatial reversal task (lamda ratio=3.21, df=4,20, p=.0345) but not on the other two learning tasks. The results were similar to those obtained by others in studies of the Cd-Pt.

PARASAGGITAL THALAMIC KNIFE CUTS RETARD PAVLOVIAN EYEBLINK CONDITIONING AND ABOLISH THE TACHYCARDIAC COMPONENT OF THE HEART RATE CONDITIONED RESPONSE. S.L. Buchanan and D.A. Powell. Neuroscience Lab, VA Medical Center and University of South Carolina, Columbia, SC.

Rabbits received parasaggital knife cuts lateral to the mediodorsal nucleus of the thalamus (MD), severing afferents and efferents to and from the prefrontal cortex. These animals were compared to sham animals in a Pavlovian eyeblink and heart rate conditioning experiment in which a tone was the conditioned stimulus and paraorbital shock was the unconditioned stimulus. Knife cuts retarded acquisition of the eyeblink conditioned response (CR), and abolished the late-occurring tachycardiac component of the heart rate CR. These data are compatible with previous experiments, which suggest that MD participates in the sympathetic control associated with somatomotor learning.

SPATIAL MEMORY DEFICITS FOLLOWING MAMMILLARY BODY LESIONS IN MICE ARE DEPENDENT OF THE EFFORTFUL REQUIREMENTS OF THE TASK. D.J. Beracochea and R. Jaffard, Lab. Psychophysiologie, UA CNRS 339, Université de Bordeaux I, Avenue des Facultés 33405 TALENCE FRANCE.

We have previously shown that electrolytic lesions of the mammillary bodies (MM) in mice induce memory deficits in tasks based on spontaneous alternation (S.A.) in a T-maze. Subsequent experiments showed that these deficits could be alleviated by using between-trials contextual changes. This suggests that the observed impairments might stem from the automatic (as opposed to effortful) form of memory involved in S.A.. The present experiments compared the effects of ibotenic acid lesions of MM in either sequential (successive trials separated by intertrial intervals ranging from 30 sec to 3 min) or delayed (2 forced trials followed by a test free trial given up to 6 hours) procedures using S.A., reinforced win-shift or win-stay protocols. Results showed that when tested with the win-shift rule, MM-lesioned mice still exhibited deficits as compared tc controls but with longer intervals than in spontaneous alternation. The use of the win-stay rule, however, produced no observable deficit in contrast to that seen in ther S.A. and win-shift protocols. These results suggest that MM lesions might impair primarily automatic form of memory.

494.27

SPATIAL BEHAVIOR OF NORMAL AND SEPTAL RATS ON ALTERNATE ROUTE MAZE PROBLEMS. T. Herrmann, B. Bolson* and B. Poucet Dep. of Psychol., U. of Guelph, Guelph, Ontario N1G2W1.

The behavior of septal lesioned and normal rats was compared on a variety of alternate route variations of the 3-table problem. Septal rats displayed impaired test trial behavior on all variations of the task. However, the route choice pattern did provide some insight into the nature of the septal deficit. Septal rats were able to distinguish and use a consistent route during both exploration and test trial phases. If available, the chosen route was usually the most direct between any two tables. When no direct route was available, septal rats took the boundary route, i.e the route which formed the peripheral edge of the apparatus In contrast, normal rats chose the most direct route only in the simplest configurations. In the more complex configurations, normal rats consistently chose the central but longer route which may have allowed delayed choice or single point reference orientation.

These results suggest that septal rats are able to store and use information about distances if not locations, and that normal rats are able to dissociate routes and locations according to several other variables.

494.28

OBJECT EXPLORATION, HABITUATION AND RESPONSE-TO-CHANGE IN RATS FOLLOWING FRONTAL CORTEX LESIONS, SEPTAL LESIONS, OR SCOPOLAMINE INJECTIONS. B. Poucet, C. Thinus-Blanc and M.-C. Buhot*. CNRS, Lab. of Functional Neurosc., Ulbis, 13402 Marseille cedex 9, France.

The possible involvment of the central cholinergic system in the exploratory behavior of objects in an open-field was studied in rats following a) medial frontal cortex lesions (FC), b) septal lesions (S), and c) i.p. scopolamine (1mg/kg) injections (SC). When compared with normal animals S rats 1) displayed a lower level of initial exploratory activity, 2) did not habituate, and 3) provided no evidence of reaction to the displacement of an object. FC rats were very similar to normal rats except for their response-to-change behavior which focused exclusively on the displaced object.

In a similar task using both a spatial and a non spatial change test, SC rats displayed a low level of initial exploratory activity and did not habituate over time in much the same manner as S rats. In addition, SC rats a) did not evidence reaction to either a spatial or a non spatial change and b) developed a stereotyped pattern of locomotor activity.

These results point to a) the central role of the septo-hippocampal cholinergic system in object exploration, and b) a non specific disruption by scopolamine of cholinergic related attentional processes.

494.29

STIMULATION OF THE LATERAL SEPTUM IS A MORE EFFECTIVE CS THAN STIMULATION OF THE MEDIAL SEPTUM DURING CLASSICAL CONDITIONING OF THE EYEBLINK RESPONSE.
B.J. Knowlton and R. F. Thompson. Department of Psychology, University of Southern California, Los Angeles, CA 90089.

Eight rabbits were trained in the classically conditioned eyeblink response procedure using stimulation of the septal nuclei as the conditioned stimuli (CS). Each rabbit was trained with both medial septal stimulation and lateral septal stimulation. Stimulation of the medial septum was a far less effective CS than stimulation of the lateral septum. This effect may be due to the different roles of these two nuclei in classical conditioning. Conditioning using lateral septal stimulation as a CS is dependent on the cerebellar interpositus nucleus, as is conditioning using peripheral and other brain stimulation CSs.

INSULAR PREFRONTAL CORTEX LESIONS PREVENT INCENTIVE CONTRAST EFFECTS IN THE RAT.
Ann Robertson and Andrê Laferrière*. Dept. of Psychology, Univ. of Alberta, Edmonton, Alberta, Canada T6G 2E9.

The role of the anterior agranular insular cortex (AI) in mediating the over-response to unexpected shifts in the quality of food reinforcement (incentive contrast effect) was evaluated in two expts. In the first, rats with bilateral electrolytic lesions of the AI and sham-operated rats were trained to bar-press for either a highly preferred or less preferred liquid reward. Once performance had stabilized, the reinforcers were reversed. Control rats displayed significant contrast effects when their performance after the switch in rewards was compared to that of the rats receiving the same reward before the switch. However AI lesioned rats failed to show any contrast effect, even though they could exhibit sizeable preferences. In the second expt., the ability of AI lesioned rats to change their response rates as a function of variations in response contingencies was studied using a procedure which selectively reinforced responding or not responding. AI lesioned rats could alter their response rates to match changing schedule requirements as well and as fast as controls. This rules out motor perseveration as the reason for the lack of contrast in the first study. The results suggest that the AI is specifically involved in the response to novel changes in the quality of reward.

494.31

CONCURRENT LEARNING AND RETENTION TESTED WITH REVERSIBLE COOLING OF VENTROMEDIAL TEMPORAL CORTEX.
P. George, R. Cirillo*, Q. Chen* and J. Horel. Dept. of Psychology, Syracuse University and Dept. of Anatomy and Cell Biology, Health Science Center, Syracuse, NY 13210.

We have found a strip of cortex on the ventromedial temporal lobe (VMT) that is essential for performance of delayed match-to-sample, while the rest of the temporal cortex is not. It extends from posterior parahippocampal gyrus to anterior ventral inferotemporal cortex. Previously, we had found that small inferotemporal lesions impair learning but not recall and here we ask the same question of VMT. VMT was covered with a single cryode on each side of monkeys that were then trained on a concurrent learning and retention task. They were overtrained on a set of four object discriminations and these were presented concurrently with four new discriminations to measure normal learning and retention. The overlearned pairs were then presented together with four new discriminations while cooling VMT. The hypothesis was that with VMT suppressed, the animals would recall the overlearned discriminations but not learn the new discriminations; however, they were severely impaired both in learning and recall. This is the most severe retention deficit we have found with small temporal cortex lesions. (Supported by NINCDS grant NS18291).

PARAHIPPOCAMPAL GYRUS AFFERENT CORTICAL CONNECTIONS AS DEMONSTRATED BY RETROGRADELY LABELING CELLS WITH WGA-HRP.
C.L. Martin-Elkins* and J. Horel (SPON: J. Horel). Dept. of Anatomy, SUNY Health Science Center, Syracuse, NY 13210.

Inferotemporal cortex (IT) has been shown to play an important role in acquisition and retention of visual information. While it has generally been considered a single, homogenous visual area, recent studies have found anteroventral IT to be a distinct functional subdivision within IT. Injections of WGA-HRP in anteroventral IT, demonstrated a strong projection from the parahippocampal gyrus in area TF (Martin-Elkins, Soc. Neurosci. Abstr., 1987). Subsequently, cooling of this area was found to produce deficits on the DMS task similar to those found with anteroventral IT cooling. In an attempt to further examine the visual pathways into anteroventral IT, injections of WGA-HRP were placed in the parahippocampal gyrus (TF). Preliminary results show labelled cells in the parahippocampal gyrus, both anterior and posterior to the injection site, and in ventral IT. Similar to anteroventral IT, parahippocampal gyrus appears to receive little input from dorsal IT, since only a few, scattered labelled cells were located there. Posteriorly, cells have been mapped in the intraparietal sulcus, the rostral bank of the lunate sulcus, and the occipitotemporal gyrus. (Supported by NINCDS grant HS18291)

494.33

TEMPORO-PREFRONTAL INTERACTION IN RULE LEARNING BY MACAQUES.
J.A. Weinstein*, R.C. Saunders, and M. Mishkin (SPON: B. Turner). LN, NIMH, Bethesda, MD 20892.

Although combined amygdalo-hippocampal removals in macaques severely impair their performance on delayed nonmatching-to-sample (DNMS) when the delays between sample and choice exceed about 10 seconds, they can master the task with shorter delays. Such mastery cannot depend on the formation of specific visual discrimination habits, because (a) a different pair of objects is used on every trial and (b) within a trial, the reinforcement contingencies for responses to the sample object are inconsistent. To master the task in the absence of the limbic system, the animal must be able to learn a rule, which requires, in turn, (i) suppression of specific stimulus-response habits, (ii) abstraction of sameness and difference from specific stimulus quality with the aid of immediate memory, and (iii) formation of a stimulus/difference-response habit. We have now found that if inferior prefrontal lesions (which produce a moderate DNMS impairment by themselves) are added to amygdalo-hippocampal lesions, monkeys lose the ability to perform DNMS even when the delays are less than 10 seconds. This finding suggests that the inferior prefrontal cortex serves one or more of the processes described above needed for rule learning, and that it does so by mediating a complex set of interactions between the inferior temporal cortex and the neostriatum, with both of which the inferior prefrontal cortex is directly interconnected.

IMPAIRMENT OF SPATIAL, OLFACTORY, AND AUDITORY SERIAL REVERSAL IN AN ANIMAL MODEL OF HUMAN DIENCEPHALIC AMNESIA.
R.L. Knoth, R.G. Mair, S.A. Rabchenuk. Department of Psychology, University of New Hampshire, Durham NH 03824. P.J. Langlais. San Diego VAMC.

The post thiamine deficient (PTD) rat is an animal model of Wernicke-Korsakoff's disease, the most common cause of global diencephalic amnesia in humans. Behavioral testing of PTD rats has demonstrated learning and performance deficits on both aversively and appetitively motivated spatial tasks, including spatial delayed alternation and spatial delayed non-match to sample, but no deficit on spatial (left/right) and visual (light/dark) discrimination (Mair et al., Brain Res., in press; Knoth et al., Neurosci. Abstr., 13, 1127). The purpose of this experiment was to see the degree to which the learning and performance deficits extended to other sensory modalities.

A total of 16 PTD rats were compared to 24 controls on spatial, olfactory, and auditory serial reversal (SR). On spatial SR, experimental animals required consistently more trials than controls on initial learning and all subsequent reversals. On olfactory SR, experimental animals required significantly more trials on initial learning and completed less reversals overall. This same deficit was observed in auditory SR.

These results support the global nature of the learning and performance deficits observed in PTD rats.

ALTERED EXPLORATORY ACTIVITY IN AN ANIMAL MODEL OF DIENCEPHALIC AMNESIA. S.A. Rabchenuk*, R.G. Mair, & R.L. Knoth (SPON: E. Hagstrom). Department of Psychology, University of New Hampshire, Durham, NH 03824.

The post thiamine deficient (PTD) rat is an animal model of diencephalic amnesia, characterized by medial thalamic lesions and impaired performance on tasks measuring learning and memory. In this experiment, we videotaped open field activity of 16 PTD and 16 control animals during 3 daily 15 minute sessions. On day 1 and 2, animals were placed in an empty circular field and on day 3 a novel stimulus was placed in the center. Videotapes were coded in 1 minute intervals for line crossing, a measure of locomotor activity, and rearing, a behavior in which rats stand on their hindlegs and execute sniffing bouts and multiple shifts in head position.

Results showed that on days 1 and 2, PTD rats exhibited significantly more line crossings than controls. Both groups showed a decrease in the frequency of line crossing and rearing within each session. On day 3, the controls made more approaches to the novel object during the first 1 minute interval. However, controls made a rapid decrease in the frequency of these responses and PTD animals did not. This pattern of increased line crossing and decreased rearing was limited to rats with the lesion of the intralaminar thalamic nuclei typical of the PTD model.

FIBER TYPE COMPOSITION OF FATIGUE INTERMEDIATE MOTOR UNITS IN THE DIAPHRAGM. J.G. Enad* and G.C. Sieck. Dept. of Biomed. Eng., USC, LA, CA

The purpose of this study was to determine the fiber type composition of motor units (MU) in the cat diaphragm. MU's were classified as fast or slow (S) based on the sag test. Fatigue resistance (fatigue index, FI) was used to further subclassify fast units as FR (FI>0.75), FInt (0.25<FI<0.75), or FF (FI<0.25). MU fibers were identified using the glycogen depletion technique. Fibers were classified as type I or II based on ATPase activity. Subclassification of IIA and IIB fibers was based on ATPase activity after acid preincubation (pH 4.2 and 4.6). Fibers belonging to S units were uniformly composed of type I fibers. FR and FF units were composed exclusively of types IIA and IIB fibers respectively. FInt units showed a mixed fiber type compostion (both IIA and IIB). Those FInt units with FI<0.50 were comprised primarily of IIB fibers (80% vs 20% IIA), whereas FInt units with FI>0.50 were comprised primarily of IIA fibers (90% vs 10% IIB). We conclude that, unlike the homogeneous fiber type composition of S, FR, and FF MU's, FInt units are composed of a mixed population of type II fibers with proportions of IIA and IIB fibers related to unit fatigue resistance.

495.2

WHY ANIMALS HAVE DIFFERENT MUSCLE FIBER TYPES. L. C. Rome*, R. P. Funke*, R. McN. Alexander*, and G. Lutz*.(SPON: E. F. O'Connor). Dept. of Biology, Univ of Penn., Phila, PA 19104

It is assumed that animals have slow fibers because they are more efficient at low speed of locomotion, but need fast fibers because the slow ones cannot shorten fast enough to power rapid movements. To test these theories one must determine "where on the force-velocity curve" fibers are operating during locomotion (V/V_{max}; where V is the velocity at which the muscle is shortening during locomotion and V_{max} is the maximum velocity of shortening). V_{max} of carp slow red fibers = 4.65 lengths/s, that of fast white fibers = 12.9 lengths/s. During swimming at 20-40 cm/s (only the red fibers are active), V of red fibers = 0.7 to 1.7 lengths/s (V/V_{max} = 0.15-0.36 -- high power and efficiency.) At the same speeds, because of the different orientation of the fibers, the V of white muscle would = 0.2 - 0.4 lengths/s (V/V_{max} = 0.01 - 0.03 -- very low power and efficiency). To power the "startle response" (maximal movement), the red fibers would have to shorten at 20 length/s which far exceeds their V_{max}. The white fibers need shorten at only 4.85 lengths/s (V/V_{max} = 0.38 -- high power and efficiency). Even if the red muscle were placed in the orientation occupied by the white, it still couldn't shorten fast enough to power this movement.

We proved that animals need fast fibers to power maximal movements and provide strong evidence that slow fibers are more efficient at low speeds. Supported by MBL Summer Fellowship, Whitaker Foundation, NIH(AR38404) to LCR.

495.3

PREDICTION OF FIBER TYPES IN THE CAT QUADRICEPS MUSCLE. B.G. Samojla, L.L. Glenn, P.J. Rebeta*. *Department of Physiology, Ohio College of Podiatric Medicine, Cleveland, Ohio 44106-3082.*

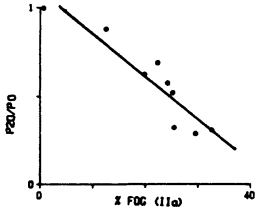
Neuromuscular compartments (NMC) have been identified in various muscles of the cat hindlimb including the quadriceps. The purpose of this study was to determine if the ratio of the tension at 20 Hz (P_{20}) vs the tension at 100 Hz (P_0) could predict the fiber type distribution in the nine quadriceps NMC.

For each NMC, single twitch tension, tension at 20 Hz and 100 Hz, and fatigue index was determined. The proportion of fiber types in each NMC was correlated to the contraction properties.

The average fiber type distribution (across all nine quadriceps NMCs) was SO = 35.8% (3.4 - 96.5), FOG = 22.4% (0.5 - 37.5), FG = 38.7% (2.2 - 63.6). The range of P_{20}/P_0 was 0.28 - 1.00 while the fatigue index ranged from 0.19 - 0.70.

The correlation coefficients of P_{20}/P_0 were -0.94 with FOG, 0.79 with SO, -0.58 with FG.

Our findings show that P_{20}/P_0 can accurately predict the percentage of FOG fibers in NMC of the cat quadriceps.



495.4

FIBER-TYPING BY ATPase HISTOCHEMISTRY OR MYOSIN IMMUNOHISTOCHEMISTRY : EFFECT OF DENERVATION ON MUSCLES OF C57BL/6J MICE. H.L. Davis and G. Desypris, Dept of Anatomy and School of P & OT, McGill U, Montreal, Canada, H3A 2B2; Dept of Physiology, U of Ottawa, Ottawa, Canada, K1H 5A3.

After unilateral hindlimb denervation of 2 wk mice for 4 wk or of 12 wk mice for 20 wk, sections of denervated (DN) and contralateral normal (NOR) extensor digitorum longus (EDL) and soleus (SOL) muscles were stained for ATPase (I,IIA and IIB fiber types) or immunohistochemically using monoclonal antibodies against fast (IIA or IIB) or slow (I) myosin heavy chain. Sections were examined for relative proportions of the various fiber types. Denervation had no effect on the total number of fibers but the proportions of fiber types were altered. Histochemically, DN muscles of young mice exhibited complete loss of type I fibers, whereas the proportion of those in muscles of older mice were unaffected ; for all mice there was marked dedifferentiation of type II fibers in DN EDL and SOL. Immunohistochemistry indicated very different results: fibers containing type I myosin increased in both DN EDL and SOL; in the latter they comprised nearly 100% compared to 33% in NOR controls. In DN EDL there were more fibers containing IIA and fewer with IIB myosin than NOR. These results indicate that histochemical and immunohistochemical techniques of fiber classification are not equivalent when examining plastic changes resulting from a perturbation such as denervation. Support: MRC and MDAC.

GENDER SPECIFIC MUSCLE FIBER AND STRENGTH ADAPTATIONS IN THE HUMAN BICEPS BRACHII.

S.E. Alway, J. Stray-Gunderson, W.J. Gonyea and W.H. Grumbt. Department of Cell Biology and Anatomy, UT Southwestern Medical Center, Dallas TX 75235

Isokinetic strength measures and computer tomographic scans were obtained on the elbow flexors of 7 elite male bodybuilders (MB) and 5 elite female bodybuilders (FB) to determine if the linear relationship between muscle CSA and strength is altered if strength is measured at high and low velocity contractions. A second purpose was to determine if male and female bodybuilders have similar ratios of strength/muscle CSA at high and low velocities of contraction. Absolute strength was significantly greater at all velocities of contractions in MB relative to FB. Strength/flexor CSA was, however, similar at 60° and 120°/s among subjects. Strength/flexor CSA was significantly lower at 180°, 240° and 300°/s in MB relative to low velocity contractions, however, this ratio was not reduced at high velocities in FB. Mean fiber cross-sectional area which was determined from biopsies of the biceps brachii was significantly greater in MB (8794.1 ± 1059.7 μm^2) relative to FB (5023.4 ± 772.7 μm^2). Mean fiber area correlated strongly to strength/biceps CSA at low (r=0.8) but not high velocities (r=0.4) of contraction. A large inter-subject range in fiber number estimated from the biceps (603,252-187,299), likely prevented a positive correlation between strength and fiber number at any velocity of contraction (r=0.1) The results indicate that adaptations of strength/CSA in bodybuilders are gender specific.

RECORDING HUMAN SINGLE MOTOR UNIT PROPERTIES: A NEW METHOD.

R.S. Johansson, G. Westling*, C. K. Thomas and B. Bigland-Ritchie. Umeå University, Sweden & J. B. Pierce Foundation, New Haven, CT 06519.

The contractile properties of individual motor units of human thenar muscles were examined by a new method derived from the technique of microneurography and analogous to that used in animal studies. Forces of both flexion and abduction were recorded simultaneously from the thumb, together with EMG from both the proximal and distal muscle surfaces, while a tungsten microelectrode was used to stimulate single motor axons in the median nerve above the elbow. When the stimulus current was increased from zero, unitary activity was accepted if: a) no force or EMG responses were seen below a critical stimulus intensity; b) signals then appeared simultaneously, and remained unchanged over a wide range, usually 2-4 μA, before any graded increments appeared; c) X/Y plots of the abduction and flexion forces showed a characteristic force vector for each unit. These criteria were satisfied repeatedly for 45 units from 12 subjects. Unit responses often remained stable for up to 1hr while applying different stimulation protocols, including 1s bursts of constant frequency (1-100Hz), pulse intervals varied to optimize force generation, and standard fatigue tests. Respiratory and circulatory baseline fluctuations were minimized by triggering each stimulus packet from the heart beat, and electronically re-setting the force baseline to zero just prior to each response. Contractile speeds, force/ frequency curves and axon conduction velocities were measured before and after fatigue. Burke fatigue indices were calculated, together with each unit's characteristic angle of pull within the muscle.

Supported by USPHS and the Swedish Medical Research Council.

495.7

TWITCH PROPERTIES OF SINGLE HUMAN MOTOR UNITS.

C. K. Thomas, R.S. Johansson, G. Westling*, and B. Bigland-Ritchie. John B. Pierce Foundation, New Haven, CT. 06519 and Umeå University, Sweden.

Twitches properties of thenar human motor units examined by stimulating single motor axons (Johansson et al., 1988 above), were compared with those measured previously by spike-triggered averaging (Thomas et al., J. Neurophysiol. 57:311, 1987). Twitch amplitudes of 45 units from 12 subjects, measured at the start of each experiment, ranged from 2.9 to 34.0 mN (mean ±SD; 11.4 ± 8.1 mN). However, less than 25% had amplitudes greater than 15.6mN. The corresponding twitch contraction and half-relaxation times had a near Gausian distribution (50.4 ± 9.2 & 59.9 ± 18.5 ms respectively). Axon conduction velocities were 45.9±5.4 m/s. These units generated force at angles between -47° to 124° relative to thumb flexion. Following other tests, the twitches potentiated, some by up to 4 fold. Twitch contraction and half-relaxation times also increased. The distribution of twitch amplitudes, both before and after potentiation, was similar to that found using spike-triggered averaging from abductor pollicis brevis muscles. However, using the latter method, higher values were also reported, some with amplitudes twice those of the largest measured in the present study. These values may be due to inevitable synchronization between unit discharge rates and some twitch potentiation during spike-triggered averaging.

Supported by USPHS grant NS 14657 and the Swedish Medical Research Council.

495.8

CLASSIFICATION OF HUMAN MOTOR UNITS.

B. Bigland-Ritchie, C. K. Thomas, G. Westling*, and R.S. Johansson. John B. Pierce Foundation, New Haven, CT. 06519 and Umeå University, Sweden.

To determine how far human motor unit contractile properties corresponded with those of other mammals, twitch and tetanic responses of the thenar muscle were examined while stimulating individual motor axons (Johansson et al., 1988; Thomas et al., 1988, above). Twitch amplitudes were not correlated with their corresponding contraction or half-relaxation times, nor their axon conduction velocities (45 units). "Sag" was not tested systematically, but none was seen when stimulating at 8, 10, 15 or 20Hz. Burke fatigue indices, measured from 25 units, varied continuously from 0.43 -1.28. Only 36% of the units showed < 25% force decline. During the Burke fatigue test relaxation from the 40Hz responses generally slowed markedly. Thus, using criteria normally applied to animal units, there was no indication that these human motor units can be separated into distinct types, based solely on differences between their contractile properties. More data are required about the histochemical composition of the human thenar muscles (63% type I, 37% type II; Johnson et al., J. Neurol. Sci.18:111, 1973) before conclusions can be drawn as to differences between animal and human motor unit properties or their relation to histochemical typing.

Supported by USPHS grant NS 14657 and HL 300062, and the Swedish Medical Research Council.

495.9

THE DISTRIBUTION AND ULTRASTRUCTURE OF INTRAFUSAL FIBERS IN THE CAT MASSETER MUSCLE.

N.F. Capra, J.M. Bernanke*, and J.W. Ball, Jr.* Department of Anatomy, University of Mississippi Medical Center, Jackson, MS 39216.

To provide initial data regarding the distribution and ultrastructural properties of masticatory muscle spindles, the superficial and deep masseter muscles were dissected from adult cats immediately after perfusion-fixation. Muscles were divided into smaller pieces which were then serially cut into 1 mm thick blocks. Blocks were processed for electron microscopic (EM) study. Neuromuscular spindles identified on 1 μm thick sections were thin sectioned for EM analysis. A total of 65 spindles were identified in 4 muscles. Most of the spindles were located in intermediate to deep portions of the masseter muscle near its attachments to the zygomatic bone as described by Lund et al. (Neuroscience 3:259). Single spindles and spindle pairs occurred most commonly, although larger complexes were sometimes observed. The number of intrafusal fibers/spindle ranged from 1-10 (x=4.2) in polar regions. In the equatorial region, fibers were easily classified as nuclear bag (NB) or nuclear chain (NC). Although the NB fibers were typically larger than NC fibers, there was overlap with respect to the diameter of these two types of intrafusal fibers. In juxtaequatorial regions, the M-line of the sarcomeres, prominent in NC fibers, were either totally absent or represented as pale double lines in NB fibers. Chain fibers possessed numerous large mitochondria in juxtaequatorial and polar regions. Bag fibers could be divided into type 1, which had sparsely distributed thinner mitochondria, or type 2, which had numerous larger mitochondria. Masseter spindles were generally comparable in structure to spindles described in limb muscles (Kucera, Histochemistry 79:457). However, there seemed to be a larger percentage of multiple bag spindles in the masseter. The diversity in spindle intrafusal fiber composition could account, in part, for differences observed in the response properties of spindle primary afferents (Inoue et al., Exp. Neurol. 74:548). Supported by NIDR DE06027.

FIBER ARCHITECTURE OF LONG, PARALLEL-FIBERED MUSCLES IN THE CAT HINDLIMB: EVIDENCE OF INTRAMUSCULAR TAPERED ENDINGS.

C.A. Pratt and C.M. Chanaud. Lab of Neural Control, NINCDS, NIH, Bethesda, MD20892

Available evidence indicates that the long, parallel-fibered muscles, sartorius (SA), tenuissimus (TEN), and the distal head of semitendinosus (St) are comprised of relatively short (~ 3.0 cm) interdigitating muscle fibers arranged in staggered longitudinal series (Loeb et al. J. Morph. 191: 1987). The presence of very small (cross-sectional areas ≤ 300 um^2) muscle fibers (VSMFs) in TEN (Lev-Tov et al. J. Neurophysiol. 59: 1988) supports other evidence (Loeb et al. ibid) that muscle fibers in muscles with this architectural arrangement have tapered intramuscular endings. If VSMFs reflect tapered endings, they should occur within all fiber types.

In this study, the incidence of VSMFs within each muscle fiber type was determined in SA, St, and TEN and compared to similar data obtained in selected pinnate muscles (medial gastrocnemius (MG), tibialis anterior (TA) and tensor fascia latae (TFL)). Fiber areas were digitized in serial cross-sections (15 um) that had been stained so as to classify muscle fibers according to their histochemical properties (SO, FOG, FG). In some experiments, prolonged stimulation of single SA or TEN motor axons in ventral root filaments was used to deplete their muscle fibers of glycogen.

With the exception of TEN, pinnate and parallel-fibered muscles did not differ in the upper limits of their fiber size distributions, but they were significantly different in the areas of their smallest fibers. Thus far, VSMFs were found in FOG and SO fibers in TFL and in all muscle fiber types in SA and TEN. The proportion of VSMFs in depleted fast twitch muscle units in SA was 8-11% and 9-53% in TEN. These data indicate that VSMFs reflect an architectural feature in parallel-fibered muscles that is independent of the normal size-histochemical relationships.

AN ANATOMICAL STUDY OF MOTOR END PLATES IN A COMPARTMENTALIZED MUSCLE. O.I. Weeks. Dept. of Biological Sciences. Florida International University., Miami, FL 33139

Previous studies (English & Letbetter '82, English & Weeks '84, Weeks & English '85, '87) have suggested that neuromuscular compartmentalization is a basic organizational feature in some skeletal muscles. To determine whether neuromuscular compartments can be reestablished following injury, the mouse LG muscle has been adopted as a study model. A baseline for compartmentalization in this muscle is also being established. The present study analyses the quantitative and qualitative profile of motor end plates (meps) in the mouse LG muscle using acethylthiocholine, bromoindigo and silver, or zinc-iodide osmium staining methods. Results show that meps are distributed on equatorial zones of both superficial and deep muscle fibers in each compartment. Type b & c meps (classification of Korneliussen & Waerhaug '73) are found throughout each compartment. Type b meps tend to be more commonly found in distal and ventral compartments which consist of more oxidative muscle fibers. Additionally, meps were also observed in various stages of degeneration. The frequency with which degeneration occured tended to be associated with collateral branching and did not appear to be compartment specific. This definition of the basic anatomy of meps is an attempt to further characterize LG neuromuscular compartments and make it more convenient for studying compartmental reinnervation.

ARCHITECTURE AND PERIPHERAL INNERVATION OF A MULTI-FUNCTION NECK MUSCLE. R.J. Callister and E.H. Peterson. Dept. Zoological & Biomed. Sci. & College of Osteopathic Med. Ohio Univ., Athens, Ohio 45701.

As part of a study aimed at understanding neuromuscular control of movement parameters we are examining the construction and innervation of the head retractor muscle RCCQ in a turtle, P.scripta. This strap muscle is used in the characteristic turtle startle response, in feeding, and in head steering during locomotion. Thus RCCQ mediates movements requiring widely different speed, force, and geometry. We used single fiber dissections of gold chloride stained muscles to examine muscle architecture. We also visualized: intramuscular territories of segmental nerves to RCCQ in muscle wholemounts using sudan black staining, motor end plate (MEP) zones in muscle wholemounts and single fibers with cholinesterase, and MEP morphology by anterograde transport of HRP applied to muscle nerves.

Individual fibers vary widely in maximum diameter (20-80um in 11cm turtles); they do not form clear size classes. Most of these presumably correspond to the fast fiber types that dominate RCCQ (Fg-60%, FOG-30%; Callister et al., '87, Soc. Neurosci. Abs. 13:1217). Fibers also vary in length (20-100% of total muscle length). There is a significant positive correlation between fiber diameter and length; approximately 70% of the largest fibers (>50um), compared with 16% of other fibers, span the full muscle length (approx 6cm). Shorter fibers are arranged in series throughout the muscle; many taper over long distances and are bound by connective tissue to other tapered fibers as well as to fibers which span the full muscle. Three of the four bellies are innervated by 2-3 segmental nerves each, whose intramuscular territories show little overlap. Single fibers bear (2-7) focal, MEP zones at 2-16mm intervals. Thus long single fibers have multi-segmental, and probably multi-neuronal, innervation. Motor axons contact the sarcolemma in 1-4 longitudinally oriented, varicose strips. There is a significant positive correlation between muscle fiber diameter and both the number and length of contacting varicosities, suggesting that larger fibers may bear greater synaptic areas.

Our data indicate that RCCQ contains >1 fiber population, and that these are structurally (as well as histochemically) specialized for different roles in head movement control. The shortest fibers, with their small diameters, tapered profiles, and series construction are poorly suited to mediate the startle response. In contrast, the largest diameter fibers exhibit multiple adaptations for high speed /force output. They probably belong to >1 motor unit, but how these motor units are coordinated is not known. (Supported by NIH grant RO1NS23498)

ULTRASTRUCTURAL CHARACTERIZATION OF WING RETRACTION MUSCULATURE IN THE PTEROPOD MOLLUSC CLIONE LIMACINA. Z. Huang*, M. Titus* and R.A. Satterlie (SPON: J. Harris). Dept. of Zoology, Arizona State Univ., Tempe, AZ 85287

Tactile stimulation of the wing-like parapodia of the pteropod mollusc Clione limacina can trigger a wing retraction reflex, during which the wing is deflated and pulled into the body. Full retraction is achieved within 2-3 seconds and the wings usually remain retracted for 20-40 seconds. The magnitude of retraction is a graded function of the stimulus intensity.

Three groups of smooth muscles involved in wing retraction are found in the wing haemocoeal: the transverse muscles, longitudinal muscles and dorsoventral muscles. Furthermore, two subtypes of muscle cells were identified. The first type (type A) appears in all three groups of muscles and forms a well organized lattice-like structure. The second type (type B), being the major component of transverse muscles, run only one dimensionally.

Quantitative ultrastructural comparisons between the two types of smooth muscles suggest that type A cells are able to contract and relax more quickly with low endurance while type B cells are capable of generating stronger contractions with higher endurance and slower relaxation speed. The role of these cell types in wing deflation and retraction is now under investigation.

MOTOR SYSTEMS AND SENSORIMOTOR INTEGRATION: POSTURE AND MOVEMENT VIII

496.1

ADAPTATION TO TELESTEREOSCOPIC VIEWING MEASURED BY ONE-HANDED BALL-CATCHING PERFORMANCE. S.J. Judge and C.M. Bradford*. University Laboratory of Physiology, Parks Road Oxford, England OX1 3PT.

A one-handed ball-catching task was used to study the disturbance of depth judgement induced by telestereoscopic viewing (i.e. viewing with effective interocular separation increased, in this case by a factor of approximately 2.3), the recovery of performance with experience in the telestereoscope, and the errors that subsequently arose when the telestereoscope was removed. Performance was videotaped. On first wearing the telestereoscope, subjects closed the hand when the ball was approximately twice as far away from the eyes as the hand. After less than 20 trials in the telestereoscope, subjects were closing the hand at approximately the correct time and place, although rather more trials were needed for ball-catching performance to recover to normal. When the telestereoscope was removed there was an after-effect with reaching errors in the opposite direction. A number of possible explanations of these data are considered.

496.2

AN EXAMINATION OF THE ROLE OF CENTRAL AND PERIPHERAL VISION IN PREHENSION. *B. Sivak and C.L. MacKenzie. Department of Kinesiology, University of Waterloo, Waterloo, Ontario Canada, N2L 3G1.*

During prehension, visual information is provided by both central and peripheral visual fields. In our study subjects reached for and grasped a dowel 2.5 cm in diameter using either peripheral vision only or central vision only. A three dimensional movement analysis yielded information about reach and grasp components during prehension. For the reach component with peripheral vision only, the proportion of movement time spent after peak velocity, acceleration and deceleration did not change compared to normal vision. However, movement time was longer and overall speed was slower with peripheral vision only than normal vision. The grasp component was affected. For the reach component with central vision only, subjects reached a lower overall speed, movement time was longer and the proportion of movement time spent from peak acceleration, velocity and deceleration was longer for central vision only than for normal vision. The grasp component was not affected with central vision only compared to normal vision. Results suggest that central and peripheral vision provide specific information to the organization of prehension.

496.3

THE EFFECT OF OBJECT SIZE AND TYPE OF GRASP ON PREHENSION. *C.L. MacKenzie and B. Sivak. Department of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1.*

A recent study by Marteniuk and Athenes (1986) has shown that a high correlation exists between the size of the opening between the index finger and thumb and the object to be grasped. The present study examined how visual information from varying size dowels integrates with the motor system when prehension requires either a collective or independent finger grasp. A three dimensional movement analysis yielded information about the grasp component during prehension movements. Subjects were required to reach for and grasp dowels varying in size from 1 cm to 7 cm in 1.5 cm increments using either a collective or an independent finger grasp. Analysis of the peak aperture revealed a grasp type by dowel interaction. Consistent with the Marteniuk study, peak aperture increased systematically for the 5 different dowel sizes when an independent grasp was used. However, although peak aperture was smaller for the smallest dowel and largest for the largest dowel size when a collective grasp was used, the increase was not systematic for all dowel sizes. This suggests that the visuo-motor integration process may be different for collective and independent grasps.

496.4

BEHAVIORAL & COMPUTATIONAL MODELLING USING BALLPARK MODELLING FOR STUDYING HUMAN PREHENSION, A.Iberall, Dept. of Computer Sci., Univ. of Southern Calif., Los Angeles, CA. 90089 and C.L. Mackenzie, Dept. of Kinesiology, Univ. of Waterloo, Ontario, Canada N2L 3G1.

Wing et al [JMB,1986] quantified prehensile movements, arguing for a differential contribution of thumb & fingers. Arbib et al [EBRS,1985] use schema theory to model these movements: a schema gets the wrist into the right'ballpark' of the location by adding a small delta to the goal location. Another one sets up a hand posture consisting of virtual fingers (VFs), again within some ballpark of the final posture. Once positioned, other schemas adjust these parameters, subtracting small deltas to ensure contact.

We performed a pilot study of a subject reaching in the sagittal plane for a horizontal dowel. At peak aperture the wrist was always 20mm of the value it would have at time of contact, and its orientation within 0.06 radians. These results indicate that the wrist was always in some ballpark at peak aperture. The orientation and length of VF1 were smaller at peak aperture than at contact (within 6mm and 0.06 radians). The orientation and length of VF2 was more variable. This supports Wing et al that the thumb seems to be more constrained.

We simulated these schemas using an Amari-Arbib neural net. Stronger weights were needed on VF1,due to the kinematic constraints. These simulation results support the behavioral results for ballpark modelling.

496.5

A KINEMATIC ANALYSIS OF PREHENSION IN APRAXIA. J.L. Charlton,*E.A. Roy, R.G. Marteniuk and C.L. MacKenzie. University of Waterloo, Ontario N2L3G1

The disorder of apraxia is primarily manifest in tasks demanding complex coordination and hand posture and orientation (Roy et al., 1986; Haaland et al., 1980). While difficulties arise when pantomiming object use, more successful performance is observed with the appropriate context of actual objects. This study examined the kinematic characteristics of apraxics' errors in reaching, prehension and object manipulations.

Coordination complexity and context were manipulated in 5 experimental conditions: 'reach'; 'reach and orient' the hand; 'reach, orient and grasp'; 'reach, orient, grasp and stir' with a dowel and imaginary cup; and with a real spoon and cup. Two apraxics and 3 non-brain-damaged control subjects participated in the study. The WATSMART system provided 3-dimensional data describing movements in terms of wrist resultant velocity and acceleration profiles and aperture profiles.

Analysis of wrist resultant velocity profiles indicated that apraxics exhibited smaller peak speeds and longer time in acceleration for all conditions. Furthermore, apraxics made more frequent adjustments of acceleration and deceleration than control subjects in Conditions 1 to 4, in which complexity was manipulated, suggesting a feedback guidance strategy. Apraxics also adopted a notably wider maximum aperture and spent longer percent time in closure, suggesting a compensatory strategy for spatial errors in guiding the hand to the object. When context was present, apraxics' wrist acceleration profiles and aperture profiles were more similar to control subjects. Context thus appears to be critical for apraxics' efficient performance. Results are discussed in terms of conceptual and production disorders of an action control system.

496.6

EFFECT OF INSTRUCTIONS ON COMPENSATORY ADJUSTMENTS DURING PRECISION GRIP.

C.J. Winstein, J.H. Abbs, and D.E. Petashnick*. Speech Motor Control Laboratories, Waisman Center, Univ. Wisconsin, Madison, WI 53706.

Successful grasp, lift, and manipulation of objects requires modulation of neuromuscular outputs by cutaneous and muscle mechanoreceptors in relation to motor set and task demands. Previous work has shown compensatory adjustments in grip force and associated muscle activity 60-80 ms following unanticipated object slips (Westling & Johansson, 1984; 1987). In this study, the effects of motor set on these grip adjustments were evaluated in four subjects. Unexpected vertical load perturbations were delivered to an object held between the thumb and index finger. Two instructional variations ("hold", "let-go") were combined with two load conditions (load, unload) resulting in four experimental conditions. Overall, a 15% increase in grip force (.6 N) was observed to loads and an 8% reduction (.3 N) to unloads. Average latency of these initial compensatory grip force changes was 55-85 ms. Several EMG changes accompanied the initial grip force adjustments, including increased and decreased activity to load and unload, respectively, in both adductor pollicis (50-60 ms latency) and extensor carpi radialis longus (12-30 ms latency). In addition, increased abductor pollicis brevis activity (50-60 ms) was associated with the unloads. Characteristics of these initial responses did not appear to be affected by the instructions. However, secondary changes associated with the "let-go" instruction were evident as early as 160 ms after perturbation in grip force, and as early as 135 ms in adductor and abductor pollicis activity. These secondary adjustments were thus influenced by motor set. In contrast to earlier work with long-latency muscle afferent responses, these findings suggest that initial compensatory grip adjustments of comparable latency may be unmodifiable by instructional variations. (Supported by NIH grants NS-13274 and HD-03352.)

496.7

TRANSITION OF PHYSIOLOGICAL TREMOR OF THE FINGER INTO FATIGUE TREMOR. S.S. Palmer and S.M. Bane* (SPON: G. Jackson). Depts. of Kinesiol., and Physiol. & Biophys., and Neur. & Behav. Biol. Program, Univ. of Illinois at Urbana-Champaign, IL 61801.

To resolve conflicting reports from different laboratories in regard to the transition of tremor frequencies and amplitudes under conditions of prolonged submaximal contractions, human subjects (6 female, 6 male) were asked to elevate the middle finger of their nondominant hand 1½" above the table top on which their hand was placed for 45-60 min. A lightweight accelerometer was taped to the finger to record tremor. EMG was recorded from extensor digitorum. Data stored on a tape recorder was analyzed using a spectral analysis program and an IBM PC/AT. Stretch reflexes were tested before and after the task by averaging 20 trials of rectified EMG.

All twelve subjects showed enhanced 8-12 Hz physiological tremor after 15-35 min, ranging from 2-115 ($\bar{x}$=28) times the original amplitude. Three subjects showed a progressive increase from 15-35 min, but even in these subjects variability predominated over clear progression. In 10 subjects measured, stretch reflex components 10-50 ms after stretch were decreased in amplitude after the task by 18-76% ($\bar{x}$=46%). 7/12 subjects showed a sudden onset of a 4-6 Hz tremor, but it was never both maintained and greater than the 8-12 Hz tremor. All humans probably experience greater physiological tremor with fatigue, but their susceptibility to a 4-6 Hz tremor varies.

496.8

COMPLEX OSCILLATIONS IN A HUMAN MOTOR SYSTEM. Beuter, A., Larocque, D.*, Glass, L.*. Univ. du Québec à Montréal and McGill University.

Experiments were performed to investigate the oscillations arising in a human motor system with delayed visual feedback. Eight subjects were instructed to maintain a constant finger position relative to a stationary baseline. The finger displacement was measured using a micro-displacement transducer connected to the index finger, and was displayed on an oscilloscope. Time delays between 40 and 1500 msec were inserted in the visual feedback loop for 100 sec. Results show that as the time delays increase irregular rhythms appear with short intermittent periods of regular oscillations. These regular low frequency oscillations have an amplitude that increases with the time delays and a period that is consistently about 2 to 4 times the time delay. Fast Fourier Transforms show a peak between 8 an 12 Hz corresponding to physiological tremor in half the subjects. No systematic variations in the FFT for the 2 to 15 Hz range were observed as time delay increased. In the 0 to 2 Hz range the FFT show a consistent increase in power with the time delay. These results indicate that under the conditions of this experiment, tremor is not affected by time delays in the visuo-motor system and that time delays in the feedback loops of motor control systems give rise to complex ocillatory behavior.

496.9

ABBERANT GRASP FORCE REGULATION AND DECREMENTS IN MANUAL FUNCTION AS A CONSEQUENCE OF REDUCED HAND SENSORY FUNCTIONING IN THE AGED. K.J. Cole and K. Grimes. Dept. Exercise Science, Univ. of Iowa, Iowa City, Iowa 52242.

Impairments of manual dexterity are commonly observed in the elderly without other signs of disease. Geriatric populations also demonstrate substantially reduced densities of cutaneous mechanoreceptors in the hands, particularly Meissner's corpuscles. Given recent demonstration of cutaneous sensory contributions to grasp force control during precision grasp (Johansson, R., Westling, G. Exp. Brain Res., 56: 550-564, 1984), it appears reasonable to hypothesize that impairments of manual dexterity in the aged are related to reduced hand sensibility. Thresholds for 2 point and moving 2 point discrimination at the finger pulps were obtained from elderly and young adults. "Manual dexterity" was assessed using common functional tests, such as the time needed to flip a series of playing cards that were lying flat on a table surface. Grasp forces during lifting of a test object with a precision grip were measured in the manner of Johansson and Westling (ibid). The elderly group showed significantly elevated tactile thresholds and increased times in the dexterity tasks. Grip forces were increased over control levels and were incompletely adapted with changes in the slipperiness of the test object. Dexterity and grip force control were related to tactile thresholds across both groups, rather than with age, per se.

496.10

ADAPTIVE VISUAL-MOTOR MODEL FOR CONTROL OF BEHAVIORAL SEQUENCES M. Kuperstein, Neurogen, 325 Harvard St. suite 211, Brookline, MA 02146

In the infant development of grasping behavior, there is an initial period of sequential groping to eventually grasp a stationary object. As the infant gains sufficient accuracy, grasping is typically optimized to one reach. How does the brain learn about the mistakes from the sequential groping experience and incorporate it into accurate control of grasping that is generalized throughout the volume of space? I will show an implemented neural model that suggests an answer.

Studies by Held, Hein and others in the last two decades have shown that, in the kitten, visually guided behavior develops only when changes in visual stimulation are systematically related to self-produced movement. This work extends these studies by hypothesizing that a *sense of space* emerges out of the correlation between object sensation and object manipulation.

The general strategy for accomplishing a representation for *space* is the sensory-motor neural circular reaction. In this reaction, motor activity for the entire range of grasping postures of an object are generated one at a time by some activating source. During each posture the two eyes see the 2-D projection of the 3-D object. Visual map activity is then correlated with whatever motor map activity was used to grasp the object. The correlation occurs from the changes of synaptic weights between visual inputs and motor outputs. After the correlation is learned, any object that is seen can trigger the visual maps to activate the motor map for the intended grasping posture of that object.

There are two key aspects to the current model called INFANT (Interacting Networks Functioning on Adaptive Neural Topographies): 1) A distributive, topographic architecture is used to combine the visual activity from an object, from both eyes and interface it with motor outputs. 2) Learning is achieved by incrementally modifying the distributions of input weights to the target map over single or sequential performance trials. On any given trial, only the weights of the active inputs in the trial are changed.

The neural model has been implemented into a working robot system with stereo cameras. The implementation learns to accurately grasp an object anywhere in space with one reach from the experience of sequential groping.

MECHANISMS OF HUMAN HEAD STABILIZATION DURING RANDOM SINUSOIDAL ROTATIONS. E.A. Keshner and B.W. Peterson. Dept. of Physiology, Northwestern University Medical School & Sensory-Motor Performance Program, Rehabilitation Institute of Chicago, Chicago, IL 60611.

Reflex, voluntary and passive biomechanical mechanisms are available to produce stability of the head-neck motor system. Guitton et al. (1986) found that longer latency, voluntary mechanisms dominated stabilization at frequencies lower than 1 Hz, but suggested that reflexes and biomechanics might be important at higher frequencies. To test this, we recorded chair and head velocities, and surface EMG's from splenius and sternocleidomastoid as seated subjects were rotated about the vertical axis. The random sum-of-sines stimulus had frequencies ranging from 0.185 to 4.18 Hz which should be high enough to elicit vestibulocollic (VCR) and cervicocollic (CCR) responses. Gain of head velocity and EMG responses were calculated using a best fit sinusoid. Four test conditions varied the relative influence of attentional processes and visual, vestibular, and proprioceptive feedback. EMG records revealed modulation of neck muscle activity in all 4 conditions. When subjects attempted to stabilize the head both with and without visual feedback, head stabilization in space was excellent at low frequencies and reached a resonant peak at about 2 Hz. When subjects performed mental arithmetic (MA), head stability was poor at low frequencies, but approached the other conditions above 1 Hz. Plotting head relative to trunk revealed a transition from neurally-dominated to inertially-dominated head stabilization at about 2 Hz. EMG activity plotted relative to head position in space, exhibited second-order lead behavior very much like that produced by the VCR in the cat. During MA, EMG activity increased with increasing head motion at higher frequencies, indicating that VCR and CCR contribute to stabilization. When actively stabilizing, subjects produced additional EMG output relative to head stabilization at lower frequencies, where EMG led head motion as expected. At high frequencies, lead was less, suggesting that VCR and CCR were responding to, and presumably damping inertially generated head movements.
Supported by grant NS22490.

TEMPORAL CHARACTERISTICS OF NECK MUSCLE EMG OF TRAINED CATS IN VISUAL ORIENTATION. M.-F. Decostre*, M. Crommelinck* and A. Roucoux. Lab. of Neurophysiology, Univ. of Louvain Sch. of Med., B-1200 Brussels, Belgium.

The distribution of EMG activity of different neck muscles in relation with orienting head movements has already been studied in the alert trained cat (Roucoux, A. et al. Soc. Neurosci. Abstr., vol. 11, p. 83, 1985). It has been shown that, on basis of the intensity of its global discharge, a preferential orientation could be attributed to each muscle: this orientation however covers a relatively wide angle with the consequence that many muscles contribute to a given movement. The purpose of this study was to examine the timing of the discharge of the different muscles as a function of the direction of the head movement. The latency, i.e. the delay between the burst and movement onsets, progressively increases as the movement direction diverges from the preferential orientation of the muscle: from a negative value of about 60ms (the burst precedes the movement) to a positive 70ms (the burst occurs during the movement). Some muscles show a late activity, occurring around the midcourse of downward movements. They may show inhibitions whose latency and duration are related to the direction of the movement.

In conclusion, the head motor system controls the direction and amplitude parameters not only by selectively activating the appropriate muscles but also by sequencing their activity to start, control the trajectory and stop the movement.

496.13

EYE, HEAD AND HAND COORDINATION WHILE GRASPING AND POINTING. H. Carnahan*, and R.G. Marteniuk. Dept. of Kinesiology, Univ. Of Waterloo, Ontario, Canada, N2L 3G1.

The sequential coordination of eye, head and hand movements under various task demands was studied. Six subjects were instructed to grasp and lift a wooden disk located on a table top in two different locations. In a second study six different subjects pointed as fast and accurately as possible to lights located at three locations. The initiation and termination of lateral eye movements were measured by an EOG and the WATSMART 3-D system was used to monitor the movements of the head and hand. Results from the first experiment showed that the head started to move an average of 75 ms before the eyes and 87 ms before the hand. In the second experiment relatively large variability masked any differences between head and eye start. The hand however, started last. The variability in this experiment appeared to be due to different strategies employed by the subject. Evidence is presented that on trials where the subject emphasized accuracy, the eyes moved first, and on trials where speed was emphasized the head moved first. These results are discussed in terms of planning and execution processes in multimovement systems.

496.14

POSTURAL POSITIONS YIELDING ALIGNED EIGENVECTORS OF COORDINATE FRAMES INTRINSIC TO VESTIBULAR AND HEAD-NECK MUSCLE SYSTEMS IN HUMAN. *A. Berthoz, M. Benamou* (Lab. Neurosensorielle, CNRS and Hopital Cochin, Paris, 75006, France) and *A.J. Pellionisz* (Dept. of Physiol. New York Univ. Med. Ctr. 10016) (SPON:J.I. Simpson)

Qualitative characterization (eg. depiction) of complex sensorimotor phenomena such as *posture* has been widely used, for its intuitive power, since ancient times. However, a *mathematical* encapsulation of what posture represents has been difficult because of a scarcity of concepts and formalisms suitable for integration and synthesis.

We propose an approach *to use multidimensional computer modeling techniques for a reconceptualization of posture in terms of functional geometry.* Given the great number of degrees of freedom which are to be controlled in maintaining a posture, we wish to identify constraints that CNS may be using in order to match systems of sensory information and motor command. The approach is based on models using *general coordinate systems that are intrinsic to the CNS.* Such functional coordinate axes can be established even in case of moving multiarticulate skeletomuscular systems with distributed centers of rotation. Using graphics-based computer anatomy, a preliminary model of human head-neck system has been developed, enabling us to calculate Eigenvectors of the neck-musculature and to compare them with the cardinal axes of the frame of vestibular canals. Initial results show that *the vestibular sensory and neck-muscle motor frames and their Eigenvectors rotate in different directions during head-pitch,* and thus in *two* distinct pitch-positions they are aligned. While models provide quantitative predictions for postural positions in which sensory and motor geometries match, experimentation will determine their accuracy. Maintaining such postural positions may be of advantage since co- and contravariant expressions may be identical and thus the sensorimotor transfer minimizes errors. -Support: CNRS & NS 22999-

496.15

TOPOGRAPHIC MAPPING OF PRESACCADIC BRAIN ELECTRICAL ACTIVITY IN HUMANS: SUPPORT FOR THE DUAL PREMOTOR SYSTEMS HYPOTHESIS. G. Goldberg and M. Moster*. Electrodiagnostic Center, Moss Rehabilitation Hospital and Temple University School of Medicine, Philadelphia, PA. 19141.

Voluntary saccadic eye movements are preceded by a series of event-related potential (ERP) components. The presaccadic negativity (PSN) beginning 500 to 800 ms before the saccade is analogous to the Bereitschaftspotential recorded in advance of finger movement and may reflect activation of the supplementary motor area (SMA--Deecke L et al, *Human Neurobiol* 4:143-154, 1985). A brief, large amplitude component called the spike potential (SP) immediately precedes the saccade. Cortical unit and microstimulation studies in monkeys (Schlag J & Schlag-Rey M, *J Neurophysiol* 57:179-200, 1987) and regional cerebral blood flow (rCBF) studies in humans (Fox PT et al, *J Neurophysiol* 54: 348-369, 1985) demonstrate a saccade-related cortical region rostral to SMA on the dorsomedial surface of the frontal lobe. Activational and microstimulation properties distinguish this "supplementary eye field" (SEF) from the classical arcuate frontal eye field. Guided by predictions from the **dual premotor systems hypothesis** (Goldberg G, *Behavioral and Brain Sciences* 8:567-615, 1985; 10:323-329, 1987), the dependence of the topography of presaccadic ERPs on behavioral context was examined in six normal human subjects. The degree to which timing and direction of saccades were exogenously constrained by visual information was systematically varied. Our general findings are as follows: (1) Prior to self-initiated "endogenous" saccades generated in the dark, there is a large, vertex-centered PSN which may be related to progressive activation of the SEF, (2) the PSN is greatly attenuated when the timing and direction of saccades are commanded by visual cues, (3) the SP always demonstrates a large negative focus over the lateral frontal electrode in the direction of the saccade suggesting that it is probably related to EMG activity from the underlying lateral rectus muscle (Thickbroom GW & Mastaglia FL, *Brain Res* 339:271-280, 1985), (4) this method provides dynamic information which complements that of cortical unit recording in subhuman primates and rCBF recording in humans using PET. These findings are generally consistent with the idea that the SEF may play a special role in self-initiated, endogenous saccades and provide support for the **dual premotor systems hypothesis** as applied to the generation of voluntary saccades.

TECTO-TEGMENTO-SPINAL CIRCUITS IMPLICATED IN SACCADIC HEAD TURNS IN THE BARN OWL (*TYTO ALBA*). T. Masino and E.I. Knudsen. Dept. Neurobiology, Stanford University, Stanford CA. 94305.

The barn owl makes quick orienting head turns towards auditory or visual objects of interest. The movement is thought to depend critically on the map of auditory and visual space in the optic tectum. To begin to understand how tectal activity controls head movements, we studied tecto-tegmento-spinal connections by injecting HRP or tritiated leucine into the tectum and HRP or rhodamine coupled latex beads into the spinal cord. Results indicate that, as in other avians, the direct tectospinal projection is extremely weak (avg. 3 cells per spinal injection). However, there are robust tectal projections to several regions of the brainstem tegmentum including the interstitial nucleus, the red nucleus, the gigantocellular reticular nucleus, regions around the oculomotor nuclei, and other sites within the midbrain and pontine reticular formation. Injections of retrograde tracers in the cervical spinal cord labeled cells throughout the brainstem and ventral thalamus. A comparison of anterograde label from tectal injections with retrograde label from the spinal cord injections revealed several regions of overlap, including the interstitial nucleus, parts of the red nucleus, and parts of the medial reticular formation.

We recorded electrophysiologically from cells in these brainstem regions while electrically stimulating the tectum. Single units were found which responded either with an abrupt increase or decrease of spontaneous firing rates or with a brief burst of spikes. Both short (6-10 msec) and long (12-30 msec) latency reponses were seen. Taken together, the anatomical and physiological observations suggest that tectal commands for saccadic head movement are mediated by several tegmental nuclei which operate in parallel to activate the spinal motor circuitry. (Supported by NIH grant R01-NS-16099.)

LOCALIZATION OF MOTONEURONS INNERVATING CERVICAL PREVERTEBRAL MUSCLES IN CAT AND RAT: IMPLICATIONS FOR CONTROL OF HEAD MOVEMENTS. L.J. Cruise and R.J. Cowie, Animal Section and Department of Anatomy, College of Medicine, Howard University, Washington, D.C., 20059.

A recent study of cat descending eye/head movement-related projections showed distinctive differences in caudal medullary and cervical spinal cord motoneuron (MN) targets (Holstege and Cowie, submitted *Exp. Brain Res*). While the location of MNs related to most dorsal and all superficial neck muscles could be identified from published accounts, an undefined medial target region seemed to contain MNs, possibly innervating deep prevertebral muscles (PVMs). Therefore, in this study PVMs including the longus capitis (LC), the rectus capitis ventralis and lateralis, as well as the epaxial obliquus capitis cranialis (OCC) were injected with HRP/WGA-HRP via a ventral surgical approach. Following 48 hr survival and standard aldehyde perfusion/postfixation, caudal medullary and cervical cord sections were reacted with TMB, mounted and counterstained, and the location and characteristic topography of the retrogradely-labeled MNs analyzed.

Preliminary results confirmed that PVMs in both species were typically innervated by MNs grouped along the ipsilateral medial gray/white margin (MMg) of the ventral horn, but not in the ventromedial nucleus. Labeled cell-columns in MMg partially overlapped dorsoventrally and extended caudally from the pyramidal decussation through the caudal end of C1. Occasional labeled cells were found in the C2 segment (or more caudally with LC injections), as well as within the anterior funiculus (AF), lamina X, and the opposite MMg. Labeled dendrites consistently extended medially into the AF, dorsally into laminae VII and X, and ventrolaterally toward lateral VIII and IX. Thus, the MNs projecting to the PVMs and OCC, which primarily act to flex, tilt and fixate the head, were found to be located optimally to intercept medial supraspinal pathways mediating control of head orientation, postural and compensatory reflexes.

NEURONAL ORGANIZATION FOR DIRECTED MOVEMENT IN THE FROG: SIMILARITIES IN VISUAL AND TACTILE PREY ORIENTING. P. Grobstein, K. Crowley* and J. Spiro*. Dept. Biology, Bryn Mawr College, Bryn Mawr, PA 19010.

The movement triggered by a prey stimulus at a given location in visual space reflects not only the retinal region activated but other neural signals as well. We have found that a similar "activity gated divergence" characterizes the circuitry for tactile orienting. In different naturally occurring postures the rostral tip of the hindlimb lies at different locations relative to the body. In individual frogs, we repeatedly first recorded the location of this cutaneous site in a body coordinate frame, and then stimulated it by gentle stroking. For nearer and more rostral locations, the resulting movement was a directed snap. For more distant and caudal locations, frogs tended to respond instead with a reorienting movement lacking a snap component. We conclude that the orienting movement triggered by a given cutaneous stimulus is not invariant, but reflects instead an interaction of cutaneous signals with additional signals related to limb position in a body coordinate frame.

Retinal information is apparently transformed within the midbrain into a lateralized and parcellated signal representing stimulus location in a head or body centered coordinate frame. Unilateral tectal lesions produce scotomas in the contralateral visual field. More caudal unilateral lesions, in contrast, affect responses to stimuli in the ipsilateral hemifield, and yield a syndrome characterized not by scotomas but by a change in responses to those appropriate for more frontal locations. We have found evidence for similar organization in the case of tactile orienting. Following unilateral ventromedial lesions in the rostral medulla, frogs responded to ipsilateral tactile stimuli with turns of abnormally small amplitude; responses to contralateral stimuli were normal. Correlated with sufficiently reduced turn amplitudes was an increase in the frequency with which animals snapped, rather than reoriented, for more caudal stimuli. As with visual behavior, the lesions caused not abnormal movements but rather the normal movements appropriate for more rostral stimulus locations.

Our findings raise the possibility that the similarities between observations on tactile and visual behavior reflect shared use of common intermediate level circuitry carrying signals related to stimulus location in a non-sensory, non-motor coordinate frame. Consistent with this, we have found that when both visual and tactile behavior are studied in the same lesioned animals the observed visual and tactile deficits are correlated in occurrence and severity. EFFECTS OF GUM HARDNESS ON VOLUNTARY CHEWING. B. Bishop, O. Plesh* and W. McCall. Depts. of Physiology and Oral Medicine, State Univ. of NY at Buffalo, Buffalo, NY 14214.

We reported previously that an individual's automatic chewing pattern is significantly modified with a change in peripheral feedback (i.e., a change in the hardness of chewing gum). In this study we asked whether the voluntary chewing pattern is similarly modified by changing gum hardness. We hypothesized that during voluntary chewing the central pattern generator which controls automatic chewing is by-passed, thus modifying the way peripheral feedback is centrally processed. Nine adults with no oro-facial dysfunctions were instructed to chew, in sequence, a standardized piece of soft and hard gum in time with a metronome set at 46, 100 or 160 BPM. We recorded jaw movements with a Kinesiograph and masseter EMGs with surface electrodes. Results showed that changing gum hardness evoked no changes in any temporal or spatial aspect of the chewing pattern or in the timing or recruitment of either masseter muscle at any chewing frequency. We conclude that neural mechanisms which process sensory feedback are by-passed when chewing is under voluntary control. (NIDR Grant DE-06717.)

LINEARITY & RELIABILITY OF JAW MUSCLE EMG & BITE FORCE. R.S. Kull, W.D. McCall, Jr., and D.C. Dixon*. Sch. Dent. Med.,SUNY, Buffalo, NY 14214.

The reports of linearity and reliability of jaw muscle EMG amplitudes with bite force are conflicting and scanty. We investigated this linearity and its reliability over two sessions.

Surface EMG activity was recorded from the anterior temporalis and masseter muscles on both sides in ten subjects while each bit on a transducer at the second molar using randomly ordered fractions of maximal isometric vertical force at two sessions separated by a week or more.

Scatter plots of EMG vs. force showed no consistent evidence of nonlinearity. Moreover, all 80 plots had $r>0.6$ ($p<.01$) with $r>.8$ in 80%.

Reliability was assessed visually by superimposing plots of EMG vs force for the two sessions and statistically by comparing the slopes of the regression lines at the two sessions. The plots superimposed well and the slopes did not differ significantly.

We conclude that masseter and temporalis EMG amplitudes are linearly related to bite force and are reliable over recording sessions.

SINGLE MUSCLE UNIT ACTIVITY DURING RHYTHMICAL JAW MOVEMENT. A. Lev-Tov, M. Tal and R. Lavy. Depatment. of Anatomy, The Hebrew Univ. Medical School, Jerusalem, Israel.

The present work characterizes the activity patterns of single muscle units during spontaneous rhythmical jaw movements (RJM) in ketamine anesthetized guinea pigs. Single unit recordings were obtained from the dorsal and ventral histochemical compartments of the anterior digastric muscle using teflon coated stainless steel wires (uncoated diameter= 90 μm).

The analysis of 5 different units (in 6 preparations) revealed 3 different patterns of activity: 1. continuous tonic activity at slow and regular firing rate (mean<25 Hz). 2. repetitive bursts of various durations at a slow and irregular firing rates. 3. high frequency (mean>63 Hz) rhythmical activity synchronized with the EMG bursts during RJM. The first two types of activity were observed mainly in the ventral compartment which is characterized by the abundance of slow-twitch muscle units (Lev-Tov, A. and Tal, M., *J. Neurophysiol.* 58:496, 1987) . The third type was evident in both compartments during the rhythmical EMG bursts and is likely to involve recruitment of fast-twitch motor units.

Further studies using refined recording techniques are now under progress.

COMPARISON OF SINGLE UNIT DISCHARGE PROPERTIES IN THE PERIAQUEDUCTAL GRAY AND NUCLEUS RETROAMBIGUUS DURING VOCALIZATION IN MONKEYS. E.A. DeRosier*, R.A.West*, C.R. Larson. Communication Sciences and Dirsorders, Northwestern University, Evanston, IL 60208.

Previous studies have shown that the midbrain periaqueductal (PAG) is involved in vocalization, but its precise function remains obscure, in part because of a lack of understanding of the location of vocalization-related PAG neuronal projections. Holstege (1987) demonstrated that PAG neurons project to the nucleus retroambiguus (NRA), and NRA cells project to the ventral horn of the spinal cord and the nucleus ambiguus, suggesting that the NRA may be involved in vocalization.

To test the hypothesis that the NRA may be involved in vocalization, extracellular recordings of NRA neurons were made in Macaca nemestrina monkeys trained to vocalize. Simultaneous recordings were made of the laryngeal and respiratory muscle activity and vocalization. Activity of the NRA neurons was evaluated with respect to vocalization and muscle activity and compared with PAG neuronal activity recorded under similar conditions.

In and around the NRA, cells with a variety of discharge patterns were observed, and some of these patterns were similar to those observed in the PAG. A few NRA cells were inactive and became active just before and during vocalization. Many cells displayed a respiratory rhythm and discharged either in phase with or out of phase with one or more of the respiratory muscles. Other neurons were phasically active with oral-facial movements and may be related to lingual, masticatory, facial, palatal or pharyngeal muscle activity. Cross-correlograms between units and EMGs indicated that NRA cells were more highly correlated with vocalization muscles than PAG cells. Microstimulation at PAG recording sites excited muscles with latencies of 12 - 20 ms. Microstimulation in the NRA excited muscles at 5 - 10 ms latencies.

The data support the idea that cells in and near the NRA are involved in vocalization. The NRA may serve as a relay and integration site for descending inputs to laryngeal and respiratory motoneurons.

MOTOR SYSTEMS AND SENSORIMOTOR INTEGRATION: CEREBELLUM III

CELLULAR PROPERTIES OF PURKINJE CELLS AND EXCITATORY TRANSMISSION IN THE ISOLATED TURTLE CEREBELLUM. N.T. Slater, D.R. McCrimmon and L.J. Larson-Prior. Dept. of Physiol., Northwestern University Medical School, Chicago, IL 60611 U.S.A.

The intact turtle cerebellum can be maintained *in vitro* for several days, allowing long-lasting (1-10 hr) somatic and dendritic intracellular impalements of Purkinje cells (PCs). We have studied the electrical properties of Purkinje cells in this preparation and the responses of Purkinje cells to activation of climbing- (CF) and parallel (PF) fibers. Somatic recordings of PCs revealed fast TTX-sensitive action potentials, slow calcium spikes, and a prominent 4-AP-sensitive outward rectification resembling A-current. Large plateau potentials were observed in solutions containing either TTX and $CdCl_2$, or TTX, TEA and 4-AP. Sodium spikes were largely absent in presumed dendritic recordings, but spontaneous bursting and calcium spikes were observed. All-or-none CF complex spikes could be activated by stimulation of the cerebellar peduncle, and PF-mediated EPSPs could be activated by 'on-beam' stimulation of the cerebellar margin. A novel slow EPSP was also observed following peduncle stimulation. The NMDA receptor antagonist DL-AP5 had little effect on these synaptic potentials, but the PF response was reversibly blocked by the broad spectrum excitatory amino acid (EAA) antagonist kynurenic acid (1-2 mM), thus EAA receptors may mediate transmission at the PF synapse. In summary, the data indicate that Purkinje cells in turtle cerebellum share many common electrophysiologic and pharmacologic properties with mammalian Purkinje cells *in vitro*. The resistance to anoxia of turtle brain will provide the opportunity to develop an intact brainstem-cerebellum preparation for routine intracellular recording. Supported by NS17489 and NS07243.

497.2

REGIONAL GLUCOSE UTILIZATION IS DIFFERENT IN THE BRAINSTEM AND CEREBELLAR NUCLEI OF GENETICALLY DYSTONIC AND NON-DYSTONIC RATS. J.F. Lorden and L.L. Brown. Dept. of Psychology, Univ. of Alabama at Birmingham, Birmingham, AL 35294, and Dept. of Neurology, Albert Einstein Coll. of Med., Bronx, NY 10461.

A survey of brain glucose utilization (GU) was carried out to identify brain regions showing abnormal metabolism in the genetically dystonic (dt) rat, a mutant with a movement disorder involving twisting of the limbs and axial musculature. For 19 rats 19-24 days old, GU was estimated with arterial plasma data (Sokoloff, 1977). Animals were quiet during the experimental period. All 6 dt rats and 5 of 8 unaffected littermates had an overall GU rate lower than that of 5 normal non-littermates in the 61 regions analyzed (Mean difference, -37%). When the dt group was compared to the group of 5 unaffected littermates with similar low GU rates, the mutants had a significantly higher GU rate than controls in the deep cerebellar nuclei (e.g., n. interpositus, p .01). When a z-score analysis was used, differences were found in the deep cerebellar nuclei, locus coeruleus, pontine gray, red nucleus, principal nucleus of the third nerve, ventrolateral and ventromedial nuclei of the thalamus, lateral habenula and basolateral nucleus of the amygdala. The data suggest that the cerebellum and its efferents are the focus of abnormal neural activity in this mutant. (Supported by NS18062).

497.3

GLUTAMIC ACID DECARBOXYLASE (GAD) ACTIVITY AT CEREBELLAR PROJECTION SITES IN THE DYSTONIC RAT. G.A. Oltmans, M. Beales* and J.F. Lorden. Dept. of Pharmacology, Chicago Med. School, Chicago, IL 60064 and Dept. of Psychology, Univ. of Alabama, Birmingham, AL 35294.

Recent work has revealed the presence of a GABAergic projection from the deep cerebellar nuclei (DCN) to the inferior olive (IO) (Nelson, et al., 1984, Soc. Neurosci. Abst., 10:539), and lesions of this pathway produce a decrease in GAD immunoreactivity in the IO (Nelson & Mugnaini, 1985, Ibid., 11:182). In the genetically dystonic rat (dt) there is significantly increased GAD activity in the DCN, suggesting increased Purkinje cell inhibition of the intrinsic DCN neural activity. In the current study we measured GAD activity at two DCN projection sites, the IO and the red nucleus, to determine if this potential increase in inhibition of DCN activity would produce neurochemical consequences at the target sites. GAD activity in the red nucleus and IO was determined in discrete samples removed from frozen sections. In the IO a significant decrease in GAD activity was found in dt rats compared to normal littermate controls (-27%, p<.05), while no significant changes in GAD activity in the red nucleus were found. These results suggest that the elevated GAD activity found in the deep nuclei of dt rats may alter the activity of a GABAergic cerebello-olivary projection in this mutant. (Supported by NS18062 and the Dystonia Medical Research Foundation).

497.4

QUANTITATION OF CEREBELLAR CELL NUMBER IN REELER MUTANT MICE. Heckroth, J.A., D. Goldowitz, and L.M. Eisenman. Dept. of Anatomy, Thomas Jefferson University, Philadelphia, PA 19107. The reeler mutant mouse suffers from a serious genetically imposed defect in nervous system histogenesis, believed to be based on a generalized disruption of neuronal migratory mechanisms. The Purkinje cells of the reeler cerebellum are located in deep cellular aggregates, instead of in their normal superficial monolayer. Their abnormal position, and possible mixing with other cell types has precluded any study of their number in this mutant. We have used antiserum to the specific Purkinje cell marker, cGMP dependent protein kinase (gift of P. Greengard), to identify the Purkinje cells in reeler, and thus to quantify their number. Our results in four reeler mice indicate that this mutant possesses an average of 82,000 Purkinje cells, compared to 178,000 found in normal mice. Reeler Purkinje cell clusters are separate from the cerebellar nuclei of this mutant allowing us to quantitate the number of nuclear neurons as well. Our results indicate that reeler mice have an average of 8,500 nuclear neurons, a 15% reduction from the normal number of 10,000 cells. It thus appears that the nuclear neurons are not effected as severely as the Purkinje cells by the reeler gene, as their position is essentially normal, and their numbers are only slightly reduced. This finding is in line with studies of other mutations which seriously effect Purkinje cell number where little loss of cerebellar nuclear cells is observed.

c-fos EXPRESSION AND 14C 2-DEOXYGLUCOSE UPTAKE IN THE CEREBELLAR COPULA PYRAMIDIS DURING HINDLIMB MOTOR / SENSORY CORTEX STIMULATION IN THE RAT. Frank R. Sharp, Manuel F. Gonzalez, Stephen M. Sagar, James W. Sharp, Tom Curran*, and Kathleen R. Zahs. Departments of Neurology and Physiology, University of California at San Francisco and VA Medical Center, SF, CA 94121.

Electrical stimulation of hindlimb motor / sensory cortex of awake rats increased 14C 2-deoxyglucose (2DG) uptake diffusely as well as in granule cell patches in the dorsal and ventral lamellae of the eighth cerebellar hemispheric lobule, copula pyramidis (CP). Forelimb cortex stimulation and trained forelimb movements activated different regions of the paramedian lobule and copula pyramidis (CP). c-fos gene expression was examined using Fos protein immunocytochemistry 3 hours following a fifteen minute period of hindlimb cortex stimulation. Induction of Fos occurred in similar granule cell patches as those seen with 2DG. Fos was also induced in discrete Purkinje cell patches. Activated Purkinje and granule cell patches either wholly overlapped, partially overlapped, or were non-overlapping at various points along the CP lobule. The results support prior suggestions of compartmentalized processing of mossy fiber inputs and Purkinje cell outputs, and show that granule and Purkinje cell patches may be non-congruent as well as congruent.

497.6

MODEL OF LATERAL LINE SYSTEM FUNCTIONING IN THREE DIMENSIONS. Richard S. Babb, Rockefeller University, York Ave., N.Y., N.Y., 10021.

Previously, a simple theory of lateral line system functioning in the yaw plane has been proposed (Babb, 1982) based on work of Braitenberg (1967). Lateral line canals, the receptors of which are sensitive to low frequency vibrations, are found in the head as well as along the trunk of sharks. The canals of the head are found one above the orbit and another below. They are innervated by branches of the anterior lateral line nerve which projects to the lateral line lobe of the cerebellum. Phase information about waves detected by receptors in vertically separated ipsilateral canals is fed to the lateral line lobe and processed by the crista cerebellaris. According to the negative feedback model processing by parallel fibers in the crista would modify excitation in the plexuses inervating the lateral fin musculature. Movement of the fin musculature would produce a rotation of the shark's body in the pitch plane in a direction which would reduce the error signal. Such corrective action in the pitch plane along with that in the yaw plane would have the result of directing the shark in three dimensions towards the source of vibration.

497.7

DIFFERENT INFORMATION IS ENCODED BY SETS OF CLIMBING FIBER RECEPTIVE FIELDS IN THE ANTERIOR LOBE VERSUS THE PARAMEDIAN LOBULE. L.T. Robertson and G. McCollum. Robert Dow Neurological Sciences Institute, Portland, OR 97209-1595

The composition of climbing fiber receptive fields is related to the type of information encoded and to the ensembles of cells that participate in the encoding. An analysis was made of receptive fields of the face and the distal paw from individual climbing fiber responses encountered in the anterior lobe (AL) and paramedian lobule (PML) of the anesthetized cat. The boundaries of the receptive fields of the face or distal paw form compartments. Receptive fields of responses recorded in both regions are unions of compartments. Analysis of the inclusions of various compartments for the paw reveals that the lateral parts of the forepaw and hindpaw are included in a large proportion of the receptive fields for cells encountered in the PML, whereas the medial parts of the paw are more frequently included in forepaw receptive fields of cells located in the AL. Although many of the receptive fields are identified in both cortical regions, the proportion of the various compartments represented in the two regions are different. Thus, mechanical stimulation of certain parts of the paw or face will synchronously elicit different ensembles of climbing fiber responses in the AL versus the PML.

RESPONSE OF RAT PARAFLOCCULAR NEURONS TO COMBINATIONS OF VISUAL AND AUDITORY STIMULI. Brian N. Maddux, S.A. Azizi, and D.J. Woodward. *Dept of Cell Biology and Anatomy, UT Southwestern Medical Center, Dallas, Texas 75235.*

As part of an ongoing investigation into sensorimotor integration in the cerebellum, previous reports from this laboratory have demonstrated visual and auditory input to the rat paraflocculus. We have shown that these projections arrive via the dorsolateral basilar pontine grey from the peripheral regions of visual and auditory cortices, respectively, and that mossy fiber responses can be evoked to physiological stimuli in the unanesthetized preparation. In this study, recordings from parafloccular neurons were obtained with glass micropipettes in immobilized, locally anesthetized Long-Evans rats during visual and auditory stimulation. Selected images were projected onto a screen in front of the rat, while orientation, position, and velocity of travel were controlled by a computer. Delivery of a tone was also controlled by the computer, such that it was possible to deliver a variety of visual and auditory stimuli, each given alone or in combination with the other modality. Temporal offsets between paired stimuli can be varied systematically. The general finding is that combined auditory and visual stimuli may facilitate response of parafloccular neurons when compared to the response to single modality stimulus. Subthreshold inputs are clearly not "weak" inputs, since they are capable of powerful control over the dynamic range of firing when properly biased by input from a paired modality. *Supported by the Biological Humanics Foundation*

TRIGEMINAL NERVE SECTION IN NEONATES LEAVES HOLES IN CEREBELLAR GRANULAR LAYER TACTILE MAPS OF ADULT RATS. **M.G. Paulin and J.M. Bower, Division of Biology 216-76, Caltech, Pasadena CA 91125.**

The granular layer of crus IIa of the rat cerebellar cortex contains a fractured somatotopic map of perioral tactile receptive fields (lips, vibrissae, teeth etc). Because non-neighbouring sections of the body surface project to neighbouring regions (patches) in the cerebellar cortical map, we are interested in how the map is established ontogenetically. Previous work in this laboratory (Schlottman and Bower, Neurosci. Abstr. 13:77, 1987) showed that partial sectioning of the trigeminal nerve in 9-day postnatal rats causes crus IIa regions which contain patches responsive to tactile stimulation of the upper lip and vibrissae in normal rats to become weakly responsive to tactile stimulation of the upper lip near the nose and the corner of the mouth. Responses to these regions are not seen in crus IIa of normal rats, suggesting that partial nerve regeneration may have occurred. Accordingly, we have now used surgical procedures designed to ensure total nV section and to limit regeneration. In anaesthetized rats ranging from 2 to 11 days postnatal, we ligated the trigeminal nerve unilaterally and sectioned it distal to the ligation. At age 2-3 months, we mapped multi-unit responses in granular layer of crus IIa to tactile stimulation of the perioral regions, using glass micropipettes (1-2MW NaCl). The majority of rats had no responses, or very weak, nonspecific responses, in the regions normally occupied by upper lip projections. In a few rats we again found corner-of-mouth and perinasal responses as previously reported. As in previous experiments, the non-upper lip regions of the map appeared normal in all respects. These results further support the view that upper lip regions of the map are specified or reserved for the upper lip during development, and that, in general, the overall patchlike organization of tactile maps in cerebellar cortex is established inflexibly during development. (Supported by NIH grant 22205 and the Lucille P. Markey Foundation).

497.10

CEREBELLAR UNIT ACTIVITY DURING POSTURE AND MOVEMENT OF THE WRIST AGAINST CONSTANT TORQUE. Ted Milner & Allan M. Smith. Univ. of Montreal, Quebec, H3C 3J7.

A monkey was trained to move a wrist manipulandum to 3 target zones and then to maintain the position. We recorded wrist position, acceleration, torque, flexor EMG, extensor EMG and discharge of single cerebellar units while the monkey was: 1) moving against a constant flexor or extensor torque; 2) holding a target position against a constant flexor or extensor torque.

Conditions 1 and 2 elicited a reciprocal pattern of muscle activation from the prime movers of the wrist. When the torque opposed movement, activity in the agonist muscle gradually increased as movement progressed from the initial to the final position. When the torque assisted movement, activity in the antagonist muscle gradually decreased throughout the movement.

We have recorded from approximately 90 task-related units (including 15 Purkinje cells) in wrist and hand regions of the cerebellar cortex. Although the discharge rate for many cells was higher during movement than holding, inhibition did occur in some cases. Discharge rates were also related to EMG, target position, torque direction and movement direction.

497.11

LINEAR SYSTEMS ANALYSIS OF CEREBELLAR DEEP NUCLEI CELLS DURING PERFORMANCE OF CLASSICALLY CONDITIONED EYEBLINK. N.E. Berthier, A.G. Barto, and J.W. Moore. Depts. of Psychology and Computer and Information Science, Univ. of Mass., Amherst, MA. 01003.

Single unit activity was recorded from the interpositus and dentate nuclei of the cerebellum during classical conditioning the nictitating membrane (NM) response in rabbits. Lesions of interpositus and dentate disrupt both the performance and retention of CRs. We found that cells of anterior interpositus and medial dentate fire in relationship to CRs. This relationship was mathmatically modeled as a time-invariant linear system where cell firing frequency was the input to the system and nictitating membrane position was the output. For each cell we estimated the coefficients of a nonrecursive (transversal) filter that approximated the system using the criterion of least mean square error. We then used the filter to generate predicted NM position from the spike data. A Pearson correlation coefficient was then computed between the predicted position and the actual position of the NM. For those cells (N= 33) with r's greater than .5 transfer functions were computed. Nine of the transfer functions could be fit by first order equations with time constants ranging from 200 to 700 ms. The firing of these 9 cells was therefore predictive of both the position and velocity of the nictitating membrane. Fifteen transfer functions could be fit with second order equations with the damping ratio ranging from .4 to .9 and the undamped natural frequency ranging from 2.6 to 5.38 Hz. One transfer function was fit by a cascade of a first and second order system, and 7 were fit by fourth order equations. These results show that some cells of interpositus and dentate fire in a way that is very predictive of subsequent NM movement.

SYNAPTOGENESIS IN CEREBELLAR CORTEX OF ADULT RATS AFTER LESS THAN 15 HOURS OF VISUOMOTOR TRAINING OVER 30 DAYS. B.J. Anderson, K.R. Isaacs, J.E. Black, L. Vinci*, A.A. Alcantara & W.T.Greenough Depts Psych & Cell&Struct Biol, Neural&Behav Biol Prog, Univ Illinois, Champaign, 61820.

This work extends our previous report that visuomotor training increases cerebellar cortex thickness (Black, et al, 1987, Soc Neurosci, 13, 1596). We put 38 adult rats in 4 groups: an acrobatic condition (AC) given extensive motor-learning with relatively little exercise, two exercise conditions (FX, VX) that allowed little learning but given 10x the amount of AC exercise, and an isolated control group (IC). After 30 days blocks from the paramedian lobule were prepared for light and electron microscopy. The density of Purkinje cells under the molecular layer and synapse density in the molecular layer were then estimated. AC rats had significantly lower Purkinje cell densities, indicating substantial expansion of the molecular layer. Synapse density was nonsignficantly higher in AC rats, suggesting either that they had larger synapses or had more synapses per unit volume. Repetitive physical activity without learning (FX and VX groups) apparently has no effect on molecular layer synapses. In contrast, the expansion of molecular layer without apparent dilution of synapses in the AC group clearly indicates that visuomotor learning induces synaptogenesis in cerebellar cortex. THE EFFECT OF BILATERAL LESIONS OF THE CEREBELLAR NUCLEI ON MOTOR PERFORMANCE IN THE MONKEY. K. Amrani*, J.-P. Pellerin* and Y. Lamarre. Centre de recherche en sciences neurologiques, Université de Montréal, Montréal, Canada H3C 3J7

Unilateral lesion of the dentate and interpositus nuclei produces severe movement dysfunction of the ipsilateral limbs which recovers in 10 to 15 days. The purpose of the present study was to determine if the intact contralateral cerebellar structures could be involved in this recovery process. Two monkeys (macaca sylvana) were trained to pick up morsels of food from the top of cylinders of different height attached to a rotating platform. A chronic chamber allowed for microelectrode recordings and electrolytic lesioning of the cerebellar nuclei on both sides. A first lesion of the nuclei on the right side produced a severe deficit in the right arm but did not affect the performance of the left arm. After total recovery of the right arm's performance 15 days later, the left cerebellar nuclei were lesioned. This produced a deficit in the left arm and also in the right contralateral arm that had recovered from the previous lesion performed on the right side. These results suggest that a functional relationship may exist between the two cerebellar hemispheres which could play a role in the motor recovery observed after unilateral cerebellar lesion. Supported by the MRC of Canada.

497.14

VELOCITY PERCEPTION IN PATIENTS WITH CEREBELLAR LESIONS. R.B. Ivry*, H.C. Diener, and S.W. Keele* (SPON: M. Flanders). Cognitive Neuropsychology Laboratory, Good Samaritan Hospital, Portland, OR 97210.

In three experiments, we examined velocity perception in patients with either degenerative damage or focal lesions in the cerebellum. The subjects were required to judge whether a line moving at a test velocity was faster or slower than a line moving at a standard velocity. In the first experiment, the test velocities ranged from 0.54 to 1.20 degrees/second. The subjects with cerebellar lesions were impaired in making the velocity judgments in comparison to age-matched control subjects. No differences were found between the two groups on a control task in which the position of the test line was varied with respect to a standard position. The second and third experiments explored a wider range of velocities. In addition, eye movements were monitored to examine whether the perceptual deficit is due to poor motoric control of eye movements. Preliminary results indicate that the perceptual deficit is observed at the higher velocities and that these findings can not be attributed to faulty eye movements.

INDUCED SLIP OF AN OBJECT HELD IN A PRECISION GRIP PRODUCES COMPENSATORY RESPONSES IN CEREBELLAR CORTEX AND THE MUSCLES OF PREHENSION. Claude Dugas and Allan M. Smith Centre de Recherche en Sci. Neurol. Univ. de Montréal, Montréal, Québec, Canada.

Monkeys were trained to lift and hold an object at a fixed height. During the static grasping a solenoid produced a downward slip of the object. With repeated trials two types of responses were observed; anticipatory responses & compensatory responses. Anticipatory responses consisted of an increase in the grip safety margin (grip force/load force ratio) and an increase in the rate of grip force application. Compensatory changes consisted of an increase in the EMG activity of muscles most directly related to grasping at a latency between 60 to 100 ms and a subsequent increase in the grip force. From a population of neurons recorded in the paravermal hand area of the cerebellar cortex about 40% of the neurons showed compensatory increases in activity between 40-60 ms. Some cerebellar neurons showed both anticipatory and compensatory responses. The results suggest that the cerebellum plays an important role in adjusting the grip forces to prevent both anticipated and unexpected object slippage between the fingers. THEORETICAL PREDICTIONS OF SPATIAL ANISOTROPY OF ACEREBELLAR DYSMETRIA IN HEAD MOVEMENTS OF CATS. *A.J. Pellionisz* and *B.W. Peterson* (Dept. of Physiology and Biophysics New York University Medical Center, New York, 10016 and Dept. Physiology, Northwestern Univ. Med.School, Chicago, IL, 60611).

The motor coordination function of the cerebellum has been characterized by ablation experiments, resulting in *acerebellar dysmetria*, since times of *Flourens* (1842) and *Holmes* (1939). Nevertheless, a quantitative mapping of dysmetria, measuring e.g. the well-known directional anisotropy of the misperformance has not been put forward, although comparison of measurements with predictions would yield direct experimental tests of theories on cerebellar function. The problem, in part, is the structural complexity of skeleto-muscular (sensori)motor systems; where an overdetermined number of joints and muscles co-act to produce a movement in a manner that is difficult both to predict and to measure. Tensorial modeling of the cat head-neck system *(Pellionisz and Peterson,* 1988, in "Control of Head Movements", Oxford Univ. Press) has facilitated theoretical predictions of acerebellar dysmetria in two ways.

First, tensor network theory puts forward a concise explanation of the coordination-function of the massively parallel cerebellar neuronal networks: *a geometrical metric tensor transformation of covariant intentional command into contravariant execution vectors,* cf. *Pellionisz,* 1985; in "Cerebellar Functions" (ed. *Bloedel et al.).* Thus, absence of the cerebellum would minimally affect movements into Eigenvector-directions of the coordinate system intrinsic to neck-muscle activations, (since for Eigenvectors co- and contravariant expressions are identical) while it would maximally distort movements furthest from these cardinal axes. *Second,* tensorial modeling yields predictions of the coordinate axes, intrinsic to head movements, even with several distributed centers of rotations, where the intrinsic multidimensional coordinate system (and its Eigenvectors) *change* with head-movements (*Laczkó et al,* 1987, Neurosci. Abst. 13:372). A video will show the *rotating* set of Eigenvectors, which specify the movements that would be least affected during acerebellar dysmetria. Methods of predicting precisely the errors during attempted movements in non-Eigendirections will also be presented. These predictions can be tested experimentally, and would provide further tests of the validity of current tensorial models of CNS function in multi-dimensional intrinsic sensorimotor coordinate frames. *Supported by: NS-22999*

HISTORY OF STEREOTAXY IN NEUROSCIENCE I. THE ORIGINS. L.H. Marshall and H.W. Magoun. Neuroscience History Program, Brain Research Institute, University of California, Los Angeles, CA 90024.

After Hitzig and Fritsch in Berlin demonstrated conclusively in 1870 that stimulation of points on the surface of the mammalian brain produced contraction of muscles on the opposite side of the body, important localization experiments were conducted in England. Responses form the cerebral surface of subhuman primates were mapped with a good deal of precision. Obtaining results from below the surface was neither precise nor reproducible. Victor Horsley, London's preeminent neurosurgeon, combined a thriving practice with laboratory experiments. He and Robert H. Clarke, a physician with engineering talent, attempted a study of function of the cerebellar nuclei. An improved technique was essential to control placement of the electrodes. Clarke applied geometric principles to the problem and designed and supervised the construction of the first instrument, which Horsley demonstrated in Canada at the annual meeting of the British Medical Association in 1906. The description of the Horsley-Clarke appeared in Brain two years later, but the experimental results were never published. The only important immediate use was by Ernest Sachs, a young American surgeon training with Horsley, who had a second instrument built and published his studies on the function and morphology of the optic thalamus. He then took the technique to America.

497.18

HISTORY OF STEREOTAXY IN NEUROSCIENCE II. REVIVAL. H.W. Magoun and L.H. Marshall, Neuroscience History Program, University of California, Los Angeles, CA 90024.

The experimental use of the Horsley-Clarke stereotaxic instrument, introduced in England in 1908, lapsed for almost 20 years and then was revived through an unusual chain of events. Shortly before he died in 1926, Robert Clarke, the instrument's inventor, urged Ernest Sachs, neurosurgeon at Washington University, St.Louis and owner of the second instrument constructed, to continue the studies on the cerebellum that Horsley and Clarke had begun in England. Sachs was conducting such studies during the short time that Stephen Walter Ranson and Joseph C. Hinsey were in St.Louis and saw the instrument in use. In 1928 they returned to Northwestern University and a copy was made of the model published in Brain and the worldwide use of stereotaxy in probing the brain from external landmarks was assured. Control of movement at several levels of the central nervous system was the first such exploration of so extensive a field. Before Ranson died unexpectedly in 1942, the role of the hypothalamus and lower brain stem in visceral integration, emotion, and the regulation of feeding,, fighting, sex, and other vital behaviors had been elucidated. The instrument was adapted to many animals, including man, and the technique improved. However, 80 years after Clarke, the determination of internal cerebral loci by external landmarks has been made obsolete by the new imaging techniques.

EFFECTS OF CHRONIC DRUGS

498.1

CHRONIC PRENATAL HALOPERIDOL EXPOSURE: EFFECTS ON D1 AND D2 DOPAMINE RECEPTOR BINDING IN MESOLIMBIC AND STRIATAL BRAIN REGIONS. B. Gough*, F.M. Scalzo, R.R.Holson and S.F. Ali (SPON: E.J. Peck, Jr.). Division of Reproductive and Developmental Toxicology, National Center for Toxicological Research, Jefferson, AR 72079.

Prenatal haloperidol (HAL) exposure in rats is known to reduce striatal D2 receptor binding sites in postnatal day 30 offspring. The effects of such HAL exposure on striatal D1 binding sites, and D1 and D2 binding sites in other regions of the dopamine (DA) system are not well described. Pregnant CD rats were given daily injections of HAL (2.5 or 5 mg/kg sc) or vehicle over gestational days 6-20. D1 and D2 DA receptor binding was measured in striatum, accumbens, amygdala and frontal cortex of male and female offspring sacrificed on postnatal day 30. In HAL treated animals there was a 20% decrease in both D1 and D2 binding sites in striatum, with a similar reduction in D2 but not D1 sites in accumbens. There was no HAL effect on D1 or D2 binding in amygdala. The data indicate that prenatal HAL exposure results in alterations in DA receptor binding that are specific to brain region and receptor subtype. The results further suggest that the developing nigrostriatal DA system may be more at risk for prenatal pharmacological insult than is the mesolimbic DA system.

498.2

CHRONIC PRENATAL HALOPERIDOL EXPOSURE: EFFECTS ON PRESYNAPTIC DOPAMINE AUTORECEPTORS. F.M. Scalzo, G. Newport*, and B. Gough*. Division of Reproductive and Developmental Toxicology, National Center for Toxicological Research, Jefferson, AR 72079.

Chronic prenatal haloperidol (HAL) treatment has been shown to have pronounced behavioral, psychopharmacological and neurochemical effects. Presynaptic dopamine (DA) autoreceptor function was assesed in the DA terminal rich regions nucleus accumbens, caudate nucleus and olfactory tubercles of rats exposed prenatally to HAL by measuring 3,4-dihydroxyphenylalanine (DOPA) and DA accumulation by HPLC following administration of the DOPA decarboxylase inhibitor NSD-1015. Pregnant rats were injected with either vehicle, 2.5 or 5.0 mg/kg haloperidol daily on gestational days 6-20. The offspring were treated with NSD-1015, NSD-1015 and gammabutyrolactone (GBL) or NSD-1015, GBL and apomorphine (APO) prior to sacrifice on postnatal day 97. There appeared to be no impairment of autoreceptor function in the caudate of animals exposed prenatally to HAL as indicated by the ability of APO to attenuate GBL induced increases in DOPA accumulation. However, HAL treated animals exhibited increased DOPA accumulation following treatment with NSD-1015 and had smaller relative increases in DOPA accumulation following NSD-1015 and GBL treatment compared to vehicle injected controls. These data suggest that prenatal HAL exposure causes long-lasting alterations in the adult dopamine system.

498.3

EFFECT OF INJECTION SCHEDULE ON TOLERANCE TO HALOPERIDOL-INDUCED "ANOREXIA." D.L. Wolgin. Dept. of Psychology, Florida Atlantic Univ., Boca Raton, FL 33431

We previously found that rats given daily injections of haloperidol became tolerant to the initial "anorexic" effect whether the drug was given before or after access to the food. These results suggest that tolerance is not contingent on access to food in the drugged state. However, because the drug is long-acting, it is possible that the group given the drug after food access was actually intoxicated during testing. To control for this possibility, rats in the present study were given the drug either before or after access to milk on alternate days. Control rats were given injections of saline. On the intervening days, all groups were given milk in order to monitor baseline levels of intake. Contrary to previous findings, little tolerance was observed in either drug group on test days, although baseline intake was constant. These results suggest that injection schedule plays an important role in tolerance to haloperidol-induced "anorexia."

498.4

DECREASED STRIATAL(S) ACH RELEASE FOLLOWING CHRONIC HALOPERIDOL(H) TREATMENT **E. Friedman, H-Y Wang and P. Butkerait* Medical College of Pennsylvania, Philadelphia, PA 19129.**

The effect of chronic H treatment on K^+-evoked [^{3}H]ACH release from superfused S slices was assessed. While acute and chronic H produced increases in S [^{3}H]ACH release, H withdrawal following chronic treatment produced decreases (34-38%) in evoked [^{3}H]ACH release. SKF-38393 produced dose-dependent (0.1-10uM) increases in S [^{3}H]ACH release which were blocked by SCH 23390 and by bicucculine. The effect of D_1-receptor stimulation was significantly reduced after 2.5 and 5 mo of H treatment. Both LY171555 and carbachol produced dose-dependent (0.1-10uM) inhibitions of S [^{3}H]ACH release. Long-term treatment with H (2.5 and 5 months) elicited increased sensitivity to the effect of LY-171555 while the effect of carbachol was diminished only following a 5 mo treatment period. The apparent desensitization of presynaptic muscarinic receptors coincided with a 19% decrease in Bmax of S muscarinic receptors labelled by [^{3}H]N-methylQNB but not of those labelled by [^{3}H]pirenzepine. These findings demonstrate that withdrawal from chronic H produces a hypocholinergic state in the striatum. These findings suggest that diminished S ACH release observed following discontinuation of long term H treatment may contribute to the emergence of tardive dyskinesia.

498.5

HALOPERIDOL-INDUCED VACUOUS CHEWING MOVEMENTS IN THREE DIFFERENT RAT STRAINS J.M. Dale*, C.A. Tamminga, L. Goodman*, N. Kaneda*, H. Kaneda* (SPON:W.T. Carpenter). MPRC, University of Maryland, Balto., MD, 21228

Chronic treatment of rats for 6-12 months with neuroleptics has been proposed as an animal model of tardive dyskinesia. We have examined this paradigm by studying haloperidol (HAL)-induced vacuous chewing movements (VCM) in three different rat species. 38 male rats were treated, comprised of 3 strains: Sprague-Dawley (SD), Long Evans (LE), and Wistar (W). Nine rats of each strain were treated with 1.5 mg/kg/day of HAL orally through their drinking water; four (3W) were water treated. For behavioral measurements, animals were observed individually for four consecutive 30 sec periods and VCM's quantified. Rats were examined weekly beginning 6 weeks after initiation of HAL and continued for a total of 25-27 weeks. After 20 wks the animals were challenged with atropine 5 mg/kg IP and rated for VCM at 0, 30, 60, and 120 min. At wk 20-22 the rats were weaned from HAL and rated for 2 wks. HAL treated rats from all three strains had a significant increase in VCM/2min compared with controls (C): 8.3xC (SD); 4.7xC (LE); and 6.2xC (W). Atropine decreased VCM in all groups by 27%, but VCM remained significantly above control levels. VCM in all groups remained apparent after neuroleptic withdrawal, with only a 17% decrease in SD rats. Thus, VCM's in rats approximated the pharmacologic behavior of tardive dyskinesia, but there also appear to be differences between rat strains. Biochemical analysis of brain samples from these treatment groups may suggest reasons for rat strain differences.

498.6

REVERSIBILITY OF TARDIVE DYSKINESIA FOLLOWING NEUROLEPTIC WITHDRAWAL A.C. Lahti*, G.K. Thaker, J.A. Nguyen*, M.Moran*, C.A. Tamminga (SPON: R. Lahti). MPRC, University of Maryland, Balto., MD, 21228

Tardive dyskinesia (TD) is a hyperkinetic motor disorder which is thought to be secondary to neuronal changes following chronic receptor blockade by neuroleptics in the basal ganglia. Recently it has been suggested that the process is reversible if the dopamine (DA) blockade is removed. To further explore this issue we carried out a long term follow-up (mean = 10.5 months) of 20 TD patients (mean age = 43.7 ± 7.2 yrs.), who had been withdrawn from their neuroleptic treatment during the follow-up period.

The study demonstrated that there was a marked decrease in TD (average reduction of 43.5 ± 32.3%) in 17 patients during the neuroleptic free period. Three patients who did not show improvement were all elderly (>65 yrs) females. Multiple regression analysis revealed a significant negative correlation (partial $r = -0.38$, $p<0.03$) between the age of the patients and their observed change in TD score. There was also a significant correlation between the duration of NL free period and the change in TD scores (partial $r = 0.41$, $p<0.03$).

These results strongly suggest that TD is reversible, especially in young patients. Further, they emphasize the utility of atypical neuroleptics (e.g. clozapine), which purportedly exert low or no DA receptor blockade in the basal ganglia, in the treatment of psychotic patients with TD.

498.7

COMPARISON OF SHORT- AND LONG-TERM HALOPERIDOL ADMINISTRATION AND WITHDRAWAL ON PEPTIDE LEVELS IN THE RAT. J.M. Radke, A.J. MacLennan, M.C. Beinfeld*, G. Bissette, C.B. Nemeroff, S.R. Vincent, & H.C. Fibiger. Div. Neurological Sciences, U.B.C., Vancouver, B.C., Canada; Dept Pharmacology, St. Louis University, St. Louis, MO, USA; Dept. Psychiatry and Pharmacology, Duke University.Durham, NC, USA.

The effects of oral administration of haloperidol (1.3-1.5 mg/kg/day) for 3 weeks (short-term), 8 months (long-term), and 2 month withdrawal after 8 months (withdrawal) on the levels of somatostatin, substance P, cholecystokinin (CCK), and neurotensin were examined in the rat. Short-term administration produced changes in peptide levels similar to those reported by others, with the most pronounced changes being decreased somatostatin levels in the ventral tegmental area, the striatum and the nucleus accumbens, decreased substance P levels in the substantia nigra and nucleus accumbens, increased CCK levels in the ventral tegmental area and medial prefrontal cortex, and increased neurotensin levels in the striatum and nucleus accumbens. With a few exceptions, similar observations were found following long term-term haloperidol adminstration. In contrast, withdrawal after long-term administration resulted in most peptide levels returning to control values, with the exception of neurotensin which was significantly decreased in the striatum and nucleus accumbens.

498.8

DRUG DISCRIMINATION TRAINING DURING CHRONIC DRUG TREATMENT AFFECTS THE DEVELOPMENT OF TOLERANCE. K. L. Burgin*, W. F. Caul and R. J. Barrett (SPON: M. H. Ebert). Vanderbilt University, Nashville TN, 37240.

Psychoactive drugs produce distinct primary and compensatory adaptive processes that occur in temporal sequence. These adaptive processes are thought to be the basis for pharmacodynamic tolerance. The purpose of this experiment was to evaluate the extent to which continued drug discrimination training during chronic treatment effects the development of tolerance. Rats were trained to discriminate distilled water from 0.75 mg/kg amphetamine in a two-lever drug discrimination task. Two groups were then given a chronic drug regimen of 13 daily injections of either distilled water or 10 mg/kg amphetamine. Drug discrimination training was continued for half of each chronic drug group. Tolerance was observed only for the group that was not trained during the chronic amphetamine treatment. The data show that (a) choice responding after chronic drug treatment is not influenced by the amount of training per se, and (b) rather continued training during chronic treatment provides the opportunity for reinforced responding to shifting drug and nondrug cue states.

498.9

EFFECT OF ANTIDEPRESSANT DRUGS ON SUBTYPES OF CENTRAL BETA ADRENOCEPTORS: A QUANTITATIVE AUTORADIOGRAPHIC STUDY. **G.A. Ordway*, C. Gambarana*, J. Bensler & A. Frazer, VA Med. Ctr. & Univ. of Pennsylvania School of Medicine, Philadelphia, PA, 19104.**

Repeated administration of many antidepressants to rats reduces the density of beta adrenergic receptors (BARs) in the cerebral cortex, as revealed using ligand binding techniques on homogenate preparations. Whether a similar effect is seen throughout the brain has not been well characterized. We have used in vitro quantitative autoradiography to measure subtypes of BARs (Proc. Natl. Acad. Sci. (USA) 81:1585, 1984) in brains of rats treated chronically with either the tricyclic antidepressant desipramine (DMI), the inhibitor of type A monoamine oxidase clorgyline, or the selective inhibitor of the uptake of serotonin, citalopram. Of 23 areas examined, treatment with DMI reduced the total binding of ^{125}I-iodopindolol (IPIN) significantly ($P<0.01$) in 20 regions and clorgyline had a significant effect in 16 regions. This reduction in the binding of IPIN was due almost exclusively to a decrease in IPIN binding to the beta-1 subtype. In DMI-treated rats, the beta-1 subtype was reduced significantly in 17 regions and in 12 areas of clorgyline-treated rats. DMI-treatment reduced beta-2 adrenoceptors in only one area and clorgyline treatment did this in three areas. In most areas, the quantitative effect of clorgyline on the beta-1 subtype was much less than that caused by DMI except in the paraventricular n. of the thalamus and the basolateral amygdaloid n.. Treatment with citalopram caused no significant effect on the binding of IPIN to either subtype of BAR in any area. **Supported by Research Funds from the Vet. Admin. and USPHS grant MH29094.**

498.10

BEHAVIORAL PROFILE DURING AMPHETAMINE WITHDRAWAL IN RATS: A MODEL OF DEPRESSION? D. B. Neill, G. K. Mumford*, P. R. Hartley, S. A. Murray* and G. W. Vogel*. Depts. of Psychology and Psychiatry, Emory University, Atlanta, GA 30322.

Amphetamine or cocaine withdrawal has often been reported to produce depression in humans. We investigated whether this happens in rats because of the possibility of subsequent neurobiological analysis. Because of the anhedonia in depressed humans, most of our tests focused on the rats' reactivity to rewarding stimuli. Baseline data were acquired for intracranial self-stimulation (ICSS), food-rewarded bar-pressing on fixed-ratio (FR) 20 and fixed-ratio 100 schedules in food-deprived rats, intake of a palatable food in nondeprived rats, locomotor activity, and male sexual behavior. Behavioral analyses were then stopped during 10 days of twice daily administration of 10 mg/kg *d*-amphetamine sulfate. Testing resumed during the first day of withdrawal. Locomotor activity and ICSS performance dropped 50% during withdrawal. Performance on FR was unaltered. Intake of the palatable food and sexual behavior were enhanced. We conclude that, while portions of this behavioral profile are consistent with a depression model, other portions are not. The data are most easily explained by the view that a given behavior is altered during withdrawal in a way opposite the way it is altered during acute amphetamine administration.

498.11

EFFECTS OF CHRONIC LITHIUM TREATMENT ON RECEPTOR-MEDIATED INOSITOL PHOSPHOLIPID HYDROLYSIS AND PROTEIN PHOSPHORYLATION IN RAT BRAIN. T. Casebolt* and R.S. Jope, (SPON: A.L. Beckman), Dept. of Pharmacology, Univ. of Alabama, Birmingham, AL 35294

The etiologies of mania and depression, and the mechanism of action of lithium as a treatment for these disorders, are unknown. To test the hypothesis that a part of the therapeutic effect of lithium is due to altered receptor-coupled phosphoinositide (PI) hydrolysis, rats were treated with LiCl (0.17% in diet, 30 days) and agonist-induced PI hydrolysis was measured in rat brain. Norepinephrine, but not carbachol-induced PI hydrolysis was significantly reduced after chronic lithium treatment. Experiments examining the mechanism of this effect led to the hypothesis that receptor number or receptor-coupling was reduced by chronic lithium treatment. Examination of the effects of chronic lithium treatment on α_1-adrenergic binding of [^{3}H]prazosin and chlorethylchlonidine indicated that α_1-adrenergic receptor subtypes were not altered by chronic lithium treatment.

The possible role of protein phosphorylation in receptor uncoupling after chronic lithium treatment was also examined. First, the distribution of PKC activity in membrane and cytosol fractions was measured. Endogenous protein phosphorylation mediated by three kinases was also surveyed after chronic lithium treatment. Supported by MH 38752.

498.12

OPIOID RECEPTOR UPREGULATION INCREASES THE REWARD VALUE OF LATERAL HYPOTHALAMIC BRAIN STIMULATION. *S. Uysal* and E. E. Coons** (SPON: L. Kiorpes). Department of Psychology, New York University, New York, NY 10003.

We have examined the effects of naltrexone-induced opioid receptor upregulation (two 30 mg pellets s.c. over 9 days) on lateral hypothalamic self-stimulation (SS), stimulation-induced feeding (SIF), and stimulation-induced escape (SIE). Opioid receptor supersensitivity following naltrexone withdrawal potentiated SS while SIF and SIE were unaffected. The observed increase in SS was reversed by acute injection of naltrexone, demonstrating opioid receptor mediation. Upregulation-induced potentiation of SS occurred only at electrode sites that did not support SIE. These were posterior to placements supporting SIE, as previously observed (S. Carden and E. E. Coons, 1987).

While receptor upregulation-induced supersensitivity to opiates has been shown previously (M. T. Bardo et al., 1983, B. C. Yoburn et al., 1985), this is the first report we are aware of that demonstrates supersensitivity to endogenous opioids. Furthermore, though past research has shown that opioids can modulate SS (K. D. Carr and E. J. Simon, 1984), the present results indicate that under conditions of supersensitivity opioids may mediate SS as well. Paradoxically, while SIF is mediated by opioids under baseline conditions (K. D. Carr and E. J. Simon, 1983), it is unaffected by upregulation.

498.13

INTRANIGRAL INJECTION OF NALOXONE PRECIPITATES WITHDRAWAL IN MORPHINE-DEPENDENT RATS. A.A. Baumeister, T.G. Anticich* and M.F. Hawkins. Department of Psychology, Louisiana State University, Baton Rouge, LA 70803.

Recent evidence (Baumeister et al., Brain Res., in press) suggests that the substantia nigra (SN) is an important site of action of systemically administered morphine. The present study sought to determine whether this nucleus is involved in the development of physical dependence to this drug. Male Sprague Dawley rats received subcutaneous (sc) injections of morphine sulfate suspended in a sustained release preparation (Collier, et al., Nature, 237, 1972, 220) according to the following schedule: 40 mg/kg (day 1); 60 mg/kg (day 2); 80 mg/kg (day 3), and 100 mg/kg (day 4). Twenty hours after the last sc injection animals received a bilateral intranigral injection of naloxone (1 - 10 µg/ 0.25 µl saline) or saline (0.25 µl). Intranigral injection of naloxone produced several significant ($p<.05$) signs of withdrawal in morphine-dependent animals including wet dog shakes, teeth chattering, squealing and diarrhea. No withdrawal signs were observed in morphine-dependent animals that received intranigral saline or in nondependent controls that received intranigral naloxone. There was a significant correlation ($p<.01$) between naloxone dose and magnitude of the response for each withdrawal symptom. These results suggest that the SN mediates the development of physical dependence produced by repeated administration of morphine. (Supported by USPHS grant HD-21560).

498.14

EFFECTS OF CHRONIC CAFFEINE ON RAT BRAIN MONOAMINES. T.R. Taylor*, D.G. Kirch*, G.A. Gerhardt, N. Benowitz*, C. Stephen*, R. Freedman and R.J. Wyatt. National Institute of Mental Health, Washington, DC 20032

Caffeine was administered in three doses (10 mg/kg/day, 25 mg/kg/day and 50 mg/kg/day) to rats as twice-daily I.P. injections for 30 days. Plasma caffeine concentrations and regional brain concentrations of monoamines [dopamine (DA), norepinephrine (NE) and serotonin (5HT)] and their metabolites [dihydroxyphenylacetic acid (DOPAC), homovanillic acid (HVA), 3-methoxy-4-hydroxyphenylglycol (MHPG) and 5-hydroxyindoleacetic acid (5HIAA)] were determined. In striatum, data was obtained for all the above except MHPG. In frontal cortex and cerebellum, NE, 5HT and their metabolites were determined. In addition, for each monoamine an index of turnover was calculated [metabolite(s)/monoamine].

A linear dose-response relationship was found for plasma caffeine concentrations. At 10 mg/kg/day no monoamine changes were found except for a decrease in cerebellar NE. At the higher doses there were significant changes in all three brain areas. Striatal DOPAC decreased significantly, while DA increased (with a trend toward a lower DA turnover index). The 5HT index decreased significantly in striatum and cerebellum, with a similar trend in frontal cortex. The NE index decreased in frontal cortex, but increased in cerebellum (the only increase observed in the turnover indices).

498.15

EFFECT OF ORAL CAFFEINE INGESTION ON WHEELRUNNING IN RATS. **R.E. Landrum, T.A. Landrum, and C.J. Meliska. Department of Psychology, Southern Illinois University, Carbondale, IL 62901-6502.**

Twenty-four male Sprague-Dawley rats were housed continuously for 24 days in Wahmann activity wheels. Eight rats received continuous access to 0.5 mg/ml caffeine base in tap water; 8 received continuous access to tap water; and 8 received 24 hr access to 0.5 mg/ml caffeine alternating with 24 hr access to tap water. Mean wheel revolution data for the caffeine/water (C/W) group revealed a significant decrease in wheelrunning on water days compared to controls receiving continuous water, suggesting a withdrawal reaction to the absence of caffeine. When raw data were transformed into percentages of baseline wheelrunning, continuous access to caffeine failed to stimulate, and actually inhibited wheelrunning slightly, relative to water controls. For rats alternating between caffeine and water (C/W), wheelrunning was significantly greater on caffeine days than for all other conditions including continuous caffeine access. These data suggest that when given orally, caffeine's stimulatory effects on wheelrunning are particularly sensitive to the context and scheduling of drug administration.

498.16

CONTINGENT INEFFICACY AND TOLERANCE TO CARBAMAZEPINE IN AMYGDALA-KINDLED RATS. S.R.B. Weiss* and R.M. Post. Biological Psychiatry Branch, NIMH, Bethesda, MD 20892.

The relationship of the timing of drug administration to anticonvulsant efficacy against amygdala-kindled seizures was studied. During kindling development, rats received either no treatment or carbamazepine (15 mg/kg) before (carba-before) or after each stimulation (carba-after). After kindling to full seizures, all animals received carbamazepine before the stimulation. Both the drug-naive and carba-after group showed a good anticonvulsant response. The rats that received carba-before during kindled seizure development remained unresponsive (conditioned inefficacy). The two groups of responsive animals developed tolerance to carbamazepine's anticonvulsant effects (contingent tolerance), which could be reversed by switching to carba-after or kindling the animals drug-free, but not by carbamazepine administration alone or time off from both drug and seizures. Another group of rats were kindled with carba-after or vehicle-after to determine whether prior exposure to carbamzepine in a noncontingent fashion would facilitate the subsequent development of tolerance. When these rats were switched to carba-before treatment, both groups developed tolerance to carbamzepine at equal rates.

These data suggest that tolerance to or inefficacy of anticonvulsant medications may be learned phenomena susceptible to modulation through alterations in the temporal relationship between drug administration and seizure induction.

498.17

IMPAIRMENTS RELATED TO LONG-TERM USE OF DRUGS IN CHRONIC PAIN PATIENTS. D.M. Kwilosz*, L.E. Tune, G.D. Pearlson, P.J. Walsh*, P.H. Dorsey*, & M. Nossel* Psychiatry Dept., Johns Hopkins University School of Medicine, Baltimore, MD 21205

Cognitive effects of long-term use of benzodiazepines and opiates in chronic pain patients are poorly understood. Less is known about the influence of short-term fluctuations in drug levels due to metabolism. Information about persistent effects of long-term use and fluctuations due to high vs. low levels may help to identify impediments to effective pain management. The purpose of the study is to determine neuropsychological and phenomenological correlates of naturally occuring variation in medication levels.

Inpatients on a chronic pain treatment unit were tested approximately 2 hrs post administration (peak) of benzodiazepines and/or opiates and just prior to administration (trough) weekly for three weeks. The test battery included measures of psychomotor ability, distractability, memory, pain, and mood. Drug levels were measured via a saliva sample using radioreceptor assay techniques.

Preliminary results show poorer performance at peak than trough levels in psychomotor speed, set shift and in learning-memory, although anxiety and pain levels did not vary significantly. The findings suggest that the short-term fluctuations in opiate/benzodiazepine levels may affect neuropsychological abilities contributing to functional incapacity in chronic pain patients.

498.18

ALTERED MATERNAL BEHAVIOR AFTER CESSATION OF CHRONIC MORPHINE ADMINISTRATION DURING PREGNANCY. E. LaCrosse and B. Culver. Neurosci. Prog., Dept. of Psych. & Sch. of Pharm., Univ. Wyoming, Laramie, WY 82071

Disruption of normal maternal behavior is an important variable in studies designed to assess functional alterations in offspring of animals administered morphine sulfate (MS) during pregnancy. A number of studies in the literature report acute MS-induced changes in maternal behavior. Our lab has shown behavioral alterations in offspring of rats administered MS during pregnancy. It is possible that cessation of chronic MS administration during pregnancy alters maternal behavior which subsequently influences the development of the offspring. We report here the results of a study designed to examine this possibility.

Rats were implanted with 1 MS-silastic pellet (100 mg) on gd 14, and 2 more were implanted on gd 17. Paired controls (LA) were implanted with silastic lactose pellets (100 mg) on the same days. Parturition was designated as day 0. The pellets were removed on day 1. Maternal behavior was observed on days 2 through 5. Results show that cessation of MS administration disrupts maternal behavior on a number of indices.

These results indicate that there are alterations in maternal behavior associated with cessation of MS administration. The presence of wet-dog shakes suggests that MS withdrawal contributes to these alterations. Previous results from our lab show high neonatal mortality and persistent behavioral alterations in offspring of rats administered MS during pregnancy. Findings in the present study, suggest that alterations in mother-pup interactions associated with cessation of chronic MS administration may contribute to the increased mortality and alterations in the behavioral development of the offspring.

498.19

SUBCHRONIC EFFECTS OF +MDMA ON NEUROTRANSMITTER RELEASE IN THE RAT. R.E. Maloney*, B.K. Yamamoto, and M.D. Schechter (Spon.: E. Krimmer) Dept. of Pharmacology, Northeastern Ohio Univers. Col. of Med., Rootstown, OH 44272.

MDMA (5-20 mg/kg) has been shown to be neurotoxic to the serotonergic system with a minimal effect on the dopaminergic system. Subchronic treatment with low doses however, increased both serotonin and dopamine (DA) in specific rat brain nuclei (Maloney et. al., Neurosci. Abst., 1987). To further investigate these findings, rats were administered either 1.5 mg/kg +MDMA (**D**) or 1.0 ml/kg H_2O (**V**) i.p. for 6 weeks according to the following 2 week injection schedule: DVVDDVDDVV. Between 2 and 3 weeks after the last injection, DA release was measured from anterolateral caudate by in vivo microdialysis in these awake, behaving rats. Dialysis perfusion (2.5 µl/min) was with a modified a modified Ringer's solution (pH 7.25). Samples were collected every 20 min and analyzed for DA, DOPAC, and HVA by HPLC/EC. After a 1 hr stable baseline, all rats were injected with 1.5 mg/kg +MDMA. Dialysate samples were collected for 3 hrs. There was a significant increase in DA accompanied by a decrease in DOPAC. Forty min after MDMA, DA release in the subchronically treated MDMA group was significantly higher (204% of baseline + 19) than the vehicle-treated group (146% + 16) ($p<0.05$). There were no differences in DOPAC levels between these groups at this time. These results may indicate a sensitization to the DA releasing properties of MDMA following an intermittent, low dose treatment regimen. Future studies will assess the effects of this treatment regimen on neurotransmitter content in other brain nuclei. Supported by grant DA04181-01, M. D. Schechter, P.I..

VISUAL SYSTEM: DEVELOPMENT AND PLASTICITY VI

499.1

A MATHEMATICAL MODEL FOR EMMETROPIZATION IN THE CHICKEN. H. C. Howland and F. Schaeffel*. Section of Neurobiology and Behavior, Cornell University, Ithaca N.Y. 14853.

Eye growth and refractive state in the chicken has been examined under a large number of experimental treatments. Degrading the retinal image by use of occluders produces myopia, although with a high variability in individual refractions. "Image degradation myopia" can be also produced in birds without accommodation (due to lesions in the Edinger Westphal nucleus), with the optic nerve sectioned and, by local image degradation, in local parts of the visual field. Recovery occurs in both normal and EW-lesioned birds. In addition, we have shown that eye growth compensates for an imposed refractive error induced by spectacle lenses in both normal and EW lesioned chicks. Most of the results listed above argue for regulation of eye growth by local mechanisms within the eye, without the neccessity of accommodation. However, we have developed a computer simulation for regulation of eye growth in the chick which showed that there are probably (at least) two independent feedback loops controlling eye growth, one within the eye and the other dependent on accommodation.

499.2

THE VITREOUS HUMOR IN EXPERIMENTALLY INDUCED MYOPIA R.L.Seltner* J.J. Pastemak* J.G.Sivak* (SPON. R. Beauchamp) School of Optometry and Department of Biology, University of Waterloo, Waterloo, Ont. CANADA N2L 3G1

Experimentally induced myopia can be produced rapidly in chicks subjected to post-hatching blur of the retinal image. This myopia is characterized by axial and equatorial eye size increase, increase in wet weight of the eye, and a large negative refractive error, within 14 days of post-hatching goggle application. Previous results have indicated that the changes in size occur as a result of expansion of the vitreous chamber.

We have studied the volumetric changes in the vitreous humor in chicks subjected to vision blur for a 14 day period, and the reversibility of these changes after removal of the goggle. As well, the proteins of the vitreous humor have been examined for qualitative and quantitative changes accompanying the development of myopia.

In chicks, the vitreous humor is made up of 2 parts, a gel and a liquid portion. In the myopic eye, the gel:liquid ratio of the vitreous humor, as well as the total liquid vitreous increases dramatically when compared to the contralateral control eye. These effects are reversible after removal of the goggle.

Results using PAGE and protein assay methods indicate that the protein concentration in the myopic eye is decreased when compared to the non-myopic eye. There appears to be no change in the banding pattern of the proteins in the myopic eye, although the intensity of the bands is decreased when compared to the non-myopic eye. The effects observed suggest that the vitreous humor is playing a role in experimental myopia, and may also play a role in the normal post-hatching emmetropization mechanism.

ASSESSMENT OF SPATIAL VISION AND VISUAL FIELDS IN NATURALLY STRABISMIC MONKEYS. M. W. Quick,* M. Joosse* and R. G. Boothe (SPON: J. Tigges). Yerkes Regional Primate Research Center, and Departments of Psychology and Ophthalmology, Emory University, Atlanta, GA 30322.

A screening program has yielded monkeys having a naturally occurring ocular misalignment. Its occurrence was often associated with a large hyperopic refractive error, and with a difference in refractive error between eyes. Quantitative estimate of the deviation was made from photographs of the corneal reflex. Results showed monkeys with 1) alternating fixation; 2) deviations that varied with fixation angle; 3) deviations that varied with fixation distance, indicating an accommodative component.

Spatial vision was assessed operantly. Grating acuity results showed a sensory deficit in the deviating eye of some monkeys, with differences up to one octave when compared to the fixating eye. Further deficits were seen in tests of optotype acuity. This further reduction correlated with deficits in phase discrimination and increased spatial distortion. Also, a loss of sensitivity to contrast was evident at mid and high spatial frequencies. The horizontal extent of the visual fields were determined using a perimetry apparatus. Deficits were noted within the monocular segment of some non-preferred eyes, indicating field losses in deviating eyes which are unaccounted for by typical competitive mechanisms. Correlations will be drawn between oculomotor state and behavioral results. NIH grants EY-06436 and RR-00165.

499.4

BEHAVIORAL CONTRAST SENSITIVITY OF PRENATALLY UNILATERAL ENUCLEATED CATS. S. Bisti*, M.C. Cenni*, L. Maffei*, C. Trimarchi* (SPON: European Brain and Behavior Society). Ist. di Neurofisiologia del CNR, 56100 Pisa, Italy.

Prenatal unilateral enucleation in the cats leads to a complete reorganization of the visual pathways. At the level of visual cortical area 17 all neurones are driven by the remaining eye. Visual receptive fields have normal selectivity for orientation and directionality, but are smaller on average than those of normal cats. In a previous study we showed that the visual acuity of denucleated cats, measured both behaviorally and by VEPs, is similar to normal cats (Perception,16:332, 1987).

Here we report contrast sensitivity as a function of spatial frequency for two prenatally monocular enucleated kittens, measured both behaviorally and by VEPs. The results obtained by both methods show that whereas the visual acuity is comparable to the monocular acuity of normal cats, maximum contrast sensitivity is somewhat higher, and the peak in the contrast sensitivity function occurs at higher spatial frequencies.

499.5

VERNIER ACUITY, GRATING ACUITY AND CONTRAST SENSITIVITY IN EXPERIMENTALLY STRABISMIC MONKEYS. D.C. Kiper, L. Kiorpes and J.A. Movshon. Department of Psychology and Center for Neural Science, New York University, New York, 10003.

Human strabismic amblyopes show an abnormal relationship between vernier acuity and grating acuity. We studied this relationship in strabismic monkeys to better understand the neural basis of amblyopia. In addition, we investigated the hypothesis that vernier acuity can be predicted from knowledge of the contrast sensitivity function.

We measured monocular vernier acuity, grating acuity and contrast sensitivity for 7 monkeys (Macaca nemestrina) made esotropic at ages ranging from 3 to 8 weeks. All data were collected using operant methods. The relationship between vernier acuity and grating acuity in the strabismic monkeys was different from that of normal adult monkeys. However, the relationship in strabismic monkeys could be described by the performance of young normal animals. The deficits in vernier acuity were not obviously associated with the contrast sensitivity functions.

499.6

INFANT PERCEPTION OF ROTATION FROM RIGID STRUCTURE-FROM-MOTION DISPLAYS. R.V. Spitz*, J. Stiles-Davis* and R.M. Siegel (SPON: S. LeVay). Dept. of Psychology, University of California, San Diego, La Jolla, CA 92093 and The Rockefeller University, New York, NY 10021.

The term structure-from-motion refers to a class of phenomena in which perception of a structure can be abstracted from the integration of unconnected moving elements. In recent work it has been demonstrated that both adult humans and monkeys are capable of perceiving a rigid 2- or 3-dimensional structure from such displays (Siegel & Andersen, 1988). The present study seeks to extend these results through a longitudinal examination of infant ability to abstract a 2-dimensional rigid structure from displays similar to those used in the adult primate studies.

A habituation procedure was used involving two displays: one structured display and one unstructured display. The structured display consisted of 128 points which appeared to lie on the surface of a disc rotating about an axis perpendicular to its surface. The unstructured display was created by taking these same points and shuffling the set of motion trajectories from the structured display, thus the unstructured display appeared as random-motion. The displays were identical except for the presence or absence of the rotating structure, and this structure could only be perceived by integrating a set of relative motion cues across the array. Eighteen infants were tested longitudinally at 4-, 5-, 6-, and 7-months of age. Each infant viewed one of the displays for 23 8-sec trials and was then tested for dishabituation with 5 trials for the other display. The results of this study indicate that it was not until 6-months of age that infants demonstrated any dishabituation to the novel display indicating that they could discriminate the structured from the unstructured displays. This is in spite of the fact that infants as young as 4-months of age are capable of using local relative motion cues to specify an edge (Spelke, 1985). Thus, it appears that the integration of a set of spatio-temporal cues may be a later appearing phenomenon, developmentally, than is the perception of the cue itself. Future work should further extend this by examining infant ability to integrate other spatio-temporal cues.

POSITRON EMISSION TOMOGRAPHIC (PET) STUDY OF EFFECT OF AMBLYOPIA AND OPTICAL BLUR ON HUMAN CORTICAL RESPONSE TO COMPLEX VISUAL STIMULATION. J. L. Demer, N.D. Volkow*, G. K. von Noorden, K. L. Gould*. Cullen Eye Institute, Texas Children's Hospital, and Positron Diagnostic and Research Center, Houston, TX, 77030.

Amblyopic animals are known to have a paucity of neurons in primary visual cortex that can be visually stimulated via the affected eye. We used PET (resolution 12-14 mm full width at half maximum) to investigate effects of visual stimulation on relative glucose metabolism in cerebral cortex of normal and amblyopic human subjects using the tracer [^{18}F]deoxyglucose. The visual stimulus was a monocularly-presented dramatic motion picture. Two control subjects had normal vision in each eye, while 3 amblyopes had monocularly decreased vision ($\leq$20/200) and normal vision in the fellow eye. Relative glucose metabolism was quantified by dividing activity in regions of interest by total activity in the entire brain image slice.

Repeated scanning demonstrated similar relative glucose metabolism in primary visual cortex of a control viewing with either normal eye. Optical blur (~20/200) reduced relative glucose metabolism in primary visual cortex by ~8% in two controls. In two amblyopes, relative glucose metabolism in primary visual cortex was 5-6% less during stimulation of the amblyopic than the sound eye. In one amblyope, a combination of amblyopia and optical blur reduced relative glucose metabolism in primary visual cortex by 23% relative to the sound eye. Four of 5 subjects exhibited asymmetrically greater relative glucose metabolism in the contralateral hemisphere (particularly the temporal lobe) during visual stimulation of sound or amblyopic eyes; optical blur reduced the degree of asymmetry. The remaining subject exhibited persistently greater relative glucose metabolism in the right hemisphere.

These preliminary results indicate that **amblyopia reduces visual activation of relative glucose metabolism in primary visual cortex** of amblyopic humans; this effect may be **simulated by optical blur** in normal subjects. In both normal and amblyopic subjects, complex visual stimulation often produces **asymmetrically greater relative glucose metabolism in the contralateral hemisphere;** this effect is **reduced by optical blur.**

DEVELOPMENT OF LUMINANCE MODULATED VISUALLY EVOKED POTENTIALS TESTED WITH PSEUDORANDOM BINARY SEQUENCE STIMULI. **R. Srebro and M. Hutchison-Clutter*. Dept. of Ophthalmology, UT Southwestern Med. Cntr., Dallas, TX 75235-9057.**

Visually evoked potentials (VEP) were obtained from 45 healthy normal full-term infants from 4 weeks to one year of age, 6 normal and 6 amblyopic adults. The stimulus was pseudorandom binary sequences (PRBS); .8 to 66.7 Hz at 100% modulation depth, identical to band-limited white noise except for having a periodicity of 1.0s allowing signal averaging. The stimulus was presented by means of a yellow LED array subtending an homogeneous 10^{0} field at a mean luminance of 6 foot-lamberts. Each test session consisted of 32 monocular presentations (approximately 41s total). A Laplacian electrode derivation centered at Oz was used. Fourier amplitude spectra and input-output cross correlation functions (CCF) were calculated from the averaged VEP. The highest driving frequency (F_D) of the VEP was estimated by calculating CCFs using band-pass filtered (2-pole Butterworth) copies of the stimulus with 3 dB cut-offs ranging from 1 to 40 Hz. Both the Fourier amplitude spectra frequency maxima and F_D shifted towards higher frequencies with increasing age. However, adult levels were not reached by the end of the first year of life. These results may reflect the development of central nervous system mechanisms, whereas previous studies using flicker fusion may reflect retinal cone development. Differences between normal and amblyopic adults were found.

VISUAL CORTEX MAPS IN KITTENS WITH BILATERAL AMBLYOPIA. Max S. Cynader[1], Joanne A. Matsubara[1], Nicholas V. Swindale[1]*, Kathryn M. Murphy[2]*, and Donald E. Mitchell[2]. Dept. of Ophthalmology[1], U.B.C., Vancouver, B.C. V5Z 3N9, and Dept. of Psychology[2], Dalhousie University, Halifax, N.S. B3H 4J1, Canada.

We studied visual cortex functional topography in kittens reared under a deprivation regime which results in reduced visual acuity. Kittens were reared with one eyelid sutured until five weeks of age. Thereafter, they had 9 or 18 days of reverse suture, during which time the initially-deprived eye was allowed vision, while the initially exposed eye was occluded. Thereafter, both eyes were allowed normal vision. This results in a profound deterioration of vision in both eyes, with visual acuity reduced by several octaves. We searched for anomalies in visual cortex functional maps in these animals. Using multiple, closely spaced electrode penetrations, we studied cortical magnification factor, receptive field size, local receptive field scatter (the point-spread function), and the layout of ocular dominance, orientation, and direction selectivity across the cortical surface. We found that the gross properties of the cortical map are normal, despite the amblyopia. Most importantly, there appears to be no difference in the retinotopic order of the map (point-spread function).

A striking difference was found in receptive field size. In the amblyopes, receptive fields averaged 60% larger than those of normal cats. This highly significant difference, coupled with the equality of point-spread function, leads to large differences in the cortical area over which receptive fields overlap and thus in hypercolumn dimensions between normal and amblyopic animals.

499.10

INTRACORTICAL AND GENICULOCORTICAL CONNECTIONS IN CATS WITH SEVERE BILATERAL AMBLYOPIA. J.A. Matsubara, D.E. Mitchell & M.S. Cynader. Depts. of Anat. & Psych., Dalhousie University, Halifax, N.S., B3H 4H7, Canada.

The local visual cortical and geniculocortical connections in cats with severe bilateral amblyopia were studied. Kittens were reared under conditions similar to those previously described, but with variations in the frequency and duration of daily reverse occlusion, resulting in an even greater deterioration in visual acuity. Microinjections of WGA-HRP or Con A were pressure injected into areas 17 or 18. Coronal sections of the LGN and tangential sections of the cortex were processed using the TMB method or the aviden-biotin method following incubation in a primary antibody directed against Con A.

The maximum number of patches surrounding an injection in area 18 was reduced from 10, in normal animals, to 4 in bilateral amblyopes. The extent of the labeling was also reduced along the M-L but not the A-P cortical axis. Thus, patches were distributed in a long, thin strip running A-P, a pattern reminiscent of one seen in bilateral enucleates. Finally, while the intracortical connections were reduced, preliminary results on the geniculocortical connections seemed abnormally widespread, with labeled cells occuring in over 60% of the LGN after a microinjection in area 18. These results suggest that the larger size of receptive fields recorded in bilateral amblyopes may result from the abnormally widespread geniculocortical projection. This work supported by the M.R.C. (Canada).

DEVELOPMENT OF FLASH EVOKED RESPONSES IN NEONATAL RAT SUPERIOR COLLICULUS. S.K. Itaya and S. Molotchnikoff. Dept. Biomed. Sci., Univ. So. Ala., Mobile, AL 36688, and Dépt. des Sci. Biol., Univ. de Montréal, Montréal, Qué.

We looked for the earliest flash evoked responses in the superior colliculus of neonatal rats. Anesthetized hooded rat pups had the cortex exposed and the opposite eye opened. Glass microelectrodes (1-2 Mohms) were used to measure field potentials. The stimulus was a strobe flash about 0.5 m above the head. Responses were recorded in the usual manner, averaged over 32 to 64 presentations. Two ERGs were measured, and two optic nerves were stimulated directly. Some brains were examined microscopically for the electrode track. No responses were observed before postnatal day 12 (P12). On P12, in 2 of 4 rat pups, flash evoked responses were recorded in superior colliculus with a biphasic potential of very long latency (250-350 msec) compared to the adult (about 50 msec). Responses were recorded within 500 um of the collicular surface. ERGs were first seen on P12, as has been reported. On P13, all 4 pups showed stronger collicular responses and also responses in visual cortex. At P14, when eyes are normally still closed, there were collicular and cortical responses with increased amplitudes and decreased latencies, e.g., 180-200 msec in the colliculus. We did not observe reversal of potential polarity. Action potentials in response to the light were first observed in the colliculus on P14.

499.12

DEVELOPMENT OF FLASH EVOKED RESPONSES IN THE ECTOSTRIATUM OF THE ZEBRA FINCH:
J. Engelage* and H.-J. Bischof* (SPON: EBBS).
University of Bielefeld, Dept. Ethology, POB 8640, D-4800 Bielefeld 1, F.R.G.

Recently a sensitive phase for the development of the tectofugal system has been demonstrated in our laboratory by anatomical methods. We are able to demonstrate the development of VEPs in the telencephalic target area of this pathway. In 20d old birds we recorded simple negative waves with low amplitudes. The typical pattern of the CSD depth profiles of adults could not be observed in these birds. VEPs recorded in the ectostriatum of 40d old birds showed the negative-positive wave typical of sexually mature birds with amplitudes within the adult range. However, there were differences in the shape of the VEP curves in 40d old birds and adults. CSD profiles showed a typical source-sink-source pattern comparable to that in adults. In the ectostriatum of 40d old birds reliable ipsilateral VEPs could be recorded similar to those of adult birds. Although anatomical data suggest that the development and the first sensitive phase are complete by d40, we conclude that physiological changes occur up to d60. Supported by the DFG.

A MUSCLE-DERIVED FACTOR PROMOTES SURVIVAL OF EMBRYONIC MOTOR NEURONS IN CULTURE. S.J. Jeong, T.H. Oh and G.J. Markelonis. Dept. of Anatomy, Univ. of Maryland Sch. of Med., Baltimore, MD 21201.

Survival of embryonic spinal motor neurons requires a muscle-derived trophic factor(s). We have partially purified a non-laminin protein from muscle tissues which stimulates neurite outgrowth (Oh, T.H. et al., Dev. Biol., in press); we are now investigating whether this protein promotes survival and growth of motor neurons. Cultures enriched in motor neurons were prepared from chick embryos using metrizamide density gradients. Using retrograde labeling techniques, we confirmed that the large cells recovered were motor neurons. Most of the large, putative motor neurons were found in metrizamide fraction I. We then determined the quantitative influence of the protein on survival and neurite outgrowth of cultures enriched in motor neurons over longer periods. When motor neurons in fraction I were plated on polylysine-coated dishes, the protein was able to support the survival of a proportion of the motor neurons plated. These large cells also extended neurites in culture in the presence of the protein. Laminin alone supported survival of a small proportion of motor neurons plated, but the level of survival was much lower than that by the protein. Both the protein and laminin promoted survival and neurite outgrowth of cells in fraction II suggesting that the survival effect of the protein was not specific for motor neurons. (Supported by NIH grants NS15013 and NS20490).

SENSORY AND SPINAL CORD NEURONS CULTURED IN SERUM-CONTAINING OR DEFINED MEDIA: IMMUNOHISTOCHEMICAL AND ELECTROPHYSIOLOGICAL STUDIES. D. S. Grega and T. J. Cavanagh*. Boehringer Mannheim Corp. Biochem. R&D, Dept. Cell Biol. Indianapolis, IN 46250

Serum-free or defined medium (DM) provides a more reproducible environment than serum-containing medium (SCM) for studying neural regeneration in culture. We have devised several DM for primary neural culture and here report immunohistochemical (IHC) and electrophysiogical data. Spinal cord and dorsal root ganglia (DRG) cultures were prepared from 12-14 rat embryos and maintained at least 3 weeks. SCM was compared with several DM's (proprietary formulations). IHC studies consisted of staining neurons (NSE), astrocytes (GFAP) and oligodendrocytes (GalC). The morphology and relative frequency of cell types in the various media were noted. Electrophysiological recordings were made from DRG neurons. Resting potential, action potential amplitude, duration, and afterhyperpolarization were compared. At 4 weeks in culture, there were no significant differences between DM1 and SCM cultures. Further comparisons of differing DM formulations are planned.

POSSIBLE NEUROTROPHIC EFFECTS OF NIMODIPINE ON COGNITIVE BEHAVIOR AND HISTOCHEMICAL DISTRIBUTION OF AChE and B-50 (GAP43) IN UNILATERAL FIMBRIA-FORNIX LESIONED RATS. A.M. Danks*, A.B. Oestreicher*, R.L. Isaacson, B.M. Spruyt*, W.H. Gispen*. Institute of Molecular Biology and Medical Biotechnology, Univ. of Utrecht, Utrecht, NL.

Male Wistar rats (220-240 g body weight) were subjected to left unilateral fimbria-fornix transection or sham operation. For seven days beginning the day of surgery, the rats received i.p. injections of 0.06, 0.5, 1.0, or 5.0 mg/kg nimodipine (Bayer AG, Leverkusen, FRG), or vehicle.

Open field and water maze behavioral measures were taken on days 11, 12, and 13 for animals sacrificed 14 days post-surgery; or days 25, 26, and 27 for animals sacrificed 28 days after surgery. Lesioned animals showed a significant learning impairment in the water maze, as compared to sham-operated controls, and the differences were not attributed to motor deficits since the animals did not differ in open field tests of locomotion. Spontaneous recovery of function was revealed by a reduced acquisition impairment in the water maze in rats allowed to recover 28 days.

Histochemical analysis revealed a reduction in AChE staining in medial septum, hippocampus, and n. accumbens brain regions. To examine differences in the expression and distribution of B-50 (GAP43), immunohistochemistry was performed. Effects of the lesion and nimodipine on behavior and histology will be discussed.

GM1 RESTORES DOPAMINE AND ACETYLCHOLINE IN THE BRAIN OF DEVELOPING RATS AFTER HYPOXIA. T.A. Wemlinger*, L.A. Isaacs*, H.S. Weiss, N.H. Neff, A.J. Yates and M. Hadjiconstantinou, Depts. of Pharmacology, Physiology and Pathology, The Ohio State Univ. Col. of Med., Columbus, OH 43210.

Acute or chronic hypoxia alters neurotransmitter function in the brain. Perinatal hypoxia causes neonatal brain damage resulting in various symptomatologies. Neurotrophic factors are a new generation of therapeutic agents for treating degenerative diseases of brain. There is now considerable evidence suggesting that administrating exogenous GM1 ganglioside promotes the recovery of neuronal function after various lesions. We now report that hypoxia causes long-lasting neurochemical changes in various regions of the brain of developing rats and that administration of GM1 corrects these deficits. Five day old rats were exposed to hypoxia (8% oxygen remained nitrogen) for 2 h and the animals killed 24 h or 3 weeks later. Twenty-four h after the insult dopamine (DA) and its metabolites were reduced in the striatum, frontal cortex and hippocampus. Three weeks later DA content recovered in the striatum and hippocampus but was still reduced in the frontal cortex. DA uptake studies followed the same pattern. Similarly, hypoxia caused a long-lasting reduction of acetylcholine (ACh) content and choline uptake in the striatum and frontal cortex of developing rats. Pretreatment with GM1 partially prevented the short term neurotransmitter changes after hypoxia. Furthermore, continuation of the drug for 3 weeks resulted in full restoration of DA and ACh content as well as DA and choline uptake.

MYOBLAST PROLIFERATION INDUCED BY SERUM FROM PATIENTS WITH HYPERTROPHIC MUSCLE. K.E. Misulis, C.M. Stoscheck*, & K.A. Jaeckle*. Neuromuscular Disease Res. Ctr., Vanderbilt Univ., Nashville, TN 37212

We have studied sera from patients with idiopathic muscle hypertrophy for the presence of factors which may influence myoblast proliferation and differentiation.

Mouse primary myoblast cultures were prepared from 1 day-old mice. Heat-inactivated sera from patients were applied to the myoblast cultures and incubated for 5 days. Subsequently, the myoblasts were removed by trypsin and EDTA and counted in a hemocytometer. The results from the experimental sera were compared to those using sera from normal volunteers.

Myoblasts incubated in sera from normal subjects had an increase in cell number over the 5 days to 574% of plated number. Patient serum resulted in an increase in myoblast proliferation to 1330% of the pre-incubation cell number. Serum levels of many hormones, including growth hormone, thyroxin, somatomedin C, were normal.

These data suggest that myoblast proliferation may be controlled by an as yet unidentified circulating factor, and this may be present in excess in patients with idiopathic muscle hypertrophy.

Supported by NIH-CIDA grant #NS01134 to Dr. Misulis and a VA research grant to Dr. Stoscheck.

ACTH 4-10 ANALOGUE ENHANCES RECOVERY FROM BRAIN INJURY Brain Res. Lab., Clark U., Worcester, MA 01610 & Biomeasure, Inc., Hopkinton,MA 01748. M.J.Attella*, S.W.Hoffman*,J.E.Taylor&D.G.Stein

Male Sprague-Dawley rats 90-100 days old were given lesions of frontal cortex and administered s.c. either sterile water (SW), 1µg, 10µg, or 100 µg of ACTH 4-10 analogue (BIM-22015) every other day for twenty days. Seven days later they began testing in the Morris water maze to locate a submerged platform. Brain-injured subjects given either 10µg treatment or SW took significantly more trials than sham operates to reach the platform eight consecutive times, while rats with lesions given 1µg or 100µg performed better than lesion controls. No significant differences were found in distance or time taken to reach the platform. After eight days, the subjects' ability to recall the location of the platform was determined. No differences were found in trials to reach the platform eight consecutive times. Percent savings formula performed on mean time to locate the platform revealed that sham operates did not differ from subjects with lesions given 1µg, 10µg, or 100 µg of the analogue. However,lesion controls exhibited negative percent savings. Thirty days after the last injection (42 days post-injury), the rats were trained in a delayed-spatial alternation task to assess long-term effects of the treatment. Brain-injured rats initially treated with SW or 1µg took more days to score 9 out of 10 correct alternations than sham or lesion subjects given 10µg of the analogue.With respect to the mean errors to this criterion, animals given 10µg again showed superior performance over those with lesions given SW or 1µg. Rats with comparable brain injury treated with 100µg made fewer errors than the 1µg group but did not perform better than lesion controls. A count of Acetylcholinesterase-labeled neurons in the nucleus basalis of Meynert (NBM) showed that brain-injured rats treated with either SW, 1µg or 100µg of the analogue exhibited significantly fewer neurons in comparison to sham operates. However, brain-injured rats given the 10µg treatment did not differ from the sham controls with significantly more neurons in the NBM than brain-injured counterparts treated with SW or 100µg.

NEUROMODULATION OF CATECHOLAMINERGIC GROWTH IN THE CHICK EMBRYONIC BRAIN BY TWO HYPOTHALAMIC NEUROPEPTIDES. S. Kentroti and A. Vernadakis (SPON: D.G. Whitlock). Depts. of Pharmacology and Psychiatry, Univ. of Colorado Sch. of Medicine, Denver, CO 80262

We are investigating the neuromodulatory role of growth hormone-releasing hormone (GHRH) and gastrin-releasing peptide (GRP) on catecholaminergic neuronal expression in the chick embryonic brain. The activity of tyrosine hydroxylase (TH), the rate-limiting enzyme in catecholamine synthesis, was used as an index of neuronal development. The peptides were given either at embryonic days E1 to E7, a period of neuronal differentiation, or E12 to E14, a period of synaptogenesis. In the first paradigm, animals received GHRH (135ng) or saline vehicle (50ul) in ovo on days E1,3,5 and 7 and sacrificed on E8. Whole brains minus optic lobes were assayed for TH activity, expressed as pmoles $^{14}CO_2$ liberated/h/mg protein. TH activity was significantly higher ($p<.001$) in the treated embryos versus controls (4.60±0.46 vs 1.95±0.13, respectively). A second group of animals received GRP (375ng) or saline vehicle in ovo on E12 and E14 and animals were sacrificed on E15. TH activity was significantly higher ($p<.05$) in cerebral hemispheres from treated versus control embryos (7.06±1.72 vs 4.83±0.58, respectively). We interpret these data to mean that GHRH and GRP may be involved in catecholaminergic neuronal growth and synaptic function. (Support:NIH grant #AA07464)

TREATMENT OF GANGLIOSIDES AND AMPHETAMINE FAIL TO REDUCE SPATIAL LEARNING DEFICITS IN A WATER-MAZE TASK FOLLOWING BILATERAL LESIONS OF THE CAUDATE NUCLEUS. G. L. Dunbar#, L. Lescaudron*, B. S. Bitran*, S. A. Hecht*, and D. G. Stein. Brain Research Lab, Clark University, Worcester, MA 01610. #Dept. of Psychology, Central Michigan University, Mt. Pleasant, MI 48859.

Although gangliosides (GM1 and AGF2) and d-amphetamine reduce learning deficits on a two-choice, spatial reversal task after bilateral caudate nucleus (CN) lesions (Dunbar et al., Soc. Neurosci. Abstr., 12:1283, 1986), the effects do not generalize to a task which requires utilizing distal cues (i.e., the Morris water maze). Forty-one male, albino rats (Sprague Dawley, 350-450g) were given sham operations and IP saline injections (n=9) or bilateral CN lesions, followed immediately by IP injections of either 30 mg/kg GM1 (n=9), 20 mg/kg AGF2 (n=7), 2 mg/kg d-amphetamine (n=7) or physiological saline (n=9). Injections were given daily for 10 days. Five days after surgery, testing began in the Morris water maze and in an open field twice a day, for five days. None of the treatments were able to reduce lesion-induced deficits on the water maze task. Also, no between-group differences were found in open-field activity levels. These results suggest that the beneficial effects of gangliosides and amphetamines may be task-specific in reducing spatial learning deficits following CN lesions.

5,7-DHT-LESION-INDUCED NEUROTROPHIC FACTORS INCREASE SURVIVAL OF GRAFTED 5-HT NEURONS IN THE CEREBELLUM. F.C. Zhou and E.C. Azmitia Dept. Anatomy, Indiana Univ., Indianapolis, IN 46223

5,7-DHT (a 5-HT neurotoxin)-lesion in an afferent to hippocampus induces sprouting of 5-HT fibers in the hippocampus from another afferent (Azmitia et al., Nature, 274:374, 1978; Zhou and Azmitia, Brain Res., 308:53, 1984; 373:337, 1986). This 5,7-DHT-altered hippocampus was found favorable to the growth of grafted 5-HT neurons but not norepinephrine neurons. Furthermore, extracts from the altered hippocampus promotes the growth of grafted 5-HT neurons (Zhou et al., J. Neurosci. Res.17: 235, 1987). In the present study, the trophic extracts were found to support the survival of the grafted 5-HT neurons in the cerebellum where fewer 5-HT fibers innervate and grafted 5-HT neurons seldom survive.

Dissociated fetal raphe cells (1.1×10^6) from E-14 were grafted into the cerebellum (right side) of adult albino rats with neurotrophic extracts, NTF3 (1:1 or 1:100) as experimentals or with Hank's solution as control; all animals were examined 6 weeks after surgery. Both immunostaining of 5-HT neurons (0, 0, 0, 0, 51, 54 stained neurons, n=6) and HPLC measurement of 5-HT level (right/left =0.11/0.10 ng/mg, n=4) confirmed that grafted 5-HT neurons with Hank's vehicle do not survive well in the cerebellum. Grafts supplemented with NTF3, 1:100 dilution, have 86, 246, and 307 (n=3) stained 5-HT neurons. Grafts supplemented with NTF3, 1:1 , have no survivals (n=3). Furthermore, the grafted 5-HT neurons with NTF3, 1:100, have noticeably higher density of 5-HT fibers than those in control.

Current results and previous observations suggest that high-dilution NTF3 promotes growth of 5-HT fibers in favorable, (hippocampus) as well as in unfavorable (cerebellum) environments. NTF3 further supports the survival of grafted 5-HT neurons when they were placed in the unfavorable cerebellum. Finally, highly concentrated NTF3 may contain a factor inhibiting neuronal growth. Supported by NIH RO1- 23027-02.

TROPHIC SUPPORT OF ALBUMINS ON CENTRAL NEURONAL CELLS IN VITRO. D. D. SVRZIC* (SPON: J. PATRICK),Dept. of Biol. M-007, University of California, San Deigo, CA 92093.

Pure cultures of central neurons in which all cells stained positive for neurofilaments were obtained from dissociated whole chick forebrain on embryonic day 8. The cultures were grown for 1, 5 and 7 days in vitro either on untreated tissue culture plastic or on polyornithinlaminin precoated plates. We observed trophic support of bovine serum albumin (BSA) and ovalbumin (OA) when present in the serum free medium in the concentration range from 15 nM to 1.5 mM and from 0.87μM to 28 μM. respectively. At the plateau level of BSA (75μM) 66% of the cells survived for more than 24 h of incubation, whereas at the plateau level of OA (13.5 μM) only 52% of the cells survived. This neuronotrophic support exceeded by far our observation of the effects of pyruvate/catalase in the presence of a buffer in the short term cultures. Only the albumins provided an extended neuronotrophic support (7 days) which was accompanied by the appropriate neuronal sprouting. Neuronal survival was estimated by means of a strip-counting technique and an automated colorimetric micro-assay (Manthorpe, M., et al., Develop. Brain. Res. 25: 191, 1986).

Albumins of a greater purity have excluded the possibility of essential fatty acids being responsible for the described effects. It remains to be determined if the forms of somatomedins: IGF-I and IGF-II (Carlsson-Skwirut, C., et al., FEBS 201:46, 1986) are the trophic substances that permit not only the longevity of the neurons, but also the normal maintenance in culture.

NEURITE-PROMOTING ACTIVITY FROM THE BRAIN OF MPTP-TREATED MONKEYS WITH AND WITHOUT SURGICAL LESIONS. Margaret A. Palmatier, Robert Plunkett*, Kryztof Bankiewicz, Alexander C. Cummins*, and Irwin J. Kopin. CNB, NINCDS, NIH, Bethesda, MD. 20892

Cerebrospinal fluid (CSF) or gelfoam pellets from caudate cavities of untreated or unilaterally MPTP-treated Macaque monkeys were tested for neurite-promoting activity. Neurite-promoting activity was assayed using chick dorsal root ganglion (DRG) from 8 to 9-day-old chicken embryos explanted onto laminin-coated tissue culture wells in serum-free medium in the presence of various amounts of CSF. Ganglia were scored after 18 hours for neurite outgrowth relative to neurite outgrowth induced by various concentrations of Nerve Growth Factor (NGF) in the same bioassay. CSF from untreated monkeys did not induce neurite outgrowth from chick DRG. CSF from MPTP-treated monkeys induced neurite outgrowth, as did CSF and gelfoam pellets from monkeys that had received a surgically placed cavity in the caudate nucleus. These results extend the finding of lesion-induced, brain-derived neurite-promoting activity into the primate and provide evidence that chemical lesions such as MPTP treatment also may induce this neurite-promoting activity in the brain.

PROTEASE NEXIN-1, A PROTEASE INHIBITOR WITH NEUROTROPHIC ACTIVITY, IS REDUCED IN ALZHEIMER'S DISEASE. S. L. Wagner*, J.W. Geddes, C.W. Cotman, A.L. Lau*, P.J. Isackson* and D.D. Cunningham* (SPON: R. F. Young). University of California, Irvine, CA 92717.

The biochemical basis for the neuropathological lesions and the loss of cognitive functions that characterize Alzheimer's disease are unknown. The recent findings that brain amyloid deposits of Alzheimer's disease contain trypsin and chymotrypsin inhibitors indicate that an imbalance of proteases and protease inhibitors may be involved (Ponti, P. et al.; Tanzi, R., et al.; Kitaguchi N. et al.; Nature, 331:525-532, 1988). It recently was shown that thrombin, but not other proteases tested, produces retraction of neurites in cultured neuroblastoma cells (Gurwitz, D. and Cunningham, D., Proc. Natl. Acad. Sci. U.S.A., in press). This may be important in neural function since the neurotrophic activity of protease nexin-1 (PN-1) depends on its ability to inhibit thrombin.

The present studies showed that PN-1 activity was eight-fold lower in autopsy brain samples from 10 Alzheimer's disease cases compared to 6 control cases. PN-1 activity was quantitated based on its ability to form SDS-resistant complexes with ^{125}I-thrombin that were blocked by a specific anti-PN-1 monoclonal antibody (Wagner, S.L., Van Nostrand, W.E., Lau, A. and Cunningham, D., Biochemistry, 27:2173, 1988). The much reduced PN-1 activity in the Alzheimer's disease samples was not due to differences in postmortem delay, age or sex. We suggest that the reduced levels of PN-1 in Alzheimer's disease brain could result in increased thrombin levels that in turn could lead to disrupted interactions among neurites and altered neurite morphologies.

INSULIN INFLUENCES ASTROGLIAL MORPHOLOGY AND GFAP EXPRESSION IN VITRO. C.D. Toran-Allerand, J.P. Anderson* and W. Bentham*. Dept. Neurol./Anat. and Cell Biol., Ctr. for Reprod. Sci., Columbia Univ., P&S, New York, NY 10032.

We report here for the first time that variations in the levels and timing of insulin exposure influence differently the morphological patterns of astroglial differentiation as well as expression of GFAP in long-term organotypic cultures of E-17 mouse cerebellum. The medium was supplemented with no insulin, low insulin (10 pg/ml); or high insulin (10 ug/ml). Cultures were stained immunocytochemically with monoclonal antibodies to GFAP or processed for in situ hybridization, using a biotinylated cDNA GFAP probe. High insulin elicited an increase in GFAP mRNA and intense GFAP immunoreactivity. Low insulin produced minimal expression of message and protein product. The very morphology of GFAP+ cells was also influenced by the hormone concentration in an age-specific manner. Fetal radial glia were selectively increased by high insulin, comprising 64% of GFAP+ cells in contrast to a reversal of this pattern by low insulin, where 69% of GFAP+ cells were flat cells. In newborn cultures, however, the morphological responses to high and low insulin were considerably attenuated. In view of the critical dependence of interactions of developing neurons with radial glia for neuronal migration, differentiation, and the initiation of neurite growth, these changes in morphology suggest developmentally-regulated mechanisms by which insulin-related peptides may influence directly and indirectly neuronal and astroglial differentiation.

ACTION OF GANGLIOSIDE ON RESPONSIVENESS OF SENSORY GANGLIA TO TROPHIC AGENTS. D.F. Chen* and F.J. Roisen. Dept. of Anatomical Sciences and Neurobiology, Sch. of Med., Univ. of Louisville, Louisville, KY 40292.

Gangliosides potentiate the action of Nerve Growth Factor (NGF) on chick embryonic 9 day (ED) sensory ganglia (DRG). The responsiveness of DRG neurons to NGF begins on ED 7, is maximum on 9 and declines totally by ED 13. To determine if GM1 could alter sensitivity to NGF during developmentally reduced responsiveness, DRG (ED 6-14) were explanted in Medium 199 containing 10% heat-inactivated fetal bovine serum supplemented with GM1 (150 ug/ml) in the presence or absence of NGF (1 ug/ml). Neuritogenesis was evaluated in terms of neurite number and length and by ornithine decarboxylase activity. No GM1 potentiation was observed during the peak of NGF-mediated development (ED 8-10); on other days, treatment with GM1 + NGF enhanced growth. Since medium conditioned over C6 glioma cells for 3 days (GCM) stimulates DRG in the presence of anti-NGF, the ability of GM1 to potentiate GCM-mediated growth was examined (ED 6-14). Maximal potentiation of GCM by GM1 occurred on ED 9-10 when the GCM alone was submaximal. GM1 enhanced the trophic agents when their activity was submaximal by altering the extent but not the duration of the response. These studies demonstrate that gangliosides play a regulatory role in trophic interaction. Supported by NIH NS24524 and DE07734.

500.15

THE NEURITOGENIC ACTION OF PHOSPHATIDIC ACID. W.H.FENG* G. YORKE, K.C. LESKAWA* AND F.J. ROISEN. Department of Anatomical Sciences and Neurobiology, School of Medicine, University of Louisville, Louisville, KY 40292.

Gangliosides can regulate the neuritogenic and neuronotrophic development of several types of embryonic neurons and neuroblastoma in vitro. We have shown that individual gangliosides produce subtle differences in the neuritic patterns. To determine the minimum molecular structure required to produce these changes, we examined the effect of exogenous phosphatidic acid (PA) on neuritogenesis. PA was suspended in phosphate buffered saline, sonicated, diluted with nutrient medium at various concentrations (3.3×10^{-8} to 3.3×10^{-4} M) and applied to Neuro-2a cells. Growth was evaluated in terms of neuritic complexity and % cells with processes. PA was stimulatory over a broad concentration (maximal at 3.0 uM) at 24h. An index of PA's metabolic action was obtained from ornithine decarboxylase induction. Maximal activity was obtained at 30 uM. To determine if PA could potentiate Nerve Growth Factor (NGF)-mediated neuritogenesis, the effect of PA on NGF-mediated development of rat pheochromocytoma PC-12 cells and chick embryonic dorsal root ganglia (DRG) was examined. PA had a moderate effect on PC-12 and DRG differentiation. These data demonstrate that although the responses were not equivalent both PA and GM1 enhance neuritogenesis. Supported by NIH NS24524 and DE07734.

GANGLIOSIDE AGF2 PROMOTES RECOVERY OF AF64A-INDUCED BEHAVIORAL AND NEUROCHEMICAL DEFICITS. D.F. Emerich, M.J. Spates * and T.J. Walsh Rutgers University, Department of Psychology, New Brunswick, NJ 08903.

AGF2 is the internal ester of GM1 and has been shown to promote recovery of function following central nervous system insult. The studies presented here examined the effects of AGF2 on the behavioral and neurochemical alterations induced by intraventicular administration of AF64A. This cholinotoxin produces long-lasting decreases in the activity of choline acetyltransfase (ChAT) in the hippocampus (HPC) together with persistent cognitive impairments.

Sprague-Dawley rats were trained on a standard eight arm radial maze (RAM) task. Following training, rats were injected (IP) with 10 mg/kg AGF2 or 0.9% saline for 3 days prior to and for 14 days following the bilateral injection of AF64A (3nmol/side/icv.) or artificial CSF. Rats injected with AF64A (AF64A/Sal) were markedly impaired in their performance of the RAM task. In contrast, animals receiving AGF2 (AF64A/AGF2) were initially impaired but rapidly reaquired the task and performed as well as controls.

Rats were then trained to perform a working memory version of the RAM task in which they had to remember which 4 of the 8 maze arms they obtained food from prior to a one hour delay. Following the delay the rats were returned to the maze and allowed to choose freely among all 8 arms. Arms not previously choosen were baited, and entry into previously entered arms constituted an error (delayed-non match-to-sample). AF64A-treated rats, whether treated with AGF2 or not were profoundly impaired on this version of the task and showed no evidence of recovery.

AF64A produced a 35% decrease in hippocampal ChAT activity (AF64A/CSF) that was significantly attenuated by prior treatment with AGF2 (22% decrease). These data suggest that, in this model system, AGF2 promotes recovery of function by either limiting the initial effects of AF64A or by facilitating neural reorganization following the insult.

A RAT HYPOTHALAMIC CELL LINE WHICH IS SENSITIVE TO SEVERAL DIFFERENT TISSUE GROWTH FACTORS. I. Torres-Aleman*, F. Naftolin*, and R. J. Robbins (SPON: S. Spencer). Sect. of Neuroendocrinology, Dept. of OB/GYN and Medicine, Yale Medical School, New Haven, CT 06510.

Trophic factors affecting brain cell development appear to be cell-type specific. A single neuron may respond to different growth factors as a function of its developmental state. We examined the possibility that hypothalamic cells may possess responsiveness to more than one growth factor. A stable SV-40 transformed rat embryo hypothalamic cell line (F-12) was grown in the presence of either FGF_b, insulin, IGF-I or MSA (from 0.1 pM to 10 nM). Dose dependent growth promoting effects were present in the following potency: FGF_b>IGF-I = insulin. MSA had no effect. At 0.1 nM FGF_b produced a 20 fold increase in cell number, IGF-I a 10 fold, and insulin a 9 fold. ED_{50} was between 0.1 and 1 nM for all three peptides. We suggest that development of hypothalamic cells may occur in part via regulated or pre-programmed expression of a repertoire of growth factor receptors.

EFFECT OF NGF ON THE ADULT INTACT AND LESIONED SEPTOHIPPOCAMPAL CHOLINERGIC SYSTEM. M. Fusco*[1], G. Vantini[1], L. Cavicchioli*[1], N. Schiavo*[1], M. Zaremba*[2], M. Gradkowska*[2], B. Oderfeld-Nowak*[2] and A. Leon[1]. [1]Fidia Research Laboratories, Abano Terme, Italy and [2]Department of Neurophysiology, Nencki Institute for Experimental Biology, Warsaw, Poland.

In contrast to neonatal rats, intracerebrally-administered NGF has been reported to significantly affect septal and hippocampal choline acetyltransferase (Chat) activities in adult rats solely following transection of the septal-hippocampal pathway. We here report that continuous intracerebroventricular infusion of NGF (25 μg/2 weeks via mini-osmotic pumps) induces significant increase of Chat activity also in the septohippocampal cholinergic system of sham-operated rats. Furthermore, in rats with unilateral partial fimbria fornix transections, NGF increases Chat activity in the hippocampus of not only the lesioned but also unlesioned side. Whereas the more pronounced NGF effect was observed in the ventral pole of the hippocampus contralateral to the lesion (also in sham-operated animals), the NGF effect was higher in the dorsal pole of the ipsilateral hippocampus. These findings significantly extend the role of NGF in the physiological functioning of adult forebrain cholinergic neurons.

NGF ENHANCES THE EXPRESSION OF NGF RECEPTOR MESSENGER RNA IN VIVO. L. Cavicchioli*[1], G. Vantini[1], T. Flanigan*[2], F. Walsh[2], M. Fusco*[1], E. Bigon*[1], D. Benvegnù*[1] and A. Leon[1] (SPON: G. Toffano). [1]Fidia Research Laboratories, Abano Terme, Italy and [2]Institute of Neurology, The National Hospital, London, U.K.

Studies of the expression of the NGF receptor in septal cultures have shown that NGF treatment increases NGF receptor immunostaining. In an attempt to study ligand-mediated regulation of NGF receptors in vivo, we assessed NGF receptor mRNA in the septal area of neonatal rats treated daily with an intracerebral injection of NGF (5 μg) or vehicle, from postnatal days (P) 2 to 8. Northern blot hybridization of total RNA extracted from the basal forebrain of each single rat at P9 was carried out by utilizing both cDNA and cRNA probes for human NGF receptor (Chao, M. et al., Science, 232:518, 1988). In addition, choline acetyltransferase (Chat) activity in the striatum and hippocampus of the same animals was assessed to monitor NGF efficacy.

Results show that NGF i) increased both striatal and hippocampal Chat activity (220% and 180% of control, respectively), and ii) caused a marked increase (approx. 3 to 4 fold) in the NGF receptor mRNA levels in the septal area. Densitometric quantification of the latter was normalized by assessment of P1B15 mRNA. Studies are in progress to determine the correlation between the NGF-mediated increase in NGF receptor mRNA and cell surface NGF receptor availability.

501.1

LOCALIZATION OF PROTEIN BINDING SITES IN THE 5' REGION OF THE DYNORPHIN GENE. M.J. Iadarola, J.P. Quinn*[1], J. Douglass*[2] and D. Levens*[1]. Neurobiology and Anesthesiology Branch, NIDR, [1]Laboratory of Pathology, NCI, NIH Bethesda, MD 20892; [2]Vollum Institute, Oregon Health Sciences University, Portland, OR 89230.

Enhanced expression of the dynorphin gene has been observed in several CNS regions during specific types of stimuli. For example, activation of primary afferents or kainic acid seizures cause a marked accumulation of preprodynorphin mRNA in, respectively, spinal cord and hippocampus. These stimulus dependent alterations suggest an increase in dynorphin gene transcription, possibly via factors that bind to regulatory DNA elements. We have examined the 5'end of the rat dynorphin gene for regions that bind such regulatory proteins using a unique binding/exonuclease digestion procedure (Quinn et al Mol Cell Biol, 7:2735, 1987). A 3'end labeled 2,400 base sequence of the 5'region of the dynorphin gene plus the lac operator was tethered, via a lac repressor-beta galactosidase fusion protein, to an acrylamide bead by an antibody bridge. Incubation with crude tissue, whole cell or nuclear extracts allowed binding of proteins to specific recognition sequences. The bead/antibody/DNA/protein complex was separated from the remainder of the extract by centrifugation and digested with T7gene6 exonuclease. At specific sites, digestion was prevented by tightly bound proteins (stop sites). In extracts of rat spinal cord, striatum, cerebellum and 10 other regions electrophoresis revealed 6 prominent stop sites which bracketed the transcription initiation start site. Comparison with peripheral tissues and several cultured cell lines showed one of the sites to be neural specific. Binding of all proteins could be competed by excess unlabeled dynorphin gene but not by poly-dAdT or poly-dIdC or several oligonucleotides. The method provides a rapid procedure to scan large gene fragments for DNA binding proteins which may participate in transcriptional regulation. These results demonstrate the presence of a neural specific protein that recognizes a specific sequence in the dynorphin gene.

501.2

STRONG EVOLUTIONARY CONSERVATION OF NEUROPEPTIDE-Y AND THE CARBOXYTERMINAL PEPTIDE OF THE NEUROPEPTIDE-Y PRECURSOR (CPON). D. Larhammar¶ and R. J. Milner. Research Institute of Scripps Clinic, La Jolla, CA 92037, ¶ and Dept of Med. Genetics, Uppsala University, S-752 45 Uppsala, Sweden.

Neuropeptide-Y (NPY) is a 36-amino-acid neuropeptide which occurs abundantly throughout the mammalian nervous system. NPY forms a family of related peptides with peptide-YY (PYY) and pancreatic polypeptide (PP) which are 70% and 50% homologous to NPY, respectively. The NPY precursor consists of a signal peptide, mature NPY, and a 30-amino-acid carboxyterminal peptide called CPON.

We have deduced the sequence of chick prepro-NPY from gene and cDNA clones. The chick NPY precursor has the same organization as mammalian prepro-NPY. The mature chick NPY peptide has only a single amino-acid difference as compared to the rat and human sequences. To explore the evolutionary conservation of NPY further, Southern hybridizations were performed to genomic DNA of several vertebrate species using a single-exon rat NPY probe. Crosshybridizing fragments were detected in genomic DNA of a reptile, an amphibian, and a bony fish. Thus, NPY is an extremely well-conserved peptide.

Surprisingly, CPON is also highly conserved between chicken and mammals. Chick CPON is 90% homologous to its rat equivalent and 87% homologous to the human peptide. Thus, CPON is as conserved as insulin and VIP. This suggests that CPON has a biological function other than its putative involvement in the processing of prepro-NPY.

The strong sequence conservation of NPY and CPON suggests that these peptides fulfill evolutionarily old and important functions.

501.3

EVIDENCE FOR GENE CONVERSION BETWEEN THE OXYTOCIN AND VASOPRESSIN GENES OF BRATTLEBORO RATS. F.W. van Leeuwen, E.M. v.d Beek, J.P.H. Burbach* and R. Ivell**. Neth. Inst. for Brain Res., *Rudolf Magnus Inst. for Pharmacol., Utrecht, **Inst. for Horm. and Fert. Res., Hamburg, F.R.G.

Propressophysin, consisting of vasopressin (VP), neurophysin (NP) and glycopeptide (GP), is synthetized in about 4500 cells in the rat hypothalamus. In homozygous diabetes insipidus Brattleboro rats (HO-DI) a deletion of a single G residue in the NP-exon constitutes a frame shift mutation. Instead of GP a mutant peptide (MP) is synthetized that cannot be transported. However, a small number (n=20) of GP cells and fibres was found in the hypothalamus and the neural lobe of young HO-DI rats. The most likely explanation for these contradictory results is gene conversion: the oxytocin gene would transfer information to the nearby and deleted VP gene; their strongly homologous NP-exons would be relocated in front of each other by hairpin loop formation enabling mismatch-repair. The normal "reading frame" would be restored and GP synthetized again. Gene conversion means that GP-cells, which express both alleles, have become heterozygous: 1 allel remains coding for MP, the other would express GP. Indeed the same cells displayed both GP and MP immunoreacticity. Furthermore, the number of GP cells increased during life to 95 in 60-week-old HO-DI rats illustrating that gene conversion also occurs in somatic cells. These results show for the first time that long after the last mitosis the genome can undergo changes in the brain.

CLONING OF RAT CATECHOL-O-METHYLTRANSFERASE (COMT). MH GROSSMAN[1], XO BREAKEFIELD*[2], A FOOTE*[2], K SEAMAN*[3] and CR CREVELING[3] 1-Dept. Peds., Temple Univ. Sch. of Med., 2-Molec. Neurogent., Shriver Ctr., 3-Lab. Bioorganic Chem., NIH-NIAMDD.

To determine the relationship between the different molecular weight and isoelectric forms of rat COMT (EC 2.1.1.6) we have undertaken the cloning of the gene for the rat enzyme. An antiserum to highly purified rat liver COMT was used to screen a rat liver cDNA expression library. A total of 13 positives were identified from two screenings of 84,000 plaques. A frequency of about 0.1%, within the predicted range, was obtained. Several of the larger clones cross-hybridized (E1/M3, and K1/M2/28) and also identified the same size mRNA on Northerns, 1.1 kb and 1.6 kb respectively. All five clones showed hybridization patterns to mRNA from rat tissues consistent with enzyme levels; strongest signals in liver, then kidney, with weaker ones in brain and little or none in heart or spleen. In addition, we made use of an immuno-affinity -purified mRNA, which when translated in vitro coded for a single polypeptide of the size and pI of authentic COMT enzyme. A radiolabeled cDNA probe made from this message was hybridized to a Southern blot of positive clones. All of the larger clones showed signals upon autoradiography.

We are using these clones for in situhybridization to tissues, as well as in screening somatic cell hybrids with human chromosome 22. Ultimate confirmation will be made by comparison of nucleotide and amino acid sequences. Recently, peptide sequence became available. All clones are in M13. We have found sequences responsible for the cross-hybridization of some clones, but no DNA sequence corresponding to the peptide. This work was supported in part by grants from the Scottish Rite Schizophrenia Research Program, and the NIH (NS24066-02).

501.5

CHARACTERIZATION AND REGULATION OF RAT AND HUMAN TYROSINE HYDROXYLASE GENES. G.T. Coker III*, L.B. Vinnedge* and K.L. O'Malley. (SPON: L. Berg) Anatomy and Neurobiology, Washington Univiversity School of Medicine, St. Louis, MO 63110.

Previously, we have characterized the tyrosine hydroxylase (TH) gene from both rat and human sources. In order to understand the functional and evolutionary significance of particular structural features, we have compared introns and flanking DNA between these species presuming important sequences will be highly conserved. The six introns sequenced to date (1,3,4,5,7,8) together with the 3' noncoding region, have identities between 51 and 67%. In contrast, the rat and human TH promoter regions from +1 to -380 bp are 74% identical. We are currently using transient expression assays together with mutational analysis of the promoter region to delineate cis-acting transcriptional sequences for these two genes. When DNA fragments containing these upstream regions are fused to the gene for luciferase both rat and human promoters allow luciferase to be expressed in fibroblasts (3T3) and neuronal cells (PC12). The levels of luciferase produced from these constructs were between 0.5 and 27% the level observed when the rous sarcoma virus promoter was used.

Recently, we have shown that the human TH gene is contiguous with the insulin gene on chromosome 11. To determine whether this is a syntenic phenomenon, we are exploring the linkage of these genes in other species. In rat and mouse the distance between TH and insulin appears to be greater than that in humans (approximately 14-20 kb respectively, versus 2.7). Detailed examination of this unique chromosomal region may provide insights into the gene regulation of both TH and insulin.

501.6

CHARACTERIZATION OF THE RAT OPSIN PROMOTER. M.A. Morabito* and C.J. Barnstable. Rockefeller University, New York, NY 10021, and Dept. Ophthalmology, Yale Univ. Sch. Med., New Haven, CT 06510.

Rhodopsin is the light absorbing pigment of the vertebrate retina. The expression of the opsin gene is restricted to rod photoreceptor cells and is developmentally regulated. Opsin RNA accumulates to detectable levels at postnatal day 2 (PN2) and increases to the adult level at PN10. In parallel, opsin transcripts can be detected at PN1 and the transcription rate increases from PN3 to reach the adult level at about PN10, suggesting that transcriptional regulation is responsible for the increase in opsin expression (Treisman J.E. et al., Mol. Cell. Biol. 8:1570-79, 1988).

The efficient and accurate transcription of eukaryotic protein-coding genes requires *cis*-elements located upstream of the gene, together with *trans*-acting proteins capable of interacting with the promoter regions.

To analyze the role of *cis* and *trans* acting factors in the regulation of the opsin gene, we have isolated clones encoding opsin from a rat genomic library. The nucleotide sequence of the coding region, TATA box and adjacent G-rich region of the rat opsin gene shows 87% homology with the bovine opsin gene previously described (Nathans J. and Hogness D.S., Cell 34,807-814, 1983).

The promotor region has been further characterized by gel retardation and DNA footprinting using nuclear extracts from rat retina, brain and liver tissues. This analysis shows that regions of tissue specific binding are interspersed with regions recognized by ubiquitous proteins. Supported by NIH grants NS 20483 and EY 05206.

501.7

AN UPSTREAM REGION OF THE RAT PNMT PROMOTER CONFERS RESPONSIVENESS TO DEPOLARIZATION IN FUSION GENE CONSTRUCTS. *ME Ross, MJ Evinger, JM Carroll, L Mucke*, SE Hyman, DJ Reis, TH Joh and HM Goodman**, Dept. of Molec. Biol., Mass. Gen. Hosp., Boston MA 02114, Divs. of Neurobio. and Molec. Neurobio., Cornell Univ. Med. Coll., NY, NY 10021.

Neuronal stimuli modulate the expression of phenylethanolamine N-methyltransferase (PNMT) *in vivo*. *In vitro*, we found that bovine adrenal chromaffin cell levels of PNMT mRNA increase (5-8 fold) in response to K^+ depolarization (Neurosci. Abst. 13:1086, 1987). We sought to identify a region of the PNMT promoter which mediates the response to K^+. PNMT 5' flank (1.1 Kb) including the transcriptional start (CAP) site was isolated from a rat genomic library (G. Scherer), probed with rat PNMT cDNA. This fragment was sequenced and the CAP site was determined by primer extension analysis to be 22 bp downstream of the TATA box. PNMT fusion gene constructs with a chloramphenicol acetyltransferase (CAT) reporter were made using pBLCAT2 or pBLCAT3 (B.Luckow). Plasmid pBL_3900 contains the entire PNMT fragment in the promoterless pBLCAT3 while pBL_2500 contains the most distal 480 bp ligated onto the minimal thymidine kinase promoter of pBLCAT2. pBL_3900 was introduced into rat C6 glioma cells with the neomycin resistance marker pRSVneo and stable transformants were selected in G418. Several stable lines consistently displayed a 2-4 fold increase in CAT activity when treated for 16 hrs with 50 mM K^+, compared to matched Na^+ controls. pBL_2500 was cotransfected with pRSVβgal into C6 cells and transients were treated with K^+ or Na^+. CAT values were normalized to β galactosidase activity. The pBL_2500 constructs increased CAT expression 2-4 fold in response to K^+. This suggests that an element responsive to depolarization is present in the region between -400 and -900 bp, relative to the CAP site, of the PNMT promoter.

cDNA CLONING AND SEQUENCE DETERMINATION OF ARPP-16, A SUBSTRATE FOR cAMP-DEPENDENT PROTEIN KINASE, ENRICHED IN THE BASAL GANGLIA

A. Horiuchi*, T. Kurihara*, K. Horiuchi[#], K. R. Williams*[+], A. C. Nairn and P. Greengard. Lab. Molec. and Cell. Neurosci., [#] Lab. Genetics, The Rockefeller University, New York, NY 10021, and [+]Dept. Mol. Biophys. & Biochem., Yale University, New Haven, CT 06510.

ARPP-16 (a phosphoprotein substrate for cAMP-dependent protein kinase of Mr 16,000) has been found to be enriched in the basal ganglia. ARPP-16 has been purified to homogeneity from the supernatant of bovine caudate nucleus and rabbit serum antibodies prepared. An additional substrate for cAMP-dependent protein kinase, with an Mr of 19,000 (ARPP-19), was found to cross-react with the antibodies prepared against ARPP-16. Immunological analysis indicated that ARPP-16 was enriched in the basal ganglia while ARPP-19 was present in similar levels in all brain regions studied and was also present in non-neuronal tissues. cDNA clones were isolated from a bovine caudate cDNA library using in situ colony hybridization with oligonucleotide probes designed on the basis of the amino acid sequences of several peptides purified from chymotryptic digests of ARPP-16. Two distinct cDNA clones were isolated and the nucleotide sequences determined. Comparison of the nucleotide sequences and amino acid sequences indicates that one clone codes for ARPP-16 while the other codes for ARPP-19. The amino acid sequences of ARPP-16 and ARPP-19 are identical except that ARPP-19 has an additional 16 amino acids at the N-terminus. The two cDNA clones share an identical 3' untranslated region of 756 nucleotides. In addition, the cDNA clone for ARPP-16 contains 806 nucleotides following the common sequence. The 5' untranslated regions of the two clones are entirely different. These results suggest that ARPP-16 and ARPP-19 may be produced by tissue- and brain region-specific, alternative splicing of a primary transcript.

ISOLATION AND CHARACTERIZATION OF GENES SPECIFICALLY EXPRESSED IN THE ELECTROMOTOR NUCLEUS OF TORPEDO.

M. Linial*, J. Ngsee*, and R.H. Scheller. Dept. of Biological Sciences, Stanford University, Stanford, CA 94305.

Polyclonal antibodies raised against purified cholinergic synaptic vesicles from Torpedo californica were used to screen a λgt-11 expression cDNA library constructed from the electromotor nucleus (Carlson, S.S., and Kelly, R.B. (1980) J. Cell. Biol. 97, 98-103). Three of the cDNA clones were shown to be specifically expressed in the electromotor nucleus and not in the electric organ, gill, muscle, heart, skin or liver. Moreover, the level of expression is approximately 10 fold higher in the electric lobe relative to the brain. The cDNAs hybridize to three independent mRNAs of 10 kb (clone 2), 5.5 kb (clone 3) and 2.0 kb (clone 4). Searches of the protein data bank using amino acid sequences predicted from the nucleotide sequences of the cDNAs did not reveal any significant homologies. Antibodies raised against the coding region of clone 2 recognize a unique protein with an apparent molecular weight of 350,000 daltons which copurifies with Torpedo synaptic vesicles.

VISUAL CORTEX VII

502.1

CORTICAL DYNAMICS OF FORM AND COLOR PERCEPTION. S. Grossberg and E. Mingolla*. Center for Adaptive Systems, Boston Univ., Boston, MA 02215.

A model cortical architecture is described for explaining key processes of boundary detection, sharpening, regularisation, and completion; textural segmentation; shape-from-texture; and filling-in of brightness and color. The architecture clarifies the functional role of reciprocal interactions among the hypercolumns, blobs, and stripes of areas V1, V2, and V4, and of the cell types: simple, complex, hypercomplex, opponent, and double-opponent. The model characterises two functionally complementary cortical systems: A Boundary Contour System (BCS) and a Feature Contour System (FCS). The first stage of BCS (FCS) is at striate hypercolumns (blobs). The BCS controls the emergence of 3-D segmentation of a scene. The outcome of this 3-D segmentation process is perceptually invisible within the BCS. Visible percepts are a property of the FCS. A completed segmentation within the BCS elicits topographically organised output signals to the FCS. These completed BCS signals regulate the hierarchical processing of color and brightness signals by the FCS. Notable among FCS processes are the extraction of color and brightness signals that are relatively uncontaminated by changes in illumination conditions. These Feature Contour signals interact within the FCS with the output signals from the BCS to control featural filling-in processes. These filling-in processes lead to visible percepts of color-and-form-in-depth at the final stage of the FCS at V4. The model has been used to explain and predict a large body of psychophysical and neural data, such as data of Peterhans and von der Heydt on V1–V2 interactions involved in completion of illusory boundaries, Desimone *et al.* on multiplexing within V4 receptive fields, Srebo and Osetinsky on prestriate generators of vernier acuity, Spitzer and Hochstein on complex cell receptive fields, and Livingstone and Hubel on color processing.

502.2

MAXIMUM-INFORMATION PRESERVATION: A PROPOSED ORGANIZING PRINCIPLE FOR CERTAIN ASPECTS OF PERCEPTUAL NEURAL ARCHITECTURE. R. Linsker. IBM T. J. Watson Research Center, Yorktown Heights, NY 10598.

What principles might account for the strikingly complex sets of feature-analyzing properties found in mammalian perceptual systems, and for their organization and integration?

A Hebb-type synaptic modification rule causes model cells in a feedforward network to develop so that (under certain conditions) each cell's output activity conveys maximum information about its input activity values [R. Linsker, Computer 21(3): 105 (March 1988); see also Proc. Natl. Acad. Sci. USA 83: 7508, 8390, 8779 (1986)].

This suggests a potential organizing principle, 'maximum information preservation,' for each processing stage of a multilayered perceptual network having feedforward and lateral (intralayer) connections. According to this principle, each processing stage develops so that the output signal values (from that stage) jointly convey maximum information about the input values (to that stage), subject to certain constraints. (The quantity that is maximized is a Shannon information rate.) This principle may be implemented by activity-dependent mechanisms (of which a Hebb-type rule can be a part) and/or other developmental mechanisms.

For certain simple ensembles of input activities, this principle generates topographic maps, 'cortical magnification' effects, and layers of feature-analyzing cells that extract and encode statistical regularities present in their input environment (in spatial, temporal, acoustic frequency, optical wavelength, and other domains). Some extensions of these results to input ensembles and networks of biologically relevant complexity are presented and compared with experimental findings in visual cortex.

502.3

SUDDEN COLOR-BLINDNESS OF CEREBRAL ORIGIN. O. Sacks*, R.L. Wasserman*, S. Zeki* and R.M. Siegel Albert Einstein College of Medicine, New York City, NY 10461, Southhampton Hospital, Southhampton, NY 11968, University College, London, U.K. and The Rockefeller University, New York City, NY 10021.

Achromatopsia of cerebral origin was described a century ago and found to be associated, at autopsy, with vascular or other lesions of visual cortex. Such lesions have also been demonstrated in life by neuro-imaging. The majority of such patients also have visual field defects, visual alexia and some degree of form agnosia (Pearlman et al., 1979; Damasio, 1980). Pure achromatopsia is rare. The patient studied by us- a painter-is unusual in combining a complete achromatopsia with an exceptional prior sensibility for color. The achromatopsia, which followed the onset of a transient alexia, came on suddenly following a head injury. There was a complete loss of color throughout the visual field, the patient seeing only in varying shades of grey (the world appeared "as if molded in lead"). The patient, who had exceptional powers of visual imagery and recall, now found that his recalled images were equally void of color. With color perception denied him, he was forced to paint in black and white. Saturated reds and greens both looked black to him; but saturated blues looked very pale. This was even the case with isoluminant Farnsworth-Munsell buttons. His grey-scale was also impoverished, but his lightness scale at all wavebands was unaffected. Recognition was difficult in low-contrast situations. There was apparently no form-, depth- or movement-agnosia, and no defects in the visual fields (at least when seen by us ten weeks after his injury). More formal testing with color 'Mondrians' (Land, 1977) suggested that wavelength-discrimination was intact, but color "construction" entirely absent. This suggests that damage is confined to the "color coding" areas of pre-striate cortex homologous to V4 (Zeki, 1973). The apparent isolation of J.I.'s achromatopsia is in good agreement with current understanding of segregation of different visual functions with separate cortical "functional systems" (Zeki, 1978). Further psychophysical and anatomical tests are in progress to determine the precise site of damage.

502.4

THE "MOTION-BLIND" PATIENT: A PSYCHOPHYSICAL STUDY OF SPATIAL AND TEMPORAL VISION. R.F. Hess*, C.L. Baker (Jr.), and J. Zihl*. Physiological Laboratory, University of Cambridge, Cambridge, England; Psychology Dept., McGill Univ., Montreal, Canada; and Max-Planck-Institut for Psychiatry, Munich, F.R.G.

Zihl et al (1983) have described a "motion-blind" patient, who had suffered a specific loss of visual motion perception resulting from a vascular failure. Other visual functions, such as acuity, color vision, critical flicker fusion frequency, and stereopsis, were normal. We have used discrimination psychophysical methods and sinewave grating stimuli to further characterize this patient's deficit.

Contrast sensitivity to detect the presence of a grating, as a function of its spatial and temporal frequency, was found to be only slightly impaired. However contrast sensitivity to discriminate the direction of motion of a drifting grating showed severe reduction.

For suprathreshold gratings, contrast discrimination and spatial frequency discrimination were only slightly affected, even if the gratings were moving. However, temporal frequency or velocity discrimination of these gratings was severely impaired.

These findings are consistent with an extrastriate locus of damage.

NEURAL DETERMINATION OF THE DIRECTION OF MOTION: CONTRAST AFFECTS THE PERCEIVED DIRECTION OF A MOVING PLAID.

L S Stone, J B Mulligan*, and A B Watson*, Vision Group, NASA, Ames Research Center, MS 239-3, Moffett Field, CA 94035.

Plaids, the sum of sinusoidal gratings of different orientations, have been useful in studying how the primate visual system determines the motion of an object as a whole (pattern motion) from information about the motion of oriented components within that object (component motion). The intersection of the constraints imposed by the motion of the two grating components within a plaid (the constraints rule) provides a reasonable qualitative estimate of psychophysical results. Neurons which respond selectively to pattern motion have been found in the middle temporal area of extrastriate visual cortex suggesting that the neural determination of pattern motion may occur there [1]. By examining how the relative contrast of the grating components affects the perceived direction of pattern motion, we hope to shed light on the underlying neural processing.

We made quantitative measurements of the perceived direction of motion of plaids whose component gratings were of different contrasts. Human subjects viewed moving plaids composed of two achromatic luminance gratings of equal spatial frequency (1.5 cyc/deg), orientated symetrically 30 deg off the vertical axis. In each trial, the plaid moved for 300 ms, at 2 deg/s. The direction of motion of the plaid varied from trial to trial but its orientation did not. Subjects were asked to judge whether the plaid had moved to the left or to the right of vertical. Perceived vertical (the direction for which subjects randomly chose left or right) varied substantially and systematically with the contrast ratio of the grating components. We conducted experiments using different total contrasts (0.1, 0.2, and 0.4) and determined that, at the two lower contrasts, the deviation from the constraints rule (up to 20 deg) was a fixed function of the contrast of the weaker grating relative to its detection threshold. Our results are consistent with schemes in which the estimated speed of the components is subject to a contrast-dependent distortion before application of the contraints rule, and represent an important restriction on future models of the neural processing of motion within visual cortex.

502.6

THE OPTIMAL DISPLACEMENT FOR THE DETECTION OF MOTION. Jane C. Boulton* and R.F.Hess* (SPON: B. Gordon-Lickey). Physiol. Lab., Cambridge Univ., Cambridge, CB2 3EG, U.K.

Recordings from Cat striate cortex (Baker and Cynader, 1986) have indicated that direction selective cells give an optimal displacement (Dopt). To investigate whether a Dopt could be determined for human motion processing using psychophysical techniques, velocity discrimination thresholds were measured.

Drifting sinewave gratings were used with a method of constant stimuli to obtain velocity discrimination thresholds as a function of stimulus duration for a range of velocities and spatial frequencies. The predicted results on the basis of the above physiology would be that this function should be non-monotonic, exhibiting a local minimum corresponding to an optimum displacement. For stimuli of different spatial frequency a Dopt rule should emerge which can be expressed in terms of a certain fraction of a spatial cycle.

Our results show that there are indeed local minima in the velocity discrimination function and that the Dopt rule that emerges corresponds to 1/6 of a spatial cycle or integral multiples of this. This is in agreement with the single cell results cited above.

502.7

HUMAN PERCEPTION OF 3-D STRUCTURE FROM MOTION: SPATIAL AND TEMPORAL CHARACTERISTICS.

S. TREUE, M. HUSAIN and R.A. ANDERSEN, Dept. of Brain & Cognitive Sciences, MIT, Cambridge, MA 02139.

We have investigated the ability of humans to detect 3-D structure from motion using a reaction-time task. The structured stimulus was created by the parallel projection of random points from the surface of a rotating cylinder. Points lived for a fixed number of display frames (point lifetime). Subjects were required to detect the change from an unstructured stimulus to a structured one.

For the range 8-128 projected points, we found that under optimal conditions the threshold for any reliable detection of change to a structured stimulus was ~40-60 ms point lifetime (~3-4 frames at 70 Hz presentation). For point lifetimes >80 ms (i.e., well above threshold), detection was made more reliable if a large number of points were used. Detection also depends upon other parameters. By increasing the angular rotation rate to $>140^{o}\ s^{-1}$, it was possible to obtain 100% hit rates even when only 8 points were displayed, i.e., there is a trade-off between angular velocity and the number of points. Thus at least three factors interact to influence the perception of structure from motion in humans: the number of points projected, the point lifetime and the angular velocity of the stimulus.

502.8

COMPARISON OF TWO- & THREE-DIMENSIONAL STRUCTURE FROM MOTION: REACTION TIMES & GLOBAL TEMPORAL INTEGRATION.

M. HUSAIN, S. TREUE and R.A. ANDERSEN, Dept. of Brain & Cognitive Sciences, MIT, Cambridge, MA 02139.

In previous experiments, using techniques described in the accompanying abstract, we found shorter reaction times on a 2-D rotation task in comparison to a 3-D cylinder task. Two possible explanations are: i) additional direction cues in the 2-D stimulus, or ii) additional processing time required for the 3-D percept.

To determine between these two, we constructed a stimulus without additional direction cues. It is identical to the 3-D stimulus with the exception that the change in speed occurs orthogonal, rather than parallel, to the direction of movement. This new stimulus elicits a 2-D shear motion percept. Reaction times for the 2- and 3-D tasks were essentially the same over the entire range of point lifetimes and velocities tested. These results suggest that the computation of 2- and 3-D structure from motion occurs in a similar fashion and both sorts of stimuli may be analysed in the same brain region(s).

For both 2- and 3-D stimuli, perceived velocity was greater with shorter point lifetimes. This effect could be compensated for by altering the velocity of the stimulus. Interestingly, flashing, *stationary* random dots within the stimulus were not only "captured" by the moving ones but they also increased the apparent velocity of the entire stimulus. Thus the temporal characteristics of stationary dots are integrated into the computation of the global velocity field.

502.9

CONTRIBUTION OF DIFFERENT PATHS OF THE CAT VISUAL SYSTEM TO DETECTION PERFORMANCE: SINGLE CELL RECORDINGS AND BEHAVIOURAL EXPERIMENTS. W. Kiefer*, K. Krüger*, A. Groh* HRO. Dinse, G. Berlucchi* (Spons. EBBS) Dept. of Zoology III Biophys. Sect., University of Mainz, Saarstr. 21, D-6500 Mainz, West Germany

The cat's visual cortex has more than a dozen distinct areas with input via different centripetal pathways. We investigated the role of the two major pathways using a behavioural approach as well as single cell recordings. Simple geometrical patterns respectively moving bars (signal) were additively superimposed on Gaussian visual noise and the detection probability (P_D) was measured as a function of the signal-to-noise (S/N) ratio for various stimulus conditions either i.e. moving or keeping the signal and/or the background stationary. The highly interconnected system was decoupled by lesioning cortical areas in various combinations and the pre- and postoperative detection curves were compared with the electrophysiologically obtained S/N-thresholds.

The role of the geniculo-cortical system was investigated with bilateral lesions of areas 17/18, area 19, areas 17/18/19, and the role of the extra-geniculo-cortical system with bilateral lesions of the areas of the lateral suprasylvian sulcus (LSA), area 7, and areas 7/LSA.

Four major conclusions may be drawn on the basis of the currently available data: 1. The geniculo-cortical system seems highly involved in extracting patterns as such out of a structured background. 2. The extrageniculo-cortical system seems highly involved whenever patterns are associated with motion. 3. All deficits, with the exception of the large lesion of areas 17/18/19, could not be compensated even by extensive retraining. 4. This last finding is taken as evidence that the structures we investigated have redundant capacities only in a very restricted sense.

502.10

VISUAL REACTION TIME OF THE CAT AS A FUNCTION OF SPATIAL FREQUENCY. M.S. Loop and B. E. Aiken*. Dept. of Physiological Optics, School of Opt., Univ. of Alabama at B'ham., B'ham, AL 35294.

Cats were trained to respond quickly to the presentation of vertical sinewave gratings for a food reward. At 50% contrast, reaction time increased systematically with increasing spatial frequency (0.25, 0.50, 1.0, 1.5, 2.0 cpd). At 0.25 and 2.0 cpd reaction time increased as contrast decreased and reaction time was again faster for 0.25 cpd than 2.0 cpd when sensitivity differences were taken into account. Enthusiastic to attribute detection of 0.25 cpd to Y-cells and 2.0 cpd to X-cells, yet certain to meet equally enthusiastic resistance to this interpretation, we measured reaction time to 50% contract 0.25 and 2.0 cpd surrounded by a large area of 100% contrast flicker at 7 cps or 70 cps. Reaction time to 0.25 cpd was reliably slower when surrounded by 7 cps flicker than when surrounded by 70 cps flicker (which is above the cats CFF and would therefore appear steady). Surround flicker rate had no effect upon reaction time to 2.0 cpd. So whatever visual neurons detect 0.25 cpd and 2.0 cpd the former are affected by stimulation peripheral to their receptive fields while the latter are not. Supported by EY05576.

502.11

TEXTURE DISCRIMINATION AND PERCEPTION OF COGNITIVE CONTOURS IN CATS BEFORE AND AFTER CORTICAL ABLATIONS. S. Aglioti*, G. Berlucchi, M. Corbetta *, A.Antonini * Institute of Human Physiology, University of Verona, I-37134

Four cats were tested on texture discriminations using stimuli differing on some of the conspicuous local features called textons by Julesz. They were able to discriminate such textures and to tranfer this ability immediately to new textures built up by elements never seen before. The above capability survived a bilateral removal of areas 17 and 18. We have also studied the discrimination of figures delimited by the so-called Kanisza's cognitive contours which are perceived by humans in spite of being physically inexistent. The positive stimulus was a cognitive square contour tested against a visual noise constituted by a random arrangement of elements that if ordered in space give rise to the perception of the cognitive contour. Learning required a large number of trials, but the discrimination was retained after bilateral ablation of areas 17 and 18. Moreover, one of the four cats was tested post-operatively on a discrimination between a new cognitive square and a cognitive diamond, or a stimulus built up of the same elements of the cognitive square, disposed at the four angles of a square, but rotated so as to make the cognitive contour disappear. Learning required comparatively few trials, suggesting some degree of transfer from previous experience.

502.12

THE TEMPORAL DYNAMICS OF BINOCULAR RIVALRY: PSYCHOPHYSICAL SUPPORT FOR A RECIPROCAL INHIBITION MODEL. T. J. Mueller and R. Blake*. *Harvey Mudd College*, Dept. of Biology, Claremont, CA 91711 and Dept. of Psychology, *Vanderbilt University*, Nashville, TN 37240.

We present evidence that binocular rivalry responds to stimulus contrast in two ways. 1) The duty-cycle of dominance and suppression is determined by the relative image contrast between the two eyes, with dominance of the higher contrast image being favored, and 2) the overall rate of alternation is driven by monocular image contrast during the suppressed phase (increased monocular contrast increases the alternation rate) and to a lesser extent by monocular contrast during the dominant phase (increased monocular contrast decreases the rate).

These results were obtained with two experimental conditions. Human subjects viewed dichoptic orthogonal sine-wave gratings and indicated when exclusive visibility occurred in either eye. Contrast was held constant in one eye and was increased or decreased in the other eye for a number of alternation cycles (continuous presentation) or for only the duration of a single period of exclusive visibility (synchronous presentation). The synchronous presentation condition allowed us to identify the differing effects of contrast during the suppressed and during the dominant periods.

These results support a reciprocal inhibition oscillator as the underlying mechanism of binocular rivalry. (Supported in part by NSF grant BNS 8418731.)

COMPUTATIONAL AND SAMPLING CONSIDERATIONS IN THE ANALYSIS OF LOCALIZED AND DISTRIBUTED PROCESSES BY ONE DIMENSIONAL CURRENT SOURCE DENSITY TECHNIQUES. C.E. Tenke, C.E. Schroeder, J.C. Arezzo and H.G. Vaughan, Jr. Depts. of Neurosci. and Neurol., Albert Einstein Coll. of Med. Bronx, NY.

Current source density (CSD) techniques are useful for the identification of the intracranial generators of surface recorded potentials and for the characterization of intracortical processes. Profiles derived from multichannel electrodes with fixed intercontact spacing improve the CSD estimate over sequentially obtained profiles, without requiring spatial smoothing, by eliminating interrecord variability. While localized generators are reliably resolved by these techniques, there has been no analysis of the influence of spatial resolution on the CSD profile. These influences were modelled on a computer using spherical generator elements arranged in dipole and "closed field" configurations and spatially distributed to simulate variations in the dimensions of laminae and columns. Continuous, time invariant field potential profiles were simulated and discretely sampled. CSD profiles were calculated using a common 5-point CSD formula and a 3-point formula with two distinct differentiation grids.

Artifacts introduced into the CSD profile by computational and sampling procedures were more complex for the 5-point method, and were attenuated by increasing the radial area of the generator. While field and CSD profiles emphasized laminar boundaries, artifacts within a lamina could be eliminated with appropriate intercontact separations. Artifacts produced by narrow, radially distributed dipole laminae were shown to have a negligible effect on the descriptive and localizing capacity of the CSD. These results support the use of high resolution, one-dimensional CSD techniques for describing both distributed and localized cortical generators. Supported by MH06723

SEQUENCE AND DISTRIBUTION OF PATTERN-EVOKED ACTIVITY IN AREA 17 OF THE BEHAVING MONKEY. C.E. Schroeder, C.E. Tenke, S. Givre, J.C. Arezzo and H.G. Vaughan, Jr., Depts. of Neuroscience and Neurology, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

Using 16 channel, multicontact electrodes, laminar profiles of pattern visual evoked potentials, current source density and concomitant multiunit activity were recorded from striate cortex in fascicularis monkeys, performing a fixation task. Stimulation consisted of chromatic (red/green) and achromatic (black/white) patterns, varying in luminance and pattern content, modulated independently of the fixation point. The laminar response profile, in general, reflects initial activation in the granular (stellate) laminae, followed by activation of supra- and infragranular (pyramidal) laminae. While this sequence conforms to that predicted by anatomic studies, the laminar weighting of activity within the profile varies with the luminance, chromatic and pattern characteristics of stimuli. The profile of response to diffuse illumination is heavily weighted toward lamina IV, with moderate responses in infragranular laminae. Patterned stimuli shift the balance of this profile away from lamina IV. Increasing the chromatic content of stimuli enhances the response in lamina IVCb, relative to IVCa, and in the supra- relative to the infragranular laminae. Quite often our techniques are able to resolve orientation preference in the infragranular laminae, while unable to do so in the supragranular laminae. This, along with the differential sensitivity to diffuse illumination in infra- and supragranular laminae, supports the view that orientation sensitivty operates differently above and below lamina IV.

THE EQUIVALENT DIPOLES OF TEMPORALLY MODULATED LUMINANCE RESPONSES. P.Ossenblok*, D.Reits* and H.Spekreijse* (SPON: A.B.A. Kroese). The Netherlands Ophthalmic Research Institute, P.O. Box 12141; 1100 AC Amsterdam-Zuidoost, The Netherlands.

Steady state Evoked Potentials (EPs) in response to sinusoidally modulated light can be described and analyzed in terms of frequency selective processes. These frequency selective processes have amplitude peaks in three distinct frequency regions,the so-called low-, medium- and high- frequency region at about 10, 20 and 40 Hz (Spekreijse et al, Visual Evoked Potentials in man: new developments, J.E.Desmedt (ed), Oxford University Press, 1977).

This study deals with the topographical distribution and the location of the neuronal generators of luminance EPs in man, of which the harmonics are plotted as equipotential maps. The analysis is based on the assumption that in each distinct frequency-region the potential distribution of the underlying cortical activity can be ascribed to a single current dipole. A precondition for computing an equivalent dipole from topographic maps is that the phase of the harmonics in all derivations is the same; only phase changes of 180 degrees are allowed.

In correspondence with earlier findings we could confirm that the source of the evoked activity in the high-frequency region is located in the primary visual cortex and that this activity can be described by an equivalent dipole. Further, we found that the recorded potential distribution in the medium-frequency region also can be ascribed to a single current dipole. This equivalent dipole shows a similar behaviour as the one representing the high-frequency subsystem. The orientation of the dipole is radial for foveal stimululation and becomes tangential with increasing stimulus eccentricity. The activity evoked in the low- frequency region is not specific and the source seems to be situated deep in the head.

502.16

AN ANISOTROPIC MULTI-SPHERE MODEL FOR SOURCE LOCALIZATION BY VEPs IN MAN. J.C. de Munck*, B.W. van Dijk and H. Spekreijse* (SPON P.A. Apkarian). The Netherlands Ophthalmic Research Institute, POBox 12141, 1100 AC Amsterdam ZO, The Netherlands.

When multi-channel visually evoked potentials (VEPs) recordings are used for the localization of brain activity mathematical models are needed that describe the electrical properties of the head. Generally it is described as a volume conductor with a piecewise constant conductivity.

None of the present models take into account the anisotropy of the various parts of the head, although anisotropic conduction has been demonstrated for various parts of the head. The anisotropy ratio can amount to a factor of ten for the skull and the white matter, and more than a factor of two for cortical tissue. Further, the present analytic solutions of volume conductor model are restricted to a limited number of shells (four) and a spherical geometry.

It is clear that the use of a simple model may lead to systematic errors in the source localization procedure. Therefore a more general solution has been found, which includes the effects of anisotropy, the arbitrary number of shells and the fact that the head may better be described by a spheroid than a sphere. The solution was obtained by generalyzing the method of Morse and Feshbach to obtain a Greense function of the Laplace equation. The potential distribution due to a dipole source is then found by taking the gradient of the Greense function and determining the inner product of the result and the dipole vector. It is possible to present the formulas in a convenient form, such that if they are applied in practice the likelihood of software errors is minimal.

502.17

VEP EVIDENCE OF FUNCTIONAL DIFFERENCES IN UPPER AND LOWER VISUAL FIELDS IN MAN. Fred H. Previc. USAF School of Aerospace Medicine, Brooks AFB, TX.

This study investigated differences in the functional characteristics of two components of the pattern-reversal visual evoked potential (VEP) in humans: N1 (which is elicited primarily by upper visual field stimulation) and P1 (which is largely generated by lower visual field stimulation). The stimulus parameters which were used to isolate the two components were grating spatial frequency (1, 4, 8, 12 c/deg) and contrast (.1, .2, .4, .8). VEPs were recorded monopolarly from eight subjects using O_z as the source electrode site. Square-wave gratings, counterphased at 1 Hz, were used to generate each VEP. The gratings were presented at a mean luminance of 15 cd/m^2 and were contained in full-field as well as hemifield presentations. The VEP data revealed the existence of bandpass spatial tuning and little contrast saturation in the case of N1 and lowpass spatial tuning and a nonlinear contrast response (i.e., saturation at high contrasts) for P1. In general, N1 may be viewed as largely reflecting parvocellular processing in the visual cortex, whereas P1 primarily reflects magnocellular output. Thus, these VEP findings parallel recent anatomical and physiological asymmetries (Burkhalter, Felleman, Newsome, and Van Essen, Vision Research, 1986, 26, 63-80) in the processing of information in the upper and lower visual fields.

502.18

PATTERN VISUAL EVOKED POTENTIALS FROM CHILDREN UNDER GENERAL ANESTHESIA. B.E.S. Fox, K.W. Wright*, and K.J. Eriksen*. Univ. of Southern California School of Medicine and Childrens Hospital of Los Angeles, Dept. of Ophthalmology, Los Angeles, CA, 90054.

Pattern visual evoked potentials (PVEPs) were recorded from 9 normal eyed subjects, 9mo-10yrs of age, under general anesthesia. Children were anesthetized, by tracheal intubation, with either Halothane (0.6%) or Forane (1%) and nitrous-oxide for elective surgery unrelated to this study. Silver-silver chloride scalp electrodes were mounted Oz, Cz and Fz. The eye was held open by the experimenter, vision was corrected and fixation was monitored continuously. Alternating (2Hz) black-white checkerboard stimuli with check sizes ranging from 55 to 4 minutes of arc (ma) were used. Transient evoked responses were digitized and averaged. A minimum of 100 trials were obtained for each check size. In two subjects we were unable to obtain PVEPs due to the presence of alpha waves. Results from the remaining 7 subjects revealed that the mean P100 latency increased from 121msec with 55ma checks to 186msec with 14ma checks. Mean P100 amplitudes decreased from 38.1uV to 27.8uV over the same stimulus range. The mean visual threshold obtained was 8.75ma. In general, the waveforms obtained had a broad peak. Four children sedated with chloral hydrate showed PVEPs with similar latencies but smaller amplitudes than were obtained under anesthesia.

These results suggest that PVEPs can be reliably obtained to small spatial frequency stimuli under anesthesia, and may be important in the clinical visual assessment of children.

HUMAN AND RAT VISUAL EVOKED POTENTIALS IN RESPONSE TO STIMULUS SPATIAL AND TEMPORAL FREQUENCY. W.K.Boyes and H.K.Hudnell. Neurotoxicol. Div., USEPA, RTP, NC 27711.

Species comparisons can indicate the extent to which visual systems are functionally similar and demonstrate the adequacy of experimental animal models. We measured steady-state visual evoked potentials in rats and humans in response to manipulation of stimulus parameters. Spatial frequency of sine-wave gratings spanned 0.05-0.8 cycles/degree (cpd) for rats and 0.5-8.0 cpd for humans; temporal frequency of on/off square-wave modulation spanned 3-20 Hz; and contrast was 20%. Spectral amplitude of the averaged responses was measured at one (1F) and two times (2F) the stimulus rate.

The maximum 1F amplitudes usually occurred at intermediate spatial frequencies approximating the respective contrast sensitivity function peaks of both rat and human. The 2F amplitude was usually maximal at low spatial frequencies. At higher temporal frequencies (10-20 Hz), both species exhibited a drop in 2F and an increase in 1F amplitude, apparently reflecting a response transition from 2F to 1F.

In summary, (1) rat and human visual systems responded in a qualitatively similar fashion to spatial and temporal stimulus manipulations, and (2) 1F and 2F showed different spatial and temporal profiles suggesting contributions of functionally distinct generators. LATE NEGATIVE WAVE OF RAT FLASH EVOKED POTENTIALS: EFFECTS OF TESTING CONDITIONS ON AMPLITUDE. R.S. Dyer, Neurotox. Div., U.S.E.P.A., Research Triangle Park, NC 27711.

A prominent feature of flash evoked potentials (FEPs) recorded from rat visual cortex is a late negative wave with a peak latency of about 155 msec (N155). Depression of N155 amplitude occurs following treatment with a variety of toxic and pharmacological agents. This report focuses upon the relative importance of changes in behavioral state (habituation to the test environment) and stimulus parameters (flash rate and background illumination) as determinants of N155 amplitude. All studies were performed upon unanesthetized adult male Long-Evans hooded rats with previously implanted electrodes overlying visual cortex (VC). Four flash rates (0.5, 1.0, 2.0 and 4.0Hz) and two background illumination levels (0 and 115 lux) were studied. Habituation was investigated by varying the time in the test chamber before testing (1, 2, 4, and 8 min) and by repeated testing (8 test sessions over 3 wks). Amplitudes were measured from baseline. The most critical determininant of N155 amplitude was number of test sessions. As number of 64 trial sessions increased, so did N155 amplitude, which approached asymptote by the final session.Flash rate did not influence, and testing in the dark slightly reduced N155 amplitude. We conclude that although the N155 peak is elicited by a sensory stimulus, its amplitude depends more upon the behavioral state of the animal (i.e. habituation to the testing) than upon stimulus parameters.

SELECTIVE NEURONAL DEATH IN GERBIL SENSORY NEOCORTEX AFTER TRANSIENT ISCHEMIA. C.S.Lin, B.J.Crain, K.Polsky, J.V. Nadler and J.Davis. Depts. Neurobiology, Pathology, Pharmacology and Medicine,Duke Univ. Med. Cntr., Durham,NC 27710

We used cresyl violet,hematoxylin-eosin/Luxol fast blue,silver impregnation and immunostaining of the glial marker-GFAP methods to assess the selectivity of neuronal death in gerbil neocortex after varying both the duration of bilateral common carotid occlusions and the post-ischemic survival time. A specific laminar pattern was consistently found in the post-ischemic somatosensory (SM) cortex. Six hours after a 5 minute occlusion, fibers and a few scattered small- to medium-sized degenerating pyramidal cells were found in lower layer III and upper layer VI. After the following two days, neuronal death in these layers spread from the facial vibrissae representation area to other areas within SM cortex. This basic laminar pattern persisted up to five weeks (the longest time studied). Occasionally, degenerating cells and fibers were found in the auditory cortex but not in the motor or visual cortex. The pattern of GFAP reactivity also corresponds with this laminar selectivity. Finally, degenerating cells were found in all layers of cortex including the large pyramidal cells in layer V after 15 minutes occlusions. Supported by NIH NS06233.

SPATIAL MEMORY PERFORMANCE OF GERBILS FOLLOWING TRANSIENT GLOBAL ISCHEMIA. J. P. Williams and J. N. Davis (SPON: J. Hall). V. A. and Duke Univ. Medical Centers, Durham NC 27705.

We used a Morris water-maze to determine if gerbils used spatial memory to solve the maze and if gerbils developed a defect in spatial memory after transient forebrain ischemia. Animals were given a hidden platform that was either stationary (PLACE) or moved with each trial (RANDOM). Four trials were given each day and the latencies in seconds for the animal to find the platforms were recorded. Latencies for both groups decreased with repeated trials ($p<0.0001$). After the 12th trial, the PLACE animals had significantly lower latencies than the RANDOM animals ($p<0.03$). PLACE animals repeatedly crossed the spot where the platform had been ($p<0.001$) when the platform was removed, while RANDOM animals did not swim in any preferred quadrant ($p=0.47$). To study the effect of ischemia, gerbils were divided into 3 treatment groups: ISCHEMIC (5 min carotid occlusion, testing 7 days later), CONTROL (sham surgery or no surgery), and RANDOM (no surgery, random platform placement). All groups showed decreased latencies with repeated trials. The RANDOM group had longer latencies in the last four trials then the two groups with fixed platform placement ($p<0.05$). There was no difference between the final latencies of the ISCHEMIC and CONTROL groups. These data show that: 1) gerbils are capable of solving the Morris water-maze, 2) gerbils use spatial memory to escape to a hidden platform and 3) CA_1 damage in the gerbil does not disrupt this performance. There are two possible explanations for our findings: CA_1 may not be necessary to solve the maze, or the hippocampus may not subserve spatial memory in the gerbil. We prefer the hypothesis that CA_1 is not required for solving the maze.

CHANGES IN SOMATOSENSORY EVOKED POTENTIALS DURING GLOBAL BRAIN ISCHEMIA IN THE RAT. E.I. Pinkhasov*, A.J. Krieger* and H.N. Sapru (SPON: R. Howland). Section of Neurosurgery, UMDNJ - New Jersey Medical School, Newark, NJ 07103.

Somatosensory evoked potentials (SEPs), mean blood pressure (MBP) and heart rate (HR) responses were recorded in male Wistar rats anesthetized with urethane, immobilized with tubocurarine and artificially ventilated. Global brain ischemia was induced by the bilateral ligation of vertebral arteries at C1 level followed by bilateral occlusion of common carotid arteries for 3, 6 and 12 min. Control BP and HR were 89.6 ± 12.6 mmHg and 423.1 ± 60.7 bpm, respectively. Control SEPs were characterized by 3 major peaks (P1, P2 and P3) with the onset of 6.8 ± 0.6, 11.0 ± 1.4 and 16.9 ± 1.4 msec, respectively. The amplitudes of these peaks were 0.2 ± 0.1, 2.3 ± 1.7 and 2.0 ± 1.4 uvolts. Global brain ischemia for 3, 6 and 12 min, produced an increase in MBP (42.5, 60.0, and 42.5 mmHg, respectively). Concomitantly there was a decrease in the amplitude of first two peaks (P1 and P2) while P3 disappeared. The changes in BP and SEPs in response to global brain ischemia for 3 min, but not for 6 and 12 min, were reversible. This preparation may serve as a model for global brain ischemia.

PHOTOCHEMICAL NEOCORTICAL STROKE IN RATS: FLUNARIZINE PREVENTS NEUROLOGIC DEFICITS. M. De Ryck, J. Van Reempts", A. Wauquier", M. Borgers" and P.A.J. Janssen". Janssen Research Foundation, B-2340 Beerse, Belgium.

Rose Bengal (20 mg/kg iv) together with topical illumination of the skull causes photo-oxidative injury to cerebral vessels, and focal cerebral necrosis (Watson, B.D., Dietrich, W.D., et al., Ann. Neurol., 17:497, 1985; Van Reempts, J., et al., Stroke, 18:1113, 1987). Does this model of cerebral thrombotic stroke produce enduring neurologic deficits? And, if so, can those be mitigated by posttreatment with the class IV calcium antagonist flunarizine? We made unilateral infarcts in the hindlimb area of the parietal cortex. Flunarizine (1.25 mg/kg iv or 40 mg/kg po) or its solvent was administered 30 min after infarction. We measured neglect, limb placing reactions, and limb usage on elevated beams. On day 21, all rat brains were prepared for histology, including thalamic glial reactivity (typically in ipsilateral nn. VPL and posterior). All control rats displayed sustained deficits in tactile and proprioceptive placing of the contralateral hindlimb. By contrast, placing deficits were dramatically curtailed by flunarizine (FL): 70-75 % of FL rats placed contralaterally on day 1, while the others recovered within 3 to 5 days; but 21-day old infarct volumes and total thalamic density were unaffected. Following cortical infarct, flunarizine preserves behavioral function within a critical period.

503.5

PREVENTION OF MEMORY DEFICIT AFTER ISCHEMIA BY POST-ISCHEMIC INSULIN. C.L. Voll, I.Q. Whishaw and R.N. Auer. Neuroscience Research Group, University of Calgary, Calgary, Alberta, T2N 4N1, and Dept. of Psychology, University of Lethbridge, Lethbridge, Alberta, T1K 4M4.

The ability of post-ischemic insulin to modify the structural and neurobehavioral consequences of cerebral ischemia was studied. Rats were given intraperitoneal glucose 20 minutes before ischemia induced by 10½ min of hypotension and carotid occlusion. Following reperfusion, they were given either insulin (INS) or glucose (GLUC) for one week. Sham operated rats (SHAM) were used as a control group. Rats were trained on a learning-set task 1 - 3 months after ischemia, requiring them to locate an escape platform in a pool of opacified water. Escape latency and swim pattern were recorded. If a rat deviated from an 18 cm wide path to the platform, it received an error on that trial. Performance in the INS group was significantly better in both escape latency and errors ($p<0.05$). Neuropathology predominated in the hippocampus where the GLUC group showed 59% mean neuronal loss compared to 18% mean neuronal loss in the INS group ($p<0.05$). Insulin administration during the early post-ischemic recovery period thus resulted in a significant improvement in performance of behavioral tasks assessing spatial memory and learning ability, in addition to reducing CA1 hippocampal neuronal necrosis.

AUTONOMIC CHANGES IN RAT FOCAL CEREBRAL ISCHEMIA MODEL. V.C.HACHINSKI, J.X.WILSON*, K.E.SMITH*, D.F.CECHETTO. Robarts Res.Inst./Dept.of Physiol., U. of Western Ontario, London,Ont.N6A5K8.

Acute increases in plasma catecholamines and myocardial damage occur in a cat model of stroke using middle cerebral artery occlusion (MCAO). Similar changes are seen clinically in patients following stroke. Because of the advantages of using a small animal, we examined autonomic changes in two MCAO models of stroke in the rat. Blood pressure (BP), heart rate (HR) and plasma concentrations of norepinephrine (NE) and epinephrine (E) were measured in 20 male, urethane-anesthesized rats that received one of the following treatments: (i) MCAO only, (ii) MCAO and ipsilateral common carotid artery occlusion (MCAO/CCO), (iii) sham occlusions. MCAOs were made immediately distal to the inferior cerebral vein. Arterial blood samples (500 ul) for radioenzymatic assay of NE and E were made twice before the occlusions and at 90 and 180 minutes after the occlusions. At the end of the experiment, tetrazolium salts were reacted with oxidative enzymes to delineate the extent of cerebral ischemia. BP of sham and MCAO/CCO groups significantly declined during the approximately 8 h experiment. However, BP of MCAO rats did not change during the experiment, so that the final BP was significantly higher than in the other two groups. Plasma NE and E concentrations were increased significantly by MCAO compared to pre-occlusion levels and compared to post-occlusion levels in sham and MCAO/CCO groups. These results suggest that focal cerebral ischemia caused by MCAO only in the urethane-anesthesized rat is able to induce the autonomic changes seen in the cat MCAO model of stroke and seen clinically.

TEMPORAL PROFILE OF MEMORY AND HIPPOCAMPAL CA1 CHANGES PRODUCED IN 4-VO RAT MODEL OF ISCHEMIA. J.M. Ordy, P. Columbo*, T.T. Volpe, and W.P. Dunlap*, Pennwalt Corp., Rochester, NY 14623, Cornell Med. Center, New York, NY 10021, Tulane Univ., New Orleans, LA 70118.

Patients suffering from cerebral ischemia stroke or cardiac failure have circumscribed memory impairment with selective CA1 hippocampal damage. The four vessel occlusion (4-VO) rat model has been used for examining effects of forebrain ischemia on memory and CA1 cell vulnerability. To differentiate transient from permanent effect CA1 vulnerability, clarification is essential of the temporal progression of memory impairments and degree of viability of CA1 neurons during postischemic periods. The aims of this study were to examine effects of 4-VO ischemia on: 1) spatial working memory and performance from 1 to 4 months post ischemia, 2) topographic distribution and severity of CA1 damage in anterior and mid-dorsal regions of the hippocampus, and 3) correlation of degree of memory impairment with severity of CA1 cell damage. Thirty minutes of 4-VO ischemia significantly reduced working memory without effects on motor performance. Ischemia significantly reduced CA1 neurons in the anterior with lesser damage in mid-dorsal region of the hippocampus. There was a significant correlation between the degree of memory impairment and severity of CA1 cell damage. It remains to be established to what extent this significant correlation was based on compromised but viable neurons during the post-ischemic period.

CORTICAL FOCAL ISCHEMIA DISRUPTS NON-DISCRIMINATED REVERSAL LEARNING. A. Ortiz*, J.S. MacDonall*, S.P. Mahadik, and S.E. Karpiak. Div. Neuroscience, NYS Psychiatric Inst., Depts. of Psychiatry, and Biochemistry & Molecular Biophysics, Physicians & Surgeons, Columbia U., and Dept. of Psychology, Fordham U., New York.

To determine whether functional deficits after stroke can be improved, we have established a behavioral paradigm sensitive to cortical focal ischemia. Focal ischemia is induced in Sprague-Dawley rats (225-275gr) by permanent unilateral occlusion of the middle cerebral artery & the ipsilateral common carotid artery [MCAo+CCAo] with a 1 hr temporary occlusion of the contralateral CCA. Twelve days after the MCAo rats are trained in a 2-lever chamber to press for food reward. On subsequent days, after 8 consecutive correct responses on the initially reinforced lever, the opposite lever is reinforced. Lever reversals continue after 8 consecutive reinforced responses. The session ends after 10 reversals are completed. Rats with focal ischemia [largely localized to the parietal cortex] show an increase in incorrect responses. But, the largest difference between controls and ischemic rats is an increase in perseverative errors (continuing to press a level even though no reward is provided). We are evaluating the effectiveness of various agents (gangliosides, vitamin E, physostigmine etc.) in reducing this functional deficit, and relating such improvements to changes in edema, Na+, K+, Ca++ in the ischemic areas.

EFFECTS OF GRADED HYPOVOLEMIC HYPOTENSION ON SPINAL MOTOR EVOKED POTENTIALS IN THE CAT. J.J. Oro*, S.S. Haghighi (SPON: C. Watts) Division of Neurosurgery, University of Missouri, Columbia, MO 65212

Recently, new techniques have been developed to assess motor pathway integrity using electrical or magnetic pulses applied to the cortex. The evoked motor responses have been recorded from the spinal cord, peripheral nerves, or target muscles.

To study the effect of hypotension on spinal motor evoked potentials (SMEPs), we subjected twelve cats to graded hypotension from mean arterial pressure (MAP) of 100 torr down to 30 torr. SMEPs were continuously recorded from spinal cord using epidural surface electrodes. The exposed precruciate motor cortex was stimulated with 150 micro sec, 20 v (max) pulses via AgCl stimulating electrode. The onset latency of SMEPs increased from 3.22 $\pm$ 0.31 msec (n=12) at MAP 100 to 3.6 $\pm$ 0.46 msec (n=10) at MAP$\langle 30 \rangle$40 torr (p 0.05). The peak to peak amplitude was decreased from 7.46 $\pm$ 3.84 μv (n=12) at MAP 100 to 2.96 $\pm$ 2.07 μv (n=10) at MAP$\langle 30 \rangle$40 torr (p 0.05). Conduction velocity decreased from 84.76 $\pm$ 6.81 meter/second (n=12) at MAP 100 to 75.71 $\pm$ 7.81 meter/second (n=10) at MAP$\langle 30 \rangle$40 torr at the rate of approximately 1.2 meter/second/10 degrees of hypotension change. Below 30 torr, 75% of animals lost their SMEPs. Immediate blood transfusion restored SMEPs, however, latency and amplitude did not reach the baseline values within the 1 hour post transfusion period.

503.10

EFFECTS OF HEMORRHAGIC SHOCK ON SPINAL AND CORTICAL SOMATOSENSORY EVOKED POTENTIALS IN THE CAT. S.S. Haghighi, J.J. Oro. Division of Neurosurgery, Univ. Missouri, Columbia, MO 65202.

Somatosensory evoked potentials (SEPs) are being used in the evaluation od spinal and cortical function during surgical procedures. To study the effect of systemic hypotension upon spinal and cortical SEPs, we subjected twelve anesthetized cats to graded hypotension from mean arterial pressure (MAP) of 100 mm Hg down to 30 mm Hg. Spinal and cortical SEPs were recorded to sciatic nerve stimulation. The onset latency of spinal SEPs increased from 1.99$\pm$ 0.47 msec at 100 mm Hg to 2.85$\pm$ 1.04 msec at 30 mm Hg (p=0.05); while conduction velocity (CV) decreased from 95.36$\pm$ 16.22 meter/ second to 71.97$\pm$ 17.05 (p=0.05) at the rate of 2.8 meter/ second/ 10 degrees of hypotension change. Cortical SEPs onset latency increased from 8.42$\pm$0.73 msec at 100 mm Hg to 11.11$\pm$ 1.05 msec at 30 mm Hg (p=0.05). CV decreased with hypotension from 54.76$\pm$ 7.01 meter/ second down to 43.19$\pm$ 6.72 at the rate of 1.5 meter/ second/ 10 degrees hypotension. No cortical SEPs were detectable below 30 mm Hg. Spinal evoked responses were more resistant to profound hypotension and disappeared last. Blood transfusion resumed spinal SEPs first followed by cortical SEPs.

These findings suggest that ischemia associated with profound systemic hypotension can alter evoked responses.

503.11

NEW INHIBITORS OF LIPID PEROXIDATION. M.Gall*, R.I.Higuchi*, E.D.Hall, and J.M.Braughler (SPON: B.D.Greenberg), CNS Diseases Research, The Upjohn Company, Kalamazoo, MI 49001.

Amino-substituted 9,10-secosteroids are potent inhibitors of iron-dependent lipid peroxidation as determined in the malondialdehyde (IC_{50} values between 18 and 80 μM) and conjugated diene assays. In addition, they protect animals from the sequelae of head injury damage. In collaboration with Prof. T.Kuwana and associates (CBAR, Univ. of Kansas), we report redox potential data which suggests that the amino heterocycle structure of the secosteroids, and their steroidal parents (ie, Lazaroids,) may serve as a radical-quenching reducing-agent in biological systems.

503.12

INCREASE IN EXTRACELLULAR ASCORBATE DURING FOCAL CEREBRAL ISCHEMIA IN THE RAT MONITORED BY INTRACEREBRAL MICRODIALYSIS. L.Hillered (1,2), L.Persson*(2) and U.Ungerstedt*(3). Depts. of Clinical Chemistry(1) and Neurosurgery(2), University Hospital, S-751 85 Uppsala, and Dept. of Pharmacology(3), Karolinska Institute, Stockholm, Sweden.

Apart from its role as a major antioxidant in the brain, ascorbate (AA) is well known to have the paradoxical ability to induce iron-dependent lipid peroxidation. Recently, AA has been implicated as an important modulator of neostriatal activity. Administration of AA (i.p.) appears to increase neuronal activity in the striatum. It was therefor of interest to measure the extracellular levels of ascrobate during focal cerebral ischemia. Microdialysis probes (Carnegie Medicin AB, Stockholm, Sweden; membrane lenght 3 mm) were implanted stereotactically into the caudato-putamen bilaterally. Dialysis was started 2 hours later using Ringer solution at a flow rate of 2 ul/min. Samples were collected in three 30-min fractions before and six after the onset of ischemia. Ischemia was induced by middle cerebral artery occlusion on the left side. Compared to the pre-occlusion level and to the contralateral side ischemia was associated with a 4-6 fold increase in ascorbate in dialysates from the left striatum. The level of ascorbate did not change significantly on the contralateral side. We propose that ascorbate may aggravate neuronal injury in the ischemic penumbra by the induction of lipid peroxidation and/or by an excitotoxic mechanism.

503.13

CONTINUOUS TRANSCRANIAL MONITORING BY LASER DOPPLER VELOCIMETRY OF CEREBRAL BLOOD FLOW CHANGES FOLLOWING TRANSIENT ISCHEMIAS. S. Xu*, H.G. Wagner, F. Joo*, and I. Klatzo. Lab. of Neuropathol. & Neuroanat. Sci., Nat. Institutes of Health, Bethesda, MD 20892

Dynamic changes of cerebral blood flow (CBF) induced by multiple transient bilateral carotid occlusions were studied in the Mongolian gerbil. The data obtained by transcranial measurement of CBF by Laser Doppler Velocimetry (LDV) correlate well with that obtained by intracranial LDV. LDV technique made possible repeated and continuous measurement of these circulatory parameters over long periods of time with minimal attention to the hazards of exposure or infection of the brain. Transcranial LDV provided immediate information about the preischemic normalcy, the completeness of the ischemia and the recovery of blood flow following release of the occlusion which in our studies was a function of the duration of the ischemias. In very short term ischemias, LDV showed that recovery of blood flow was immediate. With longer ischemias CBF recovered partially, followed by slower further increase and formed a hyperemic peak, often with some overshoot. The CBF then slowly fell to a hypoperfusion stage. The effects of certain vasoactive drugs on this sequence were studied by LDV and demonstrated the usefulness of LDV to evaluate these substances.

503.14

A NEW MODEL TO STUDY THE ACTIONS OF REACTIVE OXYGEN SPECIES ON MAMMALIAN NEURAL TISSUE. L. Roskos*, R.K. Evans*, V. Centenera* and F.C. Kauffman. Dept. of Pharmacol. and Exper. Therap., Univ. of Maryland Sch. of Med., Baltimore, MD 21201.

Hippocampal slices from adult rat brain were used to study biochemical mechanisms of injury to neural tissue due to reactive oxygen species. The hippocampus was selected as a model because this area of brain is exceptionally sensitive to ischemia and is used widely in neurochemical and electrophysiological studies. Methylene blue (MB), a compound known to undergo redox cycling, and H_2O_2 were used to injure the tissue. Hippocampal slices could be maintained under nitrogen for at least 15 minutes with no change in energy status after recovery under 95% O_2:5% CO_2 for 3 h. The effects of reactive O_2 species and protective agents were examined in slices recovering from anoxia and in tissues that had fully recovered. Redox cycling of MB and generation of H_2O_2 occurred via a photosensitive reaction. Thus, experiments with MB were carried out in light and dark. MB produced decreases in ATP and P-creatine in the light but not in the dark. Protective agents tested include: desferoxamine, an iron chelating agent; verapamil, a Ca^{++} channel blocking agent; allopurinol, an inhibitor of xanthine oxidase; and catechin, a free radical savenger. These agents did not protect slices recovering from anoxia but did provide some protection against reactive O_2 species in slices that had recovered. All agents inhibited recovery of energy status in tissues incubated with MB in the dark suggesting that cellular injury due to MB involves events in addition to formation of reactive oxygen species. The results argue strongly that different pharmacological strategies are required to combat the actions of damaging O_2 species on neural tissue recovering from anoxia than those used to alter the actions of reactive O_2 species on normal neural tissue. (Supported in part by NIH Grant HD-16596).

503.15

PROTECTIVE EFFICACY OF THE LIPID PEROXIDATION INHIBITOR U74006F ON POST-ISCHEMIC CA_1 DEGENERATION IN GERBILS AFTER BRIEF BILATERAL VS. PROLONGED UNILATERAL CAROTID OCCLUSION: EVIDENCE FOR DIFFERENT DEGENERATIVE MECHANISMS. K.E. Pazara* and E.D. Hall (SPON: J.M. Braughler). CNS Diseases Research, The Upjohn Company, Kalamazoo, MI 49001.

A comparison was made of the efficacy of the 21-aminosteroid oxygen radical scavenger and lipid peroxidation inhibitor U74006F to antagonize post-ischemic degeneration in the hippocampal CA_1 region of mal Mongolian gerbils after either a 10 min. bilateral occlusion (BCO) of the carotid arteries or a 3 hr. occlusion of one carotid artery (UCO). At 1 week after the 10 min. BCO, pronounced (-75.4%), but selective CA_1 cell loss was apparent. Pretreatment (30 min.) with U74006F over a wide range of i.p. doses (1, 10 or 30 mg/kg) plus a second dose at 2 hrs. after BCO had no effect on the CA_1 cell loss. In the 3 hr. UCO model, a similar degree of CA_1 cell loss was observed after only 24 hrs. in addition to diffuse degeneration throughout the ipsilateral hemisphere. In this model, i.p. pretreatment with U74006F (10 mg/kg) plus a second dose at the end of the 3 hr. UCO significantly reduced CA_1 damage as well as the cell loss in other brain areas (e.g. cortex). These results suggest that the mechanism of CA_1 degeneration may differ between ischemia models with oxygen radical-induced lipid peroxidation perhaps being more involved in the 3 hr. UCO model.

COMPARATIVE NEUROANATOMY: CEREBRAL CORTEX

A HYPERCARD GLOSSARY OF MACAQUE AND HUMAN NEURO-ANATOMICAL NOMENCLATURE. D.M. Bowden and R.F. Martin. Dept. Psychiatry and Beh. Sci. and Regional Primate Research Center SJ-50, University of Washington, Seattle, WA 98195

The Macaque/Human-Glossary of Neuroanatomical Nomenclature allows the user to identify the brain structure to which any generally accepted English or Latin neuroanatomical name applies. When the user enters a structure name into the computer, the computer responds with a list of all accepted synonyms and with references to one or more macaque and human brain atlases in which the structure is defined or illustrated. The computer shows where in the hierarchy of structures and substructures the named structure lies, i.e., button clicks take the user up the limb of suprastructures or out the branches of substructures to indicate how the named structure relates to other parts of the brain. The glossary includes a total of 750 structure names and more than 2300 synonyms. The hierarchy is based on the human Nomina Anatomica with extensions based on several macaque and human brain atlases.

Supported by NIH grant RR00166 to the University of Washington.

504.2

ENCEPHALIZATION QUOTIENT AND REGIONAL BRAIN MORPHOMETRY IN THE THE WEST INDIAN MANATEE. R.L. Reep and T.J. O'Shea*. Dept. Neurosci., J-244, Univ. Florida; and USFWS, 410 NE 16th Ave.; Gainesville, FL 32610 and 32601.

We determined an encephalization quotient (EQ) of 0.275 for T. manatus, based on direct measurements of brain mass (avg-364g) and body mass (avg-756kg) in 13 specimens. This is among the lowest values for all mammals and is comparable to EQ estimates for other Sirenia species. However, when our data are adjusted for metabolic rate, actual brain weight is 1.5 times larger than predicted. The unique aquatic herbivorous lifestyle of the Sirenia has likely been a major determinant of large body size and low metabolic rate. We suggest that early in Sirenia history brain-body size allometry was uncoupled, permitting selection for an increase in body size without a corresponding change in relative brain size. Low metabolic rate may also be a factor in constraining brain size in manatees.

Gyration of the cerebral cortex, usually positively correlated with absolute brain size, is strikingly absent in these brains. However, morphometric data indicate that the telencephalon comprises 71% of total brain volume in T. manatus. This is comparable to values for prosimians and monkeys and much larger than values for insectivores and bats. Likewise, manatee cerebral cortex is well laminated and of robust cellular density. A retarded growth curve for the brain may explain the lissencephalic condition. In any case, internal structural complexity of the brain appears to have been unaffected by the size restrictions implied by low EQ, or by the lissencephaly.

Supported by grant BSR-03687 from NSF, and cooperation of US Fish and Wildlife Service, Florida DNR, and Sea World of Florida, Inc.

504.3

NEURONAL ORGANIZATION AND MICROCIRCUITRY OF LAYERS I AND II IN VISUAL CORTEX OF DOLPHINS (STENELLA COERULEOALBA AND TURSIOPS TRUNCATUS). P.J. Morgane and I.I. Glezer. Worcester Foundation for Experimental Biology., Shrewsbury, MA 01545, and CUNY Medical School., New York, NY 10031.

The neuronal composition and microcircuitry of layers I and II of the dolphin visual cortex were analyzed. We have found that these cortical layers are generally similar to those seen in most conservative eutherian mammals such as basal Insectivora. Layer I is most predominant and occupies 1/3 of the entire cortical width. Layer II is characterized by an extremely dense concentration of neurons. By using rapid Golgi impregnation, we were able to analyze the neuronal spectrum of layer II as well as the axonal and dendritic composition of layer I in the dolphin neocortex. The main neuronal types seen in layer II are transitional pyramids with slender apical dendrites extending widely into layer I and, secondarily, other transitional pyramids with two apical dendrites which ascend widely into layer I ("extraverted" neurons). The neuronal organization of layers I and II in the dolphin neocortex provides the preliminary basis for our hypothesis stating that these layers are the main afferent input layers from subcortex and for associative fibers, providing intracortical connections. (Supp. by NSF grants BNS 85-45732, 87-42032, CUNY grants BRS 442-2490, 6-67-204 and the Osborn Laboratories of the New York Aquarium of New York Zoological Society).

504.4

ULTRASTRUCTURE OF SYNAPSES IN VISUAL CORTEX OF THE DOLPHIN (STENELLA COERULEOALBA). I.I. Glezer and P.J. Morgane. CUNY Medical School., New York, NY and Worcester Foundation for Experimental Biology., Shrewsbury, MA 01545.

Qualitative and computerized quantitative analyses of ultrastructural features of synapses in different layers of visual cortex in the dolphin were carried out. Blocks from the area representing the primary visual projection zone were processed for transmission electron microscopy and rapid Golgi technique. Several features characterize the visual neocortex of the dolphin: the density of synapses in dolphin visual cortex is significantly higher than in the visual cortices of most terrestrial mammals and is comparable to that seen in some rodents (rats and mice). Another feature is the presence of extremely large numbers of synapses en passage which are especially abundant in layer I. Multiple vesicle types are seen in nearly all synaptic boutons. Most of the ascending collaterals of subcortical and intracortical axons reach layer I in the dolphin convexity neocortex. The sum of the volume of synaptic boutons per cu. mm was significantly higher in layer I than in other layers. Overall, several features of synaptic organization support our general concept of the special afferent role of layer I which may be an important level of cortical integration in the whale brain. (Supported by NSF grants BNS 85-45732, 87-42032, CUNY grants BRS 442-2490, 6-67-204 and the Osborn Laboratories of the New York Aquarium of New York Zoological Society).

504.5

THE DEGREE OF CORTICAL FOLDING IN PRIMATE BRAINS. K. Zilles,[1] E. Armstrong,[2,3] and A. Schleicher.[1] Anatomisches Inst., Univ. Koln, Koln, F.R.G.,[1] Yakovlev Collection, A.F.I.P., Washington, D.C.[2] and Dept. Anatomy, U.S.U.H.S., Bethesda, MD.[3]

The degree of cortical folding in primates varies from lissencephalic prosimians to the highly convoluted human brain and can be analyzed in serial coronal sections by measuring the lengths of the complete outer cortical contours and those parts which are superficially exposed. Ratios of the two lengths, the gyrification index (GI), were collected for 42 different primate species. GI was studied as a function of brain and body weights, and for differences in lateralization.

The mean GI of the human brain (N = 61) fits well within the anthropoid correlations of GI and brain and body weights. Anthropoid GI's are highest in the posterior parietal regions and taper rostrally with bigger brains tapering more gradually. The larger human GI is the result of a more convoluted frontal lobe. While bigger primate brains are more convoluted, for every unit increase in brain size prosimian brains gain fewer convolutions than do anthropoid brains. Within Homo GI is not associated with differences in brain size nor were differences between right and left hemispheres observed. GI symmetry in the temporal plane suggests that the observed surface lateralization here comes from an absolute increase in cortex, not in its folding.

504.6

THE ONTOGENY OF CORTICAL FOLDING IN THE HUMAN BRAIN. E. Armstrong[1,2], K. Zilles[2], M. Pan[1,2*] and A. Schleicher[2*]. Yakovlev Collection, A.F.I.P., Washington, D.C.[1], Dept. Anatomy, U.S.U.H.S., Bethesda, MD.[2], and Anatomishes Inst., Univ. Koln, Koln, F.R.G.[2].

Cortical folding in serially sectioned human brains was analyzed by measuring the lengths of the total cortical contour and dividing that by the lengths of the superficially exposed parts of this contour. This ratio or gyrification index (GI) was determined in 26 human brains ranging in age from 11 to 400 weeks postconception. The cerebral cortex is lissencephalic (GI <1.1) until week 25. The adult degree of folding is reached around 2.5 months postnatally. The increase in GI occurs when the brain grows from 100-600 g. Although the human brain doubles in size after that, the GI remains stable. The degree of convolutedness is thought to result from a more predominant growth in the outer than in the inner cortical laminae. The temporal pattern of GI development revealed in our study suggests that the degree of gyrification is not correlated with number of neurons (most of the cortical neurons have migrated to the cortical plate before GI increases), but more with the development of cell processes and interconnections which is on-going during this time. The myelination of cortico-cortical tracts begins after GI has stabilized suggesting that the space occupied by the former does not play a critical role in gyrification.

BEHAVIORAL DISORDERS

CANNABINOID POTENTIATION OF NEUROLEPTIC-INDUCED HYPOKINESIA: THE NICOTINIC HYPOTHESIS OF ACTION. D.E. Moss, P.Z. Manderscheid, A.B. Norman, and P.R. Sanberg. University of Texas at El Paso, El Paso, Texas 79968 and University of Cincinnati School of Medicine, Cincinnati, Ohio 45267

Interest in cannabinoids and nicotine in the treatment of motor disorders resulted from the discovery that cannabinoids or nicotine (NIC) potentiate neuroleptic-induced hypokinesia up to 100 fold. It has been proposed that cannabinoids and NIC produce this powerful effect through a CNS nicotinic cholinergic mechanism. The purpose of these experiments was, therefore, to determine if mecamylamine (MEC, a nicotinic antagonist) would reduce the effects of NIC and cannabinoids.

Rats were pretreated with fluphenazine HCl (FLU, 0.1 mg/kg IP) and hypokinesia was measured by the bar test. Some rats received an injection of MEC (1.0 mg/kg IP) 1 hr after FLU. MEC pretreatment significantly reduced the subsequent effect of NIC (0.1 mg/kg IP) or delta-9-THC (10 mg/kg gavage).

These results support the hypothesis that cannabinoids act through a nicotinic mechanism and further support the hypothesis that certain cannabinoids may be useful to increase the efficacy of neuroleptics in motor disorders.

505.2

NICOTINE MARKEDLY POTENTIATES NEUROLEPTIC-INDUCED CATALEPSY. P.Z. Manderscheid, P.R. Sanberg, A.B. Norman, H.M. Fogelson*, B.J. McConville*, and D.E. Moss. Lab. of Behavioral Neuroscience, Depts. of Psychology and Psychiatry, Univ. of Cincinnati College of Med., Cincinnati, OH 45267.

Haloperidol, as well as other neuroleptics, is widely used in treating hyperkinetic movement disorders. Recently, we found that nicotine produced a 10-fold increase in reserpine-induced catalepsy. Since catalepsy may provide a useful model of extrapyramidal function, the present study investigated the effect of nicotine on haloperidol-induced catalepsy in an effort to elucidate the role of nicotine in modulating the function of the extrapyramidal system.

Male Sprague-Dawley rats, age 3 to 6 months were randomly assigned to one of four treatment groups: haloperidol plus nicotine, haloperidol only, nicotine only, and vehicle control (n=8/group). Haloperidol was given in doses of 0.1, 0.3, or 0.5 mg/kg prior to nicotine (0.1 mg/kg). The bar test was used to measure catalepsy. Nicotine produced an almost 10-fold increase in catalepsy in the 0.3 mg/kg haloperidol group ($F(1,14)=9.84$, $p<.01$). At 0.1 mg/kg haloperidol, nicotine produced only a mild potentiation of catalepsy and, at 0.5 mg/kg haloperidol, the interaction was not apparent due to a ceiling effect produced by haloperidol.

This animal model may be important in elucidating the mechanisms of interaction between neuroleptics and nicotine. Insofar as neuroleptics are used to treat movement disorders such as Tourette's Syndrome and Huntington's disease, nicotine may be considered as an adjunct treatment which potentiates the therapeutic efficacy of neuroleptics.

505.3

AUTOTOMY INDUCED BY SUBCUTANEOUS INJECTION OF HYPERTONIC SALINE IN THE TAIL OF THE RAT. T.I. Kanui* and G.M.O. Maloiy* (SPON: K. Hole), Dept. of Animal Physiol., Univ. of Nairobi, P.O. Box 30197, Nairobi, Kenya.

The basis of autotomy behaviour still remains unknown (Rabin, A.G. et al., Pain, 21:117-128). The phenomenon was studied in 30 Wistar rats (150-450g). A standard dose of 0.125 ml 10% saline injected subcutaneously, 2 cm from the tip of the tail was used.

For the first 2 h, the rats licked the site of injection and also proximal to this. Three categories of responses were recognised. Fourteen rats neither showed autotomy or licking behaviour. Six rats showed autotomy (bites, blood stain) that resolved in 2.26 ± 1.52 (mean ± S.D.) weeks without signs of ischaemia and subsequent amputation. Ten rats licked, bit and showed signs of ischaemia, followed by amputation of the tail in 8 ± 3.3 weeks. The onset was 2.26 ± 1.52 weeks.

A second application of 10% saline in animals showing autotomy, resulted in autotomy in 40% of the cases. After autotomy, no signs of phantom limb pain were seen for a period of 1 year.

The data presented suggest that peripheral chronic pain may initiate autotomy followed by signs of ischaemia and necrosis which may lead to amputation.

Rabin, A.G. et al., Pain, 21:117-128, 1985.

505.4

NICOTINE GUM AND HALOPERIDOL IMPROVE TOURETTE'S SYNDROME. P.R. Sanberg, H.M. Fogelson,* P.Z. Manderscheid, K.W. Parker,* A.B. Norman, K.J. Hart,* F.P. Zemlan, and B.J. McConville,* Lab. of Behavioral Neuroscience, Dept. of Psychiatry, College of Medicine, and Dept. of Ped. Neurology, Children's Hospital, University of Cincinnati, Cincinnati, OH 45267.

Tourette's Syndrome is a complex disorder with both motor and verbal tics. While the drugs of choice for this disorder are dopamine receptor blockers, such as haloperidol, some patients show only marginal response. Furthermore, these drugs can lead to sedation, exacerbation of learning difficulties, and possible tardive dyskinesia. For these reasons, an agent that potentiates the effects of neuroleptics could allow for lower doses of neuroleptics and reduction in side effects.

In animals it has been shown that nicotine markedly potentiates the behavioral effects of haloperidol (Moss et al., and Manderscheid et al.; this issue). Nicotine gum was given to patients with Tourette's Syndrome who showed only moderate responses to haloperidol alone. A marked reduction in the intensity of tics and an increase in attention and concentration was seen in six of the seven cases. In some cases the tics stopped completely. This effect started after 15 minutes, lasting about one hour. Side effects including bitter taste and gastric distress often caused non-compliance. Chewing regular gum did not effect tics. Two patients with Tourette's Syndrome given nicotine without haloperidol showed no such beneficial effects. Although the mechanism for this beneficial effect of nicotine needs to be elucidated, nicotine may prove useful in treating neuroleptic-responsive disorders.

505.5

DECREASED IL-2 PRODUCTION, INCREASED IL-2 RECEPTORS, AND REDUCED CD8 LYMPHOCYTES IN SCHIZOPHRENIA. B.S. Rabin*, R. Ganguli*, (Spon: J. Huff). Dept. Psychiatry, Univ. Pittsburgh Med. School, Pittsburgh, PA 15213.

We have previously reported that schizophrenics show evidence of multiple autoantibodies, circulating antibody to normal brain tissue and increased mitogenic responses to brain antigens. These data can be interpreted as suggesting a disorder with an autoimmune pathogenesis. To further investigate this possibility we studied other immune parameters which are reported to be abnormal in autoimmune disease. 70 RDC schizophrenic patients had IL-2 production levels measured in morning fasting blood samples. 50 non-psychiatric controls were also studied. Analysis of variance showed that patients produced significantly less IL-2 than controls. Acutely ill patients, whether medicated or not produced significantly less IL-2 than either remitted patients or controls. Age, race and sex were not found to be correlated with IL-2 production. CD8+ and CD4+ cells were quantitated in all subjects. Regardless of whether they were medicated or not, CD8 cells and CD4+2H4+ (the inducer of suppressor cells) were significantly lower in the schizophrenic patients. Soluble interleukin-2 receptor, which is increased in autoimmune disease, was significantly increased in patients with schizophrenia. These data while not proving an autoimmune pathogenesis in schizophrenia, do support that possibility.

505.6

PERINATAL BRAIN INJURY VS GENETIC LOADING IN SCHIZOPHRENIA: MAGNETIC RESONANCE IMAGING FINDINGS. H.A. NASRALLAH, S.C. OLSON*, J.A. COFFMAN AND S.B. SCHWARZKOPF*. Department of Psychiatry and The Neuroscience Program, Ohio State University College of Medicine, Columbus, OH 43210.

Several lines of evidence suggest that genetic factors are important in schizophrenia. A substantial literature also points to an increased frequency of perinatal brain injury, some of which (in the second trimester) can impair cell elimination or migration. Cortical atrophic changes have been described in young schizophrenic patients. We conducted a Magnetic Resonance Imaging (MRI) study to compare the effects of genetic loading and perinatal complications on brain structure in schizophrenia, with the hypothesis that atrophy is more likely to be associated with perinatal brain injury than with genetic loading.

Forty schizophrenic patients (by DSM III-R) were interviewed with their parents for first degree family history (FH+) of psychosis and for various perinatal brain injuries. MRI scans were obtained (TR=1500 MS, TI=800 MS). Midsagittal cerebral, cranial, frontal and ventricular areas were measured. No significant correlations were found between perinatal events and MRI variables. On the other hand, FH+ correlated significantly with smaller cranial size (p .04) and with a strong trend for smaller cerebral and frontal size as well. The results indicate that developmental factors (such as a small cranium, not just a small cerebrum) may be associated with genetic rather than perinatal factors.

505.7

QUANTITATIVE EVALUATION OF IODOAMPHETAMINE SPECT STUDIES IN PARANOID SCHIZOPHRENICS. D.S. Schlusselberg, W.K. Smith, T.R. Simon*, J.D. Raese, and D.J. Woodward, *UT Southwestern Medical Center, Dallas VA Medical Center, Dallas, Texas.*

Ongoing studies have been performed to evaluate the cerebral uptake of I-123-Iodoamphetamine (IMP) with Single Photon Emission Computed Tomography (SPECT). Because of differences in brain size, shape, and position, three-dimensional (3D) alignment is necessary to quantitatively compare different studies. Algorithms have been developed for computer processing of 3D volumes formed by a set of serial slices, that include 3D translation, rotation, and scaling. The volume of data is then resampled at a lower resolution to provide a spatially normalized data set for statistical analysis. Voxel counts are also normalized to account for differences in the amount of IMP injected and variable uptake in non-cerebral tissues.

Studies from 18 normals were processed to calculate the mean and standard deviation for each resampled voxel. 22 DSM-III classified chronic paranoid schizophrenic patients (CPS) were evaluated for regional statistical differences from the normal group. Quantitative differences between frontal and temporal activity in normals versus CPS were confirmed. This method offers an objective quantifiable evaluation of regional IMP uptake. *(Support from the Biological Humanics Foundation and NIDA 2938)*

505.8

QUANTITATION OF ASTROCYTES IN THE MOLECULAR LAYER OF THE DENTATE GYRUS: A STUDY IN SCHIZOPHRENIC AND ALZHEIMER'S DISEASE PATIENTS. M. F. Casanova*, J. Stevens and J. E. Kleinman. Clinical Brain Disorders Branch, NIMH, Washington, D.C. 20032.

Recently several authors have claimed prominent cytoarchitectural abnormalities in the entorhinal cortex of both Alzheimer's disease (AD) and schizophrenic patients (SC). In the present study, we have attempted to corroborate the presence of such a lesion in both AD and SC patients by quantitating astrocytic markers within the terminal fields of the perforant pathway. Hippocampal blocks from 6 SC, 4 AD and 7 neurologically impaired controls were taken anterior to the lateral geniculate nucleus. The sections were stained with the Holzer technique and analyzed with a LOATS computerized morphometry system. Our results indicate marked abnormalities only for the AD patients. Since the redistribution and hyperplasia of astrocytes within the molecular layer of the deafferented gyrus depends on the chronicity of the entorhinal lesion, the abnormalities observed in AD patients suggests that the underlying etiology pursues a protracted course. The absence of changes in SC patients does not disprove entorhinal pathology but rather suggests that if a lesion exists, it is either static in nature or occurred long before the postmortem examination of the tissue sample.

505.9

BRAIN DENSITY IN SCHIZOPHRENIA. D. Kostianovsky*, E. Kim*, D. G. Daniel*, T. Goldberg*, M. Casanova, J. E. Kleinman and D. R. Weinberger (SPON: M. E. Dorman). Clinical Brain Disorers Branch, NIMH, Washington, D.C. 20032.

Several previous studies have demonstrated differences in regional brain density (as derived from CT scan attenuation values) between patients with schizophrenia and normal controls. Interpretation of these studies has been hindered by methodological shortcomings such as failure to control for head size, scanner calibration differences and other confounding variables. The present study offered methodological advances over earlier studies by controlling for head size and normalizing the attenuation values for each scan to an internal standard. CT attenuation values in multiple brain regions in 20 patients with chronic schizophrenia were compared with those of 20 age and sex matched controls. No significant differences in regional attenuation values emerged between the schizophrenics and normal controls. The results confirm the importance of controlling for artifacts in analysis of CT scan attenuation values and raise questions about the validity of regional CT attenuation values in detecting subtle anatomical abnormalities in schizophrenia.

505.10

BRAIN METABOLISM DURING AUDITORY HALLUCINATIONS. J.M. Cleghorn. Dept. of Psychiatry, McMaster University, Hamilton, Ontario Canada L8N 3Z5.

These studies attempt to locate regions of the brain associated with auditory hallucinations by means of positron emission tomography with [^{18}F] fluoro-deoxy-glucose. Data on two samples will be reported. I: first episode drug naive psychotic patients (N=17) of whom 11 were hallucinating and 6 were not hallucinating during the glucose uptake period prior to the scan. II: chronic patients (N=19) medicated for an averge of 7.4 years, in whom auditory hallucinations were still present in 9 and had disappeared in 10.

Hallucinating (H) and nonhallucinating (NonH) groups did not differ from each other in the regions in which glucose metabolism was measured: prefrontal and orbito-frontal cortex, parietal cortex, superior temporal and Wernicke's cortex. Broca's and auditory cortex metabolism was also similar in H and NonH groups.

However, correlations between some brain regions characterized both H groups and were not observed in the NonH groups: right hemisphere regions homologous for Broca's and auditory areas $r = >+.81$ ($p<.01$) and right frontal and parietal $r = >+.80$ ($p<.01$). In the drug free H group the right sided homologous regions for Broca's and Wernicke's areas $r = +.89$ $p < .001$.

These studies suggest that right hemisphere regions homologous to language areas on the left are coupled during auditory hallucinations.

505.11

NON-STATE DEPENDENT CHANGES IN PLATELET 3H-IMIPRAMINE BINDING WITH CHRONIC IMIPRAMINE TREATMENT. K.M. Bell, E.M. DeMet, R. Gerner*, C. Kauffmann*, A. Chicz-DeMet. Dept. Psychiatry, Univ. of Calif., Irvine, CA. 92717.

Unipolar depressed patients were treated with imipramine (IMI) for 4-13 wks. Bmax values were increased by 33% after 4 wks but later returned to baseline even though the patients remained euthymic. These changes were independent of plasma drug levels and were not due to drug carryover since the latter was demonstrated to alter the Kd with no change in Bmax *in vitro*. Post- treatment Bmax and plasma cortisol were inversely related but were uncorrelated at baseline and there was no difference between pre- and post-treatment cortisol levels. Treatment response was not significantly correlated with either the Bmax or plasma cortisol changes, although relatively poor responses were associated with extreme values (high and low) of pretreatment Bmax. The results suggest that chronic IMI treatment results in transient increases in Bmax through a cortisol dependent mechanism. Since these changes were not related to therapeutic response, the results further suggest the limited usefulness of 4-13 week drug trials in the assessment of the state dependence of platelet binding.

505.12

DEPRESSIVE DISORDERS FOLLOWING POSTERIOR CIRCULATION AS COMPARED WITH MIDDLE CEREBRAL ARTERY INFARCTS. S.E. Starkstein* and R.G. Robinson (SPON: P.R. McHugh) Dept. of Psychiatry, Johns Hopkins Univ Sch Med (Baltimore, MD 21205)

Patients with cerebrovascular lesions in the posterior circulation (PC) territory (n=37) were compared with patients having middle cerebral artery (MCA) (n=42) strokes for the presence of mood disorders. While both groups showed a similar profile of clinical symptoms of depression during the acute evaluation in-hospital, patients with PC lesions involving the brainstem and/or cerebellum demonstrated a significantly lower frequency of depression (27%) than patients with MCA lesions (48%) or patients with PC lesions involving the left cerebral hemisphere (100%). Moreover, at two-year follow-up, depression following brainstem and/or cerebellar infarcts was significantly shorter in duration than depression following MCA lesions (mean Present State Exam depression scores from in-hospital to 2 years follow-up were significantly lower for the brainstem/cerebellar group than the MCA patients with in-hospital depression over the same period, repeated measures ANOVA group by time $F=6.14$, $df=1,23$, $p<.05$). These differences in the frequency and duration of depression following brainstem/cerebellar as compared with MCA lesions were not explained by differences in lesion volume, physical impairment, cognitive deficits or quality of social support. They suggest that PC and MCA-induced depression may have different aetiologies.

505.13

Responses to clonidine in acute and remitted depressed patients.

Larry J. Siever, M.D., Emil F. Coccaro, M.D., Peter Knott, Ph.D., Ph.D., Ren-Yui Yang, M.D., Steven Gabriel, Ph.D., and Kenneth L. Davis, M.D.
Bronx VA Medical Center, Bronx, NY and Mount Sinai School of Medicine, New York, NY

Clonidine, an alpha$_2$-adrenergic agonist which results in increases in plasma growth hormone (GH) and decreases in plasma 3-methoxy-4-hydroxyphenylglycol (MHPG), was administered to 28 acute depressed patients, 15 remitted depressed patients, and 12 normal controls. All subjects were free of medical illness, drug-free for at least two weeks, and on a low monoamine diet for three days prior to testing. A reduced growth hormone response to clonidine (< 5 ng/ml) was found in 68% (19/28) of the acute depressed patients and in 67% (10/15) of the remitted depressed patients as compared to 25% (3/12) of the age-and sex-matched controls (acute normal, remitted normal, Fisher's Exact, $p< 0.05$). All patients initially blunted in the acute state remained blunted in the remitted state. Acute depressed patients demonstrated lower absolute (0.1 ± 0.5) or percent decrease ($0.9 \pm 10.7\%$) in plasma MHPG compared to normal controls (absolute: 0.4 ± 0.6, percent: 8.4 ± 14.8) (t-test, $p<0.05$), while remitted patients were similar to controls. These results suggest that the GH response to clonidine is blunted in depressed patients regardless of state, while the reduced MHPG response to clonidine is state-dependent.

505.14

SECONDARY vs IDIOPATHIC MANIA B. Boffi*, R. C. Young, G. Klerman* (SPON: M. Russ). The New York Hospital-Cornell Medical Center, Westchester Division, White Plains, NY 10605.

"Secondary" or symptomatic manic syndromes - those presenting in patients with associated medical disorders or drugs implicated as etiologic - have not been studied systematically. We retrospectively studied patients admitted over a three year period to two university psychiatric hospitals. Patients with a DSM III diagnosis of organic affective disorder, manic (N = 12) and with bipolar disorder, manic (N = 212) were contrasted using a computerized data base. Organic patients were older at index hospitalization (mean age 49.3 yrs $\pm$ 34.4 yrs, S.D., vs. 38.3 yrs $\pm$ 16.4 yrs; $p< .14$), were older at first psychiatric hospitalization (45.8 yrs $\pm$ 22.8 yrs vs. 31.0 yrs $\pm$ 15.1 yrs; $p< .01$), and had fewer hospitalizations (1.3 ± 0.9 vs 3.0 ± 2.8; $p< .001$). They had longer duration of index hospitalization (54.6 days $\pm$ 29.5 days vs. 37.0 days $\pm$ 34.8 days; $p< .07$), lower Global Assessment Scale (GAS) scores at discharge (41.3 ± 9.3 vs. 56.0 ± 13.8; $p< .001$), and less improvement in GAS scores during hospitalization (10.5 ± 10.4 vs. 22.5 ± 16.7; $p< .01$). These preliminary findings suggest that "secondary mania" is a syndrome with later age at onset and poorer treatment outcome.

505.15

ANTIDEPRESSANTS AND LATE LIFE MANIA. H. Jain* and R. C. Young. The New York Hospital-Cornell Medical Center, Westchester Division, White Plains, New York 10605.

Manic episodes can occurr for the first time in late life. In such patients, etiologic factors and pathophysiologies may differ from those in patients in whom mania occurs first in early life. Charts of geriatric (age ≥ 60 yrs.) psychiatric inpatients (N=40) who met DSM III criteria for bipolar disorder, manic, were reviewed. The median age at occurrence of first manic episode was 58 years, and the range was 18 to 81 yrs. Seven (35%) of the patients with later age at occurrence of first manic episode had been treated with antidepressant drugs in association with development of the index manic episode, compared to one (5%) of the patients with earlier age at occurrence of first manic episode (Fisher exact test, p=.027). Six patients had been treated with tricyclic antidepressants, one with maprotyline, and one with phenelzine. Later and earlier onset patients did not differ in number of treated depressive episodes. The relationship between antidepressant pharmacotherapy and illness course in bipolar disorder remains controversial. These preliminary findings suggest that geriatric bipolar patients with later age at occurrence of first manic episode are more vulnerable to induction of mania by antidepressant drugs than are geriatric patients with earlier first occurrence of mania.

505.16

MOOD CHANGES FOLLOWING RIGHT HEMISPHERE LESIONS. M.A.Honig* S.E.Starkstein* and R.G.Robinson (SPON: J.B.Wirth). Dept. of Psychiatry, Johns Hopkins Univ Sch Med, Baltimore, MD 21205

Ninety-three patients with right hemisphere (RH) ischemic or hemorrhagic stroke lesions were examined for mood changes. Within 2 months after stroke, 49% showed no mood changes, 18% developed major depression, 12% developed minor depression and 21% showed an unduly cheerful mood. Patients with depression (both major or minor) had a significantly higher frequency of lesions involving the parietal cortex as compared to non-depressed or unduly cheerful patients (X^2=9.6, p=.022). In addition, patients with major depression had a significantly higher frequency of family history of psychiatric disorders than: 1) patients with RH lesions and no mood disorders (X^2=4.08, p<.05); and 2) another group of 27 patients with major depression following left hemisphere lesions (X^2=4.44, p<.05). Patients displaying undue cheerfulness showed a significantly higher frequency of lesions involving the frontal operculum than depressed and non-depressed patients (X^2=7.776, p=.05).

In conclusion, depression after right hemisphere lesions are associated with parietal damage. Genetic factors also seem to play an important role in major depression following right but not left hemisphere lesions. These findings suggest that depression after right hemisphere lesions may have a different pathogenesis than mood changes after left hemisphere damage.

505.17

CAFFEINE SUPER-SENSITIVITY IN PANIC DISORDERS. E.M. DeMet, M.K. Stein*, C.K. Tran*, A. Chicz-DeMet. Dept. Psychiatry, Univ. of Calif., Irvine, CA. 92717.

Panic disorder (PD) patients are frequently sensitive to the anxiogenic effects of caffeine. These effects may be due to an antagonist action on adenosine receptors which attenuate excitatory neurotransmitters. The present study introduces a novel measure of adenosine receptor sensitivity and compares results obtained from normal controls with those from patients with PD and post-traumatic stress (PTSD). The test is based on a known action of adenosine receptors to potentiate the ability to taste quinine sulfate. Quinine taste thresholds were determined by a forced selection of trace concentrations from water standards. Adenosine receptor sensitivity was quantitated by comparing thresholds in the presence and absence of 10uM caffeine. Thresholds in the presence of caffeine were similar in the 3 subject groups. In contrast, PD patients had elevated baseline thresholds and larger difference scores than did controls or PTSD patients. The results are discussed in the context of a model whereby adenosine receptors upregulate in an attempt to control excitatory transmitter release, but this same mechanism confers caffeine supersensitivity.

505.18

D-AMPHETAMINE AFFECTS CENTRAL NORADRENERGIC MECHANISMS IN CHILDREN WITH ATTENTION DEFICIT-HYPERACTIVITY DISORDER (ADHD). B.A. Shaywitz, S.E. Shaywitz*, G.M. Anderson, P. Jatlow*, S.M. Gillespie*, B. Sullivan*, M.A. Riddle*, J.F. Leckman* and D.J. Cohen*. Yale University, New Haven, CT 06510.

Good evidence from many laboratories supports the belief that amphetamine (AMP) and methylphenidate (MPH) often produce remarkable ameliorative effects in children with ADHD, actions believed to occur via central catecholaminergic mechanisms. Despite their similarities, AMP and MPH may affect different catecholaminergic mechanisms. We employed a double-blind protocol to investigate 26 children with ADHD (24 boys, 2 girls) ages 5-14 years. Children received either AMP (.25 mg/kg, 11 children) or (0.5 mg/kg, 15 children) or placebo (n=26) and plasma MHPG and HVA were sampled:

	Hours after stimulant or placebo		
	4	5	6
Placebo	3.03±.13	2.88±.14	2.98±.15
MPH	2.83±.13	2.87±.14	3.16±.16
AMP	2.42±.12[a]	2.22±.12[b]	2.33±.15[c]

MHPG concentration (mean ± SEM) ng/ml

a: F=4.71, p=.014; b: F=3.25, p=.047; c: F=5.00, p=.011.

These findings suggest that despite their clinical similarity, d-amphetamine and methylphenidate differ in their effects on brain catecholaminergic systems with d-amphetamine influencing brain noradrenergic mechanisms, perhaps by reducing turnover of brain norepinephrine.

505.19

PRODUCTION OF NEGLECT IN RATS WITH UNILATERAL ABLATION OF VENTROLATERAL ORBITAL CORTEX. V. King*, J.V. Corwin, and R.L. Reep. Dept. of Psych., Univ. of New Orleans, New Orleans, LA 70148, and Depts. of Physio. Sci. and Neurosci., Univ. of Florida, Gainsville, FL 32610.

Neglect in humans and monkeys most often results from damage to cortical areas, including paralimbic cortex. Neglect in rodents has been produced by unilateral destruction of medial prefrontal cortex (PCm), a rodent analog of area 8 in primates. As with area 8, PCm has extensive connection with neocortical and paralimbic cortices, including bilateral reciprocal connections with the paralimbic area ventrolateral orbital cortex (VLO) (Reep, R.L. et al. 1984, 1987). The current study was conducted to determine if there is in rodents, as in primates, a cortical circuitry for directed attention by examining the effects of destruction of VLO.

Male Long-Evans hooded rats with lesions of right VLO (RV) (n=9), left VLO (LV) (n=9), and cortex just lateral to PCm (sham) (n=15) were tested for a minimum of four weeks on the following: 1) total neglect based on degree of orientation to visual, tactile and auditory stimuli; 2) extinction based on the tendency to touch the ipsilesional tab first when adhesive tabs were attached to each wrist; 3) motor asymmetry based on the difference between the number of ipsilesional and contralesional rotations during a two minute period.

No significant differences were found among the groups in rotational preference during the first 3 weeks. Although, both RVs and LVs showed significant total neglect relative to shams at week 1, the pattern of neglect within modalities differed between RVs and LVs. Whereas LVs showed significant neglect in the visual and auditory modalities versus shams at week 1, RVs were impaired on the tactile neglect measure, relative to shams at weeks 1 and 2 and on the extinction task versus shams and LVs at week 1, 2, and 3. The results indicate VLO may form part of a cortical circuitry for directed attention.

LEARNING AND LATERALITY DIFFERENCES IN BXSB MICE AS A FUNCTION OF NEOCORTICAL ANOMALY. V.H. Denenberg, G.F. Sherman, G.D. Rosen, and A.M. Galaburda. Biobehavioral Sciences Graduate Program, U-154, Univ. of CT, Storrs, CT 06268; and Neuroanatomical Dyslexia Lab and Harvard Medical School, Boston, MA 02215

As part of a study relating immune factors, neural anomalies, and behavioral deficits, 23 BXSB mice were given a series of behavioral tests. Eight had ectopias in the frontal motor region (5M, 3F) while 15 did not (8M, 7F). On Collins' paw reaching test ectopic males used their left paws almost exclusively while ectopic females were equally strongly biased rightward. The normal males and females were scattered throughout (p <.04). Water escape learning is a simple spatial task requiring the animal to swim to a submerged platform. Mice with ectopias were faster, averaging 29.0 sec over five trials while mice with normal brains took 52.8 sec (p<.05). In a non- spatial discrimination learning task non-ectopic mice swam faster (p<.02) and made somewhat more correct choices (p<.11). Further analyses determined that non-ectopic males made more correct choices than ectopic males (p<.05),while the female groups did not differ.

Since ectopic animals swam faster in the water escape task but slower in the discrimination learning task, the learning differences cannot be due to motor factors that would influence speed of swimming. Some feature distinguishing the two tasks--such as spatial vs non-spatial, or choice vs no-choice--would appear to be associated with the presence of ectopias. In addition, left pawedness, maleness, and presence of ectopias were associated on the discrimination learning task.

505.21

THE CONE ELECTRODE: A LONG-TERM ELECTRODE THAT RECORDS FROM NEURITES. Philip R. Kennedy. Bioengineering Center, Georgia Institute of Technology, Atlanta, GA 30332.

A standard wire recording technique is combined with neurite growth into a piece of sciatic nerve to produce an electrode that records for months. The electrode is made by fixing a teflon insulated 3 mil gold wire to the inside of a 1.5 mm glass cone with a diameter of less than 200 microns at one end. Before implantation in deep layers of rat cortex, 5 to 10 fibers from the rat's sciatic nerve are placed inside the cone. The pin on the other end of the wire is cemented to the rat's skull.

For a few days after implantation no activity is evident. As neurites grow into the cone, activity builds up, first as background, then as single units. At week 4, many units appear so that multi-unit activity over 100 uVs in amplitude is recorded. When implanted into the vibrissa area of cortex, many vibrissa initially evoke activity, but from week 4 onwards, only 2 to 3 adjacent vibrissa evoke multi-unit responses. This suggests that a connection can be made between the cone electrode and functional areas of cortex. Histology at 3 months when still recording shows tissue growing into the cone holding it firmly in place. Retrograde dye labelling via the corticospinal tract shows neurites in the cone.

The cone electrode is expected to connect the central nervous system with augmentative devices in patients with severe communicative disorders.

BEHAVIORAL PHARMACOLOGY: MISCELLANEOUS

506.1

Discriminative Stimulus Properties of FG 7142. N.J. Leidenheimer and M.D. Schechter, Dept. of Pharmacology, Northeastern Ohio Universities College of Medicine, Rootstown, OH 44272.

FG 7142 (N-methyl-β-carboline-carboxamide), a partial inverse agonist at the benzodiazepine receptor, produces both anxiogenic and proconvulsant effects. In the discriminative stimulus (D.S.) paradigm, FG 7142 produces drug-appropriate responding in DMCM and pentylenetetrazole trained rats. D.S. control has been established with FG 7142 and generalization to THBC and stressful environment manipulations has been reported. Furthermore, the FG 7142 D.S. is antagonized by benzodiazepine receptor agonists.

Male rats were trained to discriminate the effects of FG 7142 (5.0 mg/kg) in a food-motivated discriminative task. Dose-responsive generalization was observed following administration of the β-carbolines yohimbine (3.0-9.0 mg/kg) and norharmane (5.0-10.0 mg/kg) while coadminstration of FG 7142 with ZK 91 296 (15.0 mg/kg) resulted in antagonism of the FG 7142 D.S.. Rats trained to discriminate either yohimbine (3.0 mg/kg) or THBC (15.0 mg/kg) from vehicle failed to generalize to the FG 7142 D.S. and exposure to stressors resulted in vehicle responding. These results indicate that an asymmetrical generalization exists between FG 7142 and the β-carbolines THBC and yohimbine.

GABA-ERGIC MODULATION OF FELINE AGGRESSION ELICITED FROM THE MIDBRAIN PERIAQUEDUCTAL GRAY. M.B. Shaikh and A. Siegel. Dept. of Neurosciences, UMDNJ, Newark, N.J. 07103.

The midbrain periaqueductal gray (PAG) has been implicated in the initiation and regulation of aggressive behavior in the cat. Since the PAG is rich in GABA receptors, we examined the role of this putative transmitter in the modulation of affective defense (AD) and quiet biting attack behavior (QBA) elicited by electrical stimulation of the PAG.

Cannula-electrodes were employed for electrical stimulation as well as for microinjections of a GABA agonist (muscimol: 3, 12, 23, and 44 pmol/0.25ul) and GABA antagonist (bicuculline: 22 pmol/0.25ul). After establishing pre-drug response threshold values for AD and QBA, these drugs were microinjected into the PAG sites from which these responses were elicited. Microinjections of muscimol (12-44 pmol) significantly suppressed AD in a dose and time dependent manner. Pretreatment with bicuculline blocked the suppressive effects of muscimol (23 pmol) upon AD. In contrast, this dose of muscimol failed to alter the response threshold for QBA. Microinjections of vehicle alone (0.25 ul of saline, pH=7.4) did not modify the thresholds for either of these responses.

These results indicate that, at the level of the PAG, GABA-ergic mechanisms are selectively involved in the regulation of AD behavior in the cat.

506.3

ANTAGONISM OF THE ANTI-CONFLICT EFFECTS OF PHENOBARBITAL, BUT NOT DIAZEPAM, BY THE A-1 ADENOSINE AGONIST l-PIA. T.C. McCloskey*, R.L. Commissaris*, G.M. Damian*, B. Brown*, R.A. Barraco and H.J. Altman (SPON: C.P. Spirito). College of Pharmacy & School of Medicine, Wayne State University, Detroit, MI 48202.

The present study examined the acute effects of the anxiolytics diazepam (DZ) and phenobarbital (PhB), the A-1-selective adenosine agonist N^6-R-phenylisopropyl adenosine (l-PIA) and the A-2-selective adenosine agonist 5-N-ethylcarbox amido adenosine (NECA) on behavior in the Conditioned Suppression of Drinking (CSD) paradigm, an "animal model" used to study anti-anxiety agents. Water-restricted rats were trained to drink from a tube that was occasionally electrified (0.5mA), electrification being signalled by a tone. DZ (1.25-10 mg/kg) or PhB (10-40 mg/kg) treatment resulted in a dose-dependent increase in punished responding, while neither l-PIA (15-250 nM/kg) nor NECA (2.5-20 nM/kg) produced a significant anti-conflict effect. In combination studies, neither l-PIA nor NECA pretreatment altered the effects of DZ. In contrast, pretreatment with l-PIA, but not NECA, reduced the anti-conflict effects of PhB. These data suggest that (1) neither A-1 nor A-2 adenosine receptor activation affects basal behavior in the CSD paradigm and (2) PhB, but not DZ, anti-conflict responses may result from interactions with A-1 adenosine receptors. (MH #42501-01; protocol conforms with NIH guidelines)

506.4

ALCOHOL-BENZODIAZEPINE RECEPTOR INTERACTIONS: AGGRESSIVE BEHAVIOR AND MOTOR ACTIVITY IN RATS AND SQUIRREL MONKEYS. E. Weerts*, W. Tornatzky* and K.A. Miczek. Dept. of Psychology, Tufts University, Medford, MA 02155.

The possible antagonism of ethanol's behavioral effects by the beta-carboline Zk93426 as compared to the imidazo-benzodiazepines Ro15-1788 and Ro15-4513, were studied in confrontations between resident and intruder rats as well as in interactions in group-housed squirrel monkeys. Quantitative ethological methods permitted the measurement of drug effects on elements of aggressive, defensive, submissive, and social behavior as well as on motoric activities. The low doses of ethanol (0.1, 0.3 mg/kg) enhanced frequency of agonistic behavior, while higher doses (1.0, 3.0 mg/kg) reduced their occurrence in both species. Zk 93426 (3.0 mg/kg), Ro15-1788 (10.0 mg/kg) and Ro15-4513 (1.0 mg/kg) did not antagonize the suppressive effects of ethanol in rats. Ro15-4513 and Ro15-1788 potentiated alcohol's sedative effects, and reduced agonistic behavior; Ro 15-1788 increased feeding, and Ro15-4513 induced tremors and seizures in squirrel monkeys when administered alone. However, Ro15-4513 reduced ethanol-induced staggering. These results indicate none of these substances completely block the biphasic effects of ethanol; yet the effects of Ro15-4513 on staggering behavior show some promise for identifying one element in the multiple mechanisms of action of ethanol.

NEURAL SUBSTRATES FOR LOCOMOTION PRODUCED FROM VENTRAL PALLIDAL STIMULATION. M.C. Austin and P.W. Kalivas. Dept. of VCAPP, Washington State Univ., Pullman, WA 99164

It is well documented that nucleus accumbens efferents, which mediate locomotor behavior are GABAergic and project to the ventral pallidum/substantia innominata (VP/SI) region. The VP/SI region also contains a high density of enkephalin (ENK)-I.R. This study examines whether GABA-ergic or enkephalinergic neurons located in the VP/SI affects locomotor activity in rats. Intra-VP injection of either picrotoxin or bicuculline produced a dose-dependent increase in photocell counts with a minimum effect dose of 0.03 ug/side and 0.003 ug/side, respectively. To evaluate a possible interaction between GABA and Enk in the VP/SI, rats were pretreated with 0.1 ug/side (intra-VP) of the mu opioid antagonist naltrexone followed by injection of picrotoxin (0.1 ug/side). Naltrexone failed to attenuate the picrotoxin-induced hyperactivity. We also investigated the effect of intra-VP injection of the mu opioid agonist DAGO (Met-Enk analog). DAGO produced a dose-dependent increase in locomotor activity with a minimum effect dose of 0.01 nmoles/side. Pretreatment with 1.0 mg/kg s.c. of naloxone reversed the effect of DAGO (0.03 nmoles/side; intra-VP). These data indicate that inhibition of GABAergic transmission within the VP/SI produces a motor stimulant response which appears to be independent of ENK located in the VP. Furthermore, stimulation of enkephalinergic transmission in the VP/SI causes increased locomotor activity.

CENTRAL ADMINISTRATION OF BACLOFEN ENHANCES HABITUATION OF MOTOR ACTIVITY IN RATS. E.S. Sidel, H.A. Tilson, R.L. McLamb, H.S. Swartzwelder and W.A. Wilson. Dept. of Pharmacology, Duke Univ. Med. Ctr., Durham, NC 27710, and Lab. Mol. Integ. Neurosci., NIEHS, NIH, P.O. Box 12233, Research Triangle Park, NC 27709.

The effect of baclofen, the β-p-chlorophenyl derivative of GABA, on consolidation was assessed using habituation to motor activity as a one-trial learning paradigm. Baclofen (3 nmol intracerebroventricularly, icv), administered immediately after a 15 minute training trial, significantly decreased motor activity upon re-testing 24 hours later. Neither the low dose of baclofen (1 nmol) nor saline vehicle alone exhibited this effect. When a delay of 10 or 60 minutes was inserted prior to injections, the effect was not evident. Baclofen (both 1 and 3 nmol) administered icv immediately prior to a 30 minute testing period significantly decreased activity when compared with saline-injected controls. This effect was no longer evident 24 hours later, indicating an absence of carry-over effects of the drug. In a one-trial step-through passive avoidance paradigm, baclofen (1 and 3 nmol) administered icv, did not significantly affect retention 48 hours later. One interpretation of these results is that when administered directly into the central nervous system, baclofen, a GABA b agonist, facilitates memory consolidation as measured under the conditions of these experiments. (This work supported in part by NSF grant RCD8651791).

506.7

DEFENSIVE BURYING BEHAVIOR IN MAUDSLEY REACTIVE (MR/Har) AND NON-REACTIVE (MNRA/Har) RATS. S.L. Beardslee*, E. Papadakis*, H.J. Altman, G.M. Harrington* and R.L. Commissaris* (SPON: E.P. Schoener). College of Pharmacy & School of Medicine, Wayne State University, Detroit, MI 48202 and Dept. Psychol., U. Northern Iowa, Cedar Falls, IA 50614.

Based upon differences in open field and conflict behaviors, the MR/Har and MNRA/Har rat strains have been proposed as a genetically-based "animal model" for the study of emotionality and/or anxiety. The present study compared the MR/Har and MNRA/Har rat strains in the Defensive Burying (DB) paradigm described by Treit (Br. Res. Bull. 19:401-404, 1987). After four daily habituation sessions, female rats were placed in the DB chamber singly. Subjects received a 3 mA shock upon contact with a wire-wrapped prod and were observed for burying behavior (movement of the bedding material toward or over the prod) for 15 minutes post-shock. Although MR/Har rats tended to initiate burying sooner and exhibit a longer duration of burying than did the MNRA/Har rats, there were no differences in the frequency of subjects exhibiting burying behavior in MR/Har (12/14) as compared to MNRA/Har (11/13) rats. Thus, although they differ dramatically in open field and conflict behaviors, the Maudsley rat strains do not differ on all measures of DB behavior. (MH #42501-01) Protocol conforms with NIH Guidelines.

506.8

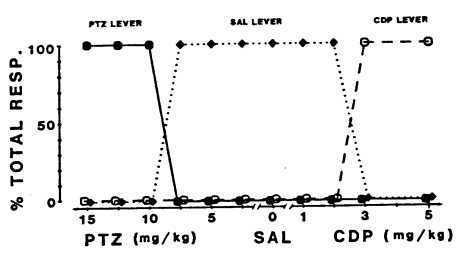
A COMPARISON OF CHLORDIAZEPOXIDE AND BUSPIRONE IN THE SHOCK-PROBE/BURYING TEST FOR ANXIOLYTICS. D. Treit and M. Fundytus*. University of Alberta, CANADA T6G 2E9.

The effects of chlordiazepoxide (2.5-10.0 mg/kg IP) and buspirone (0.05-1.0 mg/kg SC) were compared by a "blind" observer in the shock-probe/burying test for anxiolytics. Consistent with their anxiolytic effects, both agents decreased rats' burying behavior, and increased the number of shocks rats received from a constantly electrified (2 mA) shock probe, at doses that did not affect rats' general activity. The suppression of probe-burying and facilitation of probe-shocks increased linearly as a function of drug dose, with the relative potency of buspirone being substantially greater than that of chlordiazepoxide. These results contrast with those of Craft et al. and suggest that their failure to show a selective suppressive effect of chlordiazepoxide and buspirone on burying to a constantly electrified shock-probe was due to inappropriate methodology (e.g., lack of distributed pretest habituations, absence of separate placebo control groups, and a behaviorally sedating range of anxiolytic doses). In any case, under the parameters used in the present study, this "repeated shock" version of the shock-probe test for anxiolytics appears to be more efficient than the previous, single shock version (e.g., only 2% subject "attrition" compared to 20%-40%), and current studies are underway to further characterize its drug-class specificity.

506.9

THREE-CHOICE DRUG DISCRIMINATION OF AN UNIDIMENSIONAL "ANXIOGENIC/ANXIOLYTIC" CONTINUUM. D.V. Gauvin*, and F.A. Holloway. (SPON: H.D. Christensen) Univ. Oklahoma Health Sciences Center, Oklahoma City, OK 73190-3000.

To lend support to our previous suggestion that the interoceptive states induced by chlordiazepoxide (CDP) and pentylenetetrazol (PTZ) lie at polar ends along a single affective continuum (Michaelis et al., Psychopharmacology, in press, 1988), 6 Sprague-Dawley rats were trained in a 3-choice drug discrimination task utilizing CDP (5 mg/kg), saline (SAL), and PTZ (15 mg/kg) as discriminative stimuli. Average sessions to 90% criterion was 102 ± 5. Data from one representative subject is shown below. Generalization tests resulted in pharmacologically specific, quantitative, unidimensional functions.



506.10

ENHANCEMENT OF OPIOID CATALEPTIC RESPONSE BY CORTICAL FRONTAL DEAFFERENTATION OR INTRASTRIATAL INJECTION OF NMDA-RECEPTOR ANTAGONISTS. S. Consolo*, G.L. Forloni*, H. Ladinsky and E. Palazzi*. Mario Negri Institute, Milan, Italy.

The cataleptic activity of morphine and methadone was markedly potentiated in decorticated rats with no changes in the onset or duration of action. Enhancement of opioid catalepsy was not due to changes in the availability of the drugs in the brain. The potentiation of methadone induced catalepsy in decorticated rats was mimicked in naive rats by intrastriatal (i.s.) injection of AP7, a selective antagonist of NMDA receptors. The failure of AP7 to elicit an effect after injection into the n. accumbens indicates a selective involvement of the striatum in the phenomenon. That the striatum plays a critical role in opioid-induced catalepsy was substantiated by the findings that: 1) naloxone (i.s.) prevents the potentiation of catalepsy induced by methadone and morphine in decorticates, 2) oxotremorine (i.s.) reverses the enhancement of opioid catalepsy in decorticates. In conclusion, evidence is given that the corticostriatal pathway exerts an inhibitory effect upon narcotic-induced cataleptic behavior. (Supported by AFOSR-87-0399).

506.11

BLOCKADE OF THE ACOUSTIC STARTLE REFLEX BY LOCAL INFUSION OF EXCITATORY AMINO ACID ANTAGONISTS INTO THE VENTRAL COCHLEAR NUCLEUS. M.J.D. Miserendino* & M. Davis (SPON: J. ROSEN) Yale Univ., Dept. of Psychiatry, Ribicoff Res. Fac., Conn. Mental Health Ctr., New Haven, CT. 06508.

A large body of data suggests that the excitatory amino acids glutamate and/or aspartate may be the neurotransmitters released by the auditory nerve at the cochlear nucleus. We are using the acoustic startle reflex to behaviorally examine the role of excitatory amino acids and their receptors in auditory transmission at the level of the ventral cochlear nucleus (VCN), the first synaptic relay in the neural pathway mediating acoustic startle.

Rats were cannulated in one VCN and received an electrolytic lesion of the contralateral VCN. Because this surgical procedure itself decreases startle amplitude, all animals were pretreated with the phosphodiesterase inhibitor rolipram (1 mg/kg, ip) which has been shown to elevate startle. Ten minutes later, rats were infused with either 5, 25, or 50 nmols of gamma-D-glutamylglycine, a potent non-specific excitatory amino acid antagonist, or with artificial cerebrospinal fluid (ACSF). Startle elicited by 95dB, 50 msec noise bursts was measured over the next 40 minutes.

ACSF had no effect on startle. In contrast, gamma-D-glutamylglycine caused a dramatic, dose-dependent depression of the startle reflex, with the highest dose producing a complete blockade of startle. These results support the idea that excitatory amino acids are involved in startle at the level of the ventral cochlear nucleus, and illustrate that the acoustic startle reflex is a sensitive behavioral assay of VCN receptor function. Current work utilizing more specific NMDA and non-NMDA antagonists will attempt to characterize the amino acid receptor subtype(s) in the VCN mediating the acoustic startle reflex.

506.12

DIFFERENT TEMPORAL EFFECTS OF MK-801, PCP AND KETAMINE ON MEMORY RETENTION IN MICE. M.J.Benvenga, A.V.Wing*, and T.P.Jerussi. Anaquest/BOC Health Care, Murray Hill, New Jersey, 07974.

MK-801, a novel anticonvulsant, has recently been reported as the most potent ligand of the PCP receptor in vitro (Sircar, et.,al., Brain Res, 1987). MK-801 also inhibits passive avoidance retention in vivo (Benvenga & Spaulding, Pharm Biochem Behav, 1988). The purpose of the present experiment was to evaluate the effect of MK-801 given pre- and posttraining in a passive avoidance task and compare these results with phencyclidine and ketamine.

Male Swiss-Webster mice (25-30g) were injected either 30 minutes prior to or immediately following one-trial passive avoidance training (N=8/group) which consisted of footshock delivered to the animal when it entered a darkened chamber. Groups were treated with PCP (0 [vehicle = distilled water], 0.5, 0.75, 1.0, 2.0 or 5.0 mg/kg.), ketamine (0, 2.0, 5.0, 7.5, 10.0 or 15.0 mg/kg.) or MK-801 (0, 0.05, 0.1, 0.15, 0.75, 1.0 or 1.5 mg/kg.). All mice were tested 24 hours after initial exposure to the test apparatus and the latency to reenter the darkened chamber was recorded. Median group latencies were compared by Mann-Whitney U-tests.

The results indicated that all drugs tested produced an inhibition of retention in the passive avoidance task. However, MK-801 produced a posttraining effect only at 10 times the dose necessary to cause a pre-training effect while PCP and ketamine produced posttraining effects at 2 times the pretraining dose. One possible mechanism for this effect may be that PCP interacts with endogenous opioidergic and cholinergic systems whereas MK-801 does not.

506.13

EFFECTS OF CHRONIC NIMODIPINE TREATMENT ON BEHAVIOR OF OLD RATS

A.Friedl*, T.Schuurman*, H.Klein* and J. Traber* (SPON: K.A. Braun), Neurobiology Department, Tropon Pharmaceuticals, Neurather Ring 1, D-5000 Köln 80, F.R.G.

Growing evidence ascribes an important role in aging processes in the brain to a dysregulation of the Ca^{2+}-homeostasis in neurons. Compounds which interfere with Ca^{2+}-fluxes such as Ca^{2+}-entry blockers might therefore possess a therapeutic potential in age related brain disorders. Nimodipine, a Ca^{2+}-blocker of the dihydropyridine type, was investigated after subchronic and chronic treatment for its ability to improve behavioral deficits occuring in old rats such as impaired learning and memory capacity, reduced open field activity and social behavior, impaired motor coordination etc. Nimodipine treatment for one week improved the learning rate of old rats in a water maze. Rats chronically fed with nimodipine containing food showed a higher level of exploration in an open field than normally fed old rats. Furthermore, motor coordination of nimodipine fed animals was significantly better than that of age-matched controls. Chronic nimodipine treatment also delayed the onset of age-related walking patterns in old rats as measured by analysis of the foot prints in an alley-walking test.

The present results indicate that nimodipine may be an useful drug for the treatment of certain aspects of brain aging and support recent findings obtained from clinical studies with aged people treated with nimodipine.

506.14

OXYTOCIN RECEPTORS SENSITIZE BRAIN TO VASOPRESSIN'S CONVULSIVE ACTIONS. P.P.Poulin and Q.J. Pittman. Neuroscience Research Group, Univ of Calgary, Calgary, Alberta T2N 4N1 Canada.

Vasopressin (AVP) administered into the ventral septal area (VSA) of rats produces severe motor disturbances which appear to result from an interaction of AVP with V1 type of AVP receptors and appear to involve a sensitization process whereby a first administration (sensitization) of AVP causes minor motor disturbances, while a second dose two days later causes sever motor disturbances. In binding studies, oxytocin (OT) has been shown to bind to VSA V1-like AVP receptors (Poulin et al., J. Neurochem. 50(3)889-897), with 100 times less potency than AVP. Thus we have investigated whether OT could sensitize or induce motor disturbances in rats after intracerebroventricular (icv) injections. Dose response studies show that AVP can sensitize and induce motor disturbances at threshold doses of 10 ng and 1 ng icv respectively. OT (1 ng icv) was 10 times more potent that AVP (10 ng icv) in sensitizing the rat brain to AVP (1 ng icv) induced motor disturbances. In AVP or OT sensitized animals however, OT (100 ng), was ineffective in inducing motor disturbances at 100 times AVP (1 ng icv) effective dose. Thus, it is possible that AVP or OT sensitization effects, but not AVP induced motor disturbances, are mediated via an oxytocin type receptor which also recognizes AVP. Supported by MRC. P.P. is an AHFMR student.

506.15

SELECTIVE ENHANCEMENT OF LATENT INHIBITION BY ANTIPSYCHOTIC DRUGS IN THE RAT:A POSSIBLE MODEL FOR CLINICAL ACTION. L.A. Dunn*, G.E. Atwater*, G.W. Christison*, C.D. Kilts*,(SPON:R.D. Weiner) Dept. of Psychiatry, Duke Univ. Med. Ctr., Durham, NC 27710.

Latent inhibition (LI) of conditioned responding is a quantitative measure of the ability to screen out irrelevant sensory stimuli. This ability has been shown to be deficient in schizophrenia patients and to improve with antipsychotic medication. We have assessed the ability of several classes of psychoactive drugs to enhance LI in rats using an established paradigm (Christison et al., Biol. Psychiat., 23:746-749, 1988). All drugs were given i.p. for 7 days. Following the final injection, drug and vehicle treated rats were divided into groups and placed in darkened test cages. Half were preexposed 20 times to a 28v, 40 mA cage light. All groups were conditioned with 2 CS-US pairings. The CS was identical to the pre-exposure stimulus. The US consisted of a 1 sec, 0.75 mA scrambled footshock. The following day, conditioned emotional response (CER), as measured by interruption of drinking in response to the CS, was recorded. Statistical significance was evaluated using a 2x2 ANOVA for each experiment. LI was enhanced by treatment with haloperidol 0.3mg/kg (p=0.008), and fluphenazine 0.3mg/kg (p=0.026). Clozapine 10mg/kg, imipramine 10mg/kg and chlordiazepoxide 10mg/kg showed no enhancement of LI. A further experiment in which clozapine 10mg/kg was given only once prior to preexposure also failed to show LI enhancement. The fact that clozapine did not enhance LI may indicate that this paradigm is sensitive to typical but not atypical antipsychotics. (MH39967)

506.16

POLYAMINES, EXPLORATORY ACTIVITY AND SENSATION-SEEKING. P.A. Ferchmin, V.A. Eterović, J.R. Cotto Aponte*, E.M. Rivera*, W.I. Rodríguez*, and S.A. Alvareztorre*, Dept. of Biochemistry, Univ. Central del Caribe, Cayey, P.R. 00633 and Interamerican Univ. San Juan, Puerto Rico, USA.

We have studied the effect of drugs which affect brain polyamine levels on rat activity in a Greek cross-shaped maze, with two white and two black compartments, communicated with a central gray compartment. Total entries into peripheral compartments measure exploratory activity, while white entries are a measure of sensation-seeking behavior. Thirty day-old, male, albino rats were used. Difluoromethylornithine (DFMO), 400 mg/Kg, decreased brain putrescine (Pu) to 50% of normal level; other polyamines (PA) were not affected. DFMO did not affect white entries but depressed total entries. Exogenous Pu, 400 mg/Kg, increased brain Pu level to six times normal 15 min after injection, declining slowly afterwards. Spermidine and spermine levels were not affected, and acetylated PA were undetectable. Pu injection depressed white entries and this effect was reversed by DFMO. Pu also depressed entries to black compartments (and therefore total entries), but this effect was not reversed by DFMO. Cyclohexylamine, 400 mg/Kg, which increase endogenous Pu, depressed total, but not white entries. In summary, depression of total entries was observed with any disturbance of Pu level, while white entries were only affected by exogenous Pu.

INVOLVEMENT OF ENDOGENOUS MELATONIN IN THE ANTIDEPRESSANT-LIKE ACTIVITY OF LUZINDOLE (N-0774). Areso, P.*, and Dubocovich, M.L. (SPON: R.S. Eisenberg). Dept. Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611.

The selective melatonin receptor antagonist luzindole (LUZ) exerts antidepressant-like activity in the C3H/HeN mice behavioral despair test (Mogilnicka & Dubocovich, Neurosci. Abs. 13:1039, 1987). Here, we further investigated the involvement of melatonin (MEL) in the behavioral despair test using LUZ. The time of immobility (sec) during swimming was determined in the dark phase of a 14:10 h, L:D cycle in C3H/HeN mice which synthesize MEL and in C57BL/6 mice which do not synthesize the hormone. In controls, the duration of immobility was 59 ± 5 (n=47) in C3H/HeN and 147 ± 4 (n=24) in C57BL/6. Desipramine (30 mg/kg, i.p.) significantly reduces the duration of immobility both in C3H/HeN (3 ± 1, $p<0.001$, n=16) and in C57BL/6 (104 ± 18, $p<0.001$, n=8). LUZ (10 mg/kg, i.p.) reduces the duration of immobility in C3H/HeN (17 ± 3, $p<0.001$, n=31) but not in C57BL/6 (170 ± 3, n=24). While MEL (30 mg/kg, i.p.) did not affect the time of immobility in C3H/HeN (52 ± 5, n=24) it reversed the anti-immobility effect of LUZ (57 ± 9, n=15). The lack of effect of LUZ in C57/BL6 mice and the antagonism of its effect by MEL in C3H/HeN mice suggest an involvement of endogenous MEL in the behavioral despair test. It is suggested that the antidepressant-like activity of LUZ occurs through a different mechanism than that of classical antidepressants.

DISCOVERY OF A CANNABINOID RECEPTOR IN RAT BRAIN.
W.A. Devane*, L.S. Melvin*, M.R. Johnson* and A.C. Howlett (SPON: M.M. Voigt). Dept. of Pharmacology, St. Louis Univ., St. Louis, MO 63104 and Pfizer Central Research, Groton, CT 06340.

CP-55,940 is a nonclassical cannabinoid analgetic agent whose ability to inhibit adenylate cyclase in a neuronal cell model has recently been reported (Howlett et al., Mol. Pharm. 33:297, 1988, cmpd 8). ^{3}H-CP-55,940 was used to characterize a receptor site in brain. Using a P2 preparation from rat cortex, a binding site was characterized which was saturable with either 1 μM CP-55,940 or delta-9-tetrahydrocannabinol. Cannabinol and cannabidiol, cannabinoid drugs lacking CNS activity, did not displace CP-55,940. Scatchard analysis of saturation curves indicated a high affinity site having a K_d of 110 pM and a lower affinity site having a K_d of 1.4 nM. K_d values calculated from the association and dissociation rates were similar. Guanylylimidodiphosphate eliminated the binding to the high affinity site, and increased the number of low affinity sites, indicating that a characteristic interaction of the receptor with G-proteins is likely. Divalent cations increased binding, and Na and other monovalent cations decreased binding of CP-55,940. This behavior is characteristic of other receptors associated with inhibition of adenylate cyclase.

NEUROTOXICITY: STUDIES IN TISSUE CULTURE

507.1

CALBINDIN D-28K PROTECTS AGAINST GLUTAMATE INDUCED NEUROTOXICITY IN RAT CA1 PYRAMIDAL NEURON CULTURES. K.G. Baimbridge and J. Kao*. Dept. Physiology, University of British Columbia, Vancouver, B.C., Canada. V6T 1W5

When neuronal cultures of rat CA1 pyramidal cells are exposed briefly to high levels of glutamate a delayed, (24hr), and Ca^{++} dependent neuronal death occurs. Depending upon the glutamate concentration, however, some neurons do survive. We have now measured both resting and glutamate stimulated intracellular Ca^{++} concentrations using neurons loaded with Fura II, and have correlated these values with the presence or absence of Calbindin D-28K, (CaBP).

Stimulation of the neurons with glutamate over the range 0.1-100 uM produced a dose dependent increase in the Ca^{++} levels. At the highest dose the range of Ca^{++} clearly fell into two distinct groups with mean Ca^{++} levels of 500 or 2000 nM. Of the 100 neurons measured 26 were CaBP positive as determined immunohistochemically (ICC) immediately after the glutamte insult. All of these CaBP positive neurons had Ca^{++} levels in the lower group range. When CaBP ICC was done on surviving neurons 24 hours following the glutamate insult the percentage of CaBP-positive neurons doubled when compared to non-stimulated controls. We suggest that these results are consistent with a calcium-buffering role for CaBP which may buffer the glutamate induced rise in intraneuronl Ca^{++} and as a result limit the effectiveness of the glutamate induced delayed neurotoxicity.

PHOTOLYTIC EFFECT OF POLYLYSYL-PHTHALOCYANINE DERIVATIVES ON MURINE NEURO 2a NEUROBLASTOMA CELLS. S. Kornguth, F. Sieber* and T. Kalinke*. University of WI, Madison WI 53706 and Med. Coll. WI, Milwaukee WI.

Poly-L-lysine (PL) was modified covalently with tetracarboxy-cobalt-phthalocyanine (Pc) using varying ratios of Pc per lysyl residue. The effect of incubating murine neuroblastoma neuro 2a cells with the PL-Pc complexes was examined as a function of duration of light exposure and the degree of modification of the PL with the Pc. The PL-Pc complexes are of interest because: a) PL binds many tumor cells more avidly than normal cells, b) Pc is taken up more rapidly by tumor than by normal cells, c) cells that bind Pc are damaged after exposure to light, d) the paramagnetic cobalt of Pc may serve as a MRI probe to detect cellular uptake of Pc, e) Pc has a high molar extinction coefficient. In our experiments, $6x10^5$ cells were incubated in 2 ml of HEPES buffered medium containing 14% fetal bovine serum with polylysine alone or with PL-Pc (between 0.1 to 1.0 mg/ml). Two preparations of PL-Pc were used (10 lysyl residues per Pc and 30 lysyl residues per Pc). The cells were incubated with the PL or with the PL-Pc under three conditions (in the dark for 90 min.; in the dark for 30 min and then in light for 30 or for 60 min). The cells were then washed and cultured in methyl cellulose for 8 days. The clonogenic assay revealed that polylysine alone was toxic to the cells and that the PL-Pc treatment resulted in photolysis of the neuro 2a cells. These data suggest that the PL-Pc may be useful in the treatment of some tumors.

507.3

EFFECTS OF HALOTHANE ON MICROFILAMENTS IN CULTURED RAT FIBROBLASTS. E. Uemura, S. Jeftinija and D. Gledic. Dept. of Vet. Anatomy, Iowa State University, Ames, IA 50011.

To examine the mechanism of halothane toxicity that was characterized by the suppression of axonal and dendritic extension, actin distribution in fibroblasts in vitro, was studied by immunocytochemistry using the anti-biotin peroxidase complex technique. Rat fibroblasts were cultured in the presence of 1% halothane in gas phase up to 41 hours. The growth rate of the cell was significantly slowed down by halothane. Although halothane did not affect the size of cells, it affected the distribution pattern of actin. The control cells were characterized by the deeply stained mesh-work of actin throughout the cytoplasm. However, the cells that were exposed to halothane showed diffusely stained actin confined to the perinuclear area, and a large portion of the cytoplasm was not stained. Analysis of staining intensity of cells by an image analyzer clearly supported such qualitative observation. It appears that the effect of halothane on neuronal extension is a reflection of the microfilaments inability to function in the presence of halothane.

MEASUREMENT OF INTRACELLULAR CALCIUM ION CONCENTRATIONS IN NG108-15 CELLS BY FLUORINE-19 NUCLEAR MAGNETIC RESONANCE SPECTROSCOPY: A MODEL FOR THE STUDY OF LEAD NEUROTOXICITY.
F.A.X. Schanne*, T.L. Dowd*, R.K. Gupta* and J.R. Moskal (SPON:A. Herschfeld). Albert Einstein College of Medicine, Bronx, New York 10467.

Intracellular Ca ion concentrations $[Ca^{2+}]_i$ were measured in NG108-15 cells using the intracellular divalent cation indicator 1,2-bis(2-amino-5-fluorophenoxy)ethane-N,N,N',N'-tetraacetic acid (5F-BAPTA) and fluorine-19 Nuclear Magnetic Resonance Spectroscopy (NMR). This methodology provides for the simultaneous identification and measurement of $[Ca^{2+}]$ and a variety of heavy metals, including $[Pb^{2+}]$. The NG108-15, a hybrid cell line of murine neuroblastoma x rat glioma, makes synapses upon chemically induced differentiation and co-culturing with fetal rat myotubes. NG108-15 cells were grown on Cytodex 1 microcarriers (Pharmacia) in Dulbecco's Modified Eagle's Medium (GIBCO) supplemented with 10% fetal bovine serum. Cells were loaded with 5F-BAPTA and superfused at 2 ml/min with oxygenated medium during NMR observation. NMR measurements were performed on a Varian VXR 500 using a 10 mm broad band probe tuned to 470 MHz for fluorine. Using this methodology the average $[Ca^{2+}]_i$ was measured to be 105 nM. Thus, NG108-15 cells will be used as a model to study the effects of Pb on the early events leading to synaptogenesis, specifically as it affects $[Ca^{2+}]_i$.

MODULATION OF MPP+ NEUROTOXICITY IN THE N_2AB-1 NEUROBLASTOMA CELL LINE. S. J. Simmons and M. F. D. Notter. Environ. Health Sci. Ctr. and Dept. of Neurobio. and Anat., Univ. of Rochester Sch. of Med., Rochester, NY 14642.

A mouse adrenergic neuroblastoma cell line (N_2AB-1) was used to investigate toxicity of 1-methyl-4-phenylpyridinium iodide(MPP+), the active metabolite of 1-methyl-4-phenyl-1,2,3,6 tetrahydropyridine(MPTP) in an in vitro model. Cells were differentiated by prostaglandin E_1 and dibutyryl cyclic AMP to induce a neuronal phenotype. Both differentiated and mitotic cells were exposed to MPP+(3.4 - 340μM) for 24-72 hr.

Differentiated cells were less sensitive to or protected from MPP+ toxicity as compared to mitotic cells. Toxic response was seen morphologically as increased cytoplasmic inclusions, loss of neurites, loss of intact cells and cell death. Measurement of cell number over the 3 day observation period confirmed the morphologic findings of protection with differentiation.

To further explore the benefits of differentiation, cells were treated with mixed gangliosides(GA)(200μg/ml), a neurite promoting factor in the CNS. GA have been shown to aid in neuronal recovery in vivo from MPTP toxicity(Hadjiconstantinou M. et al., Neuropharm. 25:1075, 1986). GA induced neurite formation in both mitotic and previously differentiated cells. 24 hr pretreatment or cotreatment of GA with MPP+ reduced the loss of [3H]-leucine incorporation during protein synthesis and prevented the loss in total protein induced by MPP+ in mitotic and differentiated cells. GA aided in the recovery of both mitotic and differentiated cells following removal from MPP+ exposure. Recovery included cell proliferation and the extension of neurites.

This in vitro model of neurotoxicity provides a system in which agents can be tested for their ability to protect against a neurotoxin.

Supported in part by NIEHS Pilot Grant from ES01247.

BIOCHEMICAL AND ULTRASTRUCTURAL MODIFICATION IN PC12 CELLS TREATED WITH "PARKINSON MIMETIC" TOXINS. A. Vescovi*, M. Gebbia*, M. Mora*, G. Cappelletti*, E. A. Parati. (SPON: L. M. Vicentini). Inst. "C. Besta" Milan, Italy, 20133.

We studied the effects at different incubation time of 1.5mM MPTP or MPP^+ or $MnCl_2$ on PC12 cultured cells. We analized cellular death, intracellular levels of dopamine and dopac and ultrastructural morphology. Data show that within 3 days neither MPTP nor $MnCl_2$ affected cells survival, while after 24 hours MPP^+ led to a complete cells death (97%). A strong difference between manganese and MPTP was observed at biochemical level; after 3 hours 1.5 mM MPTP induces a decrease in dopamine and dopac intracellular levels (-80%), while 3 hours of 1.5m manganese chloride treatment results in an increase of about 120 %, followed by a slow decrease reaching a value of 56% of untreated cells after 24 hours. These biochemical data seem to be confirmed by ultrastructural observations, considering that despict the unaltered vitality, PC12 cells show signes of sufferring, with an intracellular accumulation of lipofuscin-like material in both MPTP and $MnCl_2$ treated cells. Our observations suggest that although both manganese and MPTP induce similar anatomopathological damages in man and primates, at least in the earlier stages of intoxications the biochemical mechanisms involved seem very different, inducing opposite neurochemical modifications.

507.7

ALUMINUM NEUROTOXICITY IN CULTURED NG108-15 CELLS. H.S. Singer*, C. Searles*, J.L. March§*, and J.C. Troncoso§. Dept. of Neurology and §Neuropathology Lab., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205-2182.

In order to better understand the pathogenesis of neurofilament (NF) and neurotransmitter changes in aluminum (AL) neurotoxicity, we have begun to explore the effects of AL lactate on cell cultures. Rapidly dividing neuroblastoma x glioma hybridoma (NG108-15) cells, passages 24-28, were cultured for up to eight days in concentrations of AL lactate (0.5-4 mM). Cell growth, as determined by total protein content, was not reduced until AL in the media exceeded 2 mM. In the presence of 1-2 mM AL, the activity of choline acetyltransferase (ChAT) was increased (132% of control), whereas glutamate decarboxylase (GAD) activity was unchanged from control. Saturation kinetics showed an increased amount of ChAT with a stable affinity. At 4 mM Al, both ChAT and GAD activities were reduced (85% and 33%, respectively). Alterations of NF were not identified with either light or electron microscopy, even after exposure to the highest AL concentrations. Analysis of proteins separated by gel electrophoresis also failed to document any increase in NF polypeptides. AL neurotoxicity is a complex phenomenon known to affect both synaptic neurotransmission and cytoskeletal proteins. The NG108-15 cell line is a useful in vitro model for further characterization of the effect of AL on the cholinergic system.

INHIBITION OF NEURITE GROWTH BY ORGANIC AND INORGANIC LEAD. G. Audesirk, G. Nelson,* D. Shugarts* and J. Przekwas*. Biology Department, University of Colorado at Denver, 1200 Larimer St., Denver, CO 80204.

We investigated the effects of inorganic lead and triethyl lead on neurite growth in primary cultures of neurons from the brains of pond snails (Lymnaea stagnalis) and chick embryos. Neurons were cultured for 3 to 4 days in medium that contained no toxins, inorganic lead ($PbCl_2$), or triethyl lead chloride. Lymnaea neurons were scored for neurite growth, with a neurite defined as a process at least one soma diameter in length. Inorganic lead reduced the fraction of cells that grew neurites, with an IC_{50} of about 13 uM. Triethyl lead reduced the fraction of cells growing neurites with an IC_{50} of about 0.5 uM, and exerted significant toxicity at 0.2 uM. Neurite length was not measured. In chick neuron cultures, the neurites of all the neurons in randomly selected areas of the culture dishes were measured with a digitizing tablet. Inorganic lead reduced the fraction of neurons that grew neurites (IC_{50} of 226 uM), but did not reduce the mean neurite length per neurite-growing cell. Triethyl lead reduced both the fraction of neurons growing neurites (IC_{50} = 0.25 uM) and the mean neurite length (IC_{50} = 0.42 uM).

Supported by grants from NIH (ES03158) and EPA (R-813228) to G. Audesirk.

507.9

EFFECT OF MPTP ON PRIMATE ADRENAL CHROMAFFIN CELLS IN VITRO: AN ACUTE AND CHRONIC STUDY. M. Kaniucki*, J.T. Hansen, M.S. Fiandaca, J.H. Kordower, D.M. Gash, S. Okawara, and M.F.D. Notter. (SPON: L. Abood). Dept. Neurobiol. and Anat., and Div. of Neurosurg., Univ. of Rochester, Rochester, New York 14642.

Primate adrenal medullary cells were exposed to 1 methyl 4 phenyl 1,2,3,6 tetrahydropyridine (MPTP) in vitro to examine the effect of this neurotoxicant on peripheral catecholamine (CA)-containing tissues. Chromaffin cells obtained from either monkey or the Human Organ Donor Program at the University of Rochester were enriched by differential plating and cultured in the presence or absence of nerve growth factor (NGF, 100 ng/ml). After one week, cells were exposed to 150 uM MPTP for an additional week. Cells which had extended neurites in the presence of NGF showed no morphological effect of MPTP at the light microscopic level. However, there was a significant loss in CA as seen by histofluorescence and high performance liquid chromatography (HPLC). Electron microscopy revealed a depletion in dense core vesicles after chronic exposure to MPTP. Replacement of MPTP medium with standard medium stimulated a restoration of CA histofluorescence after seven days. An acute 15 min pretreatment of chromaffin cells with MPTP or its active metabolite methylpyridinium ion (MPP+) induced a dose dependent secretion of CA over a one hour pulse with MPP+ (150 uM) producing the maximum and most rapid secretion as determined by HPLC. Exposure of chromaffin cells to these neurotoxicants did not affect the physiological response to acetylcholine (10-9 M) as all cultures showed a stimulated release of CA. These data indicate that MPTP induces a dramatic loss in catecholamines in primate chromaffin cells in vitro after both acute and chronic exposures, while CA can be restored to chromaffin cells following removal of this toxic agent without effect on the integrity or physiological function of these cells.

AFFECTS OF MPTP ON A HUMAN ADRENERGIC CELL LINE, LA-N-1. S. Sullivan and M.F.D. Notter. Univ. of Rochester Sch. of Med., Dept. of Neurobiology and Anatomy, Rochester, NY 14642

The effects of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) were studied on a human neuroblastoma cell line in vitro before and after differentiation. LA-N-1 cells, which are neural crest derivatives, are adrenergic and differentiate morphologically and biochemically when treated with 10^{-5}M retinoic acid (RA), a vitamin A analog.

Mitotic cultures exhibited a dose dependent decrease in cell number after treatment with 1, 10 or 50 μg/ml MPTP (4.77, 47.7 or 238.5 μM respectively). Cultures treated with 1 μg/ml had similar growth curves to control cultures. Cultures treated with 10 μg/ml showed a 35% decrease in cell number by day 2 of treatment; this decrease remained throughout the 5 day test period. Cultures treated with 50 μg/ml exhibited an 85% decrease in cell number by day 2 and continued to decline to a 99% decrease by day 5.

Cell numbers in differentiated cultures were less affected by MPTP treatment. The growth curves of cultures treated with 1 and 10 μg/ml were similar to controls. However, treatment with 50 μg/ml was still acutely toxic, causing a 70% decrease in cell number which remained constant from day 2 until day 5.

Although cell numbers were not severely affected by low doses of MPTP there were apparent morphological changes in differentiated cultures. Differentiation with RA causes cells to stop dividing and to send out long neuritic processes. MPTP caused a dose dependent "dedifferentiation." Cells retracted their neurites and also changed in size and shape.

These data indicate that this human neural cell line is a good in vitro model of MPTP toxicity and that early changes seen in vitro may reflect long term effects seen in vivo.

EFFECT OF LEAD AND MERCURY ON LIPID METABOLISM OF SCIATIC NERVES IN VITRO AND CULTURED SCHWANN CELLS.

P.Clouet* and J.M. Bourre*(SPON: Michael White)
INSERM U 26 Hopital F.Widal 200 rue du Fbg St Denis PARIS 75010.

The goal of this study was to analyse the action of lead and mercury on the lipid metabolism of Schwann cells in different states of functional differentiation.

In the first series of experiments, endoneuria of sciatic nerve from mice were preincubated at 37°C in the presence of various concentrations of lead nitrate or mercuric chloride. After 30 minutes preincubation, radiolabeled acetate or acetoacetate was added as precursors for lipid synthesis and the mixture was incubated for 2 hours. In a second set of experiments, Schwann cells isolated from sciatic nerves of 4 old-day mice were cultured for 15 days, then incubated 18 hours at 37°C with various concentrations of lead or mercury in the presence of one of the same precursors. Lipids were then extracted, separated, and level of the radioactivity was measured.

Lead did not affect lipid metabolim of endoneurium and Schwann cells in culture, consistent with the hypothesis that Schwann cells are resistant to low concentrations of lead. 10^{-5}M $HgCl_2$ caused an increase in the incorporation of acetate into phospholipids of endoneurium and modified the pattern of acetate incorporation into lipids of both endoneurium and Schwann cells in culture. With acetoacetate as precursor, 10^{-5}M $HgCl_2$ modified only the pattern of its incorporation into lipids of endoneurium. These results suggest that the effect of mercury on lipid metabolism in Schwann cells depends on the state of functional differentiation of these cells.

NEUROTOXIC EFFECTS OF METHAMPHETAMINE ON DOPAMINE AND SEROTONIN NEURONS IN REAGGREGATE TISSUE CULTURE. P.J. Kontur, L.A. Won, P.C. Hoffmann and A. Heller. Dept. of Pharmacological and Physiological Sciences, University of Chicago, Chicago, IL 60637.

Reaggregate tissue cultures composed of neurons from the mesencephalic tegmentum and corpus striatum of 14 day old embryonic mice were treated with methamphetamine (meth; 10^{-9} - 10^{-3}M) at 15 days in culture for 7 days. This caused parallel decreases in reaggregate dopamine (DA) levels and cell numbers (visualized by histofluorescence) and reductions in serotonin (5HT) levels. Accumulation of exogenous DA expressed per visualized DA neuron and endogenous GABA levels were not altered by this treatment. Time-course studies showed that the levels of DA are decreased to 38 and 68% of control after 1 day of treatment with 10^{-4}M or 10^{-5}M meth at 15 days in culture and remain depressed after 4 and 7 days of treatment. 10^{-6}M meth decreased DA levels to 63% of control but only after 7 days of treatment. Serotonin levels decreased gradually between 1 and 7 days of treatment with 10^{-4} and 10^{-5}M meth but were not decreased until after 4 days of treatment with 10^{-6}M meth. Thus, it appears that the levels of DA decreased more rapidly than those of 5HT at any given concentration of meth. The potential recovery from effects of meth was assessed by treating reaggregates with 10^{-4}M or 10^{-5}M meth for 2 days, discontinuing exposure to meth and allowing the reaggregates to continue in culture for an additional 5 days. Dopamine and 5HT levels were reduced after 2 days of treatment with meth. However, 5 days after removal of meth, DA levels had recovered while 5HT levels were still decreased. These experiments indicate that the decreases in DA levels can be reversed after removal of meth while the reducation in 5HT levels appears to be more persistent. Supported by MH42134 and NIDA contract #271-87-8114.

DOPAMINE NEURONS INCREASE THEIR RESISTANCE TO THE NEUROTOXINS MPTP AND MPP^+ DURING DEVELOPMENT IN CULTURE. C. Mytilineou and P. Danias*. Dept. of Neurology, Mount Sinai School of Medicine, New York, N.Y., 10029.

Prerequisites for MPTP neurotoxicity are its metabolic oxidation by monoamine oxidase B (MAO-B) to MPP^+ and the uptake of MPP^+ by the dopamine (DA) neurons. We have studied the relationship between MAO activity and uptake capacity and the efficacy of the neurotoxins MPTP and MPP^+ in dissociated mesencephalic cultures during 4 weeks of in vitro growth. The specific activity of both MAO increased from 18.6±0.6 at 1 week to 68.6 ±3.0 nmoles/mg protein/hr at 4 weeks for MAO-A and from 1.2±0.2 to 24.3±0.6 nmoles/mg protein/hr for MAO-B. The uptake capacity for [^{3}H]DA also increased during development reaching a plateau at 3 weeks. When the effect of MPTP and MPP^+ upon the DA neurons was examined, we observed that, contrary to our expectations, toxicity was diminishing during development. At on week in vitro, exposure to 5 µM MPTP for 4 days resulted in a 77% reduction of [^{3}H]DA uptake sites, while 1 µM MPP^+ during the same time produced a 93.8% reduction. In 2 week old cultures MPTP, under the same conditions, caused a 60.1% and MPP^+ a 52.3% reduction of DA uptake sites. The efficacy of the neurotoxins continued to decrease for the next 2 weeks and at 4 weeks MPTP caused only a 46.3% and MPP^+ 33.5% reduction of uptake sites. Intraneuronal accumultation of [^{3}H]MPP^+ increased during in vitro development. The decrease in toxicity was not associated with an increased storage capacity of the DA neurons. Supported by NIH grant NS-23017 and American Parkison Disease Association.

ENDOGENOUS MECHANISMS OF PROTECTION AGAINST CATECHOLAMINE TOXICITY IN RAT CEREBRAL CORTEX IN DISSOCIATED CELL CULTURE. S. Vasquez* and P. A. Rosenberg (SPON: S. Fischel). Dept. of Neurology, Children's Hospital and Harvard Medical School, Boston, MA 02115.

We have previously demonstrated the toxicity of norepinephrine (NE) and other catecholamines to both cortical neurons and glia in dissociated cell culture (J. Neurosci. 8: in press, 1988). This effect occurs at or above 25 uM NE, does not appear to be mediated by adrenergic receptors, and is blocked by catalase. Three types of cultures were used for experiments to be described, all derived from 16 day embryonic embryonic rats: 1) "immature" cultures used at 24 hours in vitro; 2) "mixed-mature" cultures comprised predominantly of astrocytes but containing c. 10% neurons, used at 4-8 weeks in vitro; 3) "neuronal-mature" cultures comprised of 70-90% neurons, used at 2-4 weeks in vitro. Cultures were exposed to NE for 72 hours. In immature cultures, vulnerability to toxicity of 25 uM NE was found to be highly dependent upon culture density. At 250 uM NE this effect of culture density was not demonstrable. In mixed-mature cultures, no evidence of toxicity could be demonstrated even at 250 uM NE. However neuronal-mature cultures were devastated by exposure to 25 uM NE. Further work will attempt to characterize the mechanisms of protection involved as well as their localization, developmental expression, and regulation. This work was supported by a Robert Morison Fellowship from the Grass Foundation, NS 00993, and CH MR Core HD 06276.

MEMBRANE COMPOSITION AND CELL SURFACE MACROMOLECULES III

508.1

THE ROLE OF NCAM IN GM1-MEDIATED NEURITOGENESIS. H.T. Safferstein* and F.J. Roisen (SPON: R. Dagirmanjian). Department of Anatomical Sciences and Neurobiology, School of Medicine, Univ. of Louisville, Louisville, KY 40292.

Exposure of the murine neuroblastoma cell line Neuro-2a to the ganglioside GM1 has been shown to facilitate neuritogenesis. The neurotrophic action of GM1 on Neuro-2a was characterized by assaying ornithine decarboxylase induction and neurite development with light and electron microscopy. Treatment of Neuro-2a with GM1 produced a redistribution of cytoskeletal components. In this study, the role of the neural cell adhesion molecule (NCAM) in GM1-mediated neuritogenesis was examined by determining the distribution of NCAM during several growth conditions. Fluorescent and electron microscopic immunolocalization of Neuro-2a cultures treated with exogenous GM1 revealed a redistribution of NCAM along the perikaryal and neuritic membranes. Neurites produced in response to serum deprivation or dibutyryl cAMP had a different NCAM distribution. Studies are in progress to identify the source of the newly distributed NCAM as well as the cytoskeletal components essential for the resultant redistribution. Supported by NIH grant NS24524.

ASSESSMENT OF THE BIOLOGICAL ROLE OF THY-1 BY MODIFICATION OF ITS EXPRESSION AND STRUCTURE IN TRANSGENIC MICE. R.J. Morris*[1], C.Mettling*[1], G.Raisman[1], M. Vidal*[2], F. Grosveld*[2] and F.L.Margolis[3], (SPON: P.Kirkwood), Norman & Sadie Lee Res.Ctr., Lab.Neurobiol.[1], & Lab.Gene Structure and Expression[2], Nat. Inst. Med. Res., London NW7 1AA U.K.; and Roche Institute of Molecular Biology, Nutley NJ 07110[3].

Thy-1, a major neuronal surface glycoprotein, is the simplest member of the immunoglobulin superfamily and is therefore thought to be involved in mediating, as yet undefined, cellular interactions in nervous tissue. The molecule appears on virtually all neurons after axonogenesis, with the notable exception of primary olfactory neurons. These cells have the unique ability in mammals to grow normally, and to regenerate, into adult CNS, a property reflected in their unusual interactions with glial cells on entering the olfactory bulb. Will the expression of high levels of Thy-1 on these axons affect these properties? We have constructed hybrid genes containing the Thy-1 protein coding region flanked by the regulatory elements of the olfactory marker protein gene which is uniquely expressed by the olfactory neurons. Transgenic mice have been produced with these constructs, and their pattern of expression, and its functional consequences, will be described. We have also demonstrated (Kollias,G. *et al.* Cell 51:21 1987) that ectopic expression of transgenic Thy-1 in non-neural tissue can cause transformation; we will describe alterations in the Thy-1 structural gene which affect this property.

508.3

CHARACTERIZATION OF ALLELIC FORMS OF 1B236/MAG IN MOUSE. L.H. Farber, C.Lai* and R.J. Milner. Research Institute of Scripps Clinic, La Jolla, CA 92037.

The protein 1B236 was originally identified by analysis of rat brain-specific cDNA clones and has been shown to be identical to myelin-associated glycoprotein (MAG). A single 1B236/MAG gene has been mapped, (D'Eustachio, P., et al., *J. Neurochem.*, 50:589, 1988; C. Blatt, personal communication), near the quivering locus on chromosome 7 of the mouse. Quivering is a recessive mutation in mouse that is characterized by a progressive instability of gait.

We have identified two forms of 1B236/MAG mRNA expressed in different mouse strains using RNase protection experiments. These probably correspond to allelic differences in the 1B236/MAG gene: one form was found in most mouse strains tested, while the second was detected only in DBA/2 and in quivering mice. Because the quivering mutation (*qv*-J) used in these studies arose in a DBA/2 strain mouse, the expression of the DBA/2 allele of 1B236/MAG in quivering mice, but not in the background strain (C3FeB6) for the mutant, suggests that the quivering and 1B236/MAG genes are very closely linked, if not identical.

The mapping data combined with the results of our RNase protection experiments have led us to investigate these allelic differences more thoroughly. We are using nucleic acid sequence analysis to compare 1B236/MAG cDNAs from DBA/2, C3FeB6 and quivering mice. Preliminary data has revealed differences in the sequences of the C-terminal regions. These studies may lend insight into the limits of structural variability allowable in the 1B236/MAG gene product. (Supported by a Fellowship from the National Multiple Sclerosis Society to L.H.F. and grant NS 20728 from NIH).

1B236/MAG EXPRESSION IN NEURONS C. Lai*, E.L.F. Battenberg, R.J. Milner, F.E. Bloom. Research Institute of Scripps Clinic, La Jolla, CA 92037

The rat protein 1B236 was isolated as a brain-specific gene product and has been shown to be identical to the myelin-associated glycoprotein (MAG). This protein exists in two forms, a longer form whose expression is maximal at approximately postnatal day 25, and a shorter form whose expression peaks at approximately postnatal day 60. We have previously observed 1B236 immunoreactivity in a subset of neurons in both adult and young rats (Bloom, F.E. et al., *J. Neurosci.* 5:1781, 1985 and Lenoir, D. et al., *J. Neurosci.* 6:522, 1986). Here we extend those analyses using antibodies generated against MAG to examine young (postnatal day 21) and adult (>3 months) rats as well as 75 day old mutant *quaking* (*qk*/*qk*) and normal background strain (B6C3Fe) mice. One rabbit polyclonal and two mouse monoclonal antibodies against MAG (gifts of R.H. Quarles, NINCDS) each show a pattern of immunoreactivity similar to that seen with the 1B236 anti-peptide antibodies used in the original surveys. All of these antisera recognize both oligodendrocytes and neurons and reveal a near coincident pattern of expression. In situ hybridization studies were conducted utilizing oligonucleotide probes that distinguish between the mRNAs encoding the two protein forms. Hybridization is observed to mRNA contained within oligodendrocytes and neurons in a pattern consistent with the immunohistochemical results. 1B236/MAG is believed to function as a cell adhesion molecule in oligodendrocytes; whether neuronal 1B236/MAG is involved in similar interactions remains to be established. Supported by NIH grant NS 20728.

CNS DISTRIBUTION OF MONOCLONAL ANTI-THY 1 ANTIBODY (OX7) AFTER SINGLE INTRAVENTRICULAR INJECTION. T.L. Davis and R.G. Wiley (SPON: P. Loosen) Lab of Experimental Neurology, VAMC, Nashville, TN 37212.

Thy 1 is a surface glycoprotein abundantly displayed on neurons and certain lymphocytes of adult rats. Previous studies have demonstrated neuronal uptake and axonal transport of the monoclonal anti-Thy 1 antibody, OX7, after intraparenchymal or subepineural injection. The present study sought to determine the anatomical fate and neurotoxicity of single intraventricular injections of OX7. 75 - 187 ug of OX7 dissolved in PBS were pressure microinjected (10 - 25 ul) into the left lateral ventricles of anesthetized adult, male Sprague-Dawley rats. After 1-4 d, rats were reanesthetized and transcardially perfused with 4% formaldehyde followed by 30% sucrose in phosphate buffer. 50 um frozen sections of brain and spinal cord were processed to demonstrate mouse IgG using rabbit anti-mouse IgG (Cappel) and biotin-avidin-peroxidase (Vector) with DAB as chromagen. All rats remained healthy after OX7 injections. Immunoperoxidase staining was present: 1 - in the head of the caudate nucleus at the injection site, 2 - superficially along ventricular surfaces, 3 - in the molecular and Purkinje cell layers of the cerebellar cortex, 4 - in the area postrema/nucleus tractus solitarius region of the dorsal medulla, and 5 - within motor neurons of the brainstem and spinal cord. Control rats injected with 200-500 ug of non-immune mouse IgG showed less intense staining than the lowest dose of OX7, particularly in the cerebellar cortex, in spite of the much larger dose. Most staining for OX7 was maximal with 24 hrs survival, although motor neuron staining intensity increased at longer survival times. These results are interpreted as indicating that limited neuronal uptake of OX7 occurs after single intraventricular injections and such injections are not neurotoxic. Chronic infusions and/or higher doses of antibody may be necessary to deliver OX7, or immunotoxins based on OX7, to CNS neurons other than cerebellar cortex. Staining of motor neurons and area postrema may represent systemic distribution of antibody. (This work supported by the Veterans Administration.)

PURIFICATION OF NEURON-SPECIFIC ANTIGENS FROM ZEBRAFISH. M.B. Bass* and M. Westerfield (SPON: W. Metcalfe). Institute of Neuroscience, University of Oregon, Eugene, OR 97403.

Two monoclonal antibodies that recognize antigens on surfaces of specific subsets of neurons in developing zebrafish have been selected for studying mechanisms of neurogenesis.

The Zn-5 antibody labels secondary motoneurons in the spinal cord as well as subsets of cells in the hindbrain. The antigen, recognized by this antibody, has been affinity purified and appears as a band of 75 kDa on a Western blot. The antigen is highly expressed in developing zebrafish, reaching maximal expression at 3 to 4 days after fertilization. Expression then decreases rapidly and by 14 days is extremely low. This temporal pattern of expression correlates with the time these neurons are extending axons and making synapses.

The Zn-12 antibody labels sensory neurons quite specifically in early development but later recognizes nearly all neurons. Affinity purification yields a major band at 65 kDa on a Western blot, although an extremely heterogeneous band is labelled in adult brain extracts with a range of molecular weights from 65 to more than 200 kDa.

Supported by NIH grant HD 22486.

NCAM REGULATION IN MUSCLE CULTURED IN SERUM-FREE DEFINED MEDIA. J.M. Lyles and C.L. Weill. Dept. of Neurology, LSU Medical Center, New Orleans, LA 70112.

Chemically defined media (CDM) are useful in cellular regulation studies since variations in serum or chick embryo extract (CEE) are eliminated. Two such systems which we developed for chick muscle culture were 5% adsorbed horse serum(aHS)/CDM on collagen matrix and serum-free(SF)-CDM on basement membrane protein matrix. In both systems, cultures developed as large, multi-nucleated, cross-striated myotubes that occassionally contracted. Standard myotube culture media (5%CEE/10%HS/MEM) initially produced straighter, narrower myotubes; after 2 weeks in vitro they appeared similar to SF-CDM cultures. Relative NCAM levels increased 2 to 3 fold during development, from low levels in myoblasts, to peak levels of 400mOD/ug protein (in our ELISA) at myotube day 5-7; subsequently, relative NCAM levels plateaued or decreased slightly due to increasing total protein. NCAM was quantified in primary fibroblast cultures and was present at 10-20% the level in day 5 myotubes. Relative NCAM levels were slightly higher in myotube cultures in 5%aHS/CDM or SF-CDM, as compared to CEE/HS/MEM, probably due to the more rapid disappearance of fibroblasts. The SF-CDM system will be employed to study regulation of NCAM by a variety of biological agents, such as hormones, peptides and other regulatory factors. Supported by NIH grant NS25298-01.

508.8

RPE CELLS ARE LABELLED BY THREE UNIQUE MONOCLONAL ANTIBODIES AND BY ANTIBODY AGAINST LAMININ RECEPTOR. J. M. Neill, J. R. Sparrow, and C. J. Barnstable. Rockefeller Univ., N. Y., N. Y. 10021, and Dept. of Ophthalmol., Yale Univ. Sch. of Med., New Haven, CT 06510.

Retinal pigment epithelial (RPE) cells, derived from the optic cup neuroepithelium, play an important role in metabolite transport, phagocytosis of rod outer segments, and neural retina adhesion. Several monoclonal antibodies directed against RPE (RET-PE3, PE4, and PE5) were derived using a crude rat RPE membrane preparation as the immunogen. Both PE3 and PE4 stained the apical and basal regions of the RPE cell layer most heavily in frozen sections of PN 10 rat eyes, with some specular staining of the cell bodies. The basal region of RPE was stained by PE5, as were vascular structures, indicating binding of a basement membrane (BM) component. Staining patterns on cultured RPE cells showed differences between antibodies: PE3 gave a centrally localized specular pattern at 2 days in culture that was lost after one week in vitro; PE4 stained small, circular, granular bodies adhering to the RPE monolayer at both 2 and 7 days in vitro; and PE5 did not label RPE cultures at either time in vitro. Since adhesion to the extracellular matrix is one way in which RPE cells establish their characteristic polarity, the expression of laminin and laminin receptors was studied in vivo and in vitro. Sections of PN4 and adult rat eyes, stained with either rabbit antisera to laminin or to laminin receptor (gift of L. Liotta), showed codistribution: the receptor localized to the basal RPE surface, while laminin was present in the RPE BM. E16 eyes also showed staining for laminin but not for laminin receptor. RPE cells cultured up to 3 weeks do not label for laminin but do label with laminin receptor antiserum, producing a diffuse, specular central patch of staining. Supported by EY05206.

FLUORESCENCE-ACTIVATED FLOW CYTOMETRIC ANALYSIS OF MAJOR HISTOCOMPATIBILITY (MHC) CLASS I ANTIGEN EXPRESSION ON NEURAL CELLS FROM THE DEVELOPING HUMAN NERVOUS SYSTEM. B. A. Boyer* and B. Wigdahl (SPON: R. J. Ziegler). Department of Microbiology, The Pennsylvania State Univ. Col. of Med., Hershey, PA 17033.

The MHC class I antigens expressed on most nucleated cells in humans are essential for reactions of immune recognition. In particular, MHC class I antigens in conjunction with viral antigen are recognized by human cytotoxic T lymphocytes, resulting in destruction of virus-infected cells. Previous studies with central nervous system (CNS) material have demonstrated low levels of antigens encoded by the MHC. As previously observed in the development of many human tissues, MHC class I expression has been shown to be more prevalent in adult CNS tissue. Current studies are investigating the expression of MHC class I antigens in the developing human peripheral nervous system utilizing neural cell populations obtained by enzymatic dissociation of the dorsal root ganglia with associated peripheral nerves after removal from aborted human fetal specimens. Fluorescence-activated flow cytometric analysis was performed on live human fetal neural cell populations using a primary monoclonal antibody specific for the heavy chain of the HLA-ABC. MHC class I antigen expression was examined between the gestational ages of 12 and 16 weeks. These studies have indicated that the number of HLA-ABC antigen-positive cells varied between 59 and 87% in tissue isolated between 12 and 16 weeks gestation. In parallel studies, we examined the fetal DRG cell population using the A2B5 monoclonal antibody which reacts primarily with the GQ ganglioside of neurons in fetal DRG. These studies have demonstrated a 20-30% reduction in the number of A2B5-positive cells between 12 and 16 weeks gestation. The differential expression of MHC antigens on the surface of glial and neuronal cells in the developing human nervous system may be important in determining susceptibility to virus infection.

508.10

IMMUNOREACTIVITY TO ANTI-SYNAPTIC VESICLE PROTEIN IN THE RETINA AND PARIETAL EYE OF A LIZARD. G. A. Engbretson and M. A. Ringwood*. Institute for Sensory Research, Syracuse University, Syracuse, New York 13244.

The parietal eye and retina are two distinct vertebrate photoreceptive organs which display some structural and functional commonalities.

Retinal and parietal eye tissues were examined for immunoreactivity to anti-synaptic vesicle protein antibodies†. The antibodies label a 36 kDa protein (SVP-36) from the synaptosomal fraction of guinea pig cerebrum and they have been seen to label synaptically associated structures in several vertebrate classes.

In the retina the immunoreactivity was heavy in the inner plexiform layer (IPL) with distinctive banding in sublayers 2, 4, and 5. Labeling was also found surrounding most of the cells near the IPL-inner nuclear layer boundary, probably amacrine cells. Very light labeling was found in the outer plexiform layer (OPL) and was mostly restricted to a thin layer where the OPL and the horizontal cells meet. Some immunoreactivity was localized in patches in the optic nerve fiber layer. In the parietal eye the immunoreactivity was similar in density to the retinal OPL labeling though not layered in any discernable pattern.

The immunoreactivity to anti-SVP-36 is to be expected in the IPL of the retina. Electron micrography showed a high density of synaptic junctions there. However, the greatest density of synaptic vesicles in both the retina and parietal eye was seen in the photopreceptor synaptic terminals, where anti-SVP-36 immunoreactivity is sparse. Evidently synaptic vesicles from photoreceptors differ in composition from those in neurons of the IPL.

†We thank Dr. K. Obata for his generous gift of antibodies.

Supported by NIH grant EY-03359.

CONNEXIN$_{43}$ IN BRAIN AND BRAIN CELL CULTURES. R. Kadle*, R.E. Fellows[1] and B.J. Nicholson*. (SPON: M.S. Hudecki) Dept. of Biol. Sci., SUNY, Buffalo, NY 14260 and [1]Dept. of Physiology & Biophysics, Univ. of Iowa, Iowa City, IA 52242.

Multiple variants of gap junction proteins called Connexins (Cx) have been demonstrated in several tissues. The variants include Cx$_{32}$ and Cx$_{26}$ (the subscript referring to molecular weight in kD) first detected in liver, and Cx$_{43}$ first detected in heart. Previous studies from our laboratory as well as others have demonstrated the presence of Cx$_{32}$ and Cx$_{26}$ in adult rat brain, specifically in cerebellum. The present study was carried out to investigate the presence of Cx$_{43}$ in adult rat brain and in cells cultured from fetal rat brain. Neuronal and astroglial cultures prepared from 18-day fetal telencephalon and newborn cerebral cortex respectively were maintained in a serum-free defined medium. A polyclonal anti-peptide antibody to the first 20 N-terminal amino acids of Cx$_{43}$ was affinity purified using the synthetic peptide. SDS PAGE and western blotting of homogenates indicated the presence of a 38 and 40 kD proteins in brain homogenates compared to 38 and 43 kD proteins in heart homogenates. Although both 38 and 40 kD bands were observed in astroglial and neuronal cultures, the latter was markedly more prominent in glial cultures. Degradation products of identical MW were seen in both heart and brain homogenates. These results indicate the presence of proteins related to Cx$_{43}$ in adult and fetal brain and suggest that gap junctions may play a role in the development and regulation of CNS function. Supported by NIH grants HL37109-03 (BJN) and ROI NS24629-02 (REF).

REGULATION OF SCHWANN CELL SURFACE NERVE GROWTH FACTOR (NGF) RECEPTORS BY NEURONAL MEMBRANES. P.S. DiStefano and D.M. Chelsea*. Neuroscience Research Division, Pharmaceutical Discovery, Dept. 47W, Abbott Laboratories, Abbott Park, IL 60064.

Schwann cells isolated from rat sciatic nerve express high levels of NGF receptors when maintained in primary tissue culture. Experiments were carried out to examine the ability of neurons or neuronal membranes to regulate Schwann cell NGF receptor number when co-cultured with Schwann cells. Mouse superior cervical ganglion (SCG) neurons were co-cultured with rat Schwann cells for 1 wk. Schwann cells were assayed for NGF receptors using a 2-site immunoassay specific for rat NGF receptors. Mouse SCG neurons induced Schwann cell proliferation followed by down-regulation of Schwann cell NGF receptor binding. The degree of receptor down-regulation was dependent on the number of neurons co-cultured with Schwann cells. Crude membranes prepared from postnatal day 7 (P7) mouse sciatic nerve or spinal cord also caused proliferation and down-regulation of Schwann cell NGF binding after 3 days of co-culture. Membranes from P7 cerebellum, cerebral cortex, or liver had no receptor regulating activity. Membranes from P0, P14 and adult mouse spinal cord were also effective in regulating Schwann cell NGF receptor number. Preliminary experiments showed that receptor regulating activity was solubilized from spinal cord membranes with Triton-X-100 and that upon boiling the extracts activity was lost. These results show that an NGF receptor regulating activity is found in axon-rich preparations from the both the central and peripheral nervous systems.

MACROMOLECULAR STRUCTURE OF AXON MEMBRANE FROM md AND md HETEROZYGOTE OPTIC NERVES. J.A. Black, I.D. Duncan[1], S.G. Waxman, B.R. Ransom and K.F. Jackson*[1]. Dept. of Neurology Yale Univ. Sch. Med. and V.A. Med. Ctr., West Haven, CT 06516, and [1]Dept. of Medical Sci., Sch. Vet. Med., Univ. Wisconsin, Madison, WI 53706.

Myelin deficient (md) rat is a sex-linked trait which causes hypomyelination within the CNS. Female heterozygotes (mdH) exhibit CNS myelin mosaicism. As part of a study to examine the influence of glia on axon membrane structure, axolemma from md (25 d) and mdH (15 mo) optic nerve (ON) was investigated with freeze-fracture EM.

Mean$\pm$SD intramembranous particle densities for md and mdH amyelinated and mdH myelinated axons are:

Condition	PF	EF
md - pooled amyelin.	1549$\pm$572.0	177$\pm$84.3
- <.4 um dia.	774$\pm$133.4	172$\pm$22.5
- .4-.59 um dia.	1563$\pm$464.5	190$\pm$104.7
- >.6 um dia.	1886$\pm$710.1	144$\pm$32.2
mdH - pooled amyelin.	1290$\pm$518.0	155$\pm$68.5
- <.4 um dia.	753$\pm$355.7	168$\pm$43.1
- .4-.59 dia.	1459$\pm$374.9	161$\pm$72.5
- >.6 um dia.	1603$\pm$432.1	140$\pm$78.9
mdH - internode	1755$\pm$557.4	158$\pm$36.6

These data indicate that amyelinated axon membrane from md and mdH ON display similar ultrastructure, and that larger diameter (>.4 um) md and mdH amyelinated axons exhibit membrane structure similar to internodal membrane. Supported in part by grants from NIH, NMSS and VA

HIGH AFFINITY CHOLINE UPTAKE OF HIPPOCAMPAL SYNAPTOSOMES IN RESPONSE TO ENDURANCE TRAINING IN YOUNG AND OLD RATS

D.E. Fordyce* and R.P. Farrar (SPON: E. Barr). Dept. of Kinesiology and Inst. for Neurological Sci. Res., University of Texas at Austin, Austin, Texas 78712

Aging has been associated with a progressive decline in hippocampal cholinergic function. Endurance exercise has been shown to modify characteristics of brain neurons and their receptors. Due to the involvement of the hippocampus in initiation and control of voluntary movement as well as memory, it was of interest to determine whether endurance exercise would alter acetylcholine metabolism of the hippocampus in young and old animals. High affinity choline uptake, the rate limiting step in acetylcholine synthesis, was determined in synaptosomes of the hippocampus of endurance trained rats and their age matched sedentary controls. Male F344 rats were run on a treadmill for 6 months for 30 min./day at a speed of 20 m/min. Young rats, originally at 6 months of age, and old rats, originally at 19 months of age were killed by decapitation at 12 months and 25 months of age, respectively, and the synaptosomes of the hippocampus isolated. The high affinity choline uptake was determined by incubating the synaptosomes with 0.75µM (1.92µCi) 3H-Choline in both a sodium containing and sodium-free medium. Comparison of synaptosomes of untrained, young and old rats showed a 35% ($p<.05$) reduction in high affinity choline uptake which is consistent with previous reports of an age related reduction of cholinergic function. The synaptosomes of young trained rats demonstrated a 29% ($p<.02$) reduction (15.3 pmoles/mg vs. 10.8 pmoles/mg) in high affinity choline uptake. This reduction indicates alterations in presynaptic cholinergic function which may influence cholinergic synaptic transmissions and/or acetylcholine turnover. Old trained rats showed no significant difference from their age matched controls indicating a loss of synaptic adaptability in aged animals.

ENDURANCE EXERCISE ALTERS NMJ MORPHOMETRY IN C57BL/NNia MICE GLUTEUS MAXIMUS MUSCLE DURING AGING.

M.H. Andonian, D. Weese And M.A. Fahim. USC Andrus Gerontology Center, Los Angeles, CA 90089-0191.

Previous studies indicate that exercise modulates age-related changes in the neuromuscular junction, and that tonic muscles are less affected by endurance training (Andonian & Fahim, J. Neurocyt. 16, 589-99, 1987). To further study these phenomena, the effects of age and endurance exercise on the morphology of ZIO-stained gluteus maximus NMJs from 12, 18, 24 month old C57BL/NNia mice were assessed under identical conditions. This muscle is recruited to maintain posture and for locomotion. It is predominantly slow-twitch, but is a mixed muscle in the mouse.

Animals were exercised at 26-28 m/min for 60 min/day 5 days/wk for eight weeks. Camera lucida drawings made from ZIO-stained NMJs of control and exercised gluteus maximus fibers from 12, 18, 24 months were measured using a computer-aided morphometry package. Repeated-measures multivariate analysis of covariance was used to test for differences in nerve terminal area, perimeter, and extent length between ages and test conditions.

There were no significant changes in nerve terminal area between 12, 18, and 24 months of age, although qualitatively there was an upward shift in distribution of the morphometric parameters with age. Nerve terminal perimeters and lengths were significantly larger at 24 months than 12 and 18 months, with 18 month values being smaller than 12 month data. This is similar to age-related elaboration observed in slow-twitch muscle, but is of lower magnitude than fast twitch muscle. At 12 months, exercised nerve terminals were larger than controls, while at 18 months they were smaller. This data is similar to that previously observed in the soleus and EDL. However, the areas and lengths of the exercised 24 month animals were larger than controls, although the perimeters did not change. These data indicate that exercise does modulate the morphology of the NMJ, however the magnitude and direction are dependent on age, fiber type and other factors.

AGE-RELATED CHANGES IN α_1-ADRENERGIC RECEPTOR DENSITY IN RAT BRAIN: SCATCHARD ANALYSIS USING QUANTITATIVE AUTORADIOGRAGHY.

D.M. BURNETT and N.R. Zahniser Dept. Pharmacology, Univ. Colorado Hlth. Sci. Ctr., Denver, CO 80262.

It is well documented that the electrophysiological responsiveness of the CNS to noradrenergic stimulation is diminished with aging. To determine whether receptor changes accompany this diminished responsiveness, we have studied the effects of aging on the density of α_1-adrenergic receptors (AR's) in circumscribed areas of the rat brain using computer-assisted quantitative autoradiography. Sagittal sections of Fischer 344 rat brain were prepared from three aged groups: 4-5, 16-18 and 24-28 months. Saturation curves were generated using 1-200 pM [^{125}I]BE-2254 (IBE) , an α_1-selective antagonist. Nonspecific binding was defined with 1 µM prazosin. Specific IBE binding in discrete brain areas was normalized by measuring corresponding protein levels with a densitometric imaging assay. Scatchard analysis revealed signifigant age-related decreases in the density of α_1-AR's in the thalamus and olfactory tubercle, but not in cortex, striatum, hippocampus, cerebellum or brain stem. In the thalamus Bmax= 1067 ±88 fmol/mg protein at 4 months of age vs 771 ±118 fmol/mg protein at 24-28 months. In the olfactory tubercle, corresponding values were 425 ±38 vs 249 ±48. No affinity changes were found. Preliminary data suggest that signifigant decreases in the number of α_1-AR's are also evident by 16-18 months of age. These studies found that with aging, decreases in the number of central α_1-AR's are not ubiquitous but are confined to specific areas. Supported by USPHS AG-04418 and the PMA Foundation.

CYTOSOLIC CALCIUM CONCENTRATIONS IN CORTICAL SYNAPTOSOMES OF AGING RATS.

L. Giovannelli and G. Pepeu*. Dept. of Pharmacology, Florence University, 50134 Florence, Italy.

Cytosolic calcium concentrations were measured in purified synaptosomes from the cerebral cortex of 3,16 and 24 month old male Charles River Wistar rats, by the Quin-2 technique. Electron microscopy examination of the synaptosomes revealed a 15% contamination by mitochondria. Synaptosome samples were incubated at 37 °C in oxygenated medium, pH 7.4, and loaded with 20-30 µM Quin-2AM for 15 min. After dilution, centrifugation and resuspension of the samples, readings were made in a Perkin Elmer spectrofluorimeter. Neither calcium concentration at rest (124±6 nM) nor the increase after potassium (50 mM) depolarization was modified by age. The calcium load following depolarization was cleared in about 13 min in 3 month old rats. The rate of clearance was significantly slower in 24 month old rats. The addition of verapamil (60 uM) or nimodipin (10 uM) after depolarization restored calcium concentration to resting level in aged at the same rate as in young rats. An increase in calcium influx mediated through L channels may therefore be responsible for the slower clearance of calcium load in aged rats. Work supported by a CNR grant.

509.5

EXTREME SHIFTS IN CHOLINE UPTAKE AND ACETYLCHOLINE TURNOVER CONSISTENT WITH INTEGRITY OF PHYSIOLOGIC REGULATORY MECHANISMS DURING AGING.

D.O. Smith and M.R. Chapman*. Dept. of Physiology, Univ. of Wisconsin, Madison, WI 53706.

Uptake of labeled choline and its incorporation into ACh were assayed at the neuromuscular junction of the extensor digitorum longus muscle of rats aged 11 and 27 months. Under resting conditions, ACh levels per nerve terminal were 72% higher in the aged animals. However, the specific activities of ACh and choline were nearly 10-fold higher in the 11-month animals, indicating negligible uptake of labeled choline in the older animals. During nerve stimulation (1 Hz), the amount of labeled choline incorporated into ACh was 150% greater in the aged animals, although total ACh content decreased by about 60%. The specific activity of ACh released during stimulation was significantly greater in the 27-month animals, but the amount released did not change appreciably with age. These results suggest that elevated ACh levels in the aged animals (due to much reduced quantal release) inhibit choline uptake under resting conditions. During nerve stimulation, significantly more choline from extracellular sources thus enters the ACh synthesis pool in the older animals. These shifts are consistent with intact physiologic regulatory mechanisms during aging. Supported by NIH grant AG01572.

AGING AND MUSCARINIC RECEPTOR SUBTYPES: AUTORADIOGRAPHIC ANALYSIS IN RAT AND HUMAN BRAIN.

A. Biegon, B. Earley*, M. Hanau*, and M. Segal; Weizmann Inst. Sci., Rehovot, Isr.

As a step towards the characterization of age effects on the cholinergic system, we compared the distribution of muscarinic M1 and M2 receptors in brains from young and old subjects, using quantitative in vitro receptor autoradiography. Twenty four drug and pathology free human brains (age range 17 to 81 years) were collected at autopsy from the medicolegal institutes in New York and Jaffa. Seven young (4 months) and 6 old (28-31 months) rats were also used. Brains were frozen in powdered dry ice. M1 and M2 receptors were labeled on coronal, 30 or 40µ cryostat sections using 1nM 3H-QNB (N.E.N., s.a.24.3Ci/mmole) in the presence of 100µM carbachol or 200nM pirenzepine respectively. Non specific binding was assessed in the presence of 1µM atropin. The autoradiograms were analyzed by an IBM PC based computerized image analysis system. A pattern of anatomically selective, age related decreases in M1 and M2 receptors was observed in both human and rat. M1 receptors were significantly decreased (10-30%) in cortex striatum and several subregions of the hippocampus. M2 receptors in cortex and striatum were decreased, while hippocampal receptors were not. A large decrease (more than 50%) in M2 receptors was observed in the substantia innominata and other ventral forebrain cholinergic nuclei. The location and size of the age-related changes were similar in human and rat.

509.7

Age-Related Electrophysiological Changes in Cerebellar Noradrenergic Receptors. K.D. Parfitt*, R. Freedman and P. Bickford-Wimer (SPON: L. Adler). Depts. of Pharm. & Psych., Univ. of CO Health Sci. Ctr. and VAMC, Denver, CO 80262.

Previous investigations have shown deficiencies in noradrenergic transmission in the central nervous system of aged laboratory animals. In particular, subsensitivity to locally-applied norepinephrine has been observed when recording extracellularly from cerebellar Purkinje neurons of aged rats. In young rats alpha$_1$, alpha$_2$ and beta adrenergic receptors are present and functional in the cerebellar cortex. It was the purpose of this study to determine which, if any, of these receptor subtypes show altered responses with age. The ability of selective noradrenergic agonists to inhibit the spontaneous activity of Purkinje neurons was compared in young (3-mo.) and aged (18- and 28-mo.) F344 rats. Drugs were applied to Purkinje cells by pressure micro-ejection from multibarreled micropipettes and a paired-pipette paradigm was used to compare the potency of each pipette in young and aged rats. Purkinje cells of young rats were significantly more sensitive to locally-applied isoproterenol, a beta-adrenergic agonist, than Purkinje cells of both of the older age groups. Subsensitivity to the alpha$_1$ agonist phenylephrine and the alpha$_2$ agonist clonidine was not observed in the aged rats. These results suggest that postsynaptic sensitivity to beta-adrenergic agonists decreases with senescence, whereas postsynaptic sensitivity to alpha$_1$ and alpha$_2$ agonists does not change. Work supported by USPHS Grant AGO4418 and the VAMRS.

NEUROMOTOR COORDINATION MECHANISMS AND AGING. N.C. Rich. PHS Dept., Miami Univ., Oxford, OH 45056

The purpose of this investigation was to examine neuromotor coordination mechanisms in young and old males during ballistic forearm flexion and extension tasks. The subject sample included 16 males in each of the following groups: (1) 30-40 years old, (2) 50-60 years old, and (3) 61-70 years old. The IEMG patterns of the biceps brachii (agonist) and triceps brachii (antagonist) muscles were recorded during unresisted and resisted trials. Sixteen temporal and ten quantitative parameters were examined to evaluate between group differences. The parameters which exhibited significant differences between groups were: (1) agonist first burst silent period, and, (2) accuracy. In addition, age-related trends were found to exist for the following parameters: (1) movement time, (2) agonist and antagonist first burst motor time, (3) antagonist second burst duration, (4) agonist first burst IEMG slope, (5) antagonist second burst time to peak activity, (6) time to maximum acceleration, (7) agonist first burst and antagonist second burst peak amplitude, and (8) acceleration as a percentage of movement time. For forearm flexion strength groups 2 and 3 were 74.15% and 74.15% as strong as group 1, respectively. For forearm extension strength, groups 2 and 3 were 89.12% and 83.90% as strong as group 1, respectively. The data indicate that while loss of strength is indeed a true concomitant of the aging process, an individual's muscle patterns remain relatively stable into their seventh decade.

DIFFERENTIAL INFLUENCE OF THE MEDIAL SEPTUM ON CA1 "PLACE" CELLS AS A FUNCTION OF AGE. S.J.Y. Mizumori, C.A. Barnes, and B.L. McNaughton, Dept. Psychology, Univ. Colorado, Boulder, Colorado 80309.

To examine the effects of aging on septal modulation of the behavioral correlates of different hippocampal cell types, 4 young (11 mo) and 4 old (25 mo) Fischer-344 rats were trained to perform a working memory task on an 8-arm radial maze. Dorsal hippocampal neurons were recorded using stereotrodes (McNaughton, et al., J. Neurosci. Meth.,1983) mounted on moveable microdrives. A guide cannula was also implanted to permit local application of 2% tetracaine into the medial septum. When hippocampal units were encountered, the unit-behavior correlate was characterized during the first 5 trials of a recording session. The septum was then reversibly inactivated via tetracaine injection (0.5 µl). Post-injection behavioral performance and unit activity were monitored for an additional 10 trials.

Following septal inactivation, place-specific firing was maintained in 91 % of the CA1 "place" cells (N=22) from young rats, in spite of severely impaired performance on the maze and a dramatic reduction in activity of 64% of dentate gyrus cells (N=50), which include hilar "place" cells, basket and granule cells (also reported by Mizumori et al., Soc. Neurosci. Abst., 1987). In contrast, only 25% of CA1 "place fields" (N=24) from old rats were maintained during the period of behavioral impairment. Similar to young rats, 75% of dentate cells from old rats (N=57) showed reduced firing after tetracaine injection. These findings suggest at least the following two possibilities: 1) the inputs to CA1 "place" cells from within the hippocampus are more highly distributed in young rats than in old rats, and/or 2) direct inputs from entorhinal cortex to CA1 maintain place fields in young, but not old rats.

AGE - RELATED DECREASE IN PERFORANT PATH EVOKED SPIKE FACILITATION IN RAT FASCIA DENTATA E.J. Green, C.A. Barnes and B.L. McNaughton, Department of Psychology, University of Colorado, Boulder, CO 80309.

Prestimulation of the perforant path (pp) at short intervals inhibits subsequent pp-evoked granule cell discharge (spike inhibition) by activating feedforward and feedback inhibitory processes. At longer intervals such prestimulation produces a net increase in granule cell excitability (spike "facilitation"), the mechanism of which is not well understood. Spike inhibition and facilitation appear to result from the interaction of two distinct (inhibitory and facilitatory) processes which can vary independently of one another (Green et. al.,Soc. Neurosci. Abstr.,1987). Furthermore, animals walking on a treadmill exhibit robust increases in spike facilitation relative to when they are still; these differences are not a consequence of granule cell discharge, or of changes in the amplitude of the EPSP. Walking does not appear to affect inhibition elicited by pp stimulation, but does have a substantial influence on the late increase in granule cell excitability which follows pp stimulation (Green et. al., ibid).

Paired-pulse inhibition and facilitation were evaluated over a range of inter-stimulus intervals (20-200 msec) in young (10-14 month) and old (22-26 month) rats walking on a treadmill or sitting quietly in the same apparatus. Young and old rats exhibited comparable levels of spike inhibition at very short ISIs. At longer ISIs, however, old rats showed significantly less spike facilitation than young rats. These results suggest that there is an age-related decline in a process which acts to increase granule cell excitability following activation of the perforant path. DIETARY ACETYL-L-CARNITINE IMPROVES SPATIAL BEHAVIOR OF OLD F-344 RATS. C.A. Barnes, A.L. Markowska*, C. J. Elkins*, J. Kaufman*, & D. Olton. Univ. Colorado, Boulder, CO, 80309, & Johns Hopkins Univ., Baltimore, MD 21218.

Acetyl-L-Carnitine (AC), a natural component of mammalian tissue, plays an essential regulatory role in fatty acid oxidation (Bremmer, 1977). While the highest levels of AC in the body are found in muscle and heart, a metabolic pool of carnitine also exists in the central nervous system (Shug et al., 1982). A number of pharmacological properties of AC suggest its possible efficacy in attenuating age-related neural deficits. These include the observations that AC has cortical cholinomimetic properties (Falchetto et al., 1971), it increases cerebral glucose utilization (Fariello et al., 1986) and free radical scavengers (Ferraro et al., 1986). Furthermore, chronic treatment with AC slows the occurrence of morphological changes that normally occur in hippocampus of old rats (Angelucci et al., 1986), and improves spatial orientation in a circular water pool task (Ghirardi et al., 1986).

The present experiment was designed to replicate, and to extend the observations regarding the attenuation of spatial memory deficits in old rats. Thirty F-344 rats were obtained at 16 mo of age in each of two separate laboratories. Half of the animals received 75 mg/kg AC in their drinking water for six months prior to the initiation of behavioral testing on the Barnes circular platform task (8 young control animals were also included in one laboratory). In this task the animals must learn the spatial location of a hidden escape tunnel that remains fixed beneath one of 18 holes on the periphery of the platform surface. Animals were given one trial per day for 16 days with the goal in one position. The young control and old AC animals made statistically fewer errors by the end of training than did the old control rats: On day 17 the goal was changed to a different spatial location. Both the old AC group and the young controls made significantly more errors than the old control animals in the initial reversal trial, indicating better retention of the original correct location. When the ratio was taken of asymptotic performance on the regular trials to the first reversal trial, a significant main effect of Groups was found ($p < .006$). The old AC animals were significantly different from the old controls, but not from the young controls. These data suggest that dietary AC may be effective in attenuating certain cognitive impairments occurring during the process of normal aging. Supported by Sigma Tau Corp.

A LIFESPAN STUDY OF HIPPOCAMPAL NEURONAL RESPONSIVENESS TO IONTOPHORETIC APPLICATION OF *L*-GLUTAMATE *IN VITRO*. G. Rao, C. A. Barnes, B. L. McNaughton, and C. Stengel*. Department of Psychology, University of Colorado, Boulder, CO 80309, and Brainwave Systems Corp., Broomfield, CO 80020.

Barnes and McNaughton (J. Physiol. 309: 473, 1980) observed an increase with senescence of the ratio of EPSP to presynaptic fiber potential in granule cells of the fascia dentata *in vitro*, suggesting that in spite of the overall loss of afferent fibers, perforant path synapses were on average slightly stronger in old animals. In addition, an increase in the ratio of population spike to synaptic response was seen in the older animals, suggesting an increased excitability of the postsynaptic neurons. As a continuation of these studies, we have investigated the effects of aging on extracellularly recorded single unit discharge following iontophoretic application of *l*-glutamate in the three principal hippocampal subfields *in vitro*.

A total of 354 FD, 307 CA1, and 298 CA3 cells were studied from 30 animals with ages distributed uniformly between 7 and 26 months. Single units were recorded with glass-filled pipettes (7-10 micron tip diameter) filled with 0.2 M *l*-glutamic acid in calcium-free Ringer's solution. Glutamate application consisted of ten 10 second negative current pulses (7.4 nA) separated by 15 seconds each. Average firing rates were computed during the 10 seconds prior to the glutamate applications and the 10 seconds during them. Glutamate effects were assessed by computing the difference in firing rate between glutamate application and control conditions divided by their sum. Glutamate application produced a substantial increase in firing rate in all three areas. However, there was no significant linear regression on age of either the spontaneous background activity or the relative elevation of firing rate during glutamate activation.

We conclude that aging does not lead to any substantial alteration in the sensitivity of hippocampal neurons to exogenously applied glutamate.

AGING ELIMINATES THE DIURNAL RHYTHM AND DEPRESSES THE DENSITY OF ALPHA-1 RECEPTORS IN SELECTED BRAIN AREAS. N.G. Weiland and P.M. Wise. Dept. Physiology, Univ. of Maryland, School of Medicine, Baltimore, MD 21201.

The densities of α_1-adrenergic receptors exhibit a diurnal rhythm in selected hypothalamic nuclei of ovariectomized (OVX) young rats. In intact rats at 1000h α_1 receptor densities increase or decrease with age depending on the brain region and/or reproductive status. We wished to determine whether the age-related changes in α_1 receptor densities result from shifts in the diurnal rhythm and/or occur independently of reproductive status. Utilizing autoradiographic procedures, we measured the density of α_1 receptors in young, middle-aged, and old OVX rats at various times of day. In the medial preoptic nucleus, the diurnal rhythm of the density of α_1 receptors was abolished in middle-aged rats, and receptor densities were decreased in old rats. In suprachiasmatic nucleus and ventral medial nucleus, α_1 receptor densities were suppressed in middle-aged rats, and a further decrease occurred in old animals. In median eminence α_1 receptor densities declined progressively and were significantly decreased in old rats. No age or time-associated changes in α_1 receptor densities occurred in lateral septum. The data demonstrate that during middle-age there is an initial loss of the diurnal rhythm in α_1 receptor densities followed by a progressive decline in α_1 receptor concentrations in older animals. CHANGES OF N TYPE CALCIUM CHANNELS DURING AGING R.M.Moresco*,S.Govoni*,O.Gandolfi+,F.Rossi*^, F.Battaini#, M.Trabucchi#.*. Dept. of Pharmacobiol., Univ. of Bari, +Inst.of Pharmacol. Univ. of Bologna,^Sci. Inst. Sanatrix,Venafro, #Chair of Toxicol. II Univ. of Rome, ITALY.

An age-related decrease in stimulated calcium uptake has been described in various brain areas (Gibson, Neurobiology of Aging, 8:328,1987).This observation suggests the existence of an altered functioning of potential-dependent calcium channels. Along this line we previously observed an aged-dependent decrease of dihydropyridine binding sites affinity and sensitivity to calcium (Brain Res.333:374,1985). The present work studies whether N type potential-dependent calcium channels labelled with (125)I-omega-CTx are modified in membranes prepared from cortex and hippocampus of old rats. In the cortex of aged rats we found a reduced omega-CTx binding (90.8±9.1 and 58.3±5.5* ($p<0.05$) f.moles/mg prot. for 3 and 24 month old rats respectively, using 10pM (125)I-omega-CTx). No significant changes were observed in hippocampus indicating an area selectivity of N channel impairment. On the other hand the observed changes in cortex may participate to the impairment of calcium uptake and neurotransmitter release observed in this brain area in aged rats.

THE EFFECTS OF AGING AND ETHANOL ON NEURONAL ELECTRIC MEMBRANE PROPERTIES. T.A. Bunting*, B.S. Scott. Zoology Dept. U of T, Surrey Place Centre, Toronto, ON. M5S-2C2, Canada.

Intracellular recordings were made from 825 freshly dissociated DRG neurons of young (12-16 wk), mid-aged (48-52 wk) and aged (101-105 wk) mice (C57BL/6NNIA2) in 3 ethanol concentrations [0.0%, 0.5% and 1.0% (v/v)]. A variety of electric membrane properties were determined quantitatively: Specific membrane resistance (RM), capacitance (CM), time constant (T), depolarization threshold (VRH) for action potential (AP) generation, AP duration (DT), AP overshoot (OS), rate of decay of afterhyperpolarization (AHP2), AP rise (RISE) and falling phases (FALL1 and FALL2 for APs with biphasic falling phases). Total neuronal surface area was also calculated. A two way ANOVA indicated no significant interactions between ethanol and age effects. Therefore, the results were pooled and % differences were calculated for control and experimental conditions. Significant ($p<.01$) differences between zero ethanol (n=329) and 1% (n=271) ethanol conditions included a 45.8% increase in VRH (decreased electrical excitability), 22.7% decrease in CM, 12.8% decrease in T and an 11.3% increase in RM. Also, DT decreased 3.7% but only at $p=.052$. Significant differences ($p<.001$) between the young (n=297) and aged (n=271) neurons included a 60.2% increase in AHP2 a 52.1% increase in OS, 27.6% increase in VRH and a 30.9% increase in DT (due to decreased RISE, FALL1 AND FALL2). RM increased 11%, CM decreased 11% and, in addition, a small (4.56%) decrease in surface area was noted. Both ethanol and aging caused a decrease in electrical excitability and capacitance and an increase in membrane resistance. However, whereas age increased AP duration, ethanol decreased DT. The direction of the age effects are similar to those observed using cell cultures (Scott and Lew, in press, 1988). Increased AHP duration was also reported in hippocampal slices in dentate granule cells (Landfield and Pitler, Science, 226, p. 1089, 1984). These findings suggest that aging may alter EMP in DRG in situ by prolonging the AP and AHP and decreasing electrical excitability. Supported by NSERC and OMHF.

ELECTROPHYSIOLOGICAL STUDY OF THE SUBSTANTIA NIGRA PARS COMPACTA NEURONS IN YOUNG AND AGED WISTAR RATS. PRELIMINARY RESULTS. M.A. Lavín and R. Drucker-Colín. Instituto de Fisiología Celular, UNAM, México.

The substantia nigra pars compacta (SNC) cells are involved in motor control. There is evidence indicating that some characteristics of SNC cells are altered in aged rats (McGeer, E. and McGeer, L. Ergot compound and Brain function. Ed. by Goldstein, 1980).

Male Wistar rats young (3 months old) and aged (20 month old) were anesthetized with halothane, tracheostomized and fixed to a stereotaxic apparatus. Extracellular activity was recorded using single glass capillaries filled with 2% pontamine blue in 0.5 M sodium acetate (8-16 Mohms). Tip positions were marked by ejecting the dye at the end of the experiment.

15 Cells was recorded in young rats with a frequency rate of 40.5 ± 23.4 spikes/10 sec. ($\bar{X}$ ± S.D.) and 7 cells in aged rats with a frequency rate of 31.2 ± 11.6 spikes/10 sec. Although there is not difference in the average frequency rate, there is a difference in the pattern of discharge. In aged rats almost all cells (71%) have a tendency to discharge in bursts of 3 spikes, sometimes alterned with a single spike. In young rats, 73% of the cells have a tendency to discharge in a single spike. This analysis and more recording of SNC cells are in progress.

A CORTICOSTEROID-SENSITIVE COMPONENT OF THE HIPPOCAMPAL CALCIUM-DEPENDENT AFTER-HYPERPOLARIZATION INCREASES WITH AGING. D.S. Kerr* and P.W. Landfield, Dept. of Phys. & Pharm., Bowman Gray Sch. Med., Winston-Salem, NC 27103.

Although the hippocampus is a major target structure for corticosterone (CORT), little is known about its neuronal effects (*cf.* McEwen, 1982). In addition to its presumed normal actions, CORT also appears to increase the rate of aging changes in the rat hippocampus (Landfield *et al.* 1981; Sapolsky *et al.* 1985). One clue to the effects of CORT may lie in findings that Ca-dependent processes are increased in aged hippocampus (Landfield, Pitler, *Science* 1984; *J. Neurophysiol.* 1986).

In the present studies, therefore, we examined a defined Ca-dependent membrane conductance, the Ca-dependent, K-mediated afterhyperpolarization ($AHP_{(Ca)}$) in young (4-7 mo.) and aged (24-27 mo.) adrenalectomized (ADX) and intact rats. In intracellular recordings from CA1 cells in hippocampal slices the $AHP_{(Ca)}$ was substantially reduced in ADX rats, in comparison to intact rats. This effect of ADX was more pronounced in the aged rats, and the previously-observed age-related increase in AHP duration (Landfield, Pitler, *ibid.* 1984) was therefore abolished by ADX. The AHP could be lengthened in ADX rats treated with injections of CORT prior to study.

These results suggest that an identified Ca-dependent membrane conductance is partially CORT-dependent and that the impact of CORT on this conductance increases dramatically with aging. Because excessive Ca influx has been implicated in cell death, these findings raise the possibility that increased CORT-dependent Ca influx may be a factor in accelerated neuronal deterioration with aging. (AG04542).

MERKEL CELL POPULATIONS OF THE FOLLICLE-SINUS COMPLEX IN THE RAT HAVE A TEMPORAL DEVELOPMENTAL GRADIENT. T.E. Jones* and B.L. Munger* (SPON: R.D. Hartman). Dept. of Anat., M.S. Hershey Med. Ctr., Penn. St. Univ., Hershey, PA 17033.

Previous work in our laboratory has suggested that the two populations of Merkel cells associated with a follicle-sinus complex develop sequentially. To test this, rat pups of different developmental stages were obtained from timed pregnancies. Trigeminal axons innervate the superficial dermis in the mystacial region on GD13.0-GD13.5. By electron microscopy, Merkel cells were first seen associated with the vertical row sinus hairs G and H on GD16.5, and were present in the neck region of the vibrissae. On GD17.5, this population had separated from the neck region and were present in the outer root sheath. On GD17.5, nerves from the superficial nerve plexus approached the developing follicle from a lateral direction. On GD18.0, Merkel cells were identified in the epidermal rete ridge collar. The data suggest that differentiation of Merkel cells occurs subsequent to sensory innervation in the outer root sheath and the superficial epidermis. The presence of two distinct populations of a single cell type developing along a temporal gradient within a single structure may indicate a difference in behavior or function of the two cell populations. Supported in part by USPHS Grant #NS19462.

510.2

NEURON-RECEPTOR CELL INTERACTION DURING DEVELOPMENT OF THE INNER EAR: A HETEROCHRONIC GANGLION STUDY, T. R. Van De Water* and V. Galinovic-Schwartz*, (SPON: D. Spray) Depts. of Otolaryngology & Neuroscience, Laboratory of Developmental Otobiology, Albert Einstein College of Medicine, Bronx, N.Y., 10461.

It has been proposed that inner ear sensory receptors produce attractant fields that guide neurite outgrowth from the statoacoustic ganglion (SAG) to appropriate target sites within the developing labyrinth (Van De Water & Ruben, Acta. Otolaryngol. 95:470, 1983). This experiment tests the temporal limitations of the SAG in its ability to respond to these attractant fields. Statoacoustic ganglia were excised from 12, 13, 14 and 15 gestation day (GD) mouse embryos. This temporal series of SAG were implanted into explants of 12 GD inner ears, that had their SAG extirpated prior to implantation. All cultures were grown for six days in vitro, then fixed and processed for nerve fiber staining. Specimens were evaluated for the presence of neurites projecting from the implanted ganglia to inner ear sensory receptors that developed within the 12 GD otic explants. All of the implanted heterochronic SAG (i.e. 13, 14 or 15 GD SAG/12 GD OTOCYST) as well as the control homochronic ganglia extended neurities to sensory epithelium of both vestibular and auditory character. Neurites made contact with the bases of the hair cells in all of the sensory structures studied. These findings demonstrate that SAG neurons are capable of extending processes in response to otic attractant fields for an extended period during the embryonic development of this ganglion. They support the hypothesis that the onset and duration of receptor generated attractant fields may act as a controlling factor in establishing patterns of innervation within the developing inner ear.

DO CENTRAL AFFERENTS INFLUENCE TARGET DIFFERENTIATION? T. Szabo, B.O. Bratton, D. Rouilly? C.N.R.S., Lab.Physiol. Nerveuse, Dept. Neurophysiol.Sensorielle, F 91190 Gif/Yvette, Zoologisches Inst., Univ. Regensburg, RFG.

The electromotor system was investigated in the weakly teleost Gnathonemus petersii in which a larval (LEO) and an adult (AED) electromotoneuron/electric organ complex develops successively during ontogenesis. Activity begins in the larval motor complex on day 9, 30 days before that of the adult motor complex which appears at d 40-45. Both larval and adult motor complexes are controlled by a common,spontaneously active bulbar command, the axons of which form the unique afferent pathway to the motoneurons. The different somatic position (trunk for LEO,caudal peduncle for AEO) allows easy deafferentation of the AEO while keeping intact the connection and activity of the LEO. Deafferentation was performed by spinal section anterior to the AEO Anlage at the 28th spinal segment, at different developmental stages of the larvae. Since differentiation of the AEO occurs between d20 and d40, deafferentation was carried out between d4 (hatching) and d20-23. Larvae had a survival time of 40 to 80 days. If spinal sections were performed between d15-23, the AEO showed a normally developed structure on day 45. However, sectioning at earlier periods resulted in incomplete development and a slowing down of the differentiation process. Reestablishment of functional central connections was never observed, up to 85 days, in spite of partial regeneration (or incomplete section) of the spinal cord.

510.4

DEVELOPMENT OF INTER- AND INTRA-HEMISPHERIC PROJECTIONS IN HAMSTERS. C. Hedin-Pereira*, R. Lent and S. Jhaveri*. Instituto de Biofísica Carlos Chagas Filho da UFRJ, Rio de Janeiro, RJ, 21941 and Massachusetts Institute of Technology, Cambridge, MA 02139.

The development of cortical afferentation by callosal and corticocortical fibers was studied using transport of WGA-HRP applied into the cortical wall of embryonic and postnatal hamsters. In frontal cortex, callosal axons emerge from the cortical anlage on E14 (conception = E1), cross the midline and arrive at the contralateral white matter by P1 (birth = P1). Commissuration proceeds from rostral to caudal: occipital axons reach the opposite hemisphere on P4. Axons wait in the white matter for a few days before innervating restricted target sectors of the gray matter. The zones of origin of the callosal projections are exuberant initially, but are subsequently trimmed to overlap with corresponding terminal fields.

Corticocortical projections follow the same developmental sequence as the callosal axons. Target innervation occurs much earlier for frontal than for occipital fibers. The distribution of cells giving rise to these connections is also initially exuberant and later restricted to the adult-like columnar pattern.

Thus inter- and intrahemispheric axons elongate, wait in the vicinity of the target, innervate terminal regions and undergo an adjustment in the distribution of cells wherein these projections originate.

NEURONAL MORPHOGENESIS OF THE MEDIODORSAL NUCLEUS OF THE HUMAN THALAMUS:GOLGI STUDY. N.Zečević and J.Mojsilović* Dept.Neurophysiology, Inst.for Biological Res., Belgrade University, Belgrade 11000, Yugoslavia.

Golgi study of mediodorsal nucleus (MD) was performed in 10 human fetuses ranging in age from 12 gestational weeks (g.w.), crown-rump length (CRL=75mm) to 36 g.w.(CRL=480mm), one newborn and one adult. Brain tissue has been obtained through abortions performed for medical reasons or autopsies. In the group of youngest fetuses examined (12-14 g.w.) the area of the prospective MD was occupied by bipolar, branched bipolar and young multipolar neurons (mean values per neuron: total dendritic length, TDL, 272±17μm; soma area,s.a., 164±3μm; maximal diameter,dmax, 18.5±1μm). From 16 g.w. two types of MD neurons could be recognized: large (dmax>20μm) and small ones (dmax<20μm) presumingly projection neurons and interneurons, respectively. From this age to birth, TDL of both cell types combined, increased almost 5 times, s.a. increased two times and dmax 1.5 times. From birth to adult, TDL increased additional 2.2 times, while s.a. and dmax did not change significantly. In conclusion, from 16 g.w. to birth, MD neurons undergo major morphogenetic changes, but elaboration of dendritic tree continues into adulthood.

PROJECTIONS OF SUPERIOR CERVICAL GANGLION (SCG) NEURONS TO THE SUBMANDIBULAR GLAND AND IRIS IN RATS. J.I. Luebke and L.L. Wright, Dept. of Anatomy, BUSM, Boston, MA 02118

To determine whether single SCG neurons project to single or multiple target sites during different stages of development, the projections of SCG neurons to the submandibular gland (SMG) and iris were examined in 1, 8, and 24 week old rats using the retrograde tracers horseradish peroxidase (HRP) and Fluorogold (FG). Under anesthesia, five animals of each age were injected with HRP (2-3 ul) in one SMG and FG (1%, 2-3 ul) in the ipsilateral eye (anterior chamber). Also, several adult animals were injected with HRP in one SMG and FG in the other SMG, or HRP in one eye and FG in the other eye. After a survival of 3-6 days the rats were perfused and their SCGs sectioned and processed for the HRP reaction. The SCGs of rats injected in the ipsilateral SMG and eye contained no double labelled cells at any of the three ages. In SCGs of adults injected bilaterally in the eyes no double labelled cells were observed, however in adults injected bilaterally in the SMGs numerous double labelled cells were present. Only occasional neurons were labelled following application of either tracer to the SMG to simulate leakage. These data indicate that in the rat few or no SCG neurons project both to the iris and the SMG or bilaterally to the eye while some SCG neurons do project bilaterally to both SMGs. Supported by NIH grant NS2L577.

510.7

AXONAL TARGET TERRITORY INFLUENCES THE DEVELOPMENT OF DENDRITIC GEOMETRY IN THE ISTHMO-OPTIC NUCLEUS (ION) OF CHICK EMBRYOS - A GOLGI STUDY. S. Catsicas*, P. Blaser*, and P.G.H. Clarke* (SPON: J.P. Hornung). Institute of Anatomy, University of Lausanne, CH-1005, Switzerland.

In the mature ION, the neuronal perikarya are arranged in a convoluted lamina from which the dendrites project perpendicularly into the neuropil. By embryonic day 10 (E10), virtually all the dendritic trees are already highly polarized, but, unlike in the mature ION, most are directed ventralwards or ventromedialwards. Between E10 and E14, the dendrites change their direction of polarization so as to produce the adult pattern.

The afferents to the ION play little if any role in these events, because by the time they arrive in the ION (about E12) the first stage of repolarization is virtually complete. Moreover, tectal lesions at E10-E12 do not cause noticeable effects until after E14, when they are known to cause greatly enhanced neuronal death.

In contrast, the axonal targets seem to play an important role. Early removal of both eye primordia is known to cause the death of virtually all the ION neurons, beginning at E12-E13. But our present data, which are still being quantified, indicate that well before this, by E11, the dendritic trees in the target-deprived IONs are not so highly polarized as in unoperated embryos. This suggests that the axonal target may send an early retrograde signal to the ION neurons that modulates their dendritic geometry before they become dependent on the target for survival.

510.8

DEVELOPMENT OF SENSORY TRIGEMINAL AFFERENT PROJECTIONS IN *Rana Pipiens*. B.M. Rosenthal and K.E. Alley. Dept. Oral Biology, Ohio State Univ. Col. Dent., Columbus, OH 43210.

To determine if trigeminal sensory afferents undergo any reorganization during metamorphosis, ophthalmic (V1), maxillary (V2), and mandibular (V3) nerves were separately labelled with HRP and their central terminal arbors were examined in the hind brain and spinal cord of larval and adult frogs. In adults, afferents were arranged in the main sensory nucleus of V with V3 terminals medial and V1 and V2 terminals lateral. Terminals from V3 were also found in an area dorsal to the Vth motor nucleus corresponding to supratrigeminalis. The caudal extent of the spinal tract (Vsp) in adults was similar for each peripheral division (V1,2,3). A sparse projection was present at lumbar spinal root 8, but this was overshadowed by the much more dense projections to brachial and thoracic cord levels. Terminals primarily from the mandibular root ended in dense plexuses or tufts in the caudal medulla at the level of the hypoglossal nucleus. These tufts were also present in the contralateral medulla in adults. The basic pattern of sensory afferents was present in stage III larvae including the main sensory terminals and the brachial spinal projections, however, stage III tadpoles contained no Vsp axons caudal to the level of thoracic root 5, no terminals in supratrigeminalis, and no projections to the contralateral medulla. These observations suggest that larval development of the trigeminal system includes the expansion of previously existing axons into new terminal fields.

Supported by NIH grants DE 07620 (KEA) and DE 05516 (BMR).

ABNORMAL CUTANEOUS DIFFERENTIATION FOLLOWING LESIONS OF THE TRIGEMINAL GANGLION IN MONODELPHIS PUPS. B.L. Munger* and T. E. Jones* (SPON: K.E. Krebs). Dept. of Anat., M.S. Hershey Med. Cent., Penn. St. Univ., Hershey, PA 17033.

The present study was prompted by the observation that cutaneous innervation precedes differentiation of cutaneous appendages in both glabrous and hairy skin. We postulated that lesions of cutaneous nerves might perturb cutaneous differentiation and subsequently demonstrated this to be true following lesions of the caudal spinal cord in opossum pups. We have cauterized portions of the trigeminal ganglion in 1 day old Monodelphis domesticus pups and have studied the skin distal to the lesion in silver-stained serial paraffin sections. The epidermis and dermis close to the trigeminal lesion are hyperinnervated. The epidermis is hyperplastic and lacks hairs confirming findings following spinal cord lesions. The most striking changes were found in the eyelashes of both upper and lower lids. Eyelashes normally have a fixed angle with respect to the surface of the lid and are regularly and geometrically arranged. Following lesions involving the ophthalmic division of the trigeminal, the eyelashes of both upper and lower lids were irregularly spaced and had an incorrect angle with respect to the surface of the eyelid. These findings implicate afferent nerves as an important factor in the control of cutaneous differentiation. Supported in part by USPHS Grant #NS 19462.

THE USE OF SKIN EQUIVALENTS TO STUDY THE INFLUENCE OF SENSORY NERVES ON THE DIFFERENTIATION OF THE EPIDERMIS IN CULTURE. K.B. English and N. Stayner*. Dept. of Physiol., Univ. of Utah Sch. of Med., Salt Lake City, UT 84108

When collagen is mixed with dissociated fibroblasts, it is contracted into a dermis-like disk in 1 or 2 days. Keratinocytes can then be seeded on top of this tissue and grown to confluency, forming a skin equivalent (Bell et al., 1981, Science 211: 1052-1054). We have incorporated dorsal root ganglia from 21 day gestation fetal rats into dermal disks at the time of fabrication. The medium used was DMEM with glucose (600 mg/100 ml), supplements to promote keratinocyte survival [choleragen (10^{-10} M), hydrocortisone (0.4 ug/ml), and epidermal growth factor (10 ng/ml)], plus 10% fetal bovine serum and 10% heat inactivated horse serum. A 40:60 mixture of this medium plus KGM (Clonetics) was also employed. After the dermis was conditioned by the nerves it was seeded with keratinocytes. Three and 6 days later the tissue was fixed for histology and compared to cultures with non-conditioned dermis.

This system may prove useful to test the influence of various cell types on epidermal differentiation. (Supported by PHS grant 5 R23 NS23165-03)

PEANUT LECTIN STAINING IN THE MOUSE WHISKER-BARREL PATHWAY AND ITS MODIFICATION BY PERIPHERAL LESIONS AT DIFFERENT POSTNATAL AGES. J. Christensen* and T.A. Woolsey (SPON: R.S. Sohn) Division of Experimental Neurology & Neurosurgery & McDonnell Center for Studies of Higher Brain Function, Washington University School of Medicine, St. Louis, MO 63110.

Steindler, Cooper and their colleagues (J. Comp. Neurol. 249:157-169, 1986) showed that appropriately tagged plant lectins (associated with glia and components of the extracellular matrix) outline the whisker barrels of the cerebral cortex and whisker representations in the brainstem trigeminal nuclei and VB in the thalamus for a limited period in early postnatal life. The patterns change after lesions to the whiskers. We used HRP conjugated peanut agglutinin to label whisker representations in mice of known postnatal ages. In our hands, the appearance of the patterns is identical in sequence and time to that previously reported for a variety of stains including Nissl, CO, and several different specific axonal makers. The arrangement after lesions to the trigeminal nerve and its branches is as described with other markers except that the stain is denser where the lesions disrupt the whisker pattern. The obvious lack of staining in normal whisker representations, the sequence and its timing is consistent with the direction of pattern formation by projecting axons which appear to displace the lectin stained elements.

THE INFLUENCE OF MUSCLE CONTRACTILE ACTIVITY ON CROSS-STRIATIONS AND NUCLEI OF INNERVATED CULTURED HUMAN MUSCLE FIBERS (InnCHMFs). Y.C. Park,* V. Askanas, and W.K. Engel (SPON: C.K. HAUN). USC Neuromuscular Center. Los Angeles, CA 90017.

Adult human muscle fibers cultured aneurally in monolayer are poorly cross-striated, do not contract, and have nuclei located internally. We demonstrated that InnCHMFs are well cross-striated, contract continuously, and most of their nuclei are peripheral. To determine if either innervation or muscle contractile activity alone, or both together, is responsible for the development of cross-striation and the peripheralization of nuclei, we quantitated by light-microscopy of 3 um epon sections 1) area covered by cross-striation, and 2) number of peripheral vs. central nuclei, in InnCHMFs contracting for 4 weeks (Contr-InnCHMFs) vs. InnCHMFs paralyzed by tetrodotoxin for 4 weeks (Par-InnCHMFs) from the first day of their contractile activity. As compared to Par-InnCHMFs, Contr-InnCHMFs had: 1) 1400% ($p<0.001$) more of their total area covered by cross-striations; 2) 510% ($p<0.001$) more nuclei at the periphery; 3) 70% ($p<0.001$) fewer nuclei totally. In this culture system, innervation provides an essential signal to induce muscle contraction. However, development of cross-striation and peripheral migration of nuclei, a phenotype of adult muscle fibers, appears to be secondary to muscle contractile activity.

EFFECTS OF AN EXPERIMENTAL HINDLIMB GROWTH DISTURBANCE ON THE SCIATIC NERVE. C. Hildebrand, M. Westerberg and G.Y. Mustafa. Dept of Cell Biology, Faculty of Health Sciences, S-581 85 Linköping, Sweden.

The purpose of the study is to find out how a deficient length growth of the rat hindlimb influences the number of axons and the nodal spacing in the rat sciatic nerve. In neonatal rat pups the femoral and tibial epiphyseal cartilages on the left side were coagulated with the tip of a microcautery device. Postoperatively femoral and tibial length growth was markedly restricted on the left side, but the foot and pelvic region exhibited a normal longitudinal growth. Following a survival time of 6 months, the sciatic nerves were removed from both sides. Electron microscopic analysis of cross-sections from the nerve revealed that the content of axons was about 20% lower and that the myelinated fibres tended to be smaller on the growth retarded side. Light microscopic examination of teased preparations from pelvic and femoral levels of the left sciatic nerve showed that the relationship between internodal length and fibre diameter was normal in the pelvic segment and that the internodes were abnormally short in the femoral segment. These results suggest that the number of axons in the rat sciatic nerve adapts to a maldevelopment of the target that sets in at birth, and that internodal elongation during development proceeds according to the local growth in length of the nerve rather than to the length growth of the whole nerve.

COLLAGEN IN THE DEVELOPING AND INJURED ADULT MAMMALIAN CNS. R. Marchand, S. Woerly and A. Nadeau* (Spon: L.J. Poirier). Lab. Neurobio, Hop. Enfant-Jésus, 1401, 18e Rue, Québec G1J 1Z4.

Synthesis of collagen in the CNS has been reported in two circumstances (1) by the embryonic spinal cord epithelium (Cohen and Hay, 1971; Trelstad et al., 1973) (2) by primary human brain tumors (Rutka, 1987). We have investigated on the presence of collagen in the CNS by using the picrosirius red-polarization method (Junqueria et al. 1979). We visualized the presence of type I collagen in the developing rat brain on days 14.5, 15 and 16 of gestation, as a strongly birefringent red lining at the level of the internal limiting membrane of the ventricles. This collagenous membrane was occasionally associated to a non birefringent fibrinogranular substance that occupies the lumen of the ventricles and which stains with alcian blue suggesting a glycosaminoglycan-rich ependymal glycocalyx. Discrete radial type I collagen fibers were also seen in the mantle layer and at the level of the glial septum of the rhombencephalon. In the injured brain and spinal cord, collagen of type I was detected (1) in the lesion site as dense aggregations of thick bundles corresponding to the deposition of scar (2) at the lesioned interface under the form of types I-III orthogonally oriented copolymers. In addition, single, thin and green fibers of type III also occupied the neighboring healthy neural tissue. Our results show that the CNS tissue and/or the associated mesenchyme synthesize distinct genetic types of collagen in two circumstances: during organogenesis and following injury. The fact that types I and III collagens are often associated to morphogenetic and repair processes of organs suggest similar roles in the CNS: the setting of pathways for cell migration, the setting of a temporary framework for cell-cell and cell-matrix interactions, as well as the setting of a terrain for the initiation of regeneration and a role in the regulation of scar formation by the natural-occurring structural interactions between types I and III collagen fibers. NEONATE NUCLEUS BASALIS LESIONS RESULT IN CORTICAL CHOLINERGIC HYPOFUNCTION, AND COGNITIVE DEFICITS DURING ADULTHOOD. P.T. Jantzen[1]*, E.M. Meyer[2], W.J. Millard[3], A.J. Dunn[4], and G.W. Arendash[1]. (SPON: S.L. Swihart) Dept. of Biology[1], Univ. of South Florida, Tampa, FL 33620 and Depts. of Pharmacology[2], Pharmacodynamics[3], and Neuroscience[4], Univ. of Florida, Gainesville, FL 32610.

To eliminate developing cholinergic neurons within the nucleus basalis magnocellularis (nBM) region before they become functional (through their termination points in the neocortex), ibotenic acid was infused bilaterally into the nBM of 2 day-old male rats. Behavioral effects were investigated during adulthood and cortical neurochemical determinations were made at sacrifice, one year after lesioning. Histological analysis of the lesions indicated a restricted gliosis, essentially limited to the globus pallidus (including the nBM); neither the neostriatum nor the thalamus appeared to be damaged. Neurochemically, choline acetyltransferase (CAT) activity was found to be reduced by 25% in the frontal cortex of lesioned animals compared to sham-lesioned controls; cortical biogenic amine markers and neuropeptide (somatostatin and NPY) concentrations were unaffected. Behaviorally, lesioned animals showed a marked deficit in passive avoidance retention, as well as in the acquisition and retention of 2-way active avoidance behavior. These results indicate that a permanent cortical cholinergic hypofunction results from neonate nBM lesions, which chould be related to the cognitive impairments also observed. (Supported by a grant from the ADRDA)

THE INFLUENCE OF ULTRAHIGH MAGNETIC FIELDS ON CEREBRAL CORTICAL MORPHOLOGICAL DEVELOPMENT: A PRELIMINARY STUDY. M.C. Diamond, T.S. Tenforde*[1], E.R.Greer*, K.Hedges*, B.Steinke*, E. Davies*, J. Yu*, and D. Nguyen*. Dept. Physio-Anat. & Lawrence Berkeley Lab.[1], Univ. Calif. Berkeley, CA 94720.

Six 10-day-old male, unanesthetized, Long-Evans rats were housed in well-ventilated lucite holders and exposed for 17 min. to a 2.3 Tesla field (23,000 Gauss). Six 9-day-old males were similarly housed and exposed for 30 min. to a 7.5 Tesla field in a superconducting magnet. Six matched controls for each of the two experiments were placed in lucite containers in separate rooms. At 41 days of age, rats were anesthetized, perfused and brains removed. 20 micra, transverse, frozen sections were taken from the frontal, somatosensory and occipital cortex. On thionine stained sections, cortical thickness measurements of 9 areas/brain were made on microslide projected images (22.5X). All cortical measurements were done "blind", the codes broken only after all measurements were completed.

No significant differences in thickness were noted between the controls and experimental rats exposed to the 2.3 Tesla magnetic field even though 6 out of 9 areas measured were thicker. However, 8 out of 9 areas were thicker in the rats exposed to the 7.5 Tesla magnetic field with 3 areas statistically significantly different: area 4, right hem. (8%;$p<0.005$); area 10, right hem. (4%; $p<0.05$); area 3, left hem. (4%;$p<0.05$). The results suggest that exposure of neonatal rats to high-intensity magnetic fields promotes cortex development.

REGIONAL EFFECTS OF OPIOID RECEPTOR BLOCKADE ON CORTICAL THICKNESS IN ADOLESCENT RATS. J. Reyes*, D. Lewis*, and M. C. Diamond(SPON: N. Peterson). Department of Physiology-Anatomy, Univ. of California, Berkeley, CA. 94720

Investigators have demonstrated that specific regions of the cerebral cortex increase in thickness and cellular content when opioid receptors are blocked by Naltrexone. However, these studies examined preweaned rats, thus the role of opioids on CNS development are not known beyond this time. Our study examines the relationship between opioid receptor blockade, cortical thickness, and laterality in 9 regions of cerebral cortex in 41-day-old rats. Male and female Long-Evans rats were injected subcutaneously with either saline, 1, 10, or 50mg/kg of Naltrexone, an opioid receptor antagonist, for the first 41 days of postnatal life. On day 41, rats were sacrificed and morphometric analysis of the cortical regions were made on transverse, frozen, 40mu sections stained with a modified Thionine stain. Results indicated significant dose effects in the frontal and occipital cortical regions. The 10 and 50mg groups showed increases in cortical thickness. The 1mg group decreased or showed no change in comparison to saline injected controls. Cortical thickness in female rats increased significantly with each dosage of Naltrexone. The thickness in male rats increased in occipital cortex only at the 10mg dosage. At 50mg the occipital cortex decreased to below control levels. Changes in laterality patterns were noted.

510.18

EFFECTS OF OPIOID RECEPTOR BLOCKADE ON HIPPOCAMPUS DEVELOPMENT IN PREWEANED RATS. D. Fish*, J. Reyes*, T. Jensen*, D. Lewis* and M.C. Diamond (SPON: S. Roberts). Department of Physiology-Anatomy, Univ. of California, Berkeley, CA. 94720

Studies have indicated that regions of the CNS are increased in size and cellular content when opioid receptors are blocked by Naltrexone. Our study examines the relationship between opioid receptor blockade, size(thickness) and laterality in the hippocampus of 21-day-old rats. Male and female Long-Evans rats were injected subcutaneously with either saline, 1, 10, or 50mg/kg of Naltrexone, an opioid receptor antagonist, for the first 21 days of postnatal life. On day 21 rats were sacrificed and morphometric analysis of the hippocampus were made on transverse, frozen 40mu sections stained with a modified Thionine stain. Results indicated significant decreases in the hippocampal size at each dosage of Naltrexone. Male rats in each dosage group showed significant ($p<.01$) when compared to control(saline) rats. However, there was no significant differences between the dosage groups. There were no significant differences in laterality at any dosage. Female rats in the 1 and 10mg/kg group showed significant ($p<.01$) decreases in hippocampal size. Furthermore, females indicated laterality differences; as the dosage of Naltrexone increased the right hippocampus progressed from less than controls at the 1mg dosage ($p<.05$) to greater than controls at the 50mg dosage ($p<.01$). The left hippocampus remained less than controls for each dosage.

IMMUNOCOMPETENT CELLS IN HUMAN FETAL BRAIN CULTURES. F.Gremo,M.G.Ennas*,S.Torelli*,V.Sogos*, C.Marcello*&U.Lecca* Dept.of Cytomorph. & Inst. of Clin.Obst.Gynecol.,Sch.ofMed.,Cagliari,Italy

The hypothesis that glial cells can act as immunocompetent cells in the Central Nervous System has been recently advanced on the basis of in vivo and in vitro studies. However,data on humans are lacking. We had established human fetal brain cultures in our laboratory. Tissues were freshly dissected out of either spontaneous or medically induced abortions,cells were dissociated and seeded on polylysine pretreated dishes. Cultures were enriched in glial and neuronal cells. Contamination from other cells was minimal. Cells were fixed at different intervals and incubated with monoclonal antibodies against typical markers of B and T lymphocytes and of macrophages. Results showed that cells bore B_2,B_7,T_4,NH-NK,M_5,C_3B,Thy1 like antigens. Positivity for T_8,T_9,T_{11} was lacking. Double staining demonstrated that the most of these antigens were present on GFA-P positive astrocytes. Studies are in progress to test the physiological significance of these data.

TRANSPLANTATION: EYE

511.1

INNERVATION OF THE CORNEA BY ANTERIOR CHAMBER TRANSPLANTS OF NEONATAL TRIGEMINAL GANGLIA. C.S. Ogilvy*, K.R. Silverberg* and L.F. Borges. Neurosurgical Service, Massachusetts General Hospital, Boston, MA 02114.

The anterior chamber of the eye is a site which readily accepts neuronal tissue transplants and supplies the transplanted tissue with vasculature from the iris. The present study was designed to determine whether neonatal trigeminal ganglion transplants in the anterior chamber of adult rats would innervate the cornea. Transplants survived for at least 6 months after transplant. However, when these transplants were examined with retrograde fluorescent tracing studies and direct examination of corneal innervation using a gold chloride technique, no graft to cornea nerve fibers could be identified. Nor did the grafts innervate the cornea following host trigeminal nerve section.

Grafted tissue did innervate the host cornea when the neonatal trigeminal nerve fibers were inserted into the corneal stroma at the time of transplant. The extent to which host trigeminal innervation influences this sprouting is under study currently.

511.2

INHERITED RETINAL DYSTROPHY: RESCUE OF PHOTORECEPTOR CELLS BY PIGMENT EPITHELIAL CELL GRAFTS IN THE RCS RAT. L. Li* and J.E. Turner. Dept. of Anatomy, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, NC 27103.

The principal aim of research in animals that exhibit retinal degenerations, like the Royal College of Surgeons (RCS) rat, is directed at preventing, arresting or retarding photoreceptor cell (PRC) degeneration. We report that healthy retinal pigment epithelial cells injected into the subretinal space of RCS rats were found to rescue host PRC's from degeneration. RPE cells from 6 to 8 day old pigmented congenic RCS rats were injected into the subretinal space of the 26 day old RCS dystrophic rats. At P60 a time when most of the PRC's in RCS dystrophic rats have degenerated, its was found that the outer nuclear layer (ONL) of RCS dystrophic controls had been reduced to 1 to 2 cells in thickness. The same region of P26 dystrophic rats was 10 to 11 cells thick. In contrast, at P60 the presence of the RPE cell graft appeared to maintain the ONL tickness as in the P26 nongrafted RCS dystrophic control. The beneficial effects of the graft remain stable from at least neonatal life to young adulthood. This work represents the development of a successful therapeutic approach for the treatment of an inherited retinal dystrophy. It is also the first time that a cell transplantation procedure has been used to rescue a neuronal population that would normally die because of an inherited disease process. This research was supported by grants from NIH (EY04337), the National Retinitis Pigmentosa Foundation Fighting Blindness and Retinitis Pigmentosa International awarded to J.E. Turner.

TRANSPLANTATION OF ENRICHED CELL POPULATIONS DERIVED FROM IMMATURE RAT RETINA. M. del Cerro and H. H. Yeh. Dept. Neurobiology and Anatomy, University of Rochester School of Medicine, Rochester, NY. 14642.

We and others have successfully transplanted whole immature neural retina. Repair of damaged adult retina, however, may potentially be better approached by selective replacement of neuronal populations. To examine the feasibility of this more refined approach, donor retinal cells derived from selected layers of the immature retina were tested for their ability to survive and differentiate as intraocular transplants. Retinas from PN 4 Fisher 344 rat pups were isolated, treated briefly with trypsin, interposed as flatmounts between two sterile filter membranes and then cleaved at the level of the developing inner plexiform layer. Each of the two resultant adherent portions, an "outer" portion made up primarily of the neuroblastic mass and an "inner" portion which included the ganglion cells, was detached, suspended in 2 µl of medium and transplanted into the retinas of normal adult Fisher 344 hosts, or into those affected with phototoxic retinopathy. Sixteen days after transplantation the portion containing the neuroblastic cell mass had formed transplants consisting of photoreceptor cells, a plexiform layer, and a cell layer formed by inner nuclear cell profiles. These observations indicate that selected retinal populations are able to survive and to undergo histogenetic differentiation following transplantation. These enriched cell populations may be a useful source of donor tissue for attempts at repairing damaged retina.

Supported by EY05262 and Rochester Eye Bank.

511.4

TRANSPLANTATION OF IMMATURE DISSOCIATED NEURO-RETINAL CELLS ISOLATED BY FLOW CYTOMETRY. E. M. Pearlman, J. Leary*, M. del Cerro, M. F. Notter, C. del Cerro, and J. A. Olschowka. Departments of Neurobiology & Anatomy, and Pathology(*), University of Rochester Medical Center, Rochester, N.Y. 14642

Flow cytometry and cell sorting were used to characterize and isolate sub-populations of immature neural retinal cells for transplantation into adult retinas. Retinas from E22 rats were dissociated into a single-cell suspension. The cells were labeled with 6-carboxyfluorescein diacetate (cFDA), a measure of non-specific esterase, activity for sorting by an EPICS V multiparameter flow cytometer/cell sorter. Propidium iodide (PI), a DNA/RNA specific dye excluded by intact cells, was used to label damaged cells. Green cFDA fluorescence was measured between 515 and 545 nm, and red PI fluorescence was measured above 630 nm. Approximately 70-85% of cells were found to be viable based on PI dye exclusion. Cell size was measured using low-angle light scatter time-of-flight, a measure of cell diameter. These cell size measurements were in excellent agreement with cell size as measured by an IBAS image analysis system. Three sub-populations of neural retinal cells were seen based on cell size (or low angle light scatter) and cFDA staining. The brightest cFDA-positive cells were the smallest cells. The largest sized cells exhibited intermediate cFDA brightness. The medium sized cells had the dullest cFDA positivity. This group, which was the most numerous, was sorted into centrifuge tubes, labeled with Fast Blue, and used for transplantation into adult retinas. Fast Blue is a fluorescent marker shown by our laboratory (del Cerro et al., Neuroscience Abstracts, 1987)to label transplanted retinal cells for extended periods of time. Our results demonstrate the usefulness of the cell sorter for identifying and isolating developing retinal cell subpopulations suitable for intraocular transplantation. Supported by NEI grant 05262 and the Rochester Eye and Human Parts Bank.

511.5

INTRAOCULAR TRANSPLANTATION OF DEVELOPING RETINA INTO ADULT RETINAL DEGENERATION (*rd*) MICE. L.Q. Jiang, M. del Cerro, and C.M. Kalsow*. Dept. of Neurobiology and Anatomy and Ophthalmology, Univ.of Rochester, Med. Ctr., Roch., NY 14642.

The present era of intraocular retinal transplantation studies started in 1984 (del Cerro et al., ARVO 1984). Since that time our work and that of others has demonstrated that developing retinas from embryonic and perinatal donors can be successfully transplanted into host eyes with either normal or damaged retinas, and that transplantation can be effected even between animals of histoincompatable strains. All of these previous studies were performed using rats as experimental subjects. Presently we have successfully transplanted immature mouse retina into adult *rd* mutant mice. Newborn (PN 0) AKR/J mice served as donors and CBA/J adult mice as hosts which lost photoreceptor cells after birth as a result of *rd* mutation. Fragments of developing neural retina were transplanted into host retinas. The maximun survival period of animals allowed in these series was 15 days. Transplants grew into the host retina and subretinal space. Two interesting results were observed. First, the cells of AKR/J immature retina differentiated into photoreceptor cells in the CBA/J *rd* host's eyes. Second, S-antigen, a specific marker for photoreceptor cells, is expressed during the development of transplanted cells. It was seen in transplants examined at post transplantation (PT) 15 days, but not in those examined only at 3 PT days. The introduction of a murine system for retinal transplantation opens new posibilities, particularly through the use of visually defective mutant strains. Supported by NEI grant 05262 and the Rochester Eye Bank.

511.6

INTERSPECIES RETINAL TRANSPLANTATION. C. del Cerro*, L.Q. Jiang, and M. del Cerro (SPON: P. Shrager). Dept. of Neurobiology & Anatomy, Univ. of Rochester, Med. Ctr, Rochester, NY 14642.

Successful transplantation of developing neural retina into the retina of adult hosts of the same species has already been achieved by us and others. However, to our knowledge, retinal transplantation across species has not been reported. We wanted to test the feasibility of interspecies transplantation since it may permit the use of alternate sources of donor tissues and offer new oportunities to analyze host-donor cell interactions. Adult Fisher 344 albino rats were used in this study. Donors were newborn (PND 0) C57BL/6J mice. Strips of neural retinas were transplanted by injection into the posterior pole of host eyes. The transplants survived and resulted in the differentiation of ONL cells (with inner and outersegments attached to them), INL cells and a IPL. The transplants were well accepted up to 17 days after transplantation, the latest time point observed in these series. The host reaction was limited to a few macrophages surrounding the transplants. This mild reaction is comparable to that observed in the intra-species retinal transplants at the same postransplantation times. The transplants integrated closely with the host retinas, but still mouse donor and rat host cells can be differentiated from each other by their morphological features under LM and EM. These observations show that interspecies retinal transplantation is feasible and does offer interesting possibilities for the study of host-transplant interactions.
Supported by NEI grant 05262.

511.7

RABBIT RETINA TRANSPLANTS TO ADULT RABBIT RETINA.
M. Seiler, R. Aramant, B. Ehinger and A.R. Adolph.
Eye Research Institute and Harvard Medical School, Boston 02114, and University of Lund 22185, Sweden.

We report here for the first time the successful transplantation of rabbit embryonic retina to adult rabbit retina, using a modification of the Turner & Blair (1986) method. Young (4-6 weeks old) male albino rabbits were used as hosts. Under anesthesia, the dorsal scleral surface of the eye was exposed. A small (~1mm) incision was cut through sclera, choroid and retina and closed by 8-0 sutures. Retina from albino rabbit embryos (15 days after conception) was dissected free from surrounding tissues in cold PBS/1 mM Glucose and then placed into a small drop of PBS. It was taken up into a glass needle (0.2 mm dia.) injected into the lession site through a minimal lesion adjacent to the site.

Large grafts (~2 mm dia.) were found after 4 weeks survival, which consisted usually of many rosettes, visible as curls under the dissection microscope. In the graft rosettes, all retinal cell layers (with the exception of an inner limiting membrane) were observed. However, ganglion cells were not identified in the graft "ganglion cell layer". Graft photoreceptor cells frequently developed outer segments in rosettes. Often, a fusion between host and graft inner plexiform layers had taken place at the edges of the host retina lesion site. At least one specific class of retinal neurons, horizontal cells in the graft outer plexiform layers, was identified by an antibody against 160 kD Neurofilament.

511.8

NEURON-SPECIFIC MARKERS IN RETINAL GRAFTS TO ADULT RAT RETINA.
B. Ehinger, R. Aramant, M. Seiler, A. Bergström, J.E. Turner and A.R. Adolph.
University of Lund 22185, Sweden; Eye Research Institute, and Harvard Medical School, Boston 02114; Bowman Gray School of Medicine, Winston-Salem, NC 27103.

Embryonic rat E15 retinas were transplanted to an adult retinal lesion site as described (Turner & Blair, 1986). Eyes with grafts were fixed with 4% Paraformaldehyde after survival times of up to 7 weeks. Staining of frozen sections gave positive results for the following antibodies: ChAT (antibody provided by P.M. Salvaterra, CA), TH (antibody provided by P.R. Vulliet, CO), Neurofilament (160 kD), HPC-1 (specific for amacrine cells), and GABA. Amacrine cell bodies which were positive for ChAT (a cholinergic marker) could be seen in some 1 week old grafts and in all grafts at later stages. In 5 and 7 week old grafts, ChAT+ fibers were found in the graft inner plexiform layer at the border to the inner nuclear layer. TH+ processes of dopaminergic amacrine cells were stained in the graft from 1 week after transplantation. Horizontal cells in the graft stained weakly for Neurofilament one week after transplantation. From 2 weeks after transplantation, the staining intensity of horizontal cells in the graft outer plexiform layer corresponded to that of the host. The antibody HPC-1, directed against amacrine cells, stained specifically the inner plexiform layer (IPL) of adult rat retina. Weak HPC-1 staining could be seen in the graft IPL 2-3 weeks after transplantation. 5-7 weeks after transplantation, the intensity of staining was the same as in the host retina. An antibody against GABA clearly stained some cells in the graft (presumably amacrine cells) from 2 weeks after transplantation.

511.9

COGRAFTS OF RETINA AND TECTUM OR CEREBELLUM TO ADULT RAT RETINA. R. Aramant, M. Seiler and A.R. Adolph
Eye Research Institute and Harvard Medical School, Boston, MA 02114

Embryonic or neonatal rat retina has been shown to survive and differentiate when grafted to an adult retina (see Turner & Blair '86, Aramant et al. '88). Could ganglion cells develop and survive in these grafts deprived of their target? In attempting to answer this question, embryonic (E13 or E19) tectal anlage was grafted to adult rat retina, with or without a retinal cograft. As a control, some eyes received a corresponding cerebellar graft. The survival time was 4 weeks.

All E13 brain grafts survived, whereas E19 brain grafts mostly appeared to be rejected by the host. There was no difference in the high survival rate of E13 and E19 retinal grafts. E13 brain grafts fused with the host retina, pushing away host retinal tissue by their vigorous growth. E13 tectal and cerebellar grafts contained several classes of neurons corresponding to their origin, but they mostly failed to develop cell layers, and were filled with nerve fiber bundles (staining darkly for the 160 KD neurofilament (NF)). No clear effect of tectal grafts on the survival of ganglion cells (GC) in their retinal cografts was seen, but they seemed to attract ingrowth of host GC axons since heavily stained NF+ fiberbundles in the host retina were oriented towards the tectal graft. Neurons derived from the tectal graft migrated into the host inner plexiform layer even at distances of 1-2mm. Connections between the retinal and the tectal graft could be seen. Cerebellar (CB) grafts fused with the host retina, but no ingrowth of host GC axons was seen, and migration of CB neurons into the host retina was limited to the immediate environment of the CB graft. No connection between the retinal and the CB graft was observed.

511.10

ANATOMICAL AND BEHAVIORAL CORRELATES OF XENOGRAFT-MEDIATED PUPILLARY REFLEX R. D. Lund and H. Klassen* Dept. Neurobiol., Anat. & Cell Sci., Sch. of Med., U. Pittsburgh, Pittsburgh, PA 15261.

We are interested in the ability of neural transplants to make functional connections with host brains. We examine here whether cross-species transplants are able to drive a motor function in host rats through a normal pathway and whether the characteristics of the motor response correlate with the density of innervation of the appropriate brain region by the transplant.

We transplanted retinae from mouse embryos to the midbrain of neonatal rats which were unilaterally enucleated at the time of transplantation. After at least 3 weeks the remaining optic nerve was cut and the transplant exposed. Illumination of the transplant caused pupilloconstriction of the host eye, a response abolished by removal of the transplant or damage to the pupilloconstriction center, the olivary pretectal nucleus (OPN). The degree of constriction correlated directly with the intensity of illumination. We then examined how the responses correlated with patterns of host connections made by the transplant using mouse-specific monoclonal antibodies. The transplants projected only to areas of the brainstem normally innervated by the eye, including the OPN. The overall density of innervation did not, however, correlate predictably with the parameters of the pupilloconstriction response. Some animals with a brisk pupillary response had sparse innervation of the OPN while animals with heavily innervated nuclei sometimes showed a relatively slow response.

Thus ectopic neural xenografts are capable of making specific connections which can drive an appropriate response to a natural stimulus. While important in showing the ability of transplants to make specific functional connections, this study also provides a simple assay system for examining conditions which may improve the efficacy of host innervation by the transplant.

RETINAL TRANSPLANTS CAN MAKE FUNCTIONAL CONNECTIONS WITH THE MATURE MAMMALIAN BRAIN. H. Klassen* and R.D. Lund (SPON: P. Munro) Dept. Neurobiol., Anat. and Cell Sci., Sch. of Med., Univ. of Pittsburgh, Pittsburgh, PA 15261

We have shown previously that fetal retinae transplanted into neonatal rats are capable of making the connections necessary for driving a pupillary reflex in the host eye in response to light. At birth the rat brain is still developing and therefore presents a favorable environment for fiber outgrowth and synaptogenesis. It is also important to determine whether such transplants will establish functional connections within the less plastic mature brain.

Fetal retinae taken from E13 Sprague-Dawley rats were grafted into the pretectal region of allogenic hosts which ranged in age from 36 to 42 days old. The contralateral eye was removed to reduce afferent competition between graft and host. The remaining optic nerve was later cut to eliminate all input from the host visual system. In many of the animals illumination of the transplant elicited a pupilloconstriction response in the host eye. The magnitude of the response however varied considerably. In some animals the host response was as brisk as that seen after transplantation into neonatal rats and, similarly, the degree of constriction was dependent upon the level of illumination of the transplant. Other animals showed extremely small changes upon stimulation. Approximately half of the animals in this study showed no stimulus-associated pupillary activity whereas similar transplants into neonates are associated with a failure rate of only 10% or less. Transplants which did exhibit a brisk pupillary reflex were consistently found to be imbedded in the pretectal area.

Athough the microenvironment of the mature mammalian brain seems to be less conducive to the establishment of graft-host connections than that of the developing brain, these results show that retinal transplants are capable of making the specific functional connections necessary to elicit an appropriate motor response in the host.

TRANSPLANT AND HOST RETINAL INPUTS INTERACT TO DRIVE PUPILLARY REFLEX. J.D. Radel, H. Klassen* and R.D. Lund, Dept. Neurobiol., Anat. and Cell Sci., Univ. of Pittsburgh Sch. Med., Pittsburgh, PA 15261.

Retinal transplants have been shown to be capable of driving a pupillary reflex in rats after elimination of host optic input. We investigate here whether transplanted retinae can also drive the pupillary reflex in the presence of an intact host visual system.

Embryonic (E13) rat retinae were transplanted into the midbrain of one day old rats. In one group of animals one eye was removed at the time of transplantation, while in a second group both eyes were left intact. Beginning three weeks postnatally, the skull overlying the transplant was removed and the transplant exposed. Illumination of the transplant produced host eye pupilloconstriction, although the degree of constriction varied across animals. The transplant-mediated pupillary reflex was observed in both eyes of the two-eyed hosts and was in all cases obtainable immediately upon exposure of the transplant. By using 2 separate light sources it was possible to vary independently the intensity of host and transplant illumination. Photic stimulation of either the transplant or the host elicited pupilloconstriction, the extent of which was directly correlated with the luminance intensity. When host eye stimulation was maintained at an intermediate level, illumination of the transplant resulted in further constriction of the host pupil.

These results indicate that intracranial retinal transplants, which receive minimal photic stimulation until they are sugically exposed for testing, can make usable connections even when forced to compete for synaptic sites with the active, intact host visual system. Furthermore, transplant encoded luminance information received by the host brain is not overwhelmed by activity within the normal visual pathway, but is instead combined with information from host retinae to produce an additive effect on pupilloconstriction.

511.13

CORTICAL ACTIVITY CAN BE ELICITED BY LIGHT STIMULATION OF RETINAL TRANSPLANTS. S. Craner*, J.D. Radel and R.D. Lund (SPON: P. Land) Univ. of Pittsburgh School of Medicine, Pittsburgh, PA 15261.

Previous work in this laboratory has demonstrated that retinal transplants are capable of evoking unit activity in the superior colliculus in response to photic stimulation. The present study examines the ability of retinal transplants to evoke activity in the visual cortex of host rats.

Retinae were removed from embryonic (E13) rats and transplanted into the midbrain of postnatal (P1) rat hosts. One of the host's eyes was removed at that time to enhance the transplant projection. Between 4 and 8 weeks postnatally, the skull overlying the brainstem was removed. The presence of a transplant-mediated pupillary reflex was used to assay for functional transplant-host connections. With the eye shielded, the brainstem was illuminated in an effort to drive the pupillary reflex in the remaining host eye via the transplant. The right and left visual cortices were then exposed in animals exhibiting transplant-mediated pupillary reflexes.

Evoked potentials and multiunit activity were recorded in visual area 18 of the cortex ipsilateral to the remaining host eye in response to photic stimulation of the transplanted retina. These responses were graded with respect to the intensity and duration of the stimulus. Contralateral cortical responses to illumination of the host eye were compared to those responses mediated by the transplant. To confirm that the evoked activity was truly transplant-mediated, the host eye was shielded or removed. Following the testing, the presence of a transplant was confirmed histologically.

These results demonstrate that photic stimulation of retinal transplants is capable of eliciting appropriate activity in the visual cortex, presumably via transplant-mediated activity in the superior colliculus and lateral posterior nucleus of the thalamus.

This research was supported by the Emmerling Fund of the Pittsburgh Fdn. and by NIH grants EY05962 (JDR) and EY05283 (RDL).

FORMATION OF A NEURAL CIRCUIT BY TRANSPLANTED REGIONS OF RAT VISUAL SYSTEM. H.F. Zhou*, J.S Lund and R.D. Lund (SPON: S.K. Wolfson,Jr), Dept. Neurobiol., Anat. and Cell Sci., Univ. Pittsburgh, Pittsburgh, PA 15261

Previous studies show that retinae grafted to the rat cortex send projections to co-transplanted diencephalon. To determine if transplanted diencephalon also projects to the cortex and if a neural circuit could be established by several transplanted regions, diencephalon was dissected from E14 CD-1 mice and was placed in cortex of one-day old (P1) Sprague-Dawley albino rats. Host brains were fixed with 4% paraformaldehyde 3-9 weeks after transplantation. Monoclonal antibodies to mouse neuron surface antigens (M6 & M4) were used to demonstrate projections from the grafts. Transplants placed near visual cortex projected to layers I, IV and VI in the form of patches. In a further study, E14 mouse diencephalon and E16 rat occipital cortex (or the reverse: E14 mouse cortex and E16 rat diencephalon) were co-grafted into the right superior collicus (SC) of P1 rats. The left eyes of the rats were removed 36 hours prior to fixation at three or more weeks of age. The projection from host eyes to transplanted diencephalon was demonstrated by the Fink-Heimer method. Degenerating optic axon terminals were found in the host SC and in parts of the transplanted diencephalon. Using antibody staining, we found that transplanted diencephalon projected to co-transplanted occipital cortex, and cortex also projected back to the entire transplanted diencephalon.

The results indicate that co-transplanted brain regions can make appropriate connections with each other and with host neural structures. Supported by NIH grant EY05283.

RETINAL GRAFTS IMPLANTED INTO THE ADULT EYE LESION SITE STIMULATE THE DAMAGED HOST RETINA. Laedtke, Thomas W.* and James E. Turner (SPON: D.J. Goode). Dept. of Anatomy, Wake Forest University, Bowman Gray School of Medicine, Winston-Salem, NC 27103

This study tests the potential for wound repair in the host retina by retinal implants. More specifically, it examines the effects of retinal grafts on the local degeneration which follows lesion surgery. Adult Sprague-Dawley rats received a lesion incision made through the sclera, choroid, and retina. In addition, a second group of animals also received implants of embryonic day 15 retinal tissue, placed into the host lesion site. Animals were sacrificed 28 days following surgery and tissues were analyzed by light microscopy to evaluate the thicknesses of the optic fiber layer-ganglion cell layer (OFL-GCL), inner plexiform layer (IPL), inner nuclear layer (INL), and outer nuclear layer (ONL), as well as the ganglion cell density (GCD). These measurements were taken in a 1000 μm region peripheral and central to the lesion. Controls not containing retinal implants exhibited dramatic reductions in individual layer thicknesses peripheral to the lesion site. Similarly, the GCD decreased by 50% in this region compared to unlesioned control animals. The presence of a retinal implant, however, resulted in a reduced degenerative response in layer thicknesses peripheral to the lesion and a dramatic increase in the thickness of the OFL-GCL, INL, and ONL central to the lesion site. This stimulatory effect was also evident in GCD as ganglion cell loss in the peripheral retina was reduced by 20% when compared to lesioned controls. Thus, retinal implants appears to elaborate putative diffusable factors to induce a 'rescue' effect on the degenerating host retina. Supported by NIH Grant No. EY04377.

511.16

TRANSPLANTATION OF RETINAL PHOTORECEPTORS TO DYSTROPHIC RETINA. S.E. Hughes* and M.S. Silverman* (SPON:D. Parkinson), Central Institute for the Deaf and Washington University School of Medicine, St. Louis, MO 63110.

Inherited retinal degeneration afflicts a variety of animals, including humans. Several established animal models exist for inherited retinal dystrophy and retinitis pigmentosa, including the RCS rat and the rd mouse. These strains provide model systems in which it is thought that the deficit resides in the photoreceptor (the rd mouse) or is related to the pigment epithelium (the RCS rat). We have devised methods for isolating the outer plexiform layer from the retina and transplanting the resulting photoreceptor layer to the subretinal space (Silverman and Hughes, Invest. Ophthalmol. Vis. Sci. Suppl. 28: 288; Soc. Neurosci. Abstr. 13: 1301). We transplanted neonatal (8 day old) photoreceptors from nondystrophic congenics to the subretinal space of adult dystrophic animals. For definitive identification of the transplanted cells as photoreceptors we used a monoclonal antibody specific to opsin (RET-P1 from C. Barnstable). With H&E staining the transplanted cells are easily distinguished from any residual host photoreceptors.

In the rd mouse, the transplanted photoreceptors have been found to survive for at least 4 weeks. This is significant because photoreceptors of the rd show degeneration after 2 weeks, with few remaining after 3 weeks. The survival of the transplanted photoreceptors supports findings that the deficit within the rd retina is endogenous to the rd photoreceptors themselves. To our surprise, we have also found that transplanted photoreceptors survive in the RCS rat. This may be due to their limited production of outer segments. It is the failure of the pigment epithelium to remove the accumulation of shed outer segments which is thought to lead to photoreceptor elimination in the RCS retina.

Supported by grants from the National Retinitis Pigmentosa Foundation and the Monsanto Company.

511.17

TRANSPLANTATION OF HUMAN PHOTORECEPTORS TO LIGHT DAMAGED RETINA. M.S. Silverman* and S.E. Hughes* (SPON: C. Blazynski). Central Institute for the Deaf and Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

Previously we reported successful transplantation of the intact photoreceptor layer from the developing as well as mature rat retina to adult albino rats with light-induced loss of photoreceptors (Silverman and Hughes, Invest. Ophthalmol. Vis. Sci. Suppl. 28: 288; Soc. Neurosci. Abst. 13:1301). These results prompted us to ask whether mature human photoreceptors from adult eye donors might also be transplantable.

Photoreceptors were taken from the retina of donated human eyes (obtained from the MO Lions and St. Louis Eye Banks) following corneal removal. Hosts were adult albino rats (immune suppressed or immune competent) exposed to constant illumination for four weeks which decimates host photoreceptors while leaving the remaining retina intact. The isolated photoreceptor layer was transplanted using a transcorneal approach to the subretinal space. The retina reattaches to the back of the eye with the transplanted photoreceptors interposed between the retina and the underlying pigment epithelium. With immune suppression photoreceptor transplants were successful at all survival times so far examined showing apparent physical integration with the host retina and maintaining morphological features of the outer nuclear layer. The transplants stained positive for antiopsin antibody RET-P1 (C. Barnstable) identifying the transplanted cells as photoreceptors and further suggesting that they may be capable of light transduction. In contrast, transplants to immune competent hosts showed signs of rejection within one week of transplantation. Sham operates showed no repopulation of the host retina with photoreceptors.

These results show that human photoreceptors can be transplanted and, significantly, that mature photoreceptors can be transplanted while other neurons apparently must be developmentally immature for successful transplantation.

FETAL EYE AND SCIATIC NERVE SEGMENTS AS BRIDGES BETWEEN HOST ANTERIOR EYE CHAMBER AND FOREBRAIN. B. H. Hallas and M. F. Zanakis. New York College of Osteopathic Medicine, Old Westbury, New York 11568 and American BioInterface Corporation, New York, New York 10276.

Various age rat fetal eyes (e. 14-21d.) were removed intact and sutured to the proximal segment of an adult rat sciatic nerve from the same strain. The entire fetal eye/sciatic nerve combination was then inserted into the anterior eye chamber of adult hosts. The distal portion of the sciatic nerve bridge was inserted into the host's forebrain. Simultaneously as the fetal eye/sciatic nerve bridge was implanted, the ipsilateral optic nerve was crushed and dry ice applied to the area of the crush as close to the host retina as possible.

Thirty days post-implantation a 40% solution of HRP was injected intraocularly. In a second group of identically implanted animals the sciatic nerve segment was transected midportion and HRP applied directly to the transected ends. Forty-eight to seventy-two hours after the application of HRP, all animals were sacrificed. In all host animals, regardless of the age of the fetal eye, the implant survived, grew, differentiated and the label patterns in the host forebrain and implant were quantified. This implant/peripheral nerve technique is a useful model for the study of CNS regeneration and repair.

NEURAL CONTROL OF IMMUNE SYSTEM III

512.1

SUPPRESSION OF PROLACTIN BY ORAL CYSTEAMINE TREATMENT SUPPRESSES IMMUNE RESPONSES IN MICE. E.W. Bernton*, J.W. Holaday and H.U. Bryant., Dept. Med. Neurosci., Walter Reed Army Inst. Res., Washington, D.C. 20307-5100.

Suppression of pituitary prolactin (PRL) secretion by bromocryptine suppresses various immunologic responses in mice. Since cysteamine HCl (CYS) suppresses pituitary PRL secretion by mechanisms unrelated to dopamine-agonist effects, we examined its effects on immune and neuroendocrine correlates. In a time course study, male C3H/HeN mice received CYS (200 mg/kg/day; po), and were then sacrificed for determination of serum PRL and corticosterone (CS), and mitogen-induced lymphocyte blastogenesis. Serum PRL levels were unaffected after 1 day of CYS, but were suppressed following 2, 3, and 4 days (46, 51 and 47% of control, respectively). Serum PRL remained suppressed 2 and 3 days after CYS treatment (73 and 52%, respectively). Lymphocyte blastogenesis in response to 1 µg/ml concanavalin A and 2.5 µg/ml lipopolysaccharide were suppressed with 3 or 4 days CYS. Reduced blastogenic responses were noted at 2 and 3 days after stopping CYS and had recovered by 4 days. CYS treatment did not increase CS levels, suggesting this treatment was not a nonspecific stressor. Coincident treatment with PRL (50 µg/day) attenuated immunosuppression in CYS-treated mice. Cysteamine treatment also suppressed splenocyte reactivity in a mixed lymphocyte reaction and antibody secretion in a plaque-forming assay. These studies suggest that suppression of PRL secretion mediates the immunosuppressive effects of CYS, further supporting the role of PRL as an important immunotrophic hormone.

ENHANCED BLASTOGENESIS OF HUMAN LYMPHOCYTES BY PROLACTIN. S. Kennedy, W.B. Malarkey*, D.M. Shaut* and R. Glaser*. Ohio State University Coll. of Med., Columbus, OH 43210.

Recent developments in neuroimmunology have pointed to the interplay between the nervous, endocrine and immune systems. For example, lymphocytes possess receptors for a number of neurohormones, including prolactin and growth hormone.

In the present study, human lymphocytes were cultured with either human or ovine prolactin in combination with the mitogens phytohemagglutinin (PHA) or concanavalin A (Con A). Optimal culture conditions for mitogen stimulation were determined in preliminary studies. Cultures were harvested at 96 or 120 hours; blastogenesis was measured by tritiated thymidine incorporation. In contrast to prolactin or mitogen alone, treatment of cells with PHA or Con A in combination with prolactin resulted in a dose-dependent enhancement of blastogenesis. Both human and ovine prolactin were effective in their additive effects with mitogen. We are currently examining the effects of prolactin inhibitors on alterations of blastogenesis by prolactin.

The data thus far indicate that T-lymphocyte replication in response to mitogens may be influenced by levels of prolactin. These data are in agreeement with an earlier report examining prolactin function in the rat (Hiestand, et al, Proc. Natl. Acad. Sci., 1986, 83, 2599-2603), and suggest that prolactin may be a critical neuroimmune modulator.

512.3

SOMATOSTATIN (SS) AND ITS mRNAS ARE DECREASED IN GVHD. L. Chen* and W.S.T. Griffin (SPON: T.M. Badger). Depts. Ped. and Anat., U. AR Med. Sci., Little Rock, AR 72205.

Immunohistochemistry, Western immunoblotting, and Northern hybridization were used to analyze relative levels of immunoreactive SS and SS mRNA in the brain of immunoincompetent neonatal rats, bearing allogeneic-lymphocyte grafts that cause graft versus host disease (GVHD). GVHD levels were compared to those from littermates receiving alloantiserum treatment (AAS) to cure their GVHD or from uninjected littermate controls (C). The numbers of SS-immunoreactive cells in temporal lobe cortex and hippocampus regions were less in GVHD than in AAS or C as were the relative levels of both the neuropeptide and its encoding mRNAs. Hippocampectomy or experimentally decreased CSF levels of SS results in an increase in the release of hypothalamic corticotrophin releasing factor (CRF), pituitary adrenocorticotrophic hormone (ACTH), and corticosterone (CORT). As CORT titers are regulated by SS and CORT is immunosuppressive, we hypothesize that the elevation of CORT titers in GVHD is related to the decrease in SS in GVHD brain and that the elevated CORT contributes to the profound immunodeficiency syndrome that is associated with GVHD. AAS reverses both the elevation of CORT and the decrease in the number of SS-immunoreactive cells, suggesting that GVHD-related agent(s) regulate SS levels in brain cells rather than cause the loss of SS-immunoreactive cells.

512.4

AGE AND ROUTE SPECIFIC DIFFERENCES IN RESPONSE TO IL-1 L. W. Martin*, L. B. Deeter* and J. M. Lipton (SPON: G. Moushegian). Dept. of Physiol., The Univ. Tex. Southwestern Med. Ctr. at Dallas, Dallas, TX 75235.

Many aspects of the acute phase response (APR) are muted in the elderly, and the reasons are unknown. Administration of the cytokine IL-1 induces many components of the APR, implicating IL-1 as a mediator of the APR.

To determine if the route of administration or age affect the acute phase response to IL-1 we administered IL-1 intracerebroventricularly (ICV), or intravenously (IV), to young and old female rabbits and monitored fever, circulating white blood cells (WBC) and neutrophils, and plasma levels of α-MSH, a neuropeptide that antagonizes actions of IL-1.

ICV IL-1 in young rabbits caused fever, but no significant changes in WBC, neutrophils or α-MSH. ICV IL-1 in old rabbits caused no fever and modest increases in neutrophils and α-MSH. IV IL-1 in young rabbits caused fever, increased WBC, neutrophils and α-MSH. IV IL-1 in old rabbits did not cause fever nor increases in WBC, neutrophils or α-MSH. The results indicate that: (1) the response to peripheral and central IL-1 is reduced in aged animals, and (2) that the effect of IL-1 on the APR in young animals is greater when it can act both centrally and peripherally after IV injection.

OCCURRENCE OF β-ENDORPHIN AND RELATED PEPTIDES IN STIMULATED AND UNSTIMULATED HUMAN PERIPHERAL BLOOD LEUKOCYTES. A.D. Van Woudenberg*, V.M. Wiegant*, C.J. Heijnen*+ and D. De Wied*, Rudolf Magnus Institute of Pharmacology, University of Utrecht, Vondellaan 6, 3521 GD Utrecht, The Netherlands, + Dept. Pediatric Immunology, University Hospital for Children and Youth, Utrecht, The Netherlands.

Recently it has been shown that human peripheral blood leukocytes (PBL) can produce POMC-derived peptides, particularly when stimulated by virus or corticotropin releasing factor (CRF). The present study demonstrates that endorphin immuno-reactivity (IR) occurs also in unstimulated PBL. Peptides were extracted from PBL isolated from freshly obtained blood of healthy volunteers, by heating in 1M acetic acid and homogenization. The extracts were analyzed in three radio-immunoassay systems specific for: 1) β-endorphin (βE), 2) α-endorphin (αE) and 3) γ-endorphin (γE). With each of these assay systems IR was detectable in all the extracts analyzed. The IR amounted to 200, 60 and 10 pg/10^7 cells for β-, α- and γ-E respectively. When PBL were cultured in the presence of Con A for 48 hrs, the βE content of cell extracts had increased twofold compared to nonstimulated cells. PBL were separated in subsets enriched in T-cells, B-cells and monocytes. In all three subsets, βE IR was found. The concentration in T-cells however appeared to be lower than that in the non T-subsets. The present data show that human PBL contain endorphin IR and suggest that such cells may express POMC not only under stimulated, but also under normal conditions.

512.6

CHEMOTACTIC ACTIVITY OF OPIOID AND NON-OPIOID FRAGMENTS OF BETA-ENDORPHIN. P.Sacerdote, L.Palazzolo* and A.E.Panerai. Dept. of Pharmacology, School of Medicine, University of Milan, Italy.

ß-Endorphin (ßE) has been shown to modulate several immunological functions. Some of these effects are not mediated by a classical opioid receptor, as they are not reversed by naloxone. We analyzed the monocyte chemotactic activity of opioid (N-terminal) and non opioid (C-terminal) fragments of ßE. Both N-terminal and C-terminal fragments are chemotactic. ßE 1-31 is the more potent: peak activity at 10^{-12} M, CI=3: chemotaxis is reversed by naloxone. The N-terminal sequences ßE 1-17, 1-16, and 1-27 are as potent as the C terminal fragments ßE 6-31 and N-acetil, with a maximum CI of 2.5 at 10^{-11} M. Only the N-terminal fragment induced chemotaxis is reversed by naloxone, suggesting that the C-terminal fragments bind a receptor different from the classical opioid one. This analysis suggest that ßE can interact with human monocytes at two different sites, and suggest a physiological role for the circulating form N-acetil ßE function was still unknown.

512.7

ß-ENDORPHIN REVERSES PGE_1 SUPPRESSION OF RAT T-CELL MITOGEN-INDUCED PROLIFERATION. L.M. Hemmick and J.M. Bidlack. Dept. of Pharmacology, Univ. of Rochester Sch. of Med. and Dent., Rochester, NY 14642.

Prostaglandins of the E series (PGE) have been shown to increase cAMP levels, decrease phosphatidylinositol phosphate hydrolysis, and inhibit mitogen-induced proliferation of T-lymphocytes. In brain, ß-endorphin (BE) inhibits cAMP levels, while in rat thymocytes, BE enhances mitogen-stimulated Ca^{2+} uptake (Hemmick, L.M. and Bidlack, J.M., Life Sci. 41:1971 (1987). This study addressed the question: Can ß-endorphin and other opioid peptides reverse the PGE suppression of lectin-induced T-cell proliferation? Cervical and mesenteric rat lymph node cells were cultured for 72 hr with either phytohemagglutinin (PHA) or concanavalin A (Con A) in the presence of PGE_1 and opioid peptides prior to the measurement of proliferation by ^{3}H-thymidine incorporation into the DNA. BE 1-31 reversed PGE_1 suppression of PHA and Con A-stimulated proliferation. The reversal was titratable from 10^{-8} M to 10^{-5} M, with a maximal enhancement of 79 ± 13% at 10^{-5} M BE 1-31. [D-Ala^2]met-enkephalin (DAME) also reversed the PGE_1 suppression. Neither BE 1-31 nor DAME affected basal or mitogen-stimulated proliferation of T-cells. These data suggest that BE and DAME may regulate T-cell proliferation by counteracting the inhibitory actions of PGE and other compounds which stimulate cAMP levels. 512.8

OPIOID MODULATION OF INVERTEBRATE HEMOCYTE MIGRATION. P. Cadet*, L. Simmons*, J. Sinisterra*, G. B. Stefano, X.Zhao* and M.K. Leung. CTR for the Study of Aging, SUNY/Old Westbury, Old Westbury, N.Y. 11568, USA

The interaction among the immune, nervous and endocrine systems is due to the close chemical relationship between their messenger substances. In Mytilus edulis (Bivalvia), where opioid substances are known to exist, the branchial nerve was severed to determine if the immune response may involve opioid substances as noted in mammals. This area was observed via histofluorescence, immediately, 2 hours and 10 hours following the surgery. This treatment evokes a cellular immune response as noted by the directional migration of specific serotonin-containing hemocytes to the damaged nerve. Injection of DAMA (10 ul, 10^{-6} M) into an area close to the served nerve resulted in a migration of the hemocytes into this vicinity as opposed to the lesioned neuron. Naloxone injection into the immediate severed nerve area appeared to inhibit/block the specific hemocytes from adhering to the severed branchial nerve. This opioid chemotactic activity appears to be select since epinephrine, norepinephrine, dopamine, serotonin, substance P, insulin, octopamine and FMRFamide did not induce the cellular clustering. The results suggest that opioid interaction with "blood" cells arose early in the course of evolution. **Supported by grants NIH-MBRS 08180 & ADAMHA-MARC 17138.**

POTENTIATION OF IMMUNE RESPONSIVENESS FOLLOWING PITUITARY GLAND TRANSPLANTATION. R.J. Cross and T.L. Roszman (SPON: L.Boyarsky, Dept. of Microbiology & Immunology, Univ. of Kentucky, Lexington, KY 40536-0084.

Recent reports have shown that the pituitary hormone, prolactin is required for immune function. Administration of the dopamine agonist, bromocryptine, has been shown to impair macrophage function and humoral immune responsiveness, while transplantation of syngeneic pituitary grafts (SPG) in immunocompromised, hypophysectomized animals restores immunocompetence. These data extend these previous reports by showing that SPG augment the humoral antibody response of normal mice. SPG were transplanted under the kidney capsule of C57Bl/6 mice and 10-14 days later the mice were immunized with sheep red blood cells (SRBC). The resulting antibody response shows that mice with SPG have significantly enhanced IgM and IgG plaque-forming cell responses. Serum prolactin levels in these mice are also elevated. Similarly, mice with two SPG display antibody responses that are elevated compared to mice with one SPG. SPG however do not increase the number of nucleated cells in the spleen or alter the percentage of B-cells,T-cells or T-cell subsets (Lyt 2 or L3T4). Immunization of SPG-mice with the T-cell independent antigen, TNP-LPS, indicates that enhancement of immune responsiveness can occur independent of T-cell Function. TEMPORAL DISSOCIATION BETWEEN STRESS-INDUCED CHANGES IN NEUROENDOCRINE AND IMMUNE SYSTEMS. C.M. Flores*, M. Hernandez*, K.M. Hargreaves* and B.M. Bayer* (SPON: S. POTOLICCHIO). Dept. of Pharmacology, Georgetown Univ. Med. Ctr., Washington, DC 20007.

These studies examined the temporal relationships between stress-induced changes in the neuroendocrine and immune systems. Rats were implanted with jugular catheters. Following 24 hrs, animals were either stressed by immobilization or placed in individual cages. Blood samples were drawn at 0, 30, 60, 90, 120, 180 and 240 minutes and mitogen-stimulated lymphocyte proliferation and corticosterone, β-endorphin and prolactin plasma levels were determined. Basal corticosterone levels (83 + 31.3 ng/ml) increased 4 to 5 fold in stressed animals within 30 min and remained similarly elevated for 240 min. Basal β-endorphin levels (138 + 23.3 fmol/ml) increased 4 fold by 60 min and declined to basal levels within 240 min. Basal prolactin levels (12.1 + 1.9 ng/ml) maximally increased within 30 minutes (141 + 7) and declined thereafter. No significant differences were found in blood lymphocyte responses of restrained and control animals. In vitro studies showed that only corticosterone was inhibitory when added directly to lymphocyte cultures. These results suggest a temporal dissociation between the increase in corticosterone and suppression of lymphocyte activity during the response to stress.

512.11

MODULATION OF ALLOGENEIC AND AUTOLOGOUS MIXED LYMPHOCYTE REACTIVITY BY NERVE GROWTH FACTOR. L.W. Thorpe and J.R. Perez-Polo. Dept. H.B.C.&G., Univ. Tex. Med. Br., Galveston, TX, 77559.

We and others have demonstrated that nerve growth factor (NGF) plays a modulatory role in immune function. The mixed lymphocyte response (MLR) is a measure of the ability of lymphocytes to recognize and destroy foreign or transformed cells. The autologous mixed lympho- cyte reaction (AMLR) to self-antigens is thought to be critical in the maintenance of immune tolerance. The effects of NGF on MLR and AMLR activity was examined using one-way cultures of rat (LEWvsBN) splenocytes (MLR) and autologous T vs nonT cell (LEW) cultures (AMLR). The cells were incubated (5-6 days) with or without NGF (0.1-10 ug/ml) and assayed for ^{3}H-thymidine uptake. In the AMLR increased proliferation was seen for all concentrations of NGF tested, however a significant increase in DNA synthesis was observed in the MLR only at the highest NGF dose. These results suggest a differential NGF effect on the activation of responding lymphocyte subsets and a response dependent on the type of antigenic stimulus. These observations streng- then our hypothesis that NGF plays a signal role in neuro-immune interactions. Supported by ONR-RR 04108.

EFFECTS OF HUMAN AND RODENT INTERFERON ON BEHAVIOR. L.S. Crnic and M.A. Segall* Departments of Pediatrics and Psychiatry, University of Colorado School of Medicine, Denver, CO 80262.

Interferon (IFN) is known to produce nausea in humans. Therefore, to determine whether human (IFN) was effective in rodents, rats were subjected to a conditioned taste aversion (CTA) procedure. Results showed no evidence of CTA to 150 nor 600 units/g of human recombinant IFN alpha. IFN did not block LiCl CTA. No effects of human IFN upon radial maze learning in rats were seen. We had shown that this same IFN accelerates the onset of REM sleep in primates (Reite et al, Biol. Psychiat., 22, 104-7, 1987). In contrast, mouse IFN alpha altered the daily rhythm of activity and food intake in mice. These results agree with the prior findings of species specificity in the physiological effects of IFN. Thus, reports of neurophysiological and behavioral effects of human IFN in rodents should be interpreted with caution.

We have developed an immunocytochemical technique for detecting IFN in tissues which has successfully detected the production of IFN in poly rI-rC induced astrocytes.

SYNTHESIS OF THE HUMAN INTERLEUKIN-1α cDNA AND ITS EXPRESSION IN *E.coli*. **R.A.Ashton, A.Blume, B.Beer and M.Vitek. Dept. of CNS Biology, American Cyanamid Co., Lederle Labs., Pearl River, NY 10965**

Interleukin-1 (IL-1) functions peripherally as a mediator of the acute phase of the immune response. IL-1 can demonstrably evoke responses within the CNS as well, including induction of fever, hypothalamic release of corticotropin releasing factor, and increased slow-wave activity in the sleep EEG. Central effects of IL-1 may be mediated through receptors located throughout the brain (Farrar *et al., J. Immunol.*, 139: 459-463, 1987). In order to study the function and distribution of IL-1 in the CNS, we sought to obtain the IL-1α protein and its corresponding cDNA. While this could be accomplished by screening a cDNA library using conventional hybridization techniques, we elected, instead, to synthesize the cDNA corresponding to the mature and active form of the human IL-1α protein. Twelve oligonucleotides were synthesized, six per strand, annealed together, and ligated. The 468 base pair DNA was then ligated into the prokaryotic expression vector, pEV-vrf1 (Crowl *et al., Gene*, 38: 31-38, 1985) to yield pCLL706.2. DNA sequencing confirmed that the pCLL706.2 sequence exactly matched nucleotide positions 351 to 816 of the IL-1α sequence reported by Gubler *et al. (J. Immunol.*, 136: 2992-2997, 1986). This cDNA was transformed into *E. coli* expressing a temperature sensitive cI repressor protein. Shifting the growth temperature from 30° to 42° induced translation of a 17 kDa protein, the size of the mature IL-1α protein. "Western" blots of this protein react strongly with an anti-IL-1α polyclonal antibody (a generous gift of Dr. R. Chizzonite, Hoffmann LaRoche, Inc.). Finally, lysates of heat shocked cells containing pCLL706.2 stimulated [^{3}H]thymidine uptake into mouse thymocytes about 6000 fold more than control lysates. Based on these data, we conclude that pCLL706.2 directs the synthesis of a biologically active recombinant human IL-1α protein.

TUMOR NECROSIS FACTOR IMMUNOREACTIVE INNERVATION IN THE MOUSE BRAIN. C.D. Breder and C.B. Saper, Depts. of Pharm. and Physiol. Sci. and Neurology, Univ. of Chicago, Chicago, IL 60637

Tumor necrosis factor α (TNF) is a macrophage derived cytokine that is responsible in part for the cerebral component of the acute phase reaction and chronic response to infection and cancer. TNF, like other cytokines such as interleukin-1 (IL1), is thought to enter the central nervous system through the circumventricular organs (CVOs), and to act on local neurons. However, it has recently been demonstrated that IL1 is found in an intrinsic neuronal system within the brain, and acts on neurons at some distance from the CVOs. We have used an antiserum against recombinant murine TNFα to examine the hypothesis that there might also be a TNF-like immunoreactive (TNFir) neuronal system in the brain. TNFir cell bodies were seen the hypothalamus, primarily in the paraventricular nucleus and in the medial preoptic and lateral hypothalamic areas. TNFir fibers were observed innervating the lateral septum, the bed nucleus of the stria terminalis, the paraventricular nucleus of the thalamus and several regions of the hypothalamus, including the dorsomedial, paraventricular, periventricular and suprachiasmatic nuclei and the lateral hypothalamic area. In the brainstem, TNFir fibers were found to innervate the central gray matter, the parabrachial nucleus and the dorsal vagal complex. Our findings suggest that the TNFir neuronal system in the mouse brain may play a role in the autonomic and endocrine responses that occur during the inflammatory response.

NPY-POSITIVE NERVE TERMINALS CONTACT LYMPHOCYTES IN THE PERIARTERIOLAR LYMPHATIC SHEATH OF THE RAT SPLENIC WHITE PULP. J.A. Olschowka, S.Y. Felten, D.L. Bellinger, D. Lorton, and D.L. Felten. Department of Neurobiology and Anatomy, University of Rochester School of Medicine, Rochester, NY 14642.

There is a large body of evidence that sympathetic noradrenergic nerve fibers innervate smooth muscle associated with blood vessels, cardiac muscle, and secretory glands throughout the body. In many instances, neuropeptide Y has been shown to be co-localized within these noradrenergic nerves. Earlier we have demonstrated that noradrenergic nerve fibers, in addition to supplying the smooth muscle of the splenic capsule, trabeculae and blood vessels, also form very tight appositions with lymphocytes of the periarteriolar lymphatic sheath (J. Neurosci. Res. 18:38-48, 1987). The possibility that neuropeptide Y may directly effect lymphocytes by direct apposition of nerve terminals was studied by using electron microscopic immunocytochemistry to localize NPY within the spleen.

Immunocytochemistry was used to demonstrate NPY-like positive profiles in the spleen of the adult Sprague Dawley rat. At the light microscopic level, numerous varicose nerve profiles were observed in the white pulp, particularly surrounding the central arteries and their arteriole branches. At the electron microscopic level, NPY terminals were observed in close proximity to smooth muscle cells of the arteries and directly abutting lymphocytes. There was no intervening cell processes between these presumed T-lymphocytes of the periarteriolar lymphatic sheath and the labeled varicosities. The opposing membranes were smooth, evenly spaced. This association, like that for the noradrenergic system, provides a route by which the autonomic nervous system may directly influence specific immune system effector cells. We are currently working to determine the possible co-localization of NPY within noradrenergic fibers of the spleen.

LHRH PARTICIPATES IN NEURO-IMMUNE-ENDOCRINE INTERACTIONS. B. Marchetti*, V. Guarcello*, M.C. Morale* and U. Scapagnini*(SPON: M. Motta). Dept. of Pharmacology, Medical School, University of Catania, 95125 Catania, Italy.

The present paper adresses the question of whether the hypothalamic peptide LHRH might function as a natural link in the bidirectional regulation of neuroendocrine and immune systems function. Indeed, specific binding sites enabling LHRH to act upon the rat thymus gland,have been characterized. Thymic LHRH binding sites undergo important changes associated with marked modifications of the immune response, namely puberty, castration and aging.Detection of rat anti-BSA antibodies of the IgG class following 15 days in the serum of young and old rats immunized with multiple injections of complete Freund adjuvant and BSA confirmed the profound suppres sion of the humoral immune response in aging animals, while LHRH-analog treatment produced a marked increase in anti-BSA antibodies titers. Moreover, the in vitro response of thymocytes from both young and old rats to the mitogen concanavalin A (Con-A) was 7-fold higher in LHRH-treated animals. In addition, LHRH agonists directly potentiate Con-A-stimulated blastogenesis,suggesting that these peptides may also modulate immune system function.

INTERLEUKIN-2 ENHANCES CHICK AND RAT SYMPATHETIC, BUT NOT SENSORY, NEURITE OUTGROWTH. P.K.Haugen*and P.C.Letourneau, Dept. of Cell Biol. and Neuroanat., Univ. of Minn., Mpls., MN 55455.

An increasing amount of evidence suggests the nervous and immune systems are interdependent. Lymphokine growth factors may represent a link between these two systems. We wished to determine if one such lymphokine, interleukin-2 (IL-2), affects neurons in vitro. To determine if IL-2 affects neurons, sympathetic and sensory neurons from chick and rat were cultured in media with human recombinant IL-2. Ganglia from E9-E11 chicks and neonatal rats were dissected, dissociated in 0.25% trypsin, and plated on dishes coated with laminin. Cells were cultured in serum free media with or without IL-2 (2-200U/ml) and with or without NGF. IL-2 enhanced the number of neurons with neurites in chick sympathetic chain and rat SCG neurons by 200-300% over cultures without any growth factors. Sensory neurons from chick and rat DRGs were not affected by culture in IL-2. Further, sympathetic neurons cultured in IL-2 were 200-300% longer than those cultured without IL-2. In chick, the enhancement of neurite outgrowth and length by IL-2 is nearly the same as that seen with NGF. Cells cultured in NGF and IL-2 together did not show an increase in neurite outgrowth, but did have increased neurite length over cultures containing NGF or IL-2 alone (chick only). Neuron response to IL-2 was dose dependent, with an optimum around 0.2U/ml (0.1 ng/ml or 10 pM) for chick sympathetic neurons and around 2U/ml (1 ng/ml) for rat SCG. Concentrations as low as 10fM were still effective. Cultures which had been preplated to enhance for neurons by removing the more adherent fibroblasts and glia showed the same enhancement of neurite outgrowth by IL-2 as cultures which had not been preplated. This suggests IL-2 acts directly on neurons, and not by stimulating glial cells.

ANALYSIS OF STRUCTURE RELATED ACTIVITY OF CALCITONIN IN THE IMMUNE SYSTEM: COMPARISON WITH BRAIN. A.E.Panerai, and P.Sacerdote, Dept. Pharmacology, School of Medicine, University of Milan, Italy.

Calcitonin (CT) is a hypocalcemic peptide which possesses a broader range of effects including effects on the Central Nervous System. Recent data suggest that peptides can modulate several immunological functions. We have analyzed the human monocyte chemotaxis activity of different molecular forms of CT, whose activity spectrum in the bone and in the brain are well known. The rank potency order both on the brain and the bone is: eel>CT salmon CT > human CT,while CGRP, derived from an alternative RNA splicing, is the principal form and the more active in the brain. On the contrary, eel CT is the less active on chemotaxis (CI=2 at 10^{-11} M), salmon is only slightly more potent than human CT (CI=3.5 and 3, respectively) and CGRP is devoid of any chemotaxis effect. It is possible to modulate the chemotactic activity of the monocyte CT receptor, in fact monocytes of CT treated patients show an impaired chemotactic response to CT suggesting a down regulation of the receptors. These data suggest a possible specific role of CT in the immune system.

NEURAL CONTROL OF IMMUNE SYSTEM IV

513.1

RAPID DECREASE IN PERIPHERAL IMMUNE RESPONSES FOLLOWING INTRACEREBRAL INFUSION OF INTERLEUKIN-1 (IL-1) OR STIMULATED ENDOGENOUS RELEASE OF IL-1. Syam K. Sundar,* Kyra J. Becker* and Jay M. Weiss (SPON: A. Tadepalli). Duke University Medical Center, Durham, NC 27710.

Interleukin-1 (IL-1) is known to have widespread biological activities. Recent findings indicate that IL-1 activates the hypothalamic-pituitary axis when injected centrally as well as peripherally, and may be a neuromodulator (or neurotransmitter) in brain. The present results show that central administration of human recombinant beta IL-1 caused a rapid (within 15 minutes) and dramatic decrease in peripheral immune responses. Infusion of non-pyrogenic doses of beta IL-1 (dose range 0.05ng to 0.25ng) into the lateral ventricle of rats caused a significant and dose dependent decrease in Natural Killer Cell (NK) activity, responses of lymphocytes to a mitogen, and IL-2 production by activated lymphocytes. In addition, these effects of infused IL-1 could be blocked by central adminstration of a-MSH, a hormone known to block the actions of IL-1 (dose a-MSH=1.0ng). To determine whether release of endogenous IL-1 in brain might also have the same effects as infused IL-1, lipopolysaccharide (LPS), a substance known to provoke IL-1 synthesis and release, was infused into the lateral ventricle (dose LPS=10ng). LPS suppressed immune responses as did IL-1, and these effects of LPS infusion were similarly blocked by central infusion of a-MSH. These results indicate that IL-1 infusion into the central nervous system has direct effects on immune responses and that endogenous release of IL-1 in the CNS has similar effects.

513.2

STRESSFUL CONDITIONS ENHANCE AS WELL AS SUPPRESS CELLULAR IMMUNE RESPONSES. Jay M. Weiss, Syam K. Sundar,*and Kyra J. Becker* Department of Psychiatry, Duke University Medical Center, Durham NC 27710.

Non-chronic stressful conditions have almost always been found to produce immunosuppression in both humans and animals. The present results indicate that, although different intensities of stress produced immunosuppresion, stressful conditions of moderate intensity produced immunoenhancement in rats. In assessing a range of stressor conditions, effects of milder stressors than are usually studied (handling and exposure to a few brief shocks) were examined as well as effects of stronger stressors (2 hours and 19 hours of tail shock). Natural Killer cell (NK) activity, T-cell mitogenesis to Phytohemagglutinin (PHA), interleukin-2 (IL-2) production, and IL-2 receptor expression were measured. As the intensity of the stressor increased, the response of immunological cells was first mildly suppressed (in response to handling), then enhanced (in response to a few brief shocks), and then profoundly suppressed (in response to 19 hours of tail shock). These results demonstrate that the relationship between intensity of the stressor and the effects observed on a variety of measures of cell-mediated immunity is not only complex (or multiphasic) but also include a "zone" in which non-chronic stress enhances various measures of immune function.

513.3

DOMINANCE AND IMMUNITY IN NONHUMAN PRIMATES: SOME PILOT OBSERVATIONS. M. Laudenslager, M. Boccia*, and P. Held*. Behavioral Immunology Lab, University of Colorado Health Sciences Center, Denver, CO 80204.

The concept of dominance has served as an important heuristic tool for the understanding of social relationships in a variety of species. The present pilot study assessed the relationship between dominance ranking in laboratory reared group-housed macaque monkeys and several in vitro measures of the immune response. We found in stable social groups that neither mitogen stimulation nor natural cytotoxicity was related to dominance status. Plasma levels of IgG, C3, and C4 were lowest in the highest ranking monkeys, but remained within the normal range. The introduction of an ecologically relevant challenge may be necessary for the demonstration of modulation of the immune response by social status. We found that the imposition of clumped food resources, as opposed to distributed resources, was associated with reduced cytotoxicity measures in low ranking animals only. All animals, regardless of rank, showed an increase in mitogen responses under clumped feeding resources. High rank may partially buffer against the impact of environmental stressors. (Supported in part by Public Health Service Grants MH37373 and MH44131)

513.4

ALTERED T-LYMPHOCYTE RESPONSIVENESS IN C3H MICE FOLLOWING A NON-AGGRESSIVE TEST FOR DOMINANCE. C-A. Hardy, J. Quay*, R. Ader, and S. Livnat*. Dept of Psychiatry, U. of Rochester Med Ctr., Rochester, NY 14642.

Intermale aggression is a natural form of psychosocial stress that can alter a variety of physiological functions, including immune function. Spontaneous fighting among laboratory mice, often requiring long periods of isolation, pain, or the introduction of trained fighters may be needed. Subsequent fighting behavior often results in wounding which may confound the interpretation of the role of stress in producing immunological changes.

In the present experiment, 6 wk old C3H/HeJ male mice (n=20) were pair-housed (PH) for 4 wks. Individually- (IH)(n=5) and group-housed (GH)(n=5/cage) comparison groups were included. For PH mice, a test trial involved simultaneously placing each mouse head-first into opposite ends of a 10.5 in horizontal tube (1.1 in diameter) so that their snouts touched, requiring one animal to back out to escape. IH and GH mice were tested in the tube individually. All subjects were tested for 14 consecutive days, 1 trial/day. On d15, spleen cells were tested for proliferative responses to mitogens, interleukin-2 (IL-2) production, and natural killer (NK) cell activity.

In PH mice, the same mouse of each pair backed out of the tube on all 14 test days. Of the 10 pairs, 9 of the 10 animals that backed out of the tube appeared dominant in observations of home cage behavior. T-cell proliferative responses to ConA and IL-2 production were increased in the mice that backed out compared to their cagemates and to IH and GH controls. NK activity was not different between groups.

Using this simple, relatively non-aggressive test in PH mice, we found that mice that backed out of our testing tube (i.e. usually the dominant mouse of the pair) had elevated T-lymphocyte responsiveness, which may influence susceptibility to certain disease processes. (Supported by: NIMH Training Grant T32 MH18822, NIMH grant K01 MH00572, and a research grant from RJR Nabisco Co.)

513.5

Social Confrontation in Aggressive Fish (Tilapia) is associated with an Endogenous Opioid System-Mediated Suppression of Immunological Functions- Faisal, M [1,2], Chiappelli, F. [2,3], Ahmed, I [1], Cooper, E. [1] and Weiner, H. [3]. Departments of Anatomy [1] Microbiology and Immunology [2], and Psychiatry and Biobehavioral Sciences [3], University of California at Los Angeles, LA, CA 90024.

The interaction between the neuroendocrine and the immune systems is well-documented (Jankovic et al., 1987). Elegant studies reported that an intermittent footshock in rats leads to naltrexone(NAL)-reversible analgesia and suppression of splenic 'natural killer' cytotoxic activity (Shavit et al., 1985). Social confrontation evokes the massive release of prolactin, ACTH, alpha-MSH and beta-endorphin (END) in intruder and subordinate rats (Smelik, 1987). We previously showed that social confrontation among aggressive fish (e.g., Tilapia) leads to a marked suppression of several immunological parameters, including cytotoxicity and mitogen-stimulated proliferation, in the subordinate fish (Faisal et al., In Press; Cooper et al., In Press). In this study, we show that this immunosuppression is mediated in part by endogenous opioids. NAL (1mg/100g body weight) injected (s.c.) 60 min before social confrontation (5 hrs) prevents the suppression in cytotoxicity (lytic units at 20% lysis) in the dominant (saline: 12.2; NAL: 17.2) and the subordinate fish (saline: 1.7; NAL: 6.6). NAL also modulates the proliferative responses in the subordinate fish to phytohemagglutinin (saline: 33%, NAL: 64%) and concavalin A (saline: 34%, NAL: 65%), but not to lipopolysaccharide derived from Escherichia coli (saline: 27%, NAL: 34%). Isolated pronephric lymphocytes treated with END (10-8M) also show suppressed cytotoxicity and proliferative responses, which are reversible by NAL treatment in vitro. The serum isolated from subordinate fish suppresses the function of the cells obtained from control and dominant fish in a similar pattern.

513.6

PANIC ATTACKS PRODUCE AN INCREASE IN NATURAL KILLER CELL ACTIVITY. T.W. Uhde, M. Geraci*, and R.J. Weber*. BPB, NIMH, and NIDDK, NIH, Bethesda, MD 20892.(spons: D. Matsumoto).

Certain individuals suffer from a syndrome known as panic disorder. In a subgroup of these patients panic attacks can be induced by oral administration of caffeine. Eight patients were examined prior to and following oral caffeine challenge for peripheral blood natural killer(NK) cell activity. An exact temporal correlation was found between psychopathological measures consistent with a diagnosis of panic attacks and intense anxiety and concommitant increases in NK cell activity. Caffeine administered to normal volunteers caused no such change in NK cell activity. A single patient received caffeine on two separate occasions, only one of which produced panic attacks and increases in NK. Changes in NK cell activity were not observed when caffeine administration produced no generalized anxiety or panic attacks. These findings provide direct clinical evidence to support the notion that CNS activity associated with panic disorder, the major features of which are intense anxiety , fear and helplessness, can produce alterations in immune function.

513.7

SELF-ADMINISTRATION OF CYCLOPHOSPHAMIDE BY AUTO-IMMUNE MICE. T. Schachtman*, J. Moynihan*, L. Grota and R. Ader*. Department of Psychiatry, University of Rochester Medical Center, Rochester, NY 14642.

Autoimmune MRL-lpr mice consume more chocolate milk containing cyclophosphamide than congenic +/+ mice that are not autoimmune. The hypothesis is that autoimmune mice are able to determine that the immunosuppression resulting from cyclophosphamide is immunotherapeutic for them, while for +/+ mice immunosuppression is not adaptive. Male lpr mice but not female lpr mice exhibit this behavior when first exposed to drug at 20 weeks of age. We examined several factors that influence consumption of cyclophosphamide focusing on differences between lpr and +/+ females. Diluting chocolate milk reduces palatability and the ability to mask the flavor of cyclophosphamide but does not discriminate lpr and +/+ females. Drinkometers refined measurement of consumption but did not discriminate between female lpr and +/+ mice when first exposed to drug at 20 weeks of age. Both male and female lpr mice consume more cyclophosphamide than +/+ mice when first exposed to drug at 16 and 18 weeks of age. Since the onset of the autoimmune disease occurs several weeks earlier in females than males, these data suggest that the behavioral effect of immunotherapy may depend on the initiation of immunotherapy early in the development of the disease. These data indicate that immune status is able to modify behavior (CNS function) in autoimmune mice.

513.8

CRITICAL PERIODS FOR STRESSOR PROVOKED IMMUNOLOGICAL CHANGES. S. Zalcman*, M. Richter* and H. Anisman. Dept. of Psychology, Carleton University, Ottawa, Ont. Canada K1S 5B6 and Dept. of Microbiology and Immunology, University of Ottawa, Ottawa, Ont. Canada K1H 8M5.

The effects of stressors on the plaque forming cell response and on antibody titers to sheep red blood cells in mice are dependent upon the time of stressor application and the stressor regimen applied. A critical period exists after antigen administration (approximately 72 hr) during which footshock suppressed the immune response. Stressor effects were enhanced in mice that had been exposed to a single stressor session several weeks prior to immunization. Interestingly, however, initial exposure to the aversive stimulation either 24 hr prior to or immediately after antigen administration, prevented the suppression ordinarily elicited by a subsequent stressor. Moreover, compensatory changes were induced by chronic shock, such that the immunosuppression ordinarily elicited by subsequent stressor was eliminated. In fact, under these conditions an immunofacilitation was evident.

513.9

MICROIONTOPHORETIC APPLICATION OF MURAMYL-DIPEPTIDE ALTERS THE DISCHARGE FREQUENCY OF HYPOTHALAMIC AND HIPPOCAMPAL NEURONS. P.M. Dougherty* and N. Dafny (SPON: D. Redburn). Dept. Neurobiol. & Anat., The Univ. of Texas Medical School at Houston, 77225.

Muramyl-dipeptide (MDP) is an endogenous metabolite of gram negative bacterial lipopolysaccharide (endotoxin) with a variety of biologic effects. The present study investigates whether immunological products can elicit a change in the discharge frequency of single neurons in the CNS following local application of MDP within the somatosensory cortex, hippocampus, and the medial basal hypothalamus. The results obtained from a total of 90 cells of forty male Sprague-Dawley rats, demonstrate a direct, stereo-specific effect of MDP upon all three brain regions studied. Among these areas, the hypothalamus was the most responsive (64%), while the cortex was least reactive (47%). The direction of change induced by MDP was most frequently excitatory in all areas although scattered inhibition and biphasic responses were also seen. Since the hippocampus and hypothalamus have previously been shown to also play a key role in the integration of various environmental stimuli into behavioral and physiologic processes, these findings suggest that products derived from immune responses, such as MDP, may act directly in the CNS to coordinate autonomic and endocrine function into the systemic response to disease.

513.10

MURAMYL-DIPEPTIDES ALTER THE NEURONAL FIRING RATE OF THE HYPOTHALAMUS AND HIPPOCAMPUS BUT NOT THE DORSAL RAPHE. N. Dafny and P.M. Dougherty. Dept. Neurobiol. & Anat., The Univ. of Texas Medical School at Houston, 77225.

Muramyl-dipeptide (MDP) is the minimal fragment necessary for the biologic activity induced by gram negative bacterial lipopolysaccharide or endotoxin, and is hypothesized to participate in the mediation of neuro-immune inter-communication. The present study is an investigation of the electrophysiologic activity of single units recorded from freely behaving animals previously implanted with permanent electrodes within the hypothalamus, hippocampus and dorsal raphe prior to and then following incremental systemic (i.p.) dosages of 6-O-Stearoyl MDP. The results obtained from a total of 184 cells of male Sprague-Dawley rats demonstrate that single neurons of the hypothalamus and hippocampus, areas previously shown to play a role in the integration of various environmental stimuli into behavior and physiologic processes, alter their firing in rather site-specific manners. This specificity includes both the sensitivity as well as the time course of responses to MDP. In contrast, other brain regions such as the dorsal raphe showed little effect following MDP administration. These results suggest that MDP may play a role in neuro-immunologic regulatory pathways during the immune response to bacterial infections.

513.11

EVALUATION OF SUPPRESSED LYMPHOCYTE RESPONSIVENESS INDUCED BY SHOCK: ASSESSMENT OF INTERLEUKIN 2 DEPENDENT AND INDEPENDENT PATHWAYS. J. E. Cunnick*, D. T. Lysle*, A. Armfield*, and B. S. Rabin* (SPON. T. Mendelson). Div. of Clin. Immunopath., Dept. of Pathology, Univ. of Pittsburgh, Pittsburgh, PA 15213-3417.

Presentations of 16 signaled foot-shocks is capable of suppressing the spleen lymphocyte mitogenic response to concanavalin A (Con A). This suppression was not due to changes in total leukocytes, or the percentage of T cells, T-helper cells, or T-nonhelper cells as determined by flow cytometry. Although the addition of recombinant IL-2 stimulated the mitogenic response of splenocytes from shocked and control rats, the response of shocked splenocytes remained suppressed in comparison to all controls. Splenocytes from shocked rats produced normal amounts of IL-2 in response to Con A stimulation. Preliminary analysis of IL-2 receptors on the stimulated lymphocytes showed no quantitative differences between shocked and control rats. Splenocytes from shocked rats also demonstrated a suppressed incorporation of 3H-thymidine when stimulated with calcium ionophore A23187. In conclusion, shock-induced suppression of mitogenic responsiveness was not due to changes in lymphocyte subpopulations or IL-2 production. However, a calcium dependent biochemical pathway may be associated with the suppressed T cell responsiveness.

513.12

STRAIN DIFFERENCES IN IMMUNOLOGICAL RESPONSES TO STRESS. J. Irwin, S. Zalcman* and H. Anisman. Depts. of Psychology, Queen's University, Kingston, Ont. K7L 3N6 and Carleton University, Ottawa, Ont. K1S 5B6.

Genetic factors contribute to behavioral and neurochemical consequences of stress exposure. In the present study the influence of such factors on immune reactivity following stress was investigated. Because catecholamines have been implicated in the relationship between stress and immunity, noradrenergic activity was also assessed.

After stress exposure, mice of several inbred strains were sacrificed for determination of splenic Natural Killer (NK) cell cytotoxicity and C.N.S. catecholamine content. NK activity was significantly suppressed at intervals from 30 min to 48 hr following 1 hr of intermittent footshock stress. The time course of the effect as well as the magnitude of the stress-induced suppression varied across inbred strains. For example, a significant reduction of NK was noted in C3H/HeJ mice 24-48 hr after stress, whereas among C57BL/6J mice NK was reduced within 30 mins. of stress offset. Catecholamine alterations engendered by stress also varied across strains. This neurochemical reactivity was apparently more pronounced in those strains which exhibited a larger or more rapid inhibition of NK cell activity after stress.

These data indicate that there are significant strain-specific variations in the response of the immune system to stressors. Furthermore, they provisionally suggest that alterations in catecholamine activity may contribute to the effects of stress on immune function. (Supported by NSERC Grant U0569)

513.13

NEURONAL EXPRESSION OF MHC CLASS I MOLECULES IN RESPONSE TO AXONAL INJURY IS A GENERAL PHENOMENON. M. Schultzberg*, J. Maehlen and K. Kristensson. Dept. of Pathology, Karolinska Institute, Huddinge Hospital, S-141 86 Huddinge, Sweden.

Molecules coded in the Major Histocompatibility Complex (MHC) are absent in normal brain tissue. Such molecules are generally induced by immunological reactions, and this has also been shown in the brain. However, in some peripheral organs, MHC expression may also be controlled by trophic hormones. There is recent evidence that injury of a peripheral nerve triggers MHC class I expression in axotomized motor neurons and this reaction is reversed upon nerve regeneration (Maehlen et al., 1988). The aim of the present study was to investigate whether MHC class I is also induced in nerve cells terminating within the brain, and the nigrostriatal dopamine system was selected. The median forebrain bundle was interrupted either stereotactically or by 6-hydroxydopamine injection (4 ul, 2 ug/ul). The rats were decaptitated 5 and 7 days later and the brains were snap frozen and processed for immunohistochemistry with monoclonal antibodies to class I molecules. Class I-like immunoreactivity was encountered in many neurons in the substantia nigra (SN) ipsilateral to the injury, while the contralateral SN was unstained. These findings suggest that the appearence of MHC class I in injured neurons is a general phenomenon, that may play a role in cellular immunity or other cell-cell interactions in the central nervous system.

513.14

IMPAIRED ANTIBODY PRODUCTION WITH DEFEAT IN RATS. M. Fleshner*, M.L. Laudenslager, L. Simon*, and S.F. Maier. Dept. of Psychology, Univ. of Colorado, Boulder, Co. 80309.

Studies have linked physical stressors with changes in immune function. We examined the effect of a social stressor, defeat due to territorial defense, on antibody production to a specific antigen, keyhole limpet hemocyanin (KLH). Pairs of male rats living undisturbed 3-6 months formed colonies. Test rats were intruders. Every animal was immunized with KLH prior to exposures to territorially defensive colonies. Control animals were placed into colonies but separated from residents by a barrier. Behavioral measures were taken for each colony-intruder interaction. Excluding immunization, the entire procedure was repeated one week later. Blood samples were taken one, two and three weeks following immunization. KLH Ab levels were determined. Experimental animals produced less Ab to KLH than controls. Within the experimental group, total time spent in submissive posture at week one was the best predictor of Ab production. Total bites did not correlate with Ab production. Thus, the physical aspect of defeat (bites) is not critical for suppressed Ab production in defeated rats. Instead the psychological component seems most important. (Supported in part by MH37373 and N0014-85-K-0411 ONR.)

STRESS AND BRAIN REACTIVE AUTOANTIBODY LEVELS IN MURINE MODELS OF SLE. A. Narendran*, S. Harkins*, S.A. Hoffman. Dept. of Microbiology, ASU, Tempe, AZ 85287.

Psychosocial factors are known to interfere with immune system functioning. Conversely, abnormal immune activity, such as autoimmunity, has been implicated in CNS dysfunction. As part of ongoing research into the nature, function and regulation of pathogenic anti-brain autoantibodies, we have investigated the effect of stress on the production of such molecules.

Animals from 4 autoimmune strains (MRL/l, BXSB, NZB/W and NZB) and 2 non-autoimmune strains (Balb/c and C57BL/6) were divided into two age & sex matched groups per strain. The stressor was based on an animal intrusion and overcrowding model. One group (per strain) was stressed by introducing an equal number of C57BL/6 mice into their cage. This would increase 5 mice in a cage to 10 of two different strains. The control group was left with 5 mice in their cages. Seven days later sera from these animals were assayed for autoantibodies against integral brain membrane proteins using an ELISA. We report the stress induced changes in the anti-brain autoantibody levels in the different strains and discuss the implications of our findings for the effects of stress on autoimmunity.

NATURALLY OCCURRING AUTOANTIBODIES IN HUMAN SERUM: REACTIVITY WITH CENTRAL NERVOUS SYSTEM PROTEINS. J.S. Frazier* and D.M. Jacobowitz (Spon: W. Heydorn), Lab. of Clin. Sci., NIMH, Bethesda, MD 20892

Autoimmunity is being recognized as a major component, if not cause, of an increasing number of diseases including those of the CNS. In an effort to identify autoantibodies associated with various neurologic and psychiatric diseases it was discovered that sera from normal individuals contain autoantibodies which react with a number of CNS proteins.

Two-dimensional polyacrylamide gel electrophoresis was performed on 100 µg samples of frozen normal human cortex. Proteins on the resulting gels were Western blotted onto nitrocellulose membranes. Non-specific membrane binding sites were blocked with 3% BSA. The blots were then incubated individually with sera from 20 normal controls at dilutions of 1:10 to 1:1000. Bound autoantibodies were labeled and visualized by the methods of Towbin.

Reactivity against a number of CNS proteins was observed in a large percentage of sera. These proteins included, among others, neuron specific enolase, glial fibrillary acidic protein (GFAP), the ß-subunit of the G protein, serum glutamic oxaloacetic transaminase (SGOT), actin and tubulin. The identity of these proteins was confirmed by comparing the location of the blot-spots with the locations of spots produced with antibodies specific for these proteins. Antibodies against these proteins may be important in the normal and the diseased state.

514.1

FACTOR BINDING TO A CRF-INDUCIBLE ELEMENT OF THE RAT POMC GENE S.R.J. Salton, J.L. Lundblad, S. Dermer, D. Lorang, M. Blum and J.L. Roberts (SPON: R. Fremeau, Jr.). Fishberg Center in Neurobiology, Mount Sinai School of Medicine, NYC, NY, 10029

Expression of the gene encoding proopiomelanocortin (POMC), the precursor of several pituitary peptide hormones including ACTH, ß-endorphin, and ß-lipotropin, has been previously shown to be positively regulated by the hypothalamic peptide CRF, both in vivo and in primary anterior pituitary cultures in vitro. We have found that treatment of the AtT20 mouse pituitary cell line with CRF for 60 minutes increases POMC gene transcription by 2 fold, and after treatment with CRF for 24hrs, a 2-3 fold increase in POMC mRNA levels is observed. By constructing a series of deletion mutants of the rat POMC gene 5' flank fused to a heterologous promoter and chloramphenicol acetyl transferase (CAT) reporter gene, followed by transfection into AtT20 cells, we have identified a fragment within the POMC flank that confers CRF and forskolin inducibility on the TK promoter (-234 to -133). We have identified a factor(s) in heparin-agarose enriched AtT20 whole cell extracts that protects a 30bp region (-214 to -174) on both strands within this fragment using DNase footprinting. Analysis of the region of the rat POMC promoter between -478 and -320, an area which appears partially responsible for the elevated basal activity of the POMC promoter by transient transfection assay, using gel shift studies, DNase footprinting and methylation interference studies, shows several sites protected by factors present in nuclear extracts of AtT20 cells. Studies are currently underway to determine the hormone inducibility and cell/tissue distribution of these DNA-binding factors.

514.2

REGULATION OF GLUCOCORTICOID RECEPTOR GENE EXPRESSION IN THE RAT ANTERIOR PITUITARY. K.E.Sheppard*, D.J.Autelitano*, J.L.Roberts and M.Blum. Fishberg Research Center in Neurobiology , Mt. Sinai Med. Ctr., New York, NY 10029.

It has previously been shown that chronic treatment with dexamethasone (DM) decreased glucocorticoid binding capacity in rat anterior pituitary, however this decrease in binding was not observed after chronic stress. The differences observed between DM treatment and stress may reflect the involvment of other factors in GR regulation in the pituitary.

To further examine GR regulation in the rat anterior pituitary, we have analyzed cytoplasmic mRNA levels after acute and long term CRF treatment, as well as GR gene transcription after acute CRF treatment. For acute studies adult female Sprague-Dawley rats (~ 200g) were injected s.c. with 20µg of r-CRF or vehicle and sacrificed after 30', 60' and 4hrs. In chronic studies, rats were similarly injected twice daily for 7 days.To determine GR gene transcription rate, an *in vitro* nuclear run-on assay was used; cytoplasmic mRNA levels were quantitated in a solution hybridization/S1 nuclease protection assay using an antisense RNA probe.

A 2-4 fold increase in GR gene transcription was observed at 30 and 60 min after CRF administration, but had returned to control levels after 4hrs. Cytoplasmic GR mRNA levels were significantly above control at 4hrs. after CRF treatment; in contrast, chronic treatment (7 days) failed to show any change. To determine if the CRF response is a direct effect, or is mediated through ACTH stimulated release of glucocorticoids we are currently examining the effects of CRF and glucocorticoids on GR mRNA levels and GR gene transcription in primary cultures of rat anterior pituitary, as well as in AtT20 cells.

514.3

DEVELOPMENT OF BASAL AND REGULATED SECRETION IN THE INTERMEDIATE LOBE OF THE FETAL AND NEONATAL RAT PITUITARY GLAND. D.I. Lugo and I.E. Pintar. Department of Anatomy and Cell Biology, Columbia University P&S, NYC, NY. 10032.

Proopiomelanocortin (POMC) producing cells comprise nearly 100% of the adult intermediate lobe hormone producing cells. Secretion by these cells is primarily under negative regulation by dopamine. Although the POMC-derived peptide a-MSH has been detected in plasma of fetal rats and lambs, no study thus far has directly examined the secretory capabilities of fetal melanotrophs. Here we have utilized the reverse hemolytic plaque assay to assess at the single cell level basal and regulated release by melanotrophs at fetal and early post-natal ages. Only basal secretion was detected at the earliest ages examined (e17.5). CRH (10^{-8}M.)-stimulated secretion was first observed at e19.5 and continued through post-natal ages; incubation with CRH (10^{-7}M.) during this time period increased both the plaque size and the percentage of melanotrophs stimulated to secrete. Dexamethasone (10^{-6}M.) inhibition of CRH (10^{-7}M.) stimulation was detected from e19.5 to p2. At p3 dexamethasone no longer inhibited melanotroph secretion although inhibition of CRH-stimulated release in p3 corticotrophs was readily detected. The dopamine agonist ergocryptine (10^{-6}M.) inhibited secretion at the earliest ages studied (e17.5); this effect persisted throughout all ages examined (e17.5-p3). These results suggest that melanotrophs appear to undergo a maturation process in which they are first non-responsive to CRH (e17.5), next possess both functional CRH and steroid receptors (e19.5) and finally undergo loss or uncoupling of steroid receptors (p3). The loss of steroid-induced inhibition (p3) is closely coupled with the arrival of catecholaminergic input into the neurointermediate lobe (p2). However, the early response of melanotrophs to dopaminergic agonists, which can be detected seven days prior to arrival of catecholaminergic fibers into the neurointermediate lobe, appears to be an intrinsic feature of these cells that is never present in corticotrophs. Supported by HD-18592.

514.4

RECEPTOR REGULATION OF POMC GENE EXPRESSION IN PRIMARY CULTURES OF RAT INTERMEDIATE LOBE LOBULES. M.S.Rinaudo*, B.M.Chronwall, W.R.Millington, J.F.Bishop and D.R.Gehlert. ETB-NINCDS, N.I.H., Bethesda, Maryland 20892.

The intermediate lobe (IL) of the rat pituitary is primarily melanotrophs which are organized into clusters of cells called lobules. Previous culture systems using dispersed IL cells may not represent cellular behavior in vivo accurately since earlier data from our laboratory have shown that melanotrophs growing in monolayer exhibit a substantially higher proliferation rate compared to the IL in vivo. To study both the regulation of proopiomelanocortin (POMC) biosynthesis and IL proliferation, we have recently developed a primary culture system of rat IL cells using mechanically dispersed intact IL lobules. The effects of CRF, GABA and quipazine ($5HT_2$ agonist) on the synthesis of POMC mRNA, release of immunoreactive β-endorphin (iβEND) and cell proliferation were studied utilizing this model.

CRF increased the amount of iβ-END secreted at both a 10^{-9} and 10^{-7} M dose. Both concentrations of CRF augmented the relative levels of POMC mRNA although the increase was statistically significant only with the higher dose. Quipazine also increased the levels of POMC mRNA significantly at both the low (10^{-8} M) and high (10^{-6}M) doses. Total iβ-END secreted into the media was significantly increased only with the higher dose of the two compounds. No alteration in proliferation was seen with either compound. Inclusion of GABA in the media at concentrations up to 10 µM as well as muscimol and baclofen failed to produce a detectable alteration in the levels of POMC mRNA, iβ-END secretion and proliferation rate.

In conclusion, CRF and $5HT_2$ agonists not only increase the release of POMC derived-peptides from mechanically dispersed IL lobules but also increase the levels of POMC mRNA. On the other hand, GABAmimetics did not appear to affect mRNA levels nor iβ-END secretion.

514.5

INTERACTIONS OF OPIOID PEPTIDES, NALOXONE AND DOPAMINE ON POMC PEPTIDE RELEASE FROM RAT NEUROINTERMEDIATE LOBES. L. Gutierrez*, A. Samora*, M. Williams* and L.C. Saland. (SPON: E. Uhlenhuth). Dept. of Anatomy, Univ. of New Mexico Sch. Med, Albuquerque, NM 87131.

Release of POMC (α-MSH and β-endorphin) peptides from the pituitary pars intermedia is regulated by both neurotransmitters and neuropeptides. Dopamine (DA), an inhibitor, suppressed the corticotropin-releasing factor (CRF)-induced stimulation of peptide secretion in vitro (Saland et al, '87, Soc. Neurosci. Abst. 13: 418, and Neuropeptides, '88, in press). Here, rat neurointermediate lobes (NILS) were incubated for up to 120 minutes in GIBCO media containing glucose, glutamine, 0.1mM bacitracin, 0.1mM ascorbic acid, and 10 µM pargyline. D-ala-met-enkephalinamide (DALA, 10^{-6}M) or Sandoz (SAN) enkephalin peptide (10^{-6}M) were added, with or without DA (10^{-6}M) or naloxone (NAL, 10^{-6}). DALA or SAN plus DA transiently increased POMC release above levels in the presence of DA alone at some, but not all time points. NAL alone reduced α-MSH release, while addition of NAL to peptides plus DA induced POMC release above control levels in several incubations. POMC peptides were measured by radioimmunoassay (RIA). Immune staining of tissues for POMC peptides and EM cytology of NILS correlated with relative amounts of peptides released. Effects of opioid peptides or NAL may be mediated via interaction with DA, since dopamine-2, but not opioid receptors, are found on intermedia cells. Supported by NIH NS 21256 and RR 08139 (LCS).

514.6

EFFECTS OF cAMP AND CORTICOTROPIN-RELEASING FACTOR (CRF) ON PROTEIN PHOSPHORYLATION AND ACTH RELEASE IN THE ANTERIOR PITUITARY. J.C. Pryor*, S.T. Cain, and C.B. Nemeroff (SPON: E.W. Busse). Depts. of Psychiat. & Pharmacol., Duke Univ. Med. Ctr., Durham, NC 27710.

Phosphoproteins appear to be involved in the secretion of anterior pituitary hormones. A main focus of our laboratory has been CRF, which stimulates the release of adenocorticotropin (ACTH) from the anterior pituitary. Because CRF receptors are coupled to adenylate cyclase, we began investigating the role of cyclic 3'-5'adenosine monophosphate (cAMP)-dependent protein phosphorylation in CRF stimulated ACTH secretion. We have already established in an in vitro system that cAMP stimulates the phosphorylation of at least 4 different proteins in anterior pituitary homogenates obtained from rats. These have approximate molecular weights by SDS-gel electrophoresis of 93K, 63K, 48K and 43K. The reaction appears to be dependent on the concentration of cAMP with 1 µM cAMP stimulating phosphorylation of only the 93K protein, while maximal stimulation was achieved with 50 µM cAMP. To better simulate in vivo conditions, we are currently investigating CRF and cAMP stimulation of ACTH release and protein phosphorylation in a cell culture system. Adult, male rats were decapitated and anterior pituitaries were harvested. Enzymatic disassociation was used to obtain individual cells and they were cultured in multiwell culture plates. The cells were stimulated with CRF (0-10 nM) for 3.5 hr. ACTH released into the media was measured by RIA. The cells were then homogenized and aliquots phosphorylated for 60 seconds in the presence of 10 µM ATP containing [γ^{32}P-ATP] and either cAMP or vehicle. The proteins were separated by electrophoresis on SDS-polyacrylamide gels, and autoradiograms of the phosphoproteins were prepared from the dried gels. Results of studies investigating the association between CRF stimulation, cAMP formation, ACTH release and protein phosphorylation will be presented. (Supported by NIMH MH-42088 and the United Way Fund.)

514.7

IN VITRO MODELLING OF STRESS-INDUCED ACTH SECRETION. Michael Boyle*, Paul Plotsky, Gayle Yamamoto* and Wylie Vale, The Salk Institute, La Jolla, CA, 92037

ACTH secretion by the anterior pituitary is stimulated by several humoral and neural pathways, including corticotropin-releasing factor (CRF), vasopressin (AVP) and catecholamines. In the present studies, we have examined ACTH release from rat pituitary tissue using a range of concentrations found in hypophsial-portal blood of rats. At levels approximating endogenous molar ratios, these secretagogues were tested for their ability, alone and in combination, to stimulate ACTH release. To more closely mimic the response found *in vivo*, freshly removed rat anterior pituitaries were used in a superfusion system. At concentrations above 300 nM CRF elicited a maximal 6 fold increase in the release of ACTH. The EC50 for the CRF induced ACTH release was 12 nM. At concentrations above 300 nM AVP ellicited a maximal 1.7 fold increase in the release of ACTH. The EC50 for the AVP induced ACTH release was 7 nM. At concentrations above 1 μM the catecholamines epinephrine (E) and norepinephrine (NE) elicited a maximal 2.6 fold increase in the relase of ACTH. The EC50s for E and NE were 17 nM and 32 nM respectively. The EC50s for each of these compounds is well within the ranges found in hypothalamic-pituitary portal blood. The combination of CRF and AVP is additive across the full physiologic range of the secretagogues with a maximal 7.3 fold increase of ACTH release. Mimicing the increased CRF and AVP concentrations observed in hypophysial-portal plasma during hemorrhage, 150 pM and 800 pM respectively, a similar 2-3 fold elevation of ACTH is seen. The combination of CRF and E is less than additive with a maximal 7.8 fold increase in ACTH release. This is the first report of effects of endogenous portal levels of secretagogues on ACTH secretion *in vitro*, and indicates the validity of this particular preparation as a model of stress-induced ACTH release.

EXPRESSION OF BIOLOGICALLY ACTIVE RAT CORTICOTROPIN RELEASING FACTOR (CRF) IN A TRANSFECTED MEDULLARY THYROID CARCINOMA (MTC) CELL LINE. G. Hammer*, V. Fairchild*, K. Sevarino* and M. Low*. (SPON: R. Ventimiglia). Neuroscience Graduate Program, Tufts U. School of Medicine and Div. of Molecular Medicine, New England Medical Center, Boston, MA 02111.

CRF is a neuropeptide that acts as both a hypophysiotropic regulator of ACTH secretion and a mediator of central autonomic responses to stress. Studies of the biosynthesis of CRF have been limited by the lack of a suitable tissue culture system. To provide such a system, we have engineered clonal cell lines that express high levels of rat CRF. W2 cells, a transplantable rat MTC cell line (provided by B. A. Roos, Univ. of Wash., Seattle, WA), were cotransfected with a CRF cDNA (provided by R. Thompson, Oregon Health Sciences Univ., Portland, OR) driven by a cytomegalovirus immediate early promoter/enhancer and a neomycin resistance-expressing plasmid driven by an RSV promoter. These cells were chosen as the host cells because of their high concentration of secretory granules and their ability to process and amidate neuropeptides. Media from G418-resistant clones were screened by radioimmunoassay to detect CRF expression. The transfected, but not the wild type cells, secreted assayable CRF. To assess biological activity of the immunoreactive CRF, dispersed primary pituitary cultures were treated with conditioned media from the 6 clones secreting the highest concentration of CRF (1- 9 nM). ACTH release from the pituitary cells was stimulated identically by treatment with either synthetic CRF-amide or transfected W2 cell conditioned media. In conclusion, we have made stably transfected cell lines that express rat CRF. The secreted immunoreactive CRF is biologically active suggesting that the pro-CRF produced is correctly processed and amidated. Studies are in progress to characterize the biosynthesis of CRF in these cells further and to use them, via surgical implantation, as an ectopic source of CRF in transkaryotic rats.

MOLECULAR MECHANISMS CONTROLLING POMC GENE EXPRESSION. Neil Margolis, Kyriaki Thermos and Terry Reisine, Dept. of Pharmacology, Univ. of Pennsylvania, Phila., PA 19104

The control of POMC gene expression is an important event in the body's response to stress. The molecular events controlling POMC gene expression are currently unknown. Since several ligands are known to both increase POMC mRNA levels in the anterior pituitary and activate protein kinases, it is possible that phosphorylation is a key event in the control of POMC gene expression. We have examined the effects of corticotropin releasing factor (CRF), which is known to activate cAMP-dependent protein kinase, on phosphorylation of nuclear proteins. Using AtT-20 cells, a mouse anterior pituitary cell line, we have found at least three nuclear proteins which are phosphorylated in response to CRF (10^{-7} M). These proteins, which have been visualized using two-dimensional gel electrophoresis and autoradiography, have molecular weights of 45,49, and 56 kilodaltons and pI values between 5.9 and 6.4. Protein phosphorylation has been shown to be enhanced within five minutes of CRF treatment. It is possible that these proteins interact with upstream elements of the POMC gene to cause an increase in DNA transcription. Work is currently being done to examine the effects of phorbol esters and calcium ionophores, which increase POMC mRNA levels and can activate distinct protein kinases, on phosphorylation of nuclear proteins. Supported by NIH grant DK37404 and American Heart Association grant-in-aid.

514.10

LOCALIZATION OF POMC mRNA, GLUCOCORTICOID RECEPTOR mRNA AND CRF RECEPTORS IN HUMAN PITUITARIES. I.F. Lopez*, A. Mansour, H. Akil, S. Burke*, M. Palkovits*, M. Arato*, M.K.-H. Schafer* and S.J. Watson. (SPON: S. Berent). Mental Health Research Institute, University of Michigan, Ann Arbor, MI 48109 and National Institute For Nervous and Mental Diseases, Budapest, Hungary.

Human hypothalamic-pituitary axis regulation has been the focus of extensive investigation. A knowledge of how different components of this system are related anatomically can give clues to their interaction and co-regulation. We have studied the localization of pro-opiomelanocortin (POMC) and glucocorticoid receptor (GR) mRNA in post-mortem human pituitaries using *in situ* hybridization analysis. We have also looked at the localization of Corticotropin Releasing Hormone (CRH) receptors by autoradiography in the same tissue. To control for total number of cells, *in situ* hybridization with p1B15 (Sutcliffe, J.G., et al., Nature, 308:237, 1984) a cDNA clone of a ubiquitous rat mRNA was carried out in adjacent sections.

P1B15 containing cells were distributed homogenously in the pituitaries examined. In contrast, groups of POMC cells were localized in clusters. Cells containing CRH receptors were also found in clusters and for the most part were localized in the same area as the POMC cells. GR containing cells were distributed through most of the pituitary but some areas of increased density were observed to coincide at times with areas of increased POMC density.

514.11

α-ANF[1-28] BUT NOT α-ANF[5-28] INHIBITS CRF-STIMULATED ACTH SECRETION FROM CULTURED ANTERIOR PITUITARY CELLS. M.S. King* and A.J. Baertschi. Neuroscience Program and Department of Physiology, University of Virginia, Charlottesville, VA 22908.

The effectiveness of atrial natriuretic factors (ANF) as inhibitors of ACTH secretion was examined in dispersed rat anterior pituitary cells that had been in culture for 4 days. Nineteen experiments were conducted with 24-well plates using 4 wells/combination of peptides. α-ANF[1-28] significantly inhibited ACTH release stimulated by 1nM CRF. At the most effective concentrations of 10 to 100pM, α-ANF[1-28] inhibited ACTH release by 45% ($p<.001$: determined by Kruskal-Wallis ANOVA). This effect was manifested after 3 hours, but not .5 or 1 hour, of incubation suggesting that ACTH synthesis may have been reduced by α-ANF[1-28]. Conversely, at concentrations of 10 to 10,000pM, α-ANF[5-28] had no effect on ACTH secretion after .5, 1 and 3 hours. These results suggest that: 1) an intact N-terminal sequence of the ANF peptide, 2) extremely low concentrations of α-ANF[1-28] and 3) a 3 hour incubation are required for inhibition of ACTH. These requirements may explain the failure of previous experiments to demonstrate inhibition of ACTH by ANF. Thus, α-ANF[1-28] may be a physiological inhibitor of ACTH secretion. (Supported by University Technology Corporation and the Virginia Center for Innovative Technology).

THYMOSIN MODULATES BETA-ENDORPHIN SECRETION BY CORTOCOTROPHIC TUMOR CELLS. J. Michel, J.M. Farah. G.D. Searle & Co., CNS Research, St. Louis, MO 63198.

Hormones of the thymus gland have been associated with control of the hypothalamic-pituitary adrenal axis partly because the bovine thymic preparation, thymosin fraction 5 (TSN-5), was shown to increase secretion of ACTH both in vivo and in vitro. We found that TSN-5 increased secretion of immunoreactive beta-endorphin (iβ-E), from AtT-20 corticotropic tumor cells and its effects on hormone release were additive with those of corticotropin-releasing factor (CRF) (Farah et al, 1987, J Neurosci Res 18:140). We now find that TSN-5 evoked iβ-E release is additive not only with CRF but also with forskolin and phorbal myristate acetate. Since TSN-5 had no effect on basal intracellular cAMP and reduced forskolin-stimulated cAMP accumulation, the corticotropic constituent(s) of TSN-5 probably act through alternate cellular mechanisms to promote iβ-E secretion. The effects of TSN-5 on hormone release coupled to arachidonate metabolism and intracellular calcium mobilization are under investigation.

Our thanks to Dr. Allan Goldstein for TSN-5.

514.13

A PRACTICAL RADIOIMMUNOASSAY FOR PLASMA CORTICOTROPIN - RELEASING FACTOR. J.C. Ritchie, P.K. Liu*, G. Bissette, and L.H. Jennes. Department of Psychiatry, Duke Univ., Durham, NC 27710 and Department of Anatomy, Wright State Univ. Sch. Med., Dayton, OH 45435

We will describe an RIA for plasma Corticotropin - Releasing Factor (CRF). The primary antiserum for this assay was produced in rabbits against rat/human CRF coupled to hemocyanin via glutaraldehyde. The antiserum is used at a dilution of 1 to 30,000. Radiolabelled CRF is prepared by chloramine T iodination of Tyr^0-CRF and is purified by HPLC. Samples for assay are drawn into cold EDTA coated plastic syringes containing 0.1 ml of an enzyme killer solution per mL of whole blood. Plasma is extracted using two Spice Pak Cartridges (Analtech, Inc. Newark, DE) hooked in tandem. Standard curves are prepared in CRF-free plasma and extracted as samples. Recovery averages 80% (by trace-recovery studies). The assay incorporates delayed trace addition and second antibody technology to improve sensitivity. The minimal detectable quantity for the assay is 2.5 pg/mL and the 80, 50, and 20% binding points average 7, 80, 900 pg/mL respectively. No cross reactivity is detectable with ovine CRF up to 1 ug/mL. Cross reactivity with other neuropeptides is negligible.

Data concerning baseline concentrations, physiologic and physiochemical validations of the assay will also be presented.

HYPOTHALAMIC-PITUITARY-ADRENAL REGULATION III

PLASMA ACTH IN THE RAT DEMONSTRATES THREE DISTINCT RHYTHMS WITHIN 24 HOURS. M. Carnes, S.J. Lent*, J. Feyzi* and D.K. Hazel*. Wm. S. Middleton Veterans Hospital and Dept. of Medicine, University of Wisconsin, Madison, WI 53705

ACTH secretion by the pituitary is rhythmic and episodic, as reflected by fluctuations in plasma concentrations of ACTH. The present work was designed to further characterize the patterns of ACTH secretion occurring simultaneously within a 24-hour period in the rat. Blood sample collection protocols with sampling intervals of 2 minutes, 15 minutes, and 4 hours were used in awake, chronically cannulated rats. Plasma samples were assayed for ir-ACTH and resultant data were analyzed for significant pulsatile secretory episodes using the PULSAR program after determination of appropriate constants. Three distinct patterns of ACTH secretion were demonstrated within a 24-hour period. In addition to the circadian variation with peak plasma ACTH levels occurring one hour before lights-out, plasma ACTH exhibited episodic ultradian variation of two types: 11-19 pulses in 24 hours, which we have called the "larger ultradian" pulses, and shorter episodic bursts occurring approximately 3 times per hour, which we have called "micro-pulses."

515.2

NEUROTENSIN ACTIVATES TUBEROINFUNDIBULAR DOPAMINE NEURONS AND INCREASES SERUM CORTICOSTERONE CONCENTRATIONS. G.A. Gudelsky, S. Berry* and H.Y. Meltzer. Case Western Reserve University, Cleveland, OH 44106.

In view of the evidence for co-localization of neurotensin (NT) and dopamine in some neurons within the arcuate nucleus-median eminence, we have examined the effects of NT on tuberoinfundibular dopamine (TIDA) neurons, as well as on mesolimbic and nigrostriatal neurons in the rat. The activity of these DA neurons was estimated from the accumulation of DOPA in the median eminence 30 min after decarboxylase inhibition with NSD 1015 (100 mg/kg, i.p.) or from the concentrations of DOPAC in the median eminence, n. accumbens and striatum. The icv administration of NT (20 ug) significantly increased the accumulation of DOPA and DOPAC concentrations in the median eminence 1-8 hrs after its administration. NT (5 and 20 ug) also significantly increased DOPAC concentrations in the n. accumbens, but the peptide was without effect in the striatum. Serum corticosterone concentrations in rats treated with NT (1-20 ug) were 5-7 times those in vehicle-treated rats. An analogue of NT, [D-Trp^{11}]-NT (0.5 ug, icv) also significantly increased DOPAC concentrations in the median eminence and serum corticosterone concentrations. It is concluded that NT acutely increases the activity of TIDA and mesolimbic dopaminergic neurons and increases the secretion of ACTH. Supported by MH 41684 and MH 42868.

515.3

EFFECT OF ALPHA-MELANOCYTE STIMULATING HORMONE (αMSH) ON TUBEROHYPOPHYSIAL, TUBEROINFUNDIBULAR, AND NIGROSTRIATAL DOPAMINERGIC NEURONAL ACTIVITY. S.E. Lindley*, K.J. Lookingland and K.E. Moore, Dept. of Pharmacology/Toxicol., Mich. State Univ., E. Lansing, MI 48824

The purpose of this study was to determine if αMSH feedsback to regulate its own secretion by altering the activity of tuberohypophysial dopaminergic (THDA) neurons terminating in the intermediate lobe (IL) of the pituitary. Accordingly, the effect of intracerebroventricular (icv) administration of α MSH was examined on THDA neuronal activity. For comparison, the effect of αMSH was also examined on the activity of tuberoinfundibular dopaminergic (TIDA) neurons terminating in the median eminence and nigrostriatal dopaminergic (NSDA) neurons terminating in the striatum. The activity of DA neurons was estimated using biochemical techniques. Administration of αMSH (20 µg, icv) to male Long-Evans rats did not alter: 1) the concentration of dihydroxyphenylacetic acid (DOPAC), 2) the rate of DA turnover, 3) the rate of DA synthesis in the IL or striatum. These results indicate that exogenously administered αMSH does not alter THDA or NSDA neuronal activity. In the same animals it was found that α MSH increased: 1) the concentration of DOPAC, 2) the rate of DA turnover, 3) the rate of DA synthesis in the median eminence. α MSH also decreased circulating concentrations of prolactin. These results indicate that αMSH increases the activity of TIDA neurons terminating in the median eminence, thereby decreasing the secretion of prolactin. (Supported by NIH grant NS 15911)

515.4

EVIDENCE THAT ACTIVATION OF THE HPAA BY SINGLE-DOSE ADMINISTRATION OF ETHANOL IS NOT MEDIATED BY MEDIAN EMINENCE AVP OR ADRENAL CATECHOLAMINES. A.B.THIAGARAJAN* R.L.ESKAY* (Spon: S.KATZ). LCS/NIAAA, National Institutes of Health, Bldg 10, Room 3C-218, Bethesda, MD 20892.

Single-dose ethanol (Et) administration activates the hypothalamic-pituitary-adrenal axis (HPAA) as monitored by enhanced levels of adrenocorticotropic (ACTH) hormone, glucocorticoids (Corticosterone, Cs) and adrenomedullary-derived epinephrine (Epi); however, an understanding of the precise mechanism or site of ethanol's activation of the HPAA remains incomplete. In order to determine if median eminence (Me)-derived vasopressin (AVP) or adrenal-derived Epi are significant mediators of Et-induced activation of the HPAA, Et was infused (12% solution, 4gm/Kg/body wt.) via an indwelling gastric cannula into male rats which had previously (two weeks) been adrenal demedullated or pretreated with AVP antiserum. Assessment of the ability of the AVP antiserum to neutralize endogenous AVP was demonstrated in that this antiserum reduced ether-enhanced ACTH plasma levels by 40%; however the AVP antiserum did not attenuate ethanol-induced ACTH or Cs plasma levels. In addition, demedullation did not lessen activation of the HPAA by Et. The results of this study suggest that single-dose administration of Et via intragastic cannula does not involve recruitment of Me AVP or adrenal Epi as partial mediators of the Et-induced activation of the HPAA.

REDUCTION OF ACTH-LI IN PLASMA FOLLOWING I.V. INJECTION OF DELTA SLEEP-INDUCING PEPTIDE IN MAN. A. Bjartell, R. Ekman*, S. Bergquist, E. Widerlöv*. Dept. of Psychiatry and Neurochemistry, Univ. of Lund, POB 638, S-220 06 Lund, Sweden.

Recent studies have indicated in involvement of Delta sleep-inducing peptide (DSIP) in the regulation of the hypothalamic-pituitary adrenal (HPA) axis. We have now examined how DSIP affects the plasma levels of adrenocorticotropin-like immunoreactivity (ACTH-LI), cortisol and some other neuropeptides related to the HPA axis in man. The present study is a double blindcross-over challenge test in which eleven healthy male volunteers (age 25-29) achieved a single dose of synthetic DSIP (25 nmol/kg b.w.) intravenously (iv) during 4 min. An equal volume of saline served as control. The plasma conc. of DSIP increased approximately three times (mean)at 5 min after DSIP inj. and was then rapidly normalized. ACTH-LI in plasma decreased in nine out of eleven individuals and the mean conc. of ACTH-LI in plasma was significantly reduced at 5-180 min after DSIP inj. The controls showed an increased ACTH-LI level. No differences in plasma cortisol were noted between the groups. Urinary analyses of stress parameters like cortisol and monoamine metabolites did not reveal any differences either. In conclusion: A single dose of DSIP iv significantly reduces the plasma conc. of ACTH-LI in man and may thus be yet another factor involved in the regulation of ACTH secretion in man.

REEVALUATION OF NOREPINEPHRINE (NE) EFFECTS ON THE EXTRACELLULAR SINGLE UNIT ACTIVITY OF PARAVENTRICULAR (PVN) NEUROSECRETORY NEURONS. R.L. Moss and Y.I. Kim. Dept. of Physiology, UT Southwestern Med. Ctr., Dallas, Texas 75235.

In an attempt to provide a possible explanation for the conflicting reports concerning the role of NE in the control of the activity of PVN neurosecretory neurons projecting to the posterior pituitary, the effects of both electrical stimulation of the A1 noradrenergic region (the major noradrenergic input to PVN neurons) and iontophoretically applied NE on the activity of PVN neurosecretory neurons were tested in urethane-anesthetized male rats. Of 11 phasically active (P) and 84 non-phasically active (N-P) neurons studied, 5 P and 46 N-P neurons exhibited an excitatory orthodromic response (OD+) to A1 region stimulation while only 3 N-P neurons exhibited an inhibitory orthodromic response. The remaining neurons showed no response. Iontophoretically applied NE was excitatory as was A1 region stimulation in 4 of 4 P neurons tested and in 16 of 32 N-P neurons tested. However, in 9 N-P neurons exhibiting OD+, iontophoresed NE was inhibitory. Three of these 9 neurons were identified antidromically as projecting to the A1 region as well as to the posterior pituitary. The inhibitory effect of iontophoresed NE on the neurons exhibiting OD+ was selectively abolished by the co-iontophoresed alpha blocker, phentolamine, but not by the beta blocker, timolol, in 4 of 4 cases tested. This includes 2 cases where the neurons were identified as projecting to both the posterior pituitary and the A1 region.

In general, the present results agree with the postulation of an excitatory A1 noradrenergic input to PVN neurosecretory neurons. In addition, the results suggest the presence of an alpha-receptor-mediated, inhibitory noradrenergic input other than A1 to a subpopulation of PVN neurons. This may explain, at least in part, the earlier observation that NE exerts an inhibitory effect on the activity of neurosecretory neurons. Supported by HD09988-V.

THYROTROPIN-RELEASING FACTOR (TRF) EFFECTS ON PITUITARY ACTH RELEASE AND AUTONOMIC FUNCTION. M.R. Brown[1], C. Rivier[2] and T.S. Gray[3]. [1]Depts. of Medicine and Surgery, Univ. of Calif., San Diego Medical Center, San Diego, CA 92103; [2]The Salk Institute, La Jolla, CA 92037; [3]Dept. of Anatomy, Loyola Medical Center, Maywood, IL 60153.

TRF, similar to corticotropin-releasing factor (CRF), acts within the brain to increase plasma levels of catecholamines (CA), and mean arterial pressure (MAP) and heart rate (HR). The goal of these studies was twofold: 1) to determine if TRF, similar to CRF, given intracerebroventricularly (icv), would increase ACTH secretion; and 2) to determine if the CRF-like actions of TRF could be attenuated using a CRF-receptor antagonist, α-hel CRF 9-41. Experiments were performed in awake animals equipped with chronic right atrial, femoral artery, or icv cannulae. Plasma levels of ACTH and CAs, and HR and MAP were measured using established methods. TRF (800 pmols, 2.6 nmols) or CRF (2 nmols) given icv produced increases in plasma concentrations of ACTH and CA, and of MAP and HR. TRF-induced elevation of plasma ACTH levels was dose related and did not occur following iv administration of TRF. α-hel CRF 9-41, at a dose (12 nmols) that inhibited CRF-induced (2 nmols given icv) elevation of plasma levels of ACTH and CAs, and MAP and HR, did not modify TRF's actions. Since TRF does not act directly on the pituitary or via CRF release to stimulate ACTH secretion, alternative mechanisms must exist, e.g. vasopressin, CAs, or unidentified factors, to mediate the observed ACTH release.

DIURNAL INFLUENCE ON THE RELATIONSHIP BETWEEN BIOACTIVE AND IMMUNOREACTIVE ACTH IN RATS. P. Miller*, C. Cornell*, C. T. Graeber*, and W. C. Engeland (SPON: C. F. Allen-Rowlands). Sect of Neurobiology/Dept. of Surgery, Brown Univ./R.I. Hosp., Providence, RI 02902

The pituitary-adrenal system in rats is characterized by a diurnal rhythm that affects resting plasma corticosterone (B) and B responses to stress. A dissociation between changes in plasma ACTH immunoreactivity (IR) and B has suggested that extra-ACTH factors contribute to diurnal variations in B. To assess the possibility that plasma ACTH-IR does not reflect ACTH bioactivity (BIO), diurnal changes in ACTH-BIO and ACTH-IR were compared. Groups of rats(n=5-12/group) were decapitated and blood was collected in the morning (AM) and in the evening (PM) without stress, 10 minutes post ether stress, and 7 days post bilateral adrenalectomy (ADX). ACTH-BIO was assayed in plasma extracts using collagenase-dispersed rat adrenal cells; B responses were assayed by HPLC-UV. Plasma ACTH-IR was assayed by RIA using antisera directed against ACTH 1-24 and plasma B was assayed by RIA. Resting ACTH-BIO increased diurnally in the absence of a change in ACTH-IR. The ACTH-IR/BIO ratio was 8.0 in the AM and 3.6 in the PM. The AM-PM change in ACTH-BIO was two-fold(5.8±0.4 vs. 11.8±2.6pg/ml), whereas the change in B was 20-fold(6±1.3 vs. 136.1±18.4ng/ml). Ether stress resulted in increases in ACTH-BIO and ACTH-IR that were not different diurnally. However, the ACTH-IR/BIO ratio decreased to 1.5 in the AM and to 1.8 in the PM. There was no AM-PM difference in B responses to ether determined by subtracting resting B. ADX resulted in increases in ACTH-BIO and ACTH-IR that were not different diurnally. After ADX the ACTH-IR/BIO ratio decreased to 1.2 in the AM and to 1.9 in the PM. These data show that diurnal changes in ACTH-BIO occur without changes in ACTH-IR. Since the amplitude of the ACTH-BIO rhythm is less than that of the B rhythm, the B response cannot be explained totally by changes in ACTH-BIO. The ACTH-IR/BIO ratio decreases in response to stress and ADX, suggesting that ACTH-IR is a more accurate index of ACTH-BIO during hypothalamic-pituitary activation. Supported in part by NIH grant DK38951.

ENDOCRINE RESPONSE TO PHYSOSTIGMINE IN ALZHEIMER'S. E. R. Peskind*, M. A. Raskind*, R. C. Veith* and D. M. Dorsa. (SPON: A. Khan). GRECC, VA Medical Ctr., Seattle,WA 98108

Cholinergic neurons in basal forebrain degenerate in Alzheimer's Disease (AD). Both arginine vasopressin (AVP) and corticotropin releasing factor-containing neurosecretory cells are innervated by cholinergic neurons, some of which probably originate in the basal forebrain. Epinephrine (EPI) release is also mediated by a CNS cholinergic mechanism. To assess CNS cholinergic regulation in AD, we measured plasma AVP, β-endorphin (βE), and EPI responses to cholinergic challenge elicited by the cholinesterase inhibitor physostigmine (0.0125 mg/kg IV) in 12 men with AD and compared responses to 12 age-matched normal men.

Physostigmine promptly increased plasma AVP (10 fold), βE (2-3 fold) and EPI (3 fold) in elderly controls. In contrast, AD patients showed attenuated responses to physostigmine. Differences were most pronounced when control and AD patients who experienced nausea (n=2 and 6, respectively) were excluded. Expressed as area under response curves, AD patient AVP (2±1.2 pg/ml/min) and βE (5±1.5 pg/ml/min) were significantly ($p<.02$) less than those of controls (14±5 and 28±4 pg/ml/min, respectively). AD EPI (10±3 pg/ml/min) tended to be lower than that of controls (60±27 pg/ml/min; $p<0.1$).

We conclude that the cholinergic deterioration of AD also influences CNS regulation of neuroendocrine systems.

515.10

PASSIVE AND ACTIVE MEMBRANE PROPERTIES OF ARCUATE NUCLEUS (ARC) NEURONS AND EFFECTS OF OPIOID PEPTIDES. M.D. Loose* and M.J. Kelly, Dept. of Physiology, OHSU, Portland, OR.

Anatomical data have indicated that the rat ARC has a plethora of cell types that contain either dopamine, amino acids or any of numerous peptides. Since the electrophysiological characteristics of ARC neurons have not been described in similar detail we identified the passive and active membrane characteristics of these cells and examined the effects opioid peptides had on them. Intracellular recordings were made from coronal, 400-500 μm thick slices prepared from proestrous rats using established methods (Brain Res. 345:264, 1985). ARC neurons exhibited stable RMPs (-55 to -71 mV), spike amplitudes (53-89 mV) of short duration (0.9 -1.6 ms), high input resistances (100-400 mΩ) and variable time constants (5.0 - 22.8 ms). During 400ms depolarizing pulses 90% of these cells fired continuously whereas, 10% fired a maximum of 3-7 spikes and then remained silent. A majority of neurons exhibited inward rectification. 10% of the cells had a prolonged (> 200 ms) AHP, and 25% had a low threshold spike which was not blocked by TTX (1-3 μm). DAGO (1 μm), an opioid agonist, affected 55% of the cells tested, causing membrane hyperpolarization (4-12 mV) and decreases in depolarizing PSPs. Therefore, subsets of ARC neurons can be distinguished by their intrinsic electrophysiological properties. Furthermore, several of these subsets respond to opioid peptides. (Supported by DA 05158, HD 07133 and HD 00718).

AMYGDALA DIRECTLY INNERVATES PARVOCELLULAR PARAVENTRICULAR HYPOTHALAMIC CRF, VASOPRESSIN AND OXYTOCIN CONTAINING CELLS. D.J. Magnuson,* and T.S. Gray. (Spon: G.G. Celesia) Dept. Anatomy, Loyola Univ. Med. Sch., Maywood, IL 60153

Phaseolus vulgaris leucoagluttin lectin anterograde tracer (PHA-L) and immunocytochemistry were used to examine whether amygdala cells directly innervated CRF, vasopressin and/or oxytocin immunoreactive cells within the paraventricular hypothalamic nucleus. Iontophoretic injections of PHA-L were placed within the central or medial nuclei of the amygdala of anesthetized 150-250g Long-Evans rats. Two weeks later animals were overdosed with sodium pentobarbital and their brains were fixed through vascular perfusion. Amygdaloid terminals were demonstrated via PHA-L antibodies and immunocytochemistry using a brown DAB reaction. Paraventricular hypothalamic cell bodies were visualized via CRF, vasopressin or oxytocin antibodies and immunocytochemistry using a glucose oxidase-nitro blue tetrazolium reaction. The medial amygdaloid nucleus innervated oxytocin and vasopressin immunoreactive neurons in rostral regions of the paraventricular nucleus. The central amygdaloid nucleus innervated the medial and lateral parvocellular regions of the caudal paraventricular nucleus. Central amygdaloid terminals innervated CRF, vasopressin and oxytocin immunoreactive cells. The present results sugggest that the amygdala can directly influence parvocellular paraventricular nucleus neurons and therefore affect the neuroendocrine output of these cells. (Supported by ONR N00014-88-K-0010).

515.12

BEHAVIORAL AND NEUROENDOCRINE CORRELATES OF DIETHYL ETHER EXPOSURE IN THE MOUSE John R. Glowa Clinical Neuroendocrinology Branch, NIMH, Bethesda, MD 20892.

Diethyl ether has been used extensively as an neuroendocrine stressor, yet little is known of either its behavioral effects or the concentrations over which they may occur. Adult male NIH mice and Sprague-Dawley rats were exposed to a full range of concentrations of ether (1000-30000 ppm) and effects on operant behavior and neuroendocrine response were compared. When operant responding was maintained under FI 60 sec schedules of milk presentation, 30 min or shorter exposures to concentrations of diethyl ether less than 10000 ppm were without behavioral effect, 10000 ppm produced large increases (up to 300%) in responding, and higher concentrations abolished responding (although not necessarily through anesthetic action). Exposure to a similar range of concentrations of ether elevated ACTH and corticosterone in both mice and rats, from baseline levels of 18.2 pg/ml ACTH and 78.44 ng/ml corticosterone to levels in excess of 310.5 pg/ml ACTH (1700% of control) with 5 min exposure w/o altering corticosterone levels, whereas with 30 min exposures corticosterone levels increased 700%.Increaases in neuroendocrine measures generaly preceded those seen behaviorally, across doses. The imidazobenzodiazepine, Ro 15-4513 (ethyl-8-azido-5,6-dihydro-5-meth-6-oxo-4H-imidazo (1,5-a)(1,4) benzodiazepine-3-carboxylate), previously shown to block both in vivo and in vitro effects of ethyl alcohol, decreased FI responding in mice in the present studies, but only at doses of 10-30 mg/kg. Ro 15-4513 elevated ACTH and corticosterone levels in a dose-dependent manner, with increases in both neuroendocrine measures occurring at doses of Ro 15-4513 (3 mg/kg) that were without behavioral effect alone. However, behaviorally inactive doses of Ro 15-4513 were unable to antagonize the rate-increasing effects of diethyl ether.

SEX DIFFERENCES IN ANTERIOR PITUITARY POMC mRNA AND SECRETION PATTERNS. J. Kotun*, H.-L. Lin*, and H. Akil (SPON: J. Greden). Mental Health Research Institute and Department of Psychiatry, University of Michigan Medical School, Ann Arbor, MI 48109.

The hypothalamic-pituitary adrenal axis and the hypothalamic pituitary gonadal axis are thought to interact at multiple levels. While differences have been described between male and female rats at the level of plasma glucocorticoids, little is known about the differential regulation of POMC in the pituitary corticotrophs across sexes. The hypothalamic POMC system has been more extensively studied with regard to gonadal interactions. In addition, there is a suggestion that estrogen receptors may negatively regulate POMC gene expression in vitro. However, it is not yet clear if such regulation occurs in the anterior pituitary. We have compared male and female rats both basally (across the estrous cycle) and following acute swim stress. Consistent with earlier work the female rats showed, at rest, a significant elevation of corticosterone over male levels. Paradoxically, the females exhibited lower plasma ACTH throughout the estrous cycle. Acute swim stress induced comparable release of ACTH and steroids in both sexes. Anterior pituitary ACTH and β-endorphin content did not differ between males and females or across the estrous cycle; however POMC mRNA in females was significantly lower than that of males. It appears that the elevated circulating steroid levels in female rats may have resulted in a decreased steady state level of POMC mRNA and POMC product release into plasma, without altering the level of peptide stores in the gland. Yet, the female rats maintain their ability to respond to stress challenges. The role of sex steroids in this differential regulation and possible difference at the adrenal and hypothalamic levels require further investigation.

LEARNING AND MEMORY: HUMAN BRAIN

NEUROPSYCHOLOGICAL CORRELATES OF BILATERAL FRONTAL LOBE LESIONS IN HUMANS. S.W. Anderson, H. Damasio, D. Tranel, and A.R. Damasio. Div. of Behavioral Neurology & Cognitive Neuroscience, The University of Iowa College of Medicine.

The study of the effects of frontal damage in humans has been hampered by the rarity of nonpsychiatric patients with focal lesions to these areas. Here we present comprehensive neuroanatomical and neuropsychological analyses on 5 patients who sustained bilateral frontal lesions as adults. Criteria for subject selection included: 1) stability of chronic lesions caused by vascular event or surgical ablation, 2) lack of damage to nonfrontal cortices, and 3) normal premorbid social and cognitive function. The neuroanatomical study was based on magnetic resonance scans analyzed with a standard procedure. The neuropsychological study included standardized assessment of a broad range of cognitive functions and interviews with the families. All subjects had involvement of orbital and lower mesial frontal cortices bilaterally, but the dorsolateral regions were preserved; 2 had lesions which extended into basal forebrain. All subjects had personality changes which included disturbances of social conduct, decision-making, planning, motivation, and affect. Intellect, language, and perceptual abilities were intact in all, but awareness of the personality disturbances was impaired. Memory for objects and events was defective only in the 2 subjects that also had basal forebrain damage. Bilateral orbito-mesial lesions in humans are thus strongly associated with cognitive and behavioral defects largely specific to the social domain.

516.2

IMPAIRED AUTONOMIC RESPONSES TO EMOTIONAL AND SOCIAL STIMULI IN PATIENTS WITH BILATERAL ORBITAL DAMAGE AND ACQUIRED SOCIOPATHY. D. Tranel, A.R. Damasio, & H. Damasio. Div. of Behavioral Neurology & Cognitive Neuroscience, Univ. of Iowa College of Medicine, Iowa City, Iowa.

The impaired social behavior of patients with bilateral orbital lesions, can be seen as a domain-specific amnesia in which defective activation of learned somatic states plays a key role (Damasio & Tranel, 1988). Our theory predicts impaired autonomic responses to nonverbal "emotional/social" stimuli in these patients. We studied the skin conductance responses (SCRs) of 4 frontal lobe patients and 4 controls to stimuli with either high (target) or low (nontarget) emotional valence. Subjects viewed the stimuli under either a PASSIVE (no response) or ACTIVE (verbal description) response condition. The controls produced significantly larger amplitude SCRs to target stimuli in both conditions. The frontal patients, however, demonstrated a striking dissociation: in the PASSIVE condition, SCRs to targets were severely defective and not different from nontarget responses; in the ACTIVE condition, SCRs were normal (high-amplitude responses to the target, but not the nontarget, stimuli). E.g., patient EVR produced an average SCR of .031 μS for target pictures under PASSIVE viewing conditions, and an average of .218 μS in the ACTIVE condition. These findings parallel the situation outside the laboratory, where EVR is able to behave adequately only when stimulus configurations are presented in verbal form in a modified, non-real-time base.

516.3

DOMAIN-SPECIFIC AMNESIA FOR SOCIAL KNOWLEDGE.
A.R. Damasio & D. Tranel. Division of Behavioral Neurology & Cognitive Neuroscience, University of Iowa College of Medicine, Iowa City, Iowa.

Patients with bilateral lesions in orbital and lower mesial frontal cortices develop changes in social behavior that include inadequate decision making, planning, and conduct. Such patients are unaware of their predicament. The primary cognitive and neural mechanisms for these remarkable changes remain enigmatic and polemical. Based on extensive neuropsychological and psychophysiological experiments in 5 subjects, we propose that the defects (1) stem from impaired coactivation of an appropriate range of memoranda relative to the complex activities, properties, and events that characterize social interactions, and (2) are manifest when "social knowledge" configurations are presented in real-time through nonverbal channels. Prominent among the missing memoranda are somatic states, including those regulated by the autonomic nervous system. The new theory postulates that the reactivation of internal somatic states that co-occurred with pertinent representations of external events, is a necessary step for a comprehensive range of interwoven associations to become available. However, verbal stimuli can bypass this weak link and generate appropriate evocations. In this light, the "acquired sociopathy" of frontal lobe patients can be seen as a domain-specific disorder of generic memory, i.e., a categorical amnesia for social knowledge that precludes activations necessary for behavioral guidance.

516.4

ISOLATED IMPAIRMENT OF RETRIEVAL AND LEARNING OF REFERENCE LEXICON FOLLOWING LEFT ANTEROTEMPORAL DAMAGE.
H. Damasio, D. Tranel, A.R. Damasio. Div. of Behavioral Neurology & Cognitive Neuroscience, University of Iowa College of Medicine, Iowa City, Iowa.

Four patients with combined damage to mesial and nonmesial left anterotemporal structures (entorhinal cortex/hippocampus/amygdala and anterolateral neocortices) maintain accurate nonverbal records of past experiences, and acquire accurate new nonverbal records. By contrast, they have a severe defect in the retrieval and acquisition of the specific verbal tags that denote those experiences. The dissociation is revealed by experiments requiring (a) naming of entities in different domains, (b) learning of new visuo-verbal relationships, and (c) retrieval and new learning of nonverbal entities and relations. The subjects invariably recognize and accurately describe all stimuli and events that they fail to name specifically, and their ability to access and utilize functors, and to generate correct grammatical structure, is intact. Higher-order association cortices and limbic structures in the left anterotemporal region, thus play a key role in the learning and rapid retrieval of verbal markers in the entity domain but not in the relational domain.

516.5

ANATOMIC CORRELATES OF RETROGRADE AMNESIA.
P.J. Eslinger and L. Cermak*. Cognitive Neuroscience Lab, Brown University, Providence, Rhode Island 02903 and Memory Disorders Research Center, Boston VAMC, Boston, Massachusetts 02130

Studies of patients with amnesia have identified a number of structures and interconnecting pathways which are necessary for the learning and retention of new experiences. These neural units include the medial temporal region, anterior/medial diencephalon, basal forebrain, retrosplenial cortex and interconnecting pathways such as the fornix, mammillo-thalamic tract and amygdalofugal pathway. Patients with damage to these and surrounding structures may also exhibit an extended retrograde amnesia beyond the 1-3 years prior to cerebral injury. We report here the results of neuroimaging in patient SS, who developed a severe anterograde and retrograde amnesia following encephalitis 17 years ago at the age of 38 (Neuropsychologia, Vol 21, 1983, 213-234). In addition to bilateral medial temporal lobe damage and possible damage to the posterior ventromedial frontal lobe (structures which have ben associated with predominantly anterograde amnesia), SS sustained cortical damage to the insula bilaterally, to the temporal poles bilaterally, and to the left anterolateral temporal region. By comparison, patient DRB (Arch Neurol 42, 1985, 252-9) has a more severe retrograde amnesia and a highly similar but more extensive pattern of damage.

We conclude that in a neural model of memory, extended retrograde amnesia is related to damage in cortical structures of the insula and/or anterolateral temporal lobes.

516.6

A POSITRON EMISSION TOMOGRAPHIC STUDY OF ANATOMICAL STRUCTURES IN THE HUMAN BRAIN PARTICIPATING IN LEARNING, RECALL AND RECOGNITION OF COLORED PATTERNS.
P.E. Roland, L. Widén and S. Stone-Elander. Dept of Clinical Neurophysiology, Karolinska Hospital and Institute S-104 01 Stockholm, Sweden.

The regional cerebral blood flow (rCBF) was measured with 11C-labelled CH3F in ten young normal volunteers during four conditions lasting 60 s each: rest, visual learning, recall and recognition. The subjects learned ten colored geometrical patterns which contained no other information than shape and color. The color contrast and luminance was balanced. During recall, the subjects, with eyes closed, recalled the appearance of each color-pattern in the same order as originally shown. During recognition the learned patterns were mixed with other similar patterns. Visual learning increased the rCBF in several prefrontal areas, orbitofrontal cortex, insula, hippocampal regions, neostriatum, thalamus, the calcarine cortex, peri-calcarine cortex, and the visual association areas in the posterior superior parietal cortex and precuneus. Recognition of the color-patterns increased rCBF in the same structures. The purely intrinsic recall of the color-patterns did not change the rCBF in the calcarine, peri-calcarine and orbital cortex; the increase of rCBF in posterior thalamus was especially marked, apart from this the structures which increased rCBF were same as during learning and recognition.

516.7

MATERIAL-SPECIFIC MEMORY DEFICITS AFTER UNILATERAL TEMPORAL NEOCORTICECTOMY. (SPON: C. Bushnell).
T. Burke* and J.R.M. Nolan*. Univ. Coll. Dublin, Belfield, Dublin 4, Ireland.

Two studies were carried out that examined aspects of memory in patients who had undergone a unilateral temporal neocorticectomy for the relief of intractable epilepsy in the Richmond Institute, Dublin. In Experiment 1, a forced-choice recognition-memory paradigm was used to assess memory for: (a) abstract words, (b) concrete words, (c) pictures of common objects and (d) abstract geometric designs. The left temporal-lobe group (N=10) was impaired on the verbal materials and the right temporal-lobe group (N=10) was impaired on the abstract designs. These results are congruent with those observed following temporal lobectomy. Experiment 2 examined the effect of eliminating the value of a verbal label on memory for pictures of common objects. The results revealed an impairment in the right temporal-lobe group. The results of these two experiments extend, to the operation of temporal neocorticectomy, the observation of a double dissociation between the effects of left- and right-temporal lobectomy on memory and, thus, demonstrate a temporal neocortical contribution to human memory processes.

516.8

REDUCTION OF PROACTIVE INTERFERENCE FACILITATES ENDURING IMPLICIT RECALL IN KORSAKOFF AMNESICS.
T.W.Parker and A.R.Dobbs* Dept. of Psychology, Camrose Lutheran College, Camrose, Alberta, T4V 2R3.

Korsakoff amnesics and controls were presented with riddles and tested for implicit and explicit recall of these riddles at 10 minutes, 24 hours and 30 days following the presentation phase. Proactive interference (PI) arising from self-generated responses was eliminated for half the subjects by providing them with the answer immediately after presenting the riddle. In contrast the remaining subjects were encouraged to generate their own response to the riddle and then were given the correct answer. A dissociation between implicit and explicit recall was found such that amnesics for whom PI was minimized demonstrated normal levels of implicit recall for up to thirty days, although no explicit recall of the riddles occurred. This demonstration of normal recall of paired-associates is most likely due to the semantic richness of the stimuli and the automatic elaboration which is thought to take place. The results are discussed in terms of the process of restructuring which facilitates subsequent recall of stimuli which promote an "aha" experience.

516.9

NORMAL IMPROVEMENT IN MENTAL ROTATION SKILL IN GLOBAL AMNESIA. L.M. Parsons*, J.D.E. Gabrieli, J. Yucaitis*, & S. Corkin. Department of Brain & Cognitive Sciences and Clinical Research Center, MIT, Cambridge, MA 02139. (SPON: Ken Nakayama).

Patient H.M., despite severe anterograde amnesia following bilateral medial temporal-lobe resection, has the learning capacity to substantially improve a skill for mental rotation. He and healthy, age-matched control subjects made verbal responses in judging whether a non-upright letter was in its normal or mirror-reversed form. The stimuli were viewed at each of 12 orientations, 30 degrees apart. On three successive days, subjects performed two sessions, an hour apart, each with 72 trials. As with control subjects, the initially moderate slope of H.M.'s reaction-time/orientation function declined to nearly zero, and his overall mean reaction time and errors decreased. These results suggest that declines of such RT function slopes are due to an increase in the rate of mentally rotating the stimulus to upright and not due to memorizing its form at the tested orientations. Prior reports of preserved perceptual learning have been limited to stimuli viewed at one orientation, and analysis of the conditions producing the preserved learning reported here may reveal the relation between long-term memory structures and operations used to discriminate disoriented stimuli. Our findings are consistent with the view that there is a dissociation in global amnesia between skill learning and fact learning. In 1987, we reported that HM showed no such improvement when this task required a button press response, a result apparently due to his difficulties with a forced-choice motor response.

Supported by grants MH24433 and RR00088.

516.10

DISSOCIATION BETWEEN TWO KINDS OF PRIMING IN GLOBAL AMNESIA AND ALZHEIMER'S DISEASE. M.M. Keane, J.D.E. Gabrieli, M.M. Kjelgaard*, J.H. Growdon, and S. Corkin. Department of Brain & Cognitive Sciences and Clinical Research Center, MIT, Cambridge, MA 02139, & Department of Neurology, Massachusetts General Hospital, Boston, MA 02114.

This study shows that dissociable cognitive and neural mechanisms underlie performance on two priming tasks, stem completion and Gollin incomplete pictures. Twenty mildly or moderately demented patients with Alzheimer's disease (AD) and 4 patients with global amnesias (AMN) due to bilateral limbic-diencephalic lesions performed these two priming tasks. Consistent with prior findings on the stem-completion task, the AD group was impaired relative to the AMN group, which performed normally. In contrast, the AD and AMN groups performed similarly on the Gollin Incomplete-Pictures Test. Even though both groups were significantly impaired relative to normal subjects, they still showed significant and equivalent facilitation at a 1-hour delay. These results establish a dissociation between two priming tasks in AD and suggest that separable mechanisms, distinct from fact learning, underlie the two kinds of performance.

PRIMING IN THE AMNESIC PATIENT H.M.: NEW FINDINGS AND A THEORY OF INTACT AND IMPAIRED PRIMING IN PATIENTS WITH MEMORY DISORDERS. J.D.E. Gabrieli and M.M. Keane. Department of Brain and Cognitive Sciences and Clinical Research Center, MIT, Cambridge, MA 02139, & Department of Psychology, Harvard University, Cambridge, MA 02138.

We report new examples of preserved priming in the globally amnesic patient H.M., and present a theoretical interpretation of intact and impaired priming in amnesia and in Alzheimer's disease (AD). We propose that repetition priming on a visual task takes three different forms. (1) Pre-representational priming depends upon perceptual learning mechanisms that facilitate access to representations (letters, words, objects); such mechanisms are spared in amnesia and in AD. (2) Inter-representational priming depends upon learning mechanisms that guide semantic and lexical access to representations in long-term memory; these mechanisms are spared in amnesia but are impaired in mild AD. (3) Post-representational priming depends upon mechanisms that record the outcome of operations on a repre- sentation: such priming is impaired in amnesia and AD. The observed dissociations among the three forms of priming suggest that they have separable neural bases. Dissociations among forms of priming may reveal how distinct neural systems enhance the efficiency of access to representations irrespective of subsequent operations performed upon those representations.

LONGITUDINAL ANALYSIS OF THE DYSEXECUTIVE SYNDROME IN ALZHEIMER'S DISEASE. J.T. Becker, Alz. Dis. Res. Ctr., University of Pittsburgh, Pittsburgh, PA 15213 USA

The memory disorder in patients with Alzheimer's Disease (AD) may be described as the combination of an amnesic syndrome and a dysexecutive syndrome (Becker, Neuro. Abs, 1987). The performance of a cohort of 122 AD patients and 93 normal controls was analyzed on four tests of delayed recall and new learning, and three tests related to central executive function. Patients were identified as having either a "focal" dysexecutive syndrome (n=3) or an amnesic syndrome (n=4) based on the difference between scores on standardized composite variables.

One year later, 76 AD patients and 87 controls were re-evaluated on the same battery of tests. Additional patients were found to have dysexecutive (n=2) and amnesic (n=1) syndromes. Furthermore, the seven patients who had "focal" patterns of presentation at baseline were now classified as "non-focal".

These data replicate and extend the previous findings. First, more patients were found who met the criteria for focal abnormalities of memory impairment. This adds strength to the hypothesis that AD patients suffer from a loss of Central Executive System function as described in Baddeley's model of Working Memory. Furthermore, the findings that the focal syndromes are not static but can change with time suggests that they represent the relative sparing of a particular neuropsychological function in the face of a progressive dementia.

THE AGING PROCESS II

SUBSTANCE P AND SOMATOSTATIN COEXIST WITHIN SENILE PLAQUES OF PATIENTS WITH ALZHEIMER'S DISEASE. D. M. Armstrong, W. Benzing, J. Evans*, and L. Hansen*. Dept. of Neurosci., University of California, San Diego, La Jolla, CA 92093.

In recent years we and others have identified several neuropeptide and neurotransmitter-related substances within senile plaques of patients with Alzheimer's disease. At present, it is unclear whether a senile plaque can be identified according to a single transmitter or peptide substance or alternatively whether a plaque contains multiple substances.

In the present study we employed a highly sensitive dual-immunolabeling procedure and demonstrated that substance P- and somatostatin-immunoreactive profiles coexist within senile plaques of patients with Alzheimer's disease. Coexistence of somatostatin and substance P immunoreactivity within the same plaque was observed in the hippocampus and amygdala but not in the neocortex, although the latter region contained plaques within which somatostatin and substance P existed alone. Regardless of the region, the labeled processes were usually enlarged and within the peripheral (i.e., the neuritic) portion of the plaque.

GLUCOSE-6-PHOSPHATASE ACTIVITY IN HIPPOCAMPAL NEURONS. K. Cullen-Dockstader* and E. Fifkova (SPON: H. Alpern). Dept. of Psychology, University of Colorado, Boulder, Colorado 80309.

Glucose-6-phosphatase (G6Pase) is intimately involved in the mechanism of Ca^{2+} transport into the endoplasmic reticulum (ER). G6Pase in the ER hydrolyzes the glucose-6-phosphate (G6P) whereby it liberates phosphate ions. These are used to capture the actively transported Ca^{2+} into the ER. The G6Pase activity may be cytochemically detected by lead ions. We have, therefore, adapted the Brodwell-Cataldo method (J. Histochem. Cytochem., 31:1077) to be used in the hippocampus. These experiments have shown G6Pase activity in the smooth and rough ER and in the nuclear envelope. Basket cells, the inhibitory interneurons of the dentate fascia and hippocampus, show a considerably higher activity than the dentate granule cells or hippocampal neurons. Also, neurons of the hilus are intensely labeled. This method is an indicator of differential metabolic activities, and it could be useful to detect possible changes in the G6Pase activity associated with senescence. The ultimate goal of these experiments is to demonstrate the extent to which G6Pase activity may be affected by aging and thus account for the decreased Ca^{2+} sequestering capacity of the SER observed in aged rats (Fifkova and Cullen-Dockstader, Brain Res., 376:357).

517.3

AGING AFFECTS THE SIZE OF VESICLES IN THE PERFORANT PATH TERMINALS IN THE DENTATE MOLECULAR LAYER. E. Fifkova and K. Cullen-Dockstader*. Dept. of Psychology, University of Colorado, Boulder, Colorado 80309.

Aging brings about an impairment of a number of neuronal functions, out of which impairment of synaptic transmission is the most critical. Previously we have shown that migration of synaptic vesicles in the perforant path terminals towards the active synaptic site is affected with age as significantly fewer vesicles were found there at resting conditions. The obvious next step was to study the size (cross sectional area) of these vesicles. Rats (Fischer 344) ages 3, 9, 24, and 30 months old were used. Five animals per age group were prepared for electron microscopy. Vesicles were measured in axon terminals of the perforant path in the dentate molecular layer. Perforant path terminals were identified as those contacting dendritic spines. The vesicle cross sectional area was computed from the largest diameter and the diameter perpendicular to it, using an IBM PC-based three-dimensional reconstruction program (Kinnamon et al., Proc. 44th EMSA Meeting, 1986, p. 876). In these preliminary experiments, we have measured 250 terminals per age group. A significant decrease of the vesicle cross sectional area was observed by the 24th month as compared to the 3rd and 9th months. Since the majority of synaptic vesicles is generated by recycling, the present data could be interpreted as a failure of this process during aging. Such a change could bring about an impairment of the synaptic transmission, the severity of which would be enhanced by the decreased number of vesicles transported to the active site (Fifkova and Cullen-Dockstader, Soc. Neurosci. Abstr., 12:271) and by the loss of some axon terminals in the dentate molecular layer (Geinisman et al., Brain Res., 134:541; Hoff et al., J. Comp. Neurol., 205:246). Consonant with this conclusion is the age-related decrease in amplitude of the perforant path presynaptic potentials while their activation threshold remained unchanged (Barnes and McNaughton, J. Physiol., 309:473). Thus, the present data show presynaptic alteration of the perforant path in the dentate molecular layer that could contribute to the decreased synaptic efficacy observed in this region with aging.

AGE-ASSOCIATED MORPHOMETRIC CHANGES IN MONKEY PREFRONTAL CORTEX. M.D. Applegate*, R.G. Struble, C.A. Fleischman*, L.C. Cork*, and D.L. Price. Neuropathology Lab., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205-2182.

Performance on behavioral tasks dependent upon the integrity of the prefrontal cortex (e.g., direct-delayed response) [Bachevalier & Mishkin, Behav. Brain Res., 20:249, 1986] is impaired commonly in aged monkeys. To examine possible components of neuronal substrates of this impairment, we conducted a morphometric study of prefrontal cortices in young and aged monkeys. Paraffin-embedded, cresyl violet-stained tissue sections (5 μm) from lateral walls of the principal sulci of 14 monkeys (Macaca mulatta, 4-31 years of age) were analyzed for density and size of cells using the Loats image analysis system. Significant age-associated reductions in neuronal size were demonstrated ($r = -0.6759$; $p = 0.008$), but no changes were noted in the density of neurons ($r = 0.2553$; ns). In contrast, the density of glia was increased significantly with age ($r = 0.6008$; $p = 0.023$). The decline in neuronal size occurred primarily in layers II-IV, and the depths of layers III and IV decreased with age. This age-associated pattern of reduced neuronal size and cortical thickness, increased density of glia, and no change in density of neurons parallels results of studies of midfrontal cortices of aged humans [Terry et al., Ann. Neurol. 21:530, 1987]. These changes, among others, may contribute to behavioral deficits that occur in aged monkeys.

517.5

AGE AND NUCLEAR PORE COMPLEX DENSITY IN CA1 PYRAMIDAL CELLS IN THE RAT. A. Topple, E. Fifkova, K. Cullen-Dockstader* and G. Smith*. Dept. Psychology, University of Colorado, Boulder, Colorado 80309.

Studies on the aging hippocampal formation have revealed ultrastructural and physiological alterations that may underlie a number of functional deficits associated with aging. One such change is the reduced density of nuclear pore complexes (NPCs) in the granule cells of the dentate fascia which occurred in the absence of any change in the nuclear envelope perimeter (Fifkova et al., Exp. Neurol., 95, 755, 1987). This decrease is thought to reflect a decrease in the metabolic activity of these cells. We report here our preliminary findings on the density of these pores in a different area of the hippocampal formation, the CA1 pyramidal cells. Ten male Fischer 344 rats aged 3, 9, 24, and 30 months (2 animals per age) were prepared for electron microscopy and were photographed on a JEM-100C electron microscope. There were no differences in the density of pores across ages in the CA1 pyramidal cells. There was, however, a 17.8% increase in the nuclear envelope perimeter with increasing age (which did not reach significance). Such an increase may have masked any change in NPC density. These data suggest that there may be age-related regional differences within the one structure for the same parameter. However, more animals are required before definitive statements can be made regarding the effects of age on NPC density in this area.

LOW CALORIE-HIGH FIBER DIET AND AGING: EFFECT ON BRAIN LIPIDS. M.T. Tacconi, L. Lligona, M. Soldati, N Pitsikas, S.Algeri and M.Salmona. Istituto di Ricerche Farmacologiche "Mario Negri, Milano, Italy.

Food intake restriction increases longevity and delays the occurrence of age-related physiological deterioration.We studied whether brain membrane lipids and microviscosity (parameters known to be modified by age) were affected by a diet low in calories. Male rats (Charles River Italy, Calco, Italy) were fed *ad libitum* with standard diet or with a low caloric diet (LCD) in which 50% of lipids and 35% of carbohydrates have been replaced by fibers. The diet was started at weanling. Body weight, food consumption, date and possible cause of natural death were recorded. At 4, 15 and 32 months of age rats were killed, brain dissected and cortex used for analysis. Rats which received the LCD were leaner by 15-30% than their age paired controls. Survival at 32 months of age was 25% in LCD versus 10% in control rats. LCD rats showed the same age-related increase in cholesterol content as control, but total PLs (differently than in control rats) significantly increased, resulting in a reduction of Chol/PL ratios. Similary, Sph/PC ratios were reduced in LCD fed rats in respect to controls. Membrane microviscosity (which increased with age, as expected, in rats fed standard diet) was not affected significantly by LCD. Polyunsaturated FA in PLs (mainly in PE and PS) were lower in rats fed LCD for 32 months than in controls of the same age In conclusion feeding rats with a low calorie-high fiber diet in brain counteracts the age-related increase in Chol/PL and Sph/PC ratios, being not able, however, to inhibit the reduction in fluidity observed with age. Since polyunsatured FA age-related reduction in LCD rats was greater than in controls it is possible to speculate that LCD may produce a partial EFA deficiency, which worsens the age-related decrease in FA desaturases, thus counteracting the positive effect on fluidity of PLs increase.

517.7

REGIONAL CHANGES WITH AGE OF CALPAINS IN RAT BRAIN. A. Kenessey*, M. Banay-Schwartz* and A. Lajtha. (SPON: W. Sacks). Ctr. for Neurochem., N.S. Kline Inst. Ward's Island, NY, NY 10035.

Low (CANP I)- and high (CANP II)-calcium-requiring neutral proteinases (calpains) and their specific endogenous inhibitor (calpastatin) constitute an intracellular regulatory system that plays an important role in the metabolism of cytoskeletal proteins. Differences between the CANP activities in neonatal and adult brain regions have been reported; however, no data are available about their properties and activities in the senescent brain. We measured CANP activities in six brain regions (cortex, cerebellum, striatum, pons-medulla, hypothalamus, and hippocampus) from young adult (3-month-old) and aged (24-month-old) rats, using ^{14}C-methylated casein and brain protein substrates (desmin, actin, tubulin, and neurofilament preparations). Calpastatin was separated from the two enzyme fractions by Reactive Red 120-agarose. We could not detect significant CANP I activity in any of the regions. CANP II activity was the highest in the pons-medulla and the cerebellum, with casein as substrate. In aging brain CANP II activity increased greatly in striatum, only slightly in cortex and pons-medulla. Enzyme property alterations are indicated by the substrate dependence of regional activity changes with age. The determination of regional inhibitor levels is in progress to clarify its role in the age-dependent alterations of CANP activity. (Supported by NIH AG05607).

LEUPEPTIN CAUSES AN ACCUMULATION OF PHOSPHORYLATED TAU AND UBIQUITIN IN RAT BRAIN. G.O. Ivy, K. Kitani and Y. Ihara. Life Sciences, Univ.of Toronto, Toronto, Ont. M1C 1A4 and Tokyo Metropolitan Inst. Gerontology, Tokyo-173, Japan.

In Alzheimer's disease (AD) and to some extent in aging, neurofibrillary tangles (NFT), often exhibiting the form of paired helical filaments (PHF) accumulate. Several laboratories have shown that the major antigenic components of PHF are phosphorylated tau proteins and that ubiquitin is present in NFT, possibly attached to phosphorylated tau itself. As an attempt at understanding the cellular mechanisms underlying NFT formation, we administered either the protease inhibitor, leupeptin or buffered saline intraventricularly to rats for two weeks using an osmotic mini pump. Brain tissue from these and normal aged rats was processed for immunocytochemistry using antibodies to PHF (affinity purified to react with phosphorylated tau) and ubiquitin. Many Purkinje cells in the cerebellum of leupeptin treated and aged, but not saline treated rats, displayed increased immunoreactivity to both antibodies. Anti-PHF antibodies labeled the perikarya and proximal dendrites while anti-ubiquitin stained perikarya, nuclei and portions of Purkinje cell dendrites. The finding that inhibition of thiol and some serine proteases causes a buildup of abnormal neuronal inclusions with antigenic similarities to NFT and PHF supports the protease inhibitor model of aging and AD (Ivy, 1987). Supported by NIA and NSERC.

LEUPEPTIN CAUSES SOME MANIFESTATIONS OF AGING IN THE RETINA
G. M. Smith and G. O. Ivy. Life Sciences, Univ.of Toronto, Toronto, Ont. M1C 1A4.

An accumulation of lipofuscin in the retinal pigment epithelium (RPE) is a hallmark of aging. This buildup may be due to a reduced ability of aged RPE cells to catabolize the contents of both phagosomes (mainly photoreceptor outer segment discs, PD) and autosomes. In this study, two month old Sprague Dawley rats were injected intraoccularly, every 24 hours for several days; one eye with lul of the protease inhibitor leupeptin (200 mg/ml) and the other with the same volume of buffered saline. Eyes from normal young and aged rats were also examined. RPE cells of eyes from aged and leupeptin treated rats contained more Periodic Acid Schiff positive granules than did RPE cells of saline treated eyes. Electron microscopic analysis confirmed the presence of numerous dense bodies in the RPE of leupeptin treated as compared to saline treated eyes; the majority of these appeared to be composed of PD at various stages of catabolism, as seen in untreated eyes from young rats. Other dense bodies displayed morphologies typical of lipofuscin seen in the aged rats. Further, varying degrees of photoreceptor degeneration were evident in many of the leupeptin treated and aged eyes. Together, the results indicate that lipofuscin accumulation in RPE cells may be largely due to a buildup of PD caused by decreased proteolytic activity and that photoreceptor degeneration can be caused by protease inhibition. Supported by NIA and NSERC.

LOSS AND RECOVERY OF STRIATAL DENDRITIC SPINES FOLLOWING LESIONS IN THE CEREBRAL CORTEX OF ADULT AND AGED MICE.
H-W. Cheng*, Y. Anavi*, H. Goshgarian, T.H. McNeill and J.A. Rafols. Department of Anatomy and Cell Biology, Wayne State University School of Medicine, Detroit, MI 48201; and Departments of Anatomy and Neurology, University Rochester School of Medicine, Rochester, NY 14642.

The dendritic spines of medium striatal neurons are postsynaptic targets to axon terminals of afferent fibers originating in the cerebral cortex, intralaminar thalamus, substantia nigra pars compacta and midbrain raphe. Lesions which involve some of these afferent fibers have been reported to result in substantial loses of striatal spines (Kemp, J.M., and T.P.S. Powell, Phil. Trans. R. Soc. Lond., B262:429, 1971). As part of our investigation in the aging striatum, we have examined by means of Golgi impregnations (Van der Loos modification) and computer-assisted morphometry (Bioguant IV), the effect of unilateral cortical lesions on the linear density of striatal spines in both adult (6 month) and aged (25 month) C57BL/6N mice. Three days after cortical lesions the density of spines per 20μm linear segment of dendrite is significantly ($p<0.005$) reduced in both the adult (by 30%) and aged (by 28%) groups compared to matched aged normals. The maximum spine loss (46%) is detected in both groups with survival of 10 days after lesion. A return to normal densities occurs in both groups between day 10 and 20 after lesions, and, at least, in the aged group complete recovery of the normal density is attained by day 35 postlesion. The present results reveal a capacity for plasticity in surviving striatal afferents as well as in the dendrites of striatal neurons in both adult and aged mice. In addition they also indicate a capacity of striatal spines in aged striatum to recover from cortical deafferentation with no apparent lag to initiate such a response as compared to the younger striatum. EFFECT OF AGE AND LONG-TERM OVARIECTOMY ON HYPOTHALAMIC NOREPINEPHRINE (NE) ACTIVITY ASSOCIATED WITH THE ESTRADIOL-STIMULATED LH SURGE.
K. Scarbrough and P. M. Wise, Dept. Physiology, School of Medicine, Univ. of Maryland, Baltimore, Md. 21201

Estradiol (E2)-induced LH surges are attenuated and delayed in middle-age compared to young rats. This age-related change in the pattern of LH release is associated with alterations in catecholamine turnover rates in hypothalamic nuclei known to be important in the regulation of the surge. Middle-aged long-term ovariectomized (OVX) rats (OVX at 3 mo.) exhibit E2-induced LH surges which are similar in timing and amplitude to those displayed by young rats. We tested the hypothesis that long-term OVX delays the age-related changes in the rate constants of NE activity in microdissected hypothalamic nuclei.

Young (3-4 mo.) and middle-aged (11-12 mo.) cycling rats were OVX. One week later these animals, plus a group of long-term OVX rats (11-12 mo.) were treated with capsules which produced plasma levels of E2 between 15 and 25 pg/ml. The rate constants of NE activity in the medial preoptic nucleus (MPN), the suprachiasmatic nucleus (SCN) and median eminence (ME) were determined at 09.00 and 15.00 h four days after E2 treatment using the α-methyl paratyrosine method. NE content was measured using HPLC. The right and left MPN and SCN were assayed separately.

In young rats, the rate constant of NE activity increased significantly from morning to afternoon in the ME and in the left but not the right SCN and MPN. Middle-aged short-term OVX-E2 treated rats failed to exhibit any diurnal rhythm in the rate constant of NE activity in the ME, SCN, or MPN. In contrast, middle-aged long-term OVX-E2 treated rats exhibited a diurnal pattern of NE activity in the ME similar to that of young animals but there was no diurnal rhythm observed in the SCN or MPN. Therefore, long-term OVX is associated with a sparing of NE function in the ME but not in the SCN or MPN.

Our data suggest that 1) long-term OVX prevents the age-related loss of the NE rhythm in the ME and 2) the maintenance of this ME rhythm may partially account for the ability of E2 to stimulate normal LH surges in these middle-aged rats. Supported by NIH AG02224, HD15955, HD07170.

BASAL GANGLIA/CEREBELLAR CALCIFICATION IN DOWN'S SYNDROME BRAINS OF THE YAKOVLEV COLLECTION.
C.D.West*, S.Colwell*, and V.Armbrustmacher* (SPON: E.Yeterian). Dept. Neurology (BIH), Harvard Med. Sch., Boston, MA 02115, Dept. Anatomy Boston Univ. Sch. Med., Boston, MA 01730, and the Armed Forces Institute of Pathology, Washington, D.C. 20306.

The distribution, severity and local neuronal effects of basal ganglia/cerebellar calcification/mineralization deposits were examined in 8 brains of the Yakovlev Collection from Down's Syndrome (DS) individuals, 2.5 to 56 years old. Four brains (2.5, 4, 16 and 29 years) had no deposits, or trace amounts. The others (6, 26, 47 and 56 years) had deposits increasing in severity with increasing age. The oldest had deposits in the cerebellum also.

The calcification/mineralization deposits were extraneuronal and often appeared as rows of spheroids organized along blood vessels. Heavier deposits appeared as disorganized, conglomerates of spheroids. The site of greatest concentration in DS brains was in globus pallidus. In controls trace deposits when found were located both in globus pallidus and/or caudate/putamen.

Planimetric measures of cell body and nucleus cross-sectional area, and measures of cell packing density revealed no differences among effected and non-effected DS brains or age-matched controls. Neurons were clearly absent only in the area of heaviest deposit (bilaterally) in the most severely involved brain, and only in portions of the neuropil which had an abnormal, gelatinous appearance.

517.13

DIFFERENTIAL EFFECTS OF AGING ON NEUROTRANSMITTER CELL LOSS OF THE SUBSTANTIA NIGRA AND STRIATUM IN MOUSE AND HUMAN BRAIN.
T.H. McNeill, L. Koek* and S.N. Haber. Depts. of Neurology and Neurobiology and Anatomy, Univ. Rochester, Rochester, NY 14642.

This study examined age-related cell loss of neurotransmitter neurons in the substantia nigra (SN) and striatum (ST) of mouse and human brain. Immunocytochemically stained neurons were counted in the SN and ST of C57 Bl/6 mice (3, 6, 10, 20, 25 and 30 mos.) and in the SN of human tissue (43-89 yrs.) obtained at an autopsy. Tissues were fixed in 4% paraformaldehyde and coronal sections through the rostral-caudal extent of the SN and ST were immunocytochemically stained for tyrosine hydroxylase, choline acetyltransferase, somatostatin and NPY. We found a significant loss of cholinergic neurons in the ST of aged mice (30 mos.) with no significant change in the number of somatostatin/NPY cells. In addition, while there was a small decrease (13%) in the number of dopaminergic neurons of the SN in aged mice (30 mo.) this decrease did not reach statistical significance. Similarly, in the human SN there was no significant change in the total number of dopaminergic neurons between 43 and 89 years of age. These data suggest that while there is a differential age-related cell loss in the ST of old mice, decreases in dopamine content of the ST previously described after adulthood in both rodents and man is not related to loss of dopaminergic neurons from the SN. Supported by PHS grants AG00300 and AG05445.

AGED RATS SHOW INCREASED BASAL LEVELS OF ADENOSINE 3',5'-MONOPHOSPHATE (cAMP) PRODUCTION WITHIN THE OLFACTORY BULB (O.B.).
**T. Mencio-Wszalek, D.E. Dluzen and V.D. Ramirez. **Institute of Animal Behavior, Rutgers, The State University of New Jersey, Newark, N.J.,07102. Department of Physiology, University of Illinois, Urbana, IL.,61801.

In the present experiment, O.B. were dissected out of young (less than 100 days of age) and aged (greater than 500 days of age) rats. Homogenized O.B. tissue extracts were analyzed by radioimmunoassay to determine the basal levels of cAMP production. The cAMP assay used an antibody that was developed and validated in our laboratory and had a sensitivity of 0.05 picomoles/tube at 92% binding. All values were corrected for the small amount of endogenous cAMP present in control samples by incubation without ATP. The basal levels of cAMP production were as follows: AGED RATS (n=5), Mean ± SEM = 37±2 picomoles cAMP produced/mg protein/minute; YOUNG RATS (n=4), Mean ± SEM = 21±4 picomoles cAMP produced/mg protein/minute. These values represent a statistically significant ($p<0.008$) increase, and indicate that in contrast to the majority of normal aging systems which exhibit deficits with age, the basal levels of cAMP production are actually increased in aged compared to young rats.

517.15

A BIOCHEMICAL MARKER OF NEURONAL AGING IN NORMAL HUMAN BRAINS. V.M. Ingram and B.J. Blanchard*. Dept. of Biology, Massachusetts Institute of Technology, Cambridge, MA 02139.

An age-related additional phosphorylation of the 200kD neurofilament protein has been observed in normal human fixed brain tissue from individuals older than 60 years. We have studied in particular the axons of cerebellar basket cells. Only about half of the basket cell axons show this phenomenon. The probe is the Sternberger-Meyer Co.'s monoclonal antibody SMI-34, which also reacts with the neurofibrillary tangles of Alzheimer's disease, probably a phosphorylated tau protein, Our aged axons do not stain for tau. All human basket cell axons at all ages examined contain another phosphorylated NF200 epitope detectable by mAb SMI-31. Only the SMI-34 epitope appears in an age-related pattern and by a mechanism to be determined.

In sections of brainstemfrom Alzheimer'sdisease and from older Down's syndrome individuals certain axons in the medial longitudinal fasciculus and the mesencephalic trigeminal tract react strongly with SMI-34, as well as with SMI-31. In chicken and rat cerebella the SMI-31 and SMI-34 epitopes appear after hatching/birth and, in contrast with the human, appear at the same time. We are determining the structure and location on NF200 of the two epitopes and are purifying the kinases involved.

DEGENERATION IN CHOLINERGIC NUCLEI OF THE FOREBRAIN CORRELATE WITH COGNITIVE IMPAIRMENTS IN AGED RATS. W.Fischer*, F.H. Gage and A. Björklund (SPON: ENA). Dept. of Med. Cell. Res. Univ. of Lund, Sweden

Mice and rats display age-dependent declines in parameters of cholinergic function in various neocortical, hippocampal and striatal regions. Morphologically, neuronal atrophy and cell loss in the cholinergic neurons of the basal forebrain and in the striatum of aged rats and mice have previously been reported. In this study, degenerative changes in the forebrain cholinergic nuclei (medial septum, diagonal band of Broca, nucleus basalis and striatum) were analyzed morphometrically in behaviourally characterized aged rats. In all four regions the acetylcholinesterase-positive neurons were reduced in both size and number in the aged (24 months old) rats as compared to the young (3 months old) controls. The overall reduction in cell size amounted to between 20 and 30%, and the overall reduction in cell number to between 27 and 45%. Impairment in learning and memory performance in the aged rats, as assessed in the Morris'water-maze task, was significantly correlated with cholinergic cell size and cell number in the medial septum, the diagonal band of Broca and in the striatum. In nucleus basalis there was a trend in the same direction but did not reach significance. In contrast to these degenerative changes in the cell body regions, no significant differences in cortical or hippocampal choline acetyltransferase activity were detected biochemically between the young and aged rats, and the enzyme levels did not correlate with the degree of behavioural impairments in the aged rats.

The present results provide evidence that all major components of the forebrain cholinergic system undergo degenerative changes with age, and that these atrophic changes are correlated with the decline in spatial learning and memory in the aged rat.

517.17

MAO IN AGED FISHER 344 RATS. V. Luine and M. Hearns.* Hunter College, New York, N.Y. 10021.

Activity of Type A monoamine oxidase (MAO) was measured in brain areas of young and old (3.5 and 25 months) Fisher 344 female rats. Most areas examined are involved in regulation of the hypothalamic-pituitary-gonadal axis. Young rats were sacrificed in the diestrus, proestrus or estrus phase of the estrous cycle while all aged rats were in the recurrent pseudopregnant state. Sampling was by the punch out technique, and maximal in vitro MAO activity, using serotonin as substrate, was measured in the frontal cortex (FCtx), striatum (St), suprachiasmatic nucleus (SCN), bed nucleus of the stria terminalis (Nist), medial preoptic nucleus (mPOA), periventricular area of the POA (PVPOA), arcuate-median eminence area (Ar-ME) and the anterior, dorsomedial and ventromedial nuclei of the hypothalamus (AH, DMN and VMN). Comparisions between all aged and young showed changes in only 1 of the 10 areas: SCN activity was decreased by 30% in the aged females. Age related changes were evident in some areas related to neuroendocrine function when estrous state was considered: these included the mPOA, DMN, VMN and Ar-ME. Neither age nor age vs. estrous cycle variations were found in the Nist, AH or PVPOA. In the FCtx and St, areas outside of neuroendocrine regulatory centers, no differences in MAO were found. These results suggest that changes in MAO activity during aging are most evident in brain areas related to endocrine function. (Protocols in accordance with Federal and Society guidelines).

GRAFTS OF FETAL BASAL FOREBRAIN: SURVIVAL AND GROWTH IN THE ADULT AND AGED HIPPOCAMPUS. K.S Chen,* and F.H. Gage. (SPON: W.C. Wiederholt) Dept. of Neurosciences (M-024), UCSD, La Jolla, CA 92093.

Fetal basal forebrain neurons grafted to the adult hippocampus will exhibit markedly better survival and fiber outgrowth into the host hippocampus following a fimbria-fornix lesion (Gage and Bjorklund,1986). We find that fetal basal forebrain grafts to the hippocampus of aged rats also exhibit better survival following a fimbria-fornix lesion. In addition there is greater graft survival and outgrowth in the intact and denervated adult hippocampi than in the intact and denervated aged hippocampi respectively.

Adult and aged (20 month) Fisher 344 rats with unilateral aspirative lesions of the fimbria-fornix received 3ul cell-suspension grafts taken from the septal region of fetal rats (E14-E16). The cell suspensions were implanted bilaterally into the hippocampus. Following a two month survival period the average graft volume in the hippocampus, denervated at the time of grafting in the adult and aged brains, was significantly larger than the graft volume in the contralateral hippocampus. A lesion of the contralateral fimbria-fornix was made one week prior to sacrifice in order to assess the fiber outgrowth from the graft into the contralateral hippocampus without the presence of intrinsic cholinergic fibers. Immunohistochemical staining for choline acetyltransferase positive cells revealed the presence of graft-derived cholinergic cells in the denervated and non-denervated hippocampi of both adult and aged rats. Staining for acetylcholinesterase revealed substantial graft survival and fiber outgrowth from the graft into the lesioned as well as intact hippocampus of adult and aged brains. There was a significantly larger graft volume and fiber outgrowth in the adult brain. Therefore, there appears to be a loss of plasticity in the aged brain, perhaps as a result of decreased levels of trophic factors.

GLUTAMATE NEUROTOXICITY DURING DEVELOPMENT & AGING. C. Peterson, J. Neal*,[1] and C. Cotman Dept. Psychobiol., Univ. of CA at Irvine and [1]Dept. of Neurol. Surg., USC Sch. Med., Los Angeles.

Glutamate excitotoxicity has been implicated as an important factor in hypoxic-ischemic neuronal death. The resistance of young animals to hypoxia has been well described, but whether this is related to reduced glutamate receptor activation in the immature CNS is unknown. To clarify this issue, the binding of radiolabelled glutamate to the NMDA (N-methyl-D-aspartate) receptor was determined in the brains of the developing, mature and aged rodent.

Glutamate binding to the NMDA receptor increases from postnatal day 0 (14.7%), 7 (55.2%), 14 (79.0%) and 21 (93.7%) until it reaches adult levels at 90 days (100%) and then declines by 10 (-41%) and 30 months (-56%) of age. With advancing age the affinity of glutamate binding to the NMDA receptor increases despite a reduction in the number of binding sites. To determine whether development of glutamate binding correlates to NMDA neurotoxicity, an *in vitro* neuronal preparation was used.

Hippocampal neuronal cultures were prepared from rodent embryos (18-20 days). At certain days after plating, cultures were acutely treated with various concentrations of NMDA (500, 50, 0.5, 0.05 and 0.05 uM) for 5 min and alterations in cellular morphology and cell viability were noted 24 hrs later. Cultures which had been plated 5 to 9 days earlier displayed no alterations in morphology or cell survival. However, cells plated 12 days earlier showed marked dendritic degeneration and neuronal swelling while those plated 14 days earlier had widespread neuronal loss. Increasing NMDA concentrations leads to a decline in cell survival. This finding suggests that neurotoxicity due to NMDA receptor activation may be developmentally regulated.

Thus, the degeneration of hippocampal neurons in culture after acute NMDA treatment is age-dependent. This *in vitro* vulnerability correlates with the *in vivo* development of glutamate binding to NMDA receptors. The mechanisms of excitotoxicity in neuronal cultures may help develop potential strategies to prevent or reverse glutamate-induced neuronal degeneration.

DEVELOPMENTAL REGULATION AND CHARACTERIZATION OF HIGH AFFINITY LAMININ RECEPTORS IN CHICK AND RAT CNS. S. Gee*, Philippe Douville* and S.Carbonetto (SPON: C.M. Pover). Neurosciences Unit, Montreal General Hosp. Res. Inst. and McGill University, Montreal, Canada.

Laminin (LN), an extracellular matrix (ECM) glycoprotein, promotes neural cell attachment, migration and neurite outgrowth. We have previously demonstrated 67 and 120 kDa high affinity LN receptors in neurons (Douville et al., 1987, Soc. Neurosci. Abs., 13: 1982).

In these experiments, detergent extracted membrane proteins were electrophoresed, electroblotted and probed with ^{125}I-LN. The most prominent band in autoradiographs is a 120 kDa protein that is detected in a variety of chick tissues, cultured neurons and astrocytes, and in several neural and nonneural cell lines. LN binding to this protein, which can be surface radioiodinated in optic lobe neuronal cultures, requires divalent cations and is inhibited by high concentrations of salt. This protein is apparently distinct from the chick integrin laminin receptor (Smalheiser and Schwartz, 1987, P.N.A.S., 84:6457-6461).

Preliminary experiments have shown that the apparent molecular weight of the 120 kDa receptor in chick retina decreases during development. Early in development the receptor migrates as a heterodisperse band(s), which later becomes more well defined. The regulation of these receptors may be important for the interaction of neural cells with LN during development.

A NEW CATALYTIC SITE ON Na^+,K^+-ATPase IN THE BRAIN OF GUINEA PIG FETUS: AFFINITY TO STROPHANTHIDIN. O.P. Mishra and M. Delivoria-Papadopoulos, Univ. of Pa. Sch. of Med., Dept. of Physiol., Phila., PA 19104

In order to understand the bioenergetic efficacy of the fetal brain Na^+,K^+-ATPase function, the present study examines and compares the affinity of cerebral Na^+,K^+-ATPase of fetal and adult guinea pig to its specific inhibitor, strophanthidin. The activity of Na^+,K^+-ATPase was determined in fetal and adult brain membrane preparations by measuring the rate of ATP hydrolysis in the presence of concentrations of ouabain and strophanthidin ranging from 10^{-10} M to 10^{-2} M. The ouabain or strophanthidin sensitive activity was referred to as Na^+,K^+-ATPase activity. There are three catalytic sites on the fetal brain enzyme compared to only two in the adult. $K_{0.5}$ values for strophanthidin inhibition in fetal brain were: 9.5×10^{-10} M, 6.5×10^{-7} M, and 5.5×10^{-5} M; in adult brain, the values were 6.5×10^{-7} M and 5.5×10^{-5} M. The first $K_{0.5}$ value in fetal brain is 1/1,000th to 1/100,000th of the adult values. It is proposed that a highly sensitive additional site of strophanthidin-binding, an additional phosphorylation site, and an additional site of ATP-binding are required for the early functional maturation of brain during the period of rapid brain growth in this precocial species, the guinea pig, and modified later in life. These additional mechanisms of Na^+,K^+-ATPase will be of added advantage to the fetal brain under conditions such as hypoxia/ischemia which lead to lower cellular concentrations of ATP. (NIH #R01 HD-20337 and HL-37421).

SPATIOTEMPORAL VARIATIONS IN STABLE AND ALKALI-LABILE GANGLIOSIDES FROM RETINA AND BRAIN OF CHICK EMBRYO. L.N. Irwin and C. Hanlon*. Dept. Biology, Simmons Col., Boston, MA 02115.

Interest in the possibility that gangliosides might play a role in the differentiation or synaptic specificity of the nervous system has prompted us to analyze the content and distribution of both stable and alkali-labile gangliosides in the developing retina and brain of the chick embryo. Retinas were removed from 12-day embryos and dissected into quadrants. Gangliosides were extracted, purified, and developed on HP-TLC plates in two dimensions (Irwin et al. 1985. J. Neurosci. Res. 13:591), then quantified by scanning with a Zeineh SLR-2D/1D Soft Laser Densitometer. Over 20 distinct gangliosides were present in all four quadrants, but quantitative differences among quadrants were evident. In particular, a ganglioside migrating in the position of GT3 was relatively more concentrated in the dorsal than in the ventral quadrant. Alkali-labile gangliosides were detected by exposing the plates to ammonia vapor between the first and second dimensions (Somnino et al. 1983. Analyt. Biochem. 128:104). At least seven spots apparently corresponding to alkali-labile gangliosides were revealed. Our results suggest that the nature and composition of the ganglioside population varies both temporally and topologically during critical stages of neurogenesis. (We thank Biomed Instruments, Inc., Fullerton, CA, for the loan of computer equipment and image-processing software for the quantitative analysis of two-dimensional ganglioside chromatograms).

ALTERATION OF 3-HYDROXYBUTYRATE INCORPORATION INTO LIPIDS OF THE DEVELOPING RAT BRAIN BY GLYCEROL. M.C. McKenna,* J.T. Tildon* and L.I. Bezold* (Spon: G. Bergey). Dept. of Pediatrics, Univ. Md. Sch. Med., Baltimore, MD 21201.

Several reports have demonstrated that the ketone bodies, acetoacetate and 3-hydroxybutyrate (3-HOB) play an important role in the metabolic homeostasis of the developing central nervous system. Earlier reports from our laboratory showed that increases in plasma glycerol can have profound anti-ketonemic effects (Roeder, L.M. et al., J. Nutr. 112:1273, 1982). In this study we measured the effect of intraperitoneal injection of glycerol on the rate of 3-hydroxy-3^{14}C butyrate incorporation into brain lipids in 11 and 18 day old rat brains in vivo. The percent radioactivity incorporated into individual lipids was also determined. Plasma levels of 3-HOB decreased from 2.24 to 0.56 and 1.38 to 0.41 mM in 11 and 18 day old animals, respectively. The rate of incorporation of 3-HOB into lipids was decreased about 5 fold at both ages. In 11 day old rats glycerol treatment significantly increased the amount of radioactivity incorporated into neutral lipids, sulfatides and phosphatidyl inositol and decreased the amount incorporated into phosphatidyl choline and phosphatidyl ethanolamine. In 18 day old rats only the incorporation into phosphatidyl inositol was altered. These results suggest that decreases in circulating levels of 3-HOB lead to significant alterations in the synthesis of brain lipids from 3-HOB and younger rats may be particularly vulnerable to these effects. (NICHD-16596)

DEVELOPMENTAL CHANGES IN HEART PEPTIDYLGLYCINE α-AMIDATING MONOOXYGENASE (PAM) ACTIVITY AND mRNA LEVELS. L'H.Ouafik*, V.May and B.A.Eipper. Neuroscience Dept., Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Peptidylglycine α-amidating monooxygenase (PAM; EC 1.14.17.3) catalyzes the α-amidation of bioactive peptides. The PAM precursor predicted from the sequence of a cDNA cloned from bovine neurointermediate pituitary is a 108 kDal protein containing a hydrophobic putative transmembrane domain near its C-terminus. High levels of membrane-associated PAM activity and PAM mRNA have been identified in adult rat heart atrium (Eipper et al. J. Biol. Chem. in press 1988). We have quantitated soluble and membrane-associated PAM activity and examined the levels and forms of PAM mRNA in the rat heart during development. In atrium, the highest levels of PAM mRNA were found at embryonic days 18-20 (E18-E20); the levels declined dramatically at birth and gradually increased to the high levels found in adult atrium by postnatal day 14 (P14). In ventricle, the highest levels of PAM mRNA were found at E14-E16; the levels diminished at birth, transiently increased until P7 and then declined to the low levels seen in adult ventricle by P14-P21. Both 3.6 and 3.8kb forms of PAM mRNA were observed in atrium and ventricle, although their ratio varied significantly during the days studied. For atrium and ventricle, a soluble form of PAM activity predominated at E14-E16. Membrane-associated PAM activity was the dominant form from E18 to adult.

EFFECT OF NERVE GROWTH FACTOR ON THE BIOSYNTHESIS ACTIVITY OF PTERINS IN PC12h PHEOCHROMOCYTOMA. N.Nakanishi, H. Suzuki*¶, K.Akiba-Aono*¶, K.Hirayama*, K.Ozawa*, and S. Yamada*. Depts. of Biochem., and ¶Pedodont., Meikai Univ. Sch. Dent., Sakado, Saitama 350-02, Japan.

PC12h pheochromocytoma is a subclonal line of PC12, and tyrosine hydroxylase of PC12h was known to be induced by nerve growth factor (NGF) treatment of the cells. We examined the NGF effect on tetrahydrobiopterin (BPH4), which is a specific cofactor (electron donor) for aromatic amino acid hydroxylases, and found that BPH4 level was transiently increased by NGF with the maximal level of about 150 ng/mg protein (2-fold over the control) at 24 h after the treatment was initiated. Then we examine the NGF effect on the activity of the cells for synthesizing pterins. Extracts from the cells were incubated with GTP, a substrate of GTP-cyclohydrolase which catalyzes the first step of BPH4 biosynthetic pathway, and the products were analyzed by high-performance liquid chromatography. NGF increased the activity of GTP-dependent synthesis of pterins: extracts from the NGF-treated cells (50 ng/ml, 24 h) showed about 2-fold greater activity than that from the control cells did. The results suggest that the NGF-induced increase in BPH4 is due to the increased activity of pterin biosynthesis.

THE DISTRIBUTION OF GAP-43 IN THE MONKEY BRAIN. K. Andruschak, L.I. Benowitz, K.L. Moya and S.N. Haber. Dept. of Neurobiology and Anatomy, Univ. of Rochester Sch. of Med., Rochester, NY and Dept. of Psychiatry, Harvard Med. Sch., Boston, MA.

GAP-43 in a neuron-specific phosphoprotein associated with the development, regeneration, and modulation of synaptic relationships. Using immunohistochemical techniques, the distribution of this protein was studied in the brains of adult rhesus monkeys.

Within the sub-cortical telenecephalon, GAP-43-like immuno-reactivity was present in the ventromedial striatum, the olfactory tubercle, the substantia innominota, the bed nucleus of the stria terminals, and portions of the amygdala. Particularly dense diencephalic staining was observed in midline structures such as the periventricular n. the dorsomedial n. of the thalamus, the paratenial n., and in midline hypothalamic nuclei. Midbrain and brainstem nuclei which showed dense staining included portions of the superior colliculus, the substantia nigra-pars reticulata, interpeduncular n. dorsal raphe, parabrachial n., n. of the solitary tract, and dorsal motor n. of the vagus. In addition portions of the neocortex and hippocampal formation showed dense staining.

The distribution of GAP-43 in the adult monkey brain to some extent parallels that reported in the adult rat (Benowitz, et al., J. Neurosci. 8, '88). Concentrations of the protein are high in areas regarded as having limbic or associative functions. However, unlike the rat several regions associated with motor and somatosensory functions also showed relatively dense GAP-43-like immunoreactivity. The more extensive pattern of GAP-43 staining in the primate compared to that observed in the rat may reflect an increase of integration or plasticity of these nuclei.

MK-801 BINDING SITES ARE PRESENT EARLY IN DEVELOPING RAT BRAIN. A.M. Morin, H. Hattori* and C.G. Wasterlain*. Neurology Res. Lab. and Epilepsy Res. Lab., VAMC, Sepulveda, CA 91343, Dept. of Neurology, UCLA Sch. of Medicine.

MK-801, an N-methyl-D-aspartate (NMDA) antagonist, protects against hypoxic-ischemic brain damage in neonates (Hattori, et al. abst. these meetings). ^{3}H-MK-801 (3nM) binding sites are present as early as 7 days of age in cortex (91.9±21.6 fmol/mg prot.n=5) and in hippocampus (154.0±8.5 fmol/mg prot.n=5). Assay of adult brain areas gave the following: cx, 254.5±15.7 fmol/mg prot.(n=5) and hp, 404.4±88.5(n=5). Comparison of brainstem of 7 day old neonate (63.3±3.0 fmol/mg prot.n=5) and adult (26.8±6.9 fmol/mg prot. n=5) indicated a significant decrease in binding ($p<0.05$) in adult. Glutamate or glycine (10uM) stimulated binding in washed (8x) hp membranes ($p<0.05$; glu, 132.7±16.5% of baseline binding and gly, 135± 15%). Binding in cx increased but did not reach significance (glut, 118.6±19.9%, gly, 123.2±10.5%) at this age but did so at 10 days of age. Phencyclidine (1uM) reduced ^{3}H-MK-801 binding in cx (9.9±10.5%) and hp (15.6±2%) while Mg ions (100uM) completely blocked binding. The data support the presence of NMDA coupled MK-801 binding sites early in brain development.

MOLECULAR FORMS OF TRANSIENT ACETYLCHOLINESTERASE IN THE DEVELOPING RAT BRAIN. C. Gorenstein, K.A. Gallardo* and R.T. Robertson. Depts. of Pharmacology and Anatomy and Neurobiology, University of California, Irvine. Irvine, CA 92717.

During development there is a characteristic transient appearance of acetylcholinesterase in the primary sensory regions of cerebral cortex and dorsal thalamus. It is not known, however, whether unique molecular forms of acetylcholinesterase are transiently expressed in these regions. Using sucrose gradient ultracentrifugation we have determined the molecular forms of acetylcholinesterase at various stages of brain development, in regions that express transient and continued enzyme activity.

Brain regions were homogenized in the presence and absence of 1% triton X-100 and the extracts analyzed on 5-20% sucrose gradients. In the mature brain, two major molecular forms of acetylcholinesterase were resolved from the soluble and detergent extracted tissue. The 10 S and 4 S forms predominated in the soluble extracts, while the 10 S form predominated in detergent extracted tissue.

Analysis of the transient acetylcholinesterase indicated that it also consisted of 10 S and 4 S forms, suggesting that the appearance of transient acetylcholinesterase does not represent the expression of novel forms of the enzyme.

DEVELOPMENT OF CHAT ACTIVITY AND CYTO-ARCHITECTURE IN THE FOREBRAIN OF THE SNELL DWARF MOUSE. C.F. Höhmann, G. Forloni, B. O'Hara*, L.E. Wilson*, M.L. Oster-Granite, J.D. Gearhart *and J.T. Coyle. Depts. of Physiology and Neuroscience, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Dwarf (dw/dw) is an autosomal recessive mutation in Snell-Bragg mice that results in a nearly complete loss of acidophils from the anterior pituitary with accompanying hypothyroidism, dwarfism and reproductive failure. Adult dw/dw mice exhibit several CNS abnormalities, including decreased cholineacetyltransferase (ChAT) activity, increased somatostatin (SOM) and disrupted cytoarchitecture in some forebrain areas. In the present study, we examined the generation of these three abnormalities during ontogeny. We monitored ChAT activity, SOM immunoreactivity (SOM-IM) and acetylcholinesterase (AChE) histochemistry as well as Nissl staining in cortex, hippocampus and striatum of dw/dw and unaffected littermates at 7, 14, 30 and 60 days postnatal (PND). The specific activity of ChAT, in cortex or hippocampus, did not differ significantly between dw/dw and littermate controls. In contrast, beginning with PND 14, ChAT activity was significantly reduced in the striatum of dw/dw. AChE showed increased staining in layer IV of somato-sensory cortex in the adult dw/dw animals. The distribution and number of SOM-IM cells were not changed at any age in any forebrain region examined. However, a thinning of the supragranular layers of cortex, accompanied by poorly defined boundaries between layers, became apparent in Nissl stained sections by PND 14. We conclude that the dw/dw mouse does not exhibit the correlative relationship between ontogenetic cholinergic deficits and somatostatin and cytoarchitectonic abnormalities that we have previously observed in mice with neonatal basal forebrain lesions.

518.11

CORTICOSTERONE AND GROWTH HORMONE RESPONSES TO VARIOUS EXPERIMENTAL PROCEDURES IN NEONATAL RAT PUPS. S.M. Specht, C.L. Kirstein, C.M. Kuhn and L.P. Spear. Dept. of Psychology and Centers for Developmental Psychobiology and Behavioral Neuroscience, SUNY, Binghamton NY 13901 and Dept. of Pharmacology, Duke Univ., Durham NC 27710.

Intraoral cannulations require minimal time to administer and are typically assumed to be relatively unstressful in neonatal rat pups. To test the latter assumption, corticosterone (Cort) and growth hormone (GH) levels were measured in 4-day-old rat pups placed in an incubator for 15 or 60 min following: 1) no treatment; 2) subcutaneous (sc) injection of 0.9% NaCl; 3) anterior tongue cannulation; 4) posterior tongue cannulation; 5) ice anesthesia; or 6) ether anesthesia. Cort levels were elevated relative to non-treated controls 15 min after all treatments except sc injection. These levels remained elevated after 60 min in both cannulation groups and the ice anesthesia group. GH levels were significantly reduced at 15 min for all treatment groups except ice anesthesia. No significant differences in GH levels were observed at 60 min. These results indicate that intraoral cannulation as well as ice anesthesia might be moderately stressful procedures in neonatal rat pups. Whether ether anesthesia prior to cannulation will reduce these endocrine responses is currently under investigation.

518.12

5HT1A, 5HT1B and 5HT2 AGONISTS PRODUCE VARYING BEHAVIORAL RESPONSES IN 17-18 DAY OLD RAT PUPS. N.A. Frambes* C.L. Kirstein and L.P. Spear, Department of Psychology and Centers for Neurobehavioral Sciences and Developmental Psychobiology, SUNY-Binghamton, Binghamton NY 13901

There is an ontogenetic reversal in the influence of serotonergic (5HT) manipulations on mouthing and suckling during ontogeny, with these behaviors being facilitated by 5HT activation in neonatal rat pups, and inhibited in pre-weanling and weanling rats. In studies assessing the potential role of differential maturation of 5HT receptor subtypes in this ontogenetic reversal, deprived rat pups were tested both in the absence and presence of milk (low vs. high mouthing baselines, respectively) to assess both drug-induced increases and decreases in mouthing. At 3-4 days of age (P3-4), the 5HT1a agonist 8-OHDPAT inhibited mouthing, with the 5HT2 agonist DOI and the 5HT1b agonist mCPP conversely facilitating this behavior (Kirstein & Spear, in press). In contrast, at P17-18, no significant influence of DOI and mCPP were observed on mouthing, although mCPP did influence other behaviors (e.g., unusual posturing of the limbs). 8OHDPAT, however, still potently depressed mouthing at P17-18 while also resulting in poor control of the hindlimbs. Ontogenetic variations in the balance of activity among different 5HT receptor subtypes may contribute to the reversal seen in the influence of 5HT manipulations on mouthing and suckling during the neonatal to weanling age period.

EFFECTS OF PRENATAL TREATMENT WITH THE SEROTONIN AGONIST, 5-MT, ON APOMORPHINE-INDUCED HYPERACTIVITY. A. Shemer, E., Azmitia, Dept. Biology, and P. Whitaker-Azmitia, NY University.

We have developed an in vivo model for manipulating serotonin (5-HT) activity during development (Shemer et al., 1988). Pregnant rats are exposed to the 5-HT agonist 5-methoxytryptamine (5-MT) which causes the offspring to show reduced 5-HT outgrowth and deficits in behavior. The B_{max} of 5-HT receptors is also reduced as a result of the prenatal treatment. In order to test other possible changes in receptor characteristics, we challenged the drug treated neonates pharmacologically. The drugs used were acute 5-MT (1 mg/kg) to assess serotonergic sensitivity and apomorphine (1 mg/kg) to assess any changes in the dopamine system. Drug treated neonates were tested in a photoactometer at 30 days of age when there were no observable differences in activity between treated and control animals. The control animals were significantly affected by both drugs, 5-MT inhibited activity levels, and apomorphine increased activity levels. The drug neonates were unaffected by either drug. These results indicate that receptors in both the serotonergic and the dopaminergic systems were significantly less sensitive as a result of prenatal exposure to 5-MT.

Shemer, A., Whitaker-Azmitia, P.M. and Azmitia, E.C. (1988) Effects of prenatal 5-methoxytryptamine on serotonergic uptake and behavior in the neonatal rat. Pharmacol. Biochem. Behav., in press.

THE DEVELOPMENT OF STIMULATION-BOUND BEHAVIORAL ACTIVATION AND THE CORRELATED ANATOMICAL AND CHEMICAL CHANGES IN THE NUCLEUS ACCUMBENS. N.L. Goodless* and G.A. Barr (SPON: J. Gordon). Biopsychology Doctoral Program, Dept. Psychology, Hunter College, CUNY, N.Y., NY. 10021, USA and Dept. Psychiatry, Albert Einstein College of Medicine, Bronx, NY. 10461, USA.

In an attempt to identify the temporal and topographic patterns of behavioral activation, brief trains of electrical stimulation were administered to 3-, 5-, 7-, 10-, and 14-day old rat pups through stainless-steel bipolar electrodes directed at the nucleus accumbens (NAc). The resultant behavior was observed, first during a 2 min baseline period followed by three one-minute stimulation periods which alternated with one-minute non-stimulation periods. The occurrence of all behaviors was recorded every 10 sec. Pups 10 days of age and younger became behaviorally activated by stimulation and reliably emitted a series of behavioral responses including mouthing, licking, pawing, probing and locomotion. As the animal matured, electrical stimulation of the NAc elicited fewer activating behaviors. By the end of 2, weeks activation was no longer recognizable and subsequently disappeared. Grooming was the predominant behavior at this and did not appear to be concordant with stimulation. To relate the developmental changes of stimulation-induced behavioral activation with differential maturational patterns of the neuroanatomical and neurochemical systems within the NAc, the normal postnatal development of serotonin-, methionine enkephalin (Met Enk)-, and gamma-aminobutryic acid-like immunoreactivity was assessed. To relate the development of these neurotransmitters to morphological and metabolic characteristics of the NAc, we examined the ontogenetic patterns of Nissl stained cells, Bodian silver stained fibers and Cytochrome C oxidase activity. The findings revealed the differential ontogeny of various neurotransmitter systems in the NAc in the developing rat. Met Enk-like immunoreactivity was present at birth, while the other systems developed later, suggesting their possible participation in the loss of stimulation-induced behavioral activation.

RATIONALE FOR USING MATERNAL PLASMA GLUCOSE AND SCINTILATION COUNTS FOR DETERMINATION OF FETAL GLUCOSE UTILIZATION. D.R. Kostreva and J. Wood*. Dept. of Anesthesiology, Med. Col. Wis. and VA Med. Ctr. Milwaukee, WI 53295.

The operational equation of the Sokoloff [14C] deoxyglucose method (J. Neurochem. 28:897-916, 1977) is comprised of four components one of which, an integral, is derived from each animals plasma glucose and [14C] scintilation counts. Four pregnant rabbits were anesthetized, intubated, ventilated and their uterus was exposed. A connecting branch of the uterine vein was cannulated for sampling of venous blood from a single fetal-placental unit. The maternal femoral artery and vein were also cannulated for sampling. A bolus of [14C] deoxyglucose, 100 uCi/kg, was injected i.v. into the maternal circulation and the timed blood sampling procedure was initiated. The integrals were calculated for both the maternal arterial, and the fetal-placental plasma samples. The percent error in measuring glucose utilization using the maternal versus fetal plasma values was between 2 and 6% in three animals and 16% in the fourth. These differences were not statistically significant. Quantification of local fetal glucose utilization can therefore be made using the maternal plasma values.

518.16

FUNCTIONAL EFFECTS OF PRENATAL COCAINE EXPOSURE. T.A. Fico, L.A. Freed* and D.L. Dow-Edwards. Department of Developmental Psychobiology, NY State Psychiatric Instit., New York, NY 10032 and Laboratory of Cerebral Metabolism, State University of New York-Health Science Center at Brooklyn, Brooklyn, NY 11202.

Adverse neurobehavioral effects have been reported in infants prenatally exposed to cocaine. We have found that there are lasting changes in metabolic activity in several brain regions of the rat following exposure to cocaine during critical postnatal developmental periods (Dow-Edwards, et al , in press). We have now identified 2-deoxy-glucose changes in rat brain following prenatal cocaine exposure and correlated these changes with patterns of 3H-sulpiride binding.

Wistar rats were mated and housed under standard laboratory conditions. Dams received either 0 or 60 mg/kg po, from gestation day 8 through 22. Pair-feeding and surrogate fostering were used.

At 58-64 days of age, local rates of glucose utilization were determined in the male offspring using the deoxy-glucose method of Sokoloff et al. (1977). 3H-sulpiride binding was quantified and correlated with regions showing altered glucose metabolic activity. (Supported by NIDA grant #DA04118).

NIGRAL INFUSIONS OF MUSCIMOL IN RAT PUPS PRODUCE LOCAL CEREBRAL GLUCOSE UTILIZATION EFFECTS DIFFERENT FROM ADULT RATS. E.F. Sperber, L.L. Brown, J.N.D. Wurpel, S.L. Moshe, Albert Einstein College of Medicine, Bronx, NY 10461

Intranigral infusions of muscimol, a GABA agonist, are anticonvulsant in adult rats and proconvulsant in pups. This study localized the metabolic effect of nigral muscimol infusions in adult and 16 day old rat pup brains by using 14C deoxyglucose (DG) autoradiography. Unilateral cannulae were implanted in the substantia nigra (SN) of adult and rat pups. Adult rats had femoral catheters inserted for quantitative determination of local cerebral glucose utilization (LCGU) while pups were analyzed using a ratio to white matter. All rats were infused intranigrally with 100ng/0.25ul of muscimol (5 adults, 6 pups) or saline (5 adults, 4 pups) and injected with DG. Analysis of the adult autoradiograms showed changes in LCGU in globus pallidus, lateral habenula and deep layers of the superior colliculus (DLSC). In pups, changes in LCGU occurred in parietal cortex, dorsal striatum, globus pallidus, DLSC, posterior thalamic nucleus, forelimb sensory cortex and pontine reticular formation. The results suggest that the influence of nigral efferent pathways differ with age. The more widespread effects in pups may reflect the immaturity of inhibitory systems in the SN and its projection areas.

REGIONAL VARIATIONS IN TRITIUM QUENCHING IN RAT BRAIN DURING DEVELOPMENT. H.K. Happe and L.C. Murrin, Dept. of Pharmacology, Univ. Nebraska Med. Ctr., Omaha, NE 68105

Quantitative autoradiographic studies require correction for variations in quenching of tritium emissions by different brain regions. We investigated changes in regional tritium quenching during the first three weeks of neonatal life. Conditions were established for labelling the brain with [^{3}H]2-deoxyglucose (2DG) in neonatal rats using i.p. injections. Quench correction was determined by measuring 2DG labelled brain tissue before and after chloroform extraction (Brain Res. 336: 334, 1985). Image analysis used DUMAS from Drexel Univ.

Percent Tritium Quench by Region

	5 day	21 day	Adult
PC	28.1	35.4	40.0
BLA	26.5	31.3	36.1
CPu	27.3	40.3	33.7
IC	31.2	96.9	139.2
LH	33.9	42.1	72.8
CC	45.8	60.0	105.9

(PC = parietal cortex; BLA = basolateral amygdaloid n.; CPu = caudate-putamen; IC = internal capsule; LH = lateral hypothalamic area; CC = corpus callosum).

These studies demonstrate there is greater tritium quenching in white matter than in grey matter and that the level of quenching changes in particular brain regions during development, as would be expected with the development of myelination. Supported by NS23975.

THE SUPRACHIASMATIC NUCLEI (SCN) ARE ESSENTIAL FOR DAILY TORPOR AND CIRCADIAN BODY TEMPERATURE RHYTHMS IN SIBERIAN HAMSTERS. N.F. Ruby*, N. Ibuka*, B.M. Barnes*, J. Dark, and I. Zucker. Dept. of Psychology. Univ. of California, Berkeley, CA 94720.

Daily torpor was studied in hamsters, Phodopus sungorus, maintained in a short day photoperiod (8 hr Light/day) from weaning. Thirty animals implanted abdominally with radiofrequency transmitters were transferred to a cold chamber (15°C) at 60 days of age. Body temperature (T_b) and locomotor activity data were collected at 10 minute intervals using a telemetry system and stored by computer for subsequent statistical analysis. Animals manifesting two torpor bouts (T_b<30°C) in one week for two consecutive weeks received lesions of the SCN, pinealectomies, or sham operations. In the 15 weeks following surgery none of the animals with bilateral SCN lesions showed torpor, circadian body temperature, or activity rhythms as determined by Fourier analysis. All pinealectomized hamsters continued to show torpor for at least 6 weeks postsurgically, as did the sham-operated groups.

Daily torpor, once initiated, persists in the absence of the pineal gland and melatonin. Expression of torpor and manifestation of circadian body temperature and activity rhythms require intact suprachiasmatic nuclei.

PHOTIC AND NEURAL REGULATION OF PUBERTY ONSET IN MALE FERRETS. L.M. Sheppard and C.L. Sisk. Neuroscience Program and Dept. of Psychology, Michigan State University, East Lansing, MI 48824.

Transfer of male ferrets from short days (LD 8:16) to long days (LD 18:6) at 12 wk of age induces testis growth 4-6 wk earlier than in ferrets remaining in LD 8:16. Anterior hypothalamic lesions also induce precocious gonadal maturation in male ferrets. We compared within a single experiment the effects of photoperiod and hypothalamic lesions on puberty onset. Electrolytic lesions were aimed at the anterior hypothalamus of 13-wk-old ferrets housed in LD 8:16 to determine if their rate of maturity would be similar to that of other ferrets transferred from short to long days at 13 wk of age. Such a result would suggest that hypothalamic lesions mimic a photoperiodic response. Mean age at onset of testis growth was about 14 wk in ferrets transferred from short to long days, about 16 wk in ferrets in LD 8:16 with hypothalamic lesions, and about 18 wk in control animals in LD 8:16. There was considerable individual variation in onset and rate of testis growth among ferrets with lesions. Conclusions await histological evaluation of lesion placement. It will be important to determine if age at onset of testis growth correlates with lesion placement, particularly since the anterior hypothalamus contains structures associated with reproductive responses to photoperiod (e.g., suprachiasmatic nucleus).

DAYLENGTH DETERMINES THE INVOLVEMENT OF OPIOIDS IN STEROID-DEPENDENT CONTROL OF LH IN SYRIAN HAMSTERS. T.S.Juss*, M.H.Hastings* and J.Herbert*. (SPON: J.Hutchison). Dept. of Anatomy, University of Cambridge CB2 3DY U.K.

The role of endogenous opioids in the steroid-dependent control of LH was investigated by comparing the effects of castration, morphine and naloxone on LH secretion in photostimulated (PS, 16L: 8D), photoinhibited (PI, SD 8L: 16D) and photorefractory (PR, SD 8L: 16D) hamsters. Blood LH content was determined 4 days after castration or 30 min after drug administration.

In PS animals castration or naloxone adminstration increased, and morphine suppressed, serum LH. These manipulations were ineffective in PI animals maintained in SD for 12-18 weeks. Castration and drug responses were re-instated after 22 weeks in SD with the onset of PR (as determined by testicular recrudescence). The castration response therefore varied in parallel with that of opiatergic manipulations.

Exp. 2. PS or PI hamsters (after 8 weeks SD) were castrated and received sub-cutaneous testosterone implants. In PS and PR (22 weeks in SD) animals, LH secretion was responsive to opiatergic manipulations. In PI (12-18 weeks in SD) animals opiatergic manipulations were ineffective. However, the response to steriod withdrawal was present in both the PS and PR and also PI animals. Under inhibitory photoperiods steroidal inhibition of LH may therefore be independent of opioid function.

FAT PAD SPECIFIC CHANGES IN MASS, LIPOPROTEIN LIPASE ACTIVITY AND IN VIVO LIPOGENESIS IN SHORT PHOTOPERIOD-EXPOSED SIBERIAN HAMSTERS. T. J. Bartness, J. M. Hamilton, B. D. Goldman and G. N. Wade. Worcester Fnd. Exptl. Biol., Shrewsbury, MA 01545 and Univ. Mass., Amherst, MA 01003.

Short day-exposed Siberian hamsters initially decrease their body weight, a response reflected exclusively as a decrease in carcass lipid. However, with continued short day exposure body weight and carcass lipid return to long day levels. To examine whether the short day-induced changes in carcass lipid are uniformly distributed in all fat pads, adult male Siberian hamsters were housed in long (LD 16:8) or short (LD 10:14) days for 6, 12, 24 or 30 wk. After 6 or 12 wk short day exposure, body weight and carcass lipid were decreased. Fat pad mass, lipoprotein lipase (LPL) activity and *in vivo* lipogenesis were also decreased; however, the decreases were proportionally greater in the peritoneal fat pads (PFP; epididymal and retroperitoneal) than in the subcutaneous fat pads (SFP, dorsal and inguinal) relative to the long day controls. After 30 wk short day exposure body weight and carcass lipid were increased; however, the increases in mass and LPL activity of the PFP were proportionally greater than in the SFP relative to the long day controls.

EFFECT OF LGN LESIONS ON PHOTOPERIODISM AND BODY WEIGHT IN GOLDEN HAMSTERS. L.Smale, R.Y.Moore, and L.P.Morin. Psychiatry and Neurology Departments, SUNY, Stony Brook, N.Y. 11794-8101

Photoperiodic responsiveness in golden hamsters is mediated by a circadian timekeeping system that includes the suprachiasmatic nuclei (SCN). Input from the lateral geniculate nucleus (LGN) to the SCN influences entrainment, particularly in short daylengths (LD 8:16, Johnson,Moore and Morin, unpublished observations), and may therefore be an important element of the mechanism underlying photoperiodic time measurement. This hypothesis was tested by examining the effect of LGN lesions on photoperiodic responsiveness in male golden hamsters. Hamsters were given infusions of the neurotoxin n-methyl aspartate into the region of the LGN or sham lesioned while kept on a long daylength (LD 14:10). Two weeks later (wk 0), half of the animals from each group were transferred to short days (LD 8:16). Body weights and transscrotal testes length and width were measured every 3 weeks from wk 0 to wk 12, at which point running wheels were provided and locomotor rhythms recorded. Testes size did not change in hamsters kept in LD 14:10 but decreased substantially in groups kept in LD 8:16. However, regression was blocked in 2 and delayed in 2 of the 10 LGN lesioned hamsters in short days. After 12 wks in LD 8:16, LGN lesioned hamsters weighed substantially more than sham operated controls; in LD 14:10 body weights did not differ between theese groups.

PHOTOPERIODIC REGULATION OF STEROID RECEPTORS, SEXUAL BEHAVIOR, AND PITUITARY mRNA IN FEMALE GOLDEN HAMSTERS. E.L. Bittman, K. Hegarty*, M.Q. Layden*, and J.A. Jonassen*. Departments of Zoology and Physiology, University of Massachusetts, Amherst 01003 and University of Massachusetts Medical Center, Worcester 01655.

To examine neuroendocrine events which may underlie influences of daylength on behavior and synthesis of LH and prolactin (PRL), hamsters were ovariectomized and either left in long days (LD, 14L:10D) or transferred to short days (SD, 10L:14D). After 58 days, 5mm Silastic capsules containing 0%, 1%, or 5% estradiol (E2) were implanted at 1400h. Hamsters were injected with 0.5 mg progesterone at 44h and tested for receptivity at 48h. Capsules were removed and reimplanted 2 weeks later. After 44h, hypothalamus+preoptic area was dissected at 1400h for assay of nuclear estrogen (nEr, fmole/ug DNA) and cytosolic progestin receptors (cPr, fmole/mg protein). RNA was extracted from anterior pituitaries, dotted onto nitrocellulose, and probed sequentially with 32P-DNAs for rat LH-beta subunit, rat PRL, and oligo-dT. Results (mean±SEM) are listed below:

Group (%E2)	% in heat	nEr	cPr	relative LH mRNA	relative PRL mRNA
0% LD	-	5.0±1.5	4.6±.5	6.8±.6	12.0±3.1
SD	-	3.3±0.7	4.3±.3	1.0±.7	1.0±0.2
1% LD	57%	27.7±2.7	4.9±.7	2.9±.5	22.2±2.2
SD	22%	30.6±1.6	5.3±.5	1.8±.5	17.8±3.2
5% LD	100%	29.9±0.8	7.4±.8	3.8±.7	27.8±9.6
SD	50%	33.3±1.0	7.1±.6	0.4±.2	16.9±3.7

Short days decrease behavioral responsiveness to E2 without grossly influencing HPOA nEr occupancy or cPr induction, and reduce pituitary LH and PRL mRNA abundance through both E2-dependent and -independent actions. Supported by NIH HD20018 and HD20910.

SHORT DAYLENGTHS ALTER ELECTROPHYSIOLOGICAL RESPONSES OF HAMSTER SUPRACHIASMATIC NUCLEUS (SCN) NEURONS TO MELATONIN. B. Rusak and R. Mason*, Dept. of Psychology, Dalhousie Univ., Halifax, Nova Scotia, Canada B3H 4J1.

Several studies have suggested that the SCN is one target for melatonin effects that regulate seasonal reproductive cycles. We investigated whether melatonin alters firing rates of cells in the SCN of Syrian hamsters. Male hamsters were kept in a short photoperiod (10 h light daily for more than 150 days) to induce gonadal regression and spontaneous recrudescence. The reproductive systems of these hamsters become insensitive to exogenous melatonin. We compared the responses of their SCN neurons to those of animals housed in long days (14 h light), who are sensitive to melatonin. Extracellular recordings were made from hypothalamic slices in vitro to assess the effects of pressure ejection of melatonin (2 mM) on spontaneous firing rates. In long-day hamsters, melatonin evoked dose-dependent responses in approximately half the cells tested; unresponsive cells were encountered most frequently during the projected dark phase. About twice as many cells were suppressed as activated by melatonin. In contrast, nearly all SCN cells recorded in short-day hamsters were unresponsive to melatonin. These data suggest that functional insensitivity to melatonin may reflect in part a loss of neural responses to melatonin in the SCN.

THE PINEAL GLAND REGULATES REENTRAINMENT AND MELATONIN FACILITATES REST IN RATS. K.A.Dawson. Department of Psychology, University of Waterloo, Waterloo, Ontario, Canada, N2L 3G1.

In an effort to elucidate the role of the pineal gland in the regulation of activity rhythms, 7 male Long Evans rats were subjected to pinealectomy by excision and 7 were sham controls. All animals had free access to running wheels in a colony room on LD 12:12 for 1 week and then the photocycle was reversed for 10 days. Daily melatonin injections were begun following return to the LD cycle and the rats were then subjected to a second reversal of the photocycle. Only within 5 days following reversal did pinealectomy significantly increase the proportion of active time in the light phase relative to active time in the dark phase. Melatonin significantly decreased active time in the light phase both before and after reversal. These results support the interpretations that exogenous melatonin facilitates rest during the light phase and the pineal gland regulates adjustment of activity rhythms to abrupt shifts in the environmental photocycle.

CARBACHOL MIMICS THE PHASE-SHIFTING EFFECTS OF LIGHT ON THE CIRCADIAN SYSTEM OF DJUNGARIAN HAMSTERS. B. E. F. Wee and F. W. Turek. Dept. Neurobiology and Physiology, Northwestern Univ., Evanston, IL 60208.

The cholinergic agonist, carbachol, mimicks the phase-shifting effects of light on (1) pineal NAT activity in rats and (2) the circadian rhythm of locomotor activity (CRLA) in mice and golden hamsters. These results suggest that the effects of light on the circadian system may be mediated by cholinergic mechanisms. The purpose of the present study was to determine whether the phase-shifting effects of light on the CRLA in Djungarian hamsters (Phodopus sungorus) can be mimicked by carbachol. The Djungarian hamster is unusual, because, unlike other species in which the phase advance region is limited to the late subjective night (SN), the phase response curve (PRC) to light in Djungarian hamsters has an additional small phase advance region in the late subjective day (SD).

Blind adult male Djungarian hamsters received intracerebroventricular injections (1 ul) of either 10 nmol carbachol or vehicle at one of 12 circadian times, and PRCs were generated. Carbachol induced significant phase delays at CT 12, 14, and 16 ($p < .01$) and small, but significant phase advances at CT 8 and 10 ($p < .05$).

The PRCs to light and to carbachol for the CRLA in the hamster both have phase delay regions in the early SN and small phase advance regions in the late SD. Although the carbachol PRC does not appear to have a phase advance region in the late SN as does light, these results indicate that carbachol mimics some of the effects of light on the circadian system in Djungarian hamsters and support the hypothesis that the phase-shifting effects of light on the circadian clock of mammals are mediated, at least in part, by cholinergic mechanisms.

ESTROGENS MODULATE CIRCADIAN LOCOMOTOR ACTIVITY IN THE SHORT PERIOD (Tau) MUTANT HAMSTER. E. J. Ampleford* and M. Menaker. (SPON.Hossein Hashemzadeh) Dept. of Biology, Univ. of Virginia, Charlottesville, VA 22901.

Heterozygous tau mutant (T_s) golden hamsters display free-running periods of approximately 22h. Females entrained to a Light:Dark cycle display an exaggerated scalloped pattern of locomotor onsets with early onsets on days when estrogen levels are high (diestrus 2, proestrus) and later onsets when estrogen levels are low (estrus, diestrus 1). In T_s females, early onsets occur approximately 6h prior to lights off while late onsets occur up to 4h later. When ovariectomized, T_s females show a gradual reduction in overall activity and a progressive delay in the time of locomotor onset until reaching that normally associated with low estrogen levels. Implantation of silastic capsules containing estradiol increases the overall level of activity and restores the phase of the onset of locomotor activity to that associated with elevated levels of estrogen. In addition, ovariectomized estradiol treated females display large (>1h) changes in free-running period.

CIRCADIAN MODULATION OF A HOMEOSTATIC DRINKING RESPONSE IN RATS. R.F. Johnson and A.K. Johnson. Depts. of Psychology, Pharmacology and The Cardiovascular Center, University of Iowa, Iowa City, IA 52242

We tested whether the amount of water intake to hypertonic saline injections is dependent on the circadian phase of the homeostatic challenge.

Baseline drinking of rats in an LD 12:12 cycle (onset 0600 hr) was monitored with lickometers to determine a peak (1800) and trough (0900) of drinking. A dose response of drinking to concentrations of hypertonic saline (1 ml/100 g bw of 0.9, 2, 4, 6, & 8% s.c.) in a 3 hr drinking test was obtained for both times. The rats drink more at 1800 than at 0900 hr ($p<.001$). The difference increased with increased concentrations of saline ($p<.01$). Low concentrations produced differences within the 1st hour postinjection and higher concentrations in the 2nd and 3rd hours. The differences were maintained even when the 1800 hr test was done under lights; rats drank more in the 2nd and 3rd hours of tests at 1800 hr than at 0900 hr, and the difference increased with concentration (0.9, 4, & 8%; $p<.01$).

The results suggest an interaction of circadian and homeostatic controls of drinking. Possible mechanisms of such an interaction will be discussed.

Supported by NIH HL14388.

RESPONSE OF DAILY BODY TEMPERATURE RHYTHMS OF AGED, YOUNG AND SCN-LESIONED RATS TO RESTRICTED FEEDING SCHEDULES. B.Tate-Ostroff and E.C. Walcott* Harvard Medical School, Boston, MA 02115; Mailman Res. Ctr., McLean Hosp., Belmont, MA 02178; Harvard College, Cambridge, MA 02138.

Age-related dysrhythmia may be the result of abnormalities in the SCN-based, light entrainable oscillator. Entrainment to food restriction schedules (FR) appears to occur through an oscillator anatomically distinct from the SCN. The objective of the present study was to examine the response of the body temperature rhythms of intact, SCN-lesioned and aged rats to FR. Rats exposed to LD 12:12 (lights on 0700) were placed on FR for 14 days, with food available from 1300-1500. Following FR the animals were given food ad libitum for 3 days, and then food deprived for 2 days. Body temperature was measured by telemetry. During both FR and food deprivation, animals from all groups showed elevations in body temperature during the light phase and preceding food availability by 2-4 hours, a pattern resembling that of activity bouts displayed by rats exposed to FR. The food-entrainable oscillator appears to be intact in the aged, dysrhythmic rats. Support by NSF grant DCB-85-08187 and AFAR grant to BTO.

CORRELATION OF SERUM CATECHOLAMINES WITH BEHAVIOR AS A FUNCTION OF GENETIC FACTORS AND TIME OF DAY. D. F. Peeler and I. Marawi* Univ. Miss. Med. Ctr., Jackson, MS 39216.

Serum epinephrine (E) and norepinephrine (NE) levels of male mice (n=126) from 9 inbred strains (C57BL/6, BALB/c and their 7 recombinant inbred strains) were determined for several times of day using HPLC with electrochemical detection. E and NE for each strain and time of day were compared with performance of these strains in previous studies of activity, emotion and learning.

NE typically was much higher than E in morning serum samples. Afternoon serum typically had higher levels of NE and lower levels of E than did morning samples. Strain E and NE levels were significantly correlated for morning but not for afternoon samples. Levels of neither hormone were significantly correlated between morning and afternoon.

Correlation was significant between the morning E level of each strain and one measure of emotion - tail rattling, but not with another emotion measure - defecation, nor with activity. Morning NE correlated with investigatory activity at the same time of day or late afternoon, but not at other times of day nor with locomotor activity or either measure of emotion. Morning levels of NE and E correlated significantly with later phases of shock avoidance learning. Afternoon NE levels correlated only with defecation scores obtained at the same time of day. Afternoon E levels correlated only with late afternoon locomotor activity.

Serum E and NE levels, and their relation to behavior, reflect an interaction of genetic factors and time of day.

519.14

RUNNING AND A MONOAMINE OXIDASE INHIBITOR ALTER SEROTONIN CIRCADIAN RHYTHMS IN HAMSTER SUPRACHIASMATIC NUCLEI IN DIFFERENT WAYS J.S. Kruse Center for Brain Research & Psychology Department University of Rochester, Rochester, N.Y. 14642.

Serotonin (5HT) fibers in the suprachiasmatic nuclei (SCN) mediate delays in free-running and entrained running wheel onset caused by monoamine oxidase inhibitors (MAOI). Increasing the running duration prior to MAOI treatment mitigates the delays. The present study examined the effect of 2 weeks of MAOI (10 mg/kg/day LY51641) and wheel running (DRUG), or 2 weeks of running alone (RUN), on the daily pattern of indoleamine concentrations within the SCN of Golden hamsters. Hamsters caged without wheels (CAGE) served as controls. SCN were microdissected at 8 equidistant times during the 14:10 L:D cycle. For each group at each time, n = 4. Samples were analyzed by high performance liquid chromatography.

DRUG, as compared to CAGE or RUN hamsters, had increased 5HT and decreased 5HIAA at all times of day. RUN hamsters had higher 5HT and 5HIAA than did CAGE hamsters during the dark when running occurred. These findings support the hypothesis that the 5HT projection to the SCN provides feedback information about locomotion to a circadian oscillator. Antidepressants may alter rhythms by disrupting a normal modulatory action of 5HT.

EFFECTS OF CHRONIC CLORGYLINE ON CIRCADIAN WHEEL RUNNING ACTIVITY IN NORMAL AND THYOPARATHYROIDECTOMIZED (TPX) RATS. **J. Schull, W. Duncan, E. Buhl*, D. Haverstick*, and J. Walker*. Haverford College, Haverford, PA 19041.**

Manic-depressive illness has been associated with thyroid abnormalities, shortened circadian periods of physiology and behavior, sex-specific abnormalities of motivation and activity, and heightened sensitivity to photo-stimulation. Abnormal reactions to anti-depressant medications have also been reported in manic-depressives, in whom mania and rapid-cycling may be triggered. Our previous findings suggest a causal role for the thyroid in normal and pathological control of circadian rhythms and behavior: TPX rats manifest shortened circadian periods of wheel running, sex-specific abnormalities of motor activity (elevated in males but not in females) and increased sensitivity to activity-suppressing effects of light. We now report that TPX males also display abnormal reactions to an antidepressant drug, the monoamine oxidase inhibitor clorgyline.

Forty-eight male Sprague-Dawley rats, half TPX and half Sham-operated, were housed in computer-monitored running wheel cages. The experiment was conducted in three stages. After two weeks of Entrainment (LD 12:12), animals were implanted s.c. with Alzet minipumps (Model 2002) delivering clorgyline (2 mg/kg/day) or saline. Following three weeks of Entrainment with Drug, the minipumps were removed and replaced, and animals were placed in Free Running conditions (constant dim red illumination) for 3 weeks.

TPX rats had increased activity levels ($p<.01$) and shortened circadian periods ($p<.005$) relative to shams, as previously observed. Activity levels increased for all groups over the two stages of Entrainment ($p<.01$). These increases were greater for animals receiving clorgyline ($p<.01$). After the transition to Free Running conditions, activity levels decreased in Sham-Saline, Sham-Clorgyline, and TPX-Saline animals ($p<.05$, N=12 for each group). However, activity increased further in TPXs receiving Clorgyline ($p<.05$, N=12). Clorgyline did not affect circadian activity periods in Sham or TPX animals during Free Run. Results suggest that thyroid abnormalities can influence reactions to clorgyline, and that clorgyline can elevate activity levels without affecting circadian periods.

519.16

EFFECTS OF p-CHLOROPHENYLALANINE ON CIRCADIAN RHYTHMS OF BODY TEMPERATURE, DRINKING AND ACTIVITY. J.M. Tomkowiak*, S. Kent and E. Satinoff. Dept. of Psychology, Univ. of Illinois, Champaign, IL 61820.

Serotonin (5-HT) has been implicated in the control of thermoregulation. para-Chlorophenylalanine (pCPA) is a tryptophan antagonist that depletes brain levels of 5-HT. We examined the effects of pCPA on the circadian rhythms of body temperature (Tb), drinking and activity of 9 unrestrained and unhandled male and female Long-Evans rats (b.w. 275-400 g). Tb was monitored by telemetry every 10 minutes, drinking and activity every 20 minutes for 12 days after a single pCPA injection (300 mg/kg i.p.). Rats were kept on a 12:12 LD cycle at an ambient temperature of 23±1°C with food and water available ad lib.

Compared to the saline day, pCPA increases the amplitude by .7±.1°C (± SEM) on day 1 ($p\leq.01$) and decreases the amplitude for the next 4 days ($p\leq.01$). Hour by hour analysis showed the increase in amplitude on day 1 is due to a decrease in Tb minimum and the decreases in amplitude on days 2 through 5 are due to an increase in Tb minimum and a decrease in Tb maximum. No significant effects were observed after day 5.

pCPA decreases the nocturnality of drinking from 83±2% to 63±7% on day 2 ($p\leq.05$), and to 63±3% on day 3 ($p\leq.01$). Nocturnality of activity decreased from 75±2% to 45-55% for the next 3 days ($p\leq.05$). No significant effects were observed after day 3.

ENTRAINMENT BY FOOD OF CIRCADIAN LOCOMOTOR ACTIVITY RHYTHM IN THE CRAYFISH. F. Fernández de Miguel* and H. Aréchiga. Depto. Fisiología, Biofísica y Neurociencias, CINVESTAV, Apdo. Postal 14-740, México, D.F. 07000. México.

Although various sensory inputs may entrain circadian rhythms only light-dark cycles have been tested in crustaceans. In order to explore other entraining influences, the effect of food was studied on the locomotory rhythm of the crayfish Procambarus clarki. Number of movements was determined in actographic chambers in adults of either sex. Three experimental conditions were tested: a) continuous illumination (L:L), b) continuous darkness (D:D) and c) cycles 12:12 hrs L:D. A circadian period (τ) of 22.7±0.09 was determined in D:D:, in contrast to a τ = 24.8±0.02 hrs in L:L, which is in accordance with Aschoff's rule. Food was applied at different times under the three experimental conditions. Within the following hours a burst of locomotor activity ensued which lasted for 1.17±0.3 hours. It reappeared in phase during the following days. Entrainment by a single food pellet could last up to more than two weeks. The newly entrained rhythm displays peculiar circadian features: τ is longer in D:D (25.21± 0.36) than in L:L (23.26±0.17). In L:D τ is a function of the phase of the circadian cycle in which food is applied. Entrainment can be attained with food homogenates suggesting a chemical sensory input. These results suggest the interaction of two circadian systems in the control of crayfish locomotor rhythmicity.

CIRCADIAN VARIATION IN PLASMA MHPG LEVELS. **J.E.Piletz, A.Halaris, M.Marler*, J.F.Nash, and H.Y.Meltzer. Dept. of Psychiatry, Case Western Reserve Univ. and Cleveland Metropolitan General Hospital, Cleveland, Ohio 44109.**

Previous studies have demonstrated a circadian rhythm in the plasma norepinephrine metabolite, MHPG, from normal adults. Relative to healthy controls (n=12), depressed patients (n=43) displayed dysregulated rhythms in total MHPG. Patients circadian values were only weakly fit to a sinusoidal model (22/43 patients yielded $p\leq0.1$ for a sinusoidal fit as compared to 10/12 controls). Patients (n=23) completing a 6-week treatment course with desipramine did not show a significantly improved sinusoidal fit. The circadian aberration in patients was difficult to quantitate because only one 24 hr period was studied. To further study this, 48 hr blood samples were collected and free, sulfo-conjugated and glucuronide-conjugated MHPG fractions were differentiated. Previous reports indicated that plasma levels of sulfo-MHPG and free MHPG are of CNS origin, while gluco-MHPG is believed to be largely of peripheral origin. We also assessed two HPA measures (plasma cortisol and prolactin) which normally show an opposite circadian phase as MHPG. Preliminary results suggest that there is a circadian pattern in free and sulfo-conjugated but not glucuronide-conjugated MHPG. The results help to clarify the nature of the apparent dysregulated MHPG rhythm in depressed patients.

CIRCADIAN EFFECTS ON FATIGUE AND SUSTAINED PERFORMANCE (SP). W.N. Tapp and B.H. Natelson. Primate Neurobehav. Unit, VA Med. Ctr. and Dept. Neurosciences, New Jersey Med. Sch., East Orange, NJ 07018.

We have developed a monkey model for studying circadian effects on performance. However, in many of the natural uses for this information -- jet-lag, shift work, and SP -- fatigue is also an important influence on performance. Therefore, we conducted an experiment to explore the effects of SP on fatigue and its interaction with circadian rhythms. Adult rhesus monkeys -- trained to asymptote on a vigilance-discrimination (Vig-Disc) task and equipped to record circadian activity and temperature -- were fasted for 18 hrs before SP. During SP, successful performance was randomly reinforced with a food pellet 50% of the time, with trials every 2.4 min on average around-the-clock. This schedule produced continuous performance for at least 48 hrs. Performance lapses ranging from 2-15 min appeared during day 3 of SP, and performance lapses up to 72 min were seen in day 4 of SP. Despite lapses, monkeys performed on at least 86% of trials through hour 108 of SP. Performance degraded dramatically during SP. Vig was impaired 51.3% ($p<0.001$) and Disc 56.8% ($p<0.001$) during SP hrs 72-84. Circadian performance and physiology rhythms continued through SP, though fatigue altered both. These results show that we can use SP to study dramatic fatigue effects on performance and rhythms in monkeys. Supp by VA Res & USAMRDC.

DAYLIGHT SAVING TIME AND PSYCHIATRIC ILLNESS. C.M. Shapiro* (SPON: D. Apps). Dept. Psychiatry, University of Edinburgh, Edinburgh, EH10 5HF.

An improvement in mood after the spring adjustment of daylight saving time (DST) has been reported.

There are as yet no published accounts of the effect of DST on psychiatric illness.

Three groups were studied with regard to DST. In each case the analysis compared the week prior to the week following DST. The presentation of parasuicide to a regional poisons unit in Edinburgh (population 500,000) was considered. Over the years 1976-1986 there was no consistent pattern with regard to the spring or autumn DST change.

Admissions to the only psychiatric hospital serving the same population over a 16 year period were studied. All diagnosis entered in the Edinburgh Case Register were classified as having a possible affective diagnosis or not. There was no influence of DST in either group.

Information of all suicide deaths in Scotland over the period 1974-1983 was made available by the Scottish Home Office. An analysis of the date of death in relation to DST did not reveal any pattern either in the male or female subgroups.

In none of the three populations studied was there a discernible influence of DST. It may be that certain individuals are susceptible to small changes in circadian rhythm but this has not been reflected in the groups of this study with varying psychiatric morbidity.

TEMPORAL DEVELOPMENT OF THE BEHAVIORAL EFFECTS OF HERPES ENCEPHALITIS IN MICE. D. J. McFarland Wadsworth Center for Laboratories and Research, New York State Department of Health, Albany NY 12201

The sequential development of the behavioral effects due to CNS infection with the herpes simplex type 1 virus was examined in two mouse models. Following intracerebral infection of adult female NYA/Nylar with the HF strain of herpes or adult female Balb/c mice with the F strain the majority of animals survived. An increase in motor activity observed 7 days following infection of NYA/Nylar mice coincided in time with a decline in brain virus titers as measured by a standard plaque assay. Likewise an increase in errors occurring during serial reversal performance in a water Y-maze was observed 8 days following infection of Balb/c mice and coincided with the declining phase of the viral growth curve. Taken together these results suggest that processes involved in the elimination of virus from brain, such as the cellular immune response, may be important in the development of the behavioral pathology produced by non-fatal herpes encephalitis.

EXAMINATION OF THE HSV INFECTION IN THE NEURON IN CULTURE C. L. Wilcox*[1], R. L. Smith*[2], E. M. Johnson, Jr.[3], and L. I. Pizer*[1], (SPON: M. Taniuchi) [1]Departments of Microbiology and Immunology, and [2]Pediatrics, University of Colorado Medical School, Denver, CO 80262, [3]Department of Pharmacology, Washington University School of Medicine, St. Louis, MO 63110.

Herpes simplex virus (HSV) latency and viral gene expression was investigated in sympathetic neurons *in vitro*. Previously we showed that deprivation of nerve growth factor results in reactivation of latent HSV[1]. We found that inhibition of protein synthesis, pharmacological agents which elevate cyclic AMP, activation of protein kinase C with phorbol ester, and heat shock produced reactivation of latent virus.

HSV gene expression was examined during the productive infection, during latency and during the course of reactivation of latent virus in the neuronal cultures. Using conditions described previously[1] which result in the establishment of latent HSV infections in neuronal cultures, viral gene expression was below the limits of detection by dot blot analysis immediately after inoculation with virus, and at subsequent time points during the latent infection. Preliminary results using *in situ* hybridizations suggest that viral gene expression is limited during the latent infection, however the latency associated trasnscript was detected.

EFFECTS OF MUMPS VIRUS (MV) ON Na^+ AND Ca^{++} CHANNELS OF PC12 AND TE671 CELLS. E. K. Stauffer and R. J. Ziegler. *School of Medicine, Univ. Minn.-Duluth, Duluth, MN 55812

Persistent MV infection has been shown to reduce the excitable responsiveness of PC12 and TE671 cells (Ziegler & Stauffer, 1988. J.gen.Virol. 68:2501). The present study was designed to establish which electrogenic channels of PC12 and TE671 cells are altered by MV.

Stimulus-evoked action potentials (SEAPs) were recorded intracellularly from mock-infected (MI) and MV-infected cell cultures. Standard ionic channel blockers (tetrodotoxin, TTX; tetraethylammonium ion, TEA; and cobalt ion, Co^{++}) were used to differentiate and identify specific voltage-gated ionic currents/channels.

SEAPs recorded from MV cells without TTX were similar to those recorded from MI cells with TTX. Subsequent application of TTX to the MV cells had no significant effect. When MI and MV cells were examined while bathed in high Ca^{++} (20 mM), TTX and TEA, relatively small, slow rising SEAPs persisted in TE671 cells; in PC12 cells, SEAPs typical of Ca^{++} spikes for PC12 cells remained. In both cases, treatment with Co^{++} abolished the persistent SEAPs.

The results indicate that MV is exerting its effect via voltage-gated Na^+ channels. Ca^{++} channels appear not to be influenced by MV to any appreciable extent.

COGNITIVE-CEREBRAL MANIFESTATIONS OF HUMAN IMMUNODEFICIENCY VIRUS (HIV) ENCEPHALOPATHY. R. Krikorian* (SPON: D. L. Garver). Dept. of Psychiatry, Univ. of Cincinnati Med. Ctr. Cincinnati, OH 45267-0559.

HIV has been shown to infect the nervous system, and, in brain, has been associated with cognitive and behavioral changes which can be independent of the clinical manifestations of other AIDS-related disorders. Patients at various stages of illness with serologic evidence of HIV infection and without signs of gross or focal neurological disorders were recruited for study. The subjects underwent comprehensive cognitive evaluations in order to characterize the nature of the intellectual decline associated with HIV infection.

A distinctive and consistent pattern of deficits was demonstrated, including impairments of attentional, organizational, and problem-solving abilities. Other abilities such as language, visual-spatial perception, and memory consolidation were relatively preserved. The deficits suggest compromise of a particular cerebral system composed of subcortical activating centers and projections to prefrontal cortex. This is consistent with evidence from neuropathology and neuroimaging studies indicating a predilection of HIV in brain for subcortical structures and white matter.

SEMI-QUANTITATIVE IMMUNOCYTOCHEMISTRY: A NEW METHOD FOR DETERMINING ALTERED PROTEIN PRODUCTION AS A CONSEQUENCE OF VIRAL INFECTION OR TOXIC AGENTS., F. J. Denaro, UCSD Med Ct, San Diego, CA

By use of double label histochemistry it has been possible to demonstrate that the neurosecretory cells of the adrenal medulla can be infected with Cytomegalovirus in the AIDS patient. While CMV infection can eventually lead to cell death, it is important to know if the quantity of biologically relevant proteins that the adrenal medulla produces can be altered during the course of infection. In order to test this possibility, a new double label method was developed. The PAP method was used to identify virus, while cell products (dopamine, chromogranin, synaptophysin, etc) were semi-quantified by radioimmunocytochemistry. This was done by use of a ^{35}S-streptaviden label (Amersham). It was then possible to compare grains between uninfected and infected cells. Toxins and other agents can alter cell products. Pentamadine has been found to be diabtogenic. A case was examined by semi-quantitative means in which insulin production was found to be significantly decreased, while NSE, S-100, and glucagon were unaffected. These results indicate that this semi-quantitative approach may be of value when it is necessary to compare relative amounts of cell products. Work is underway to apply this approach to transmitters.

QUANTITATION OF CEREBELLAR CHANGES IN RATS INFECTED WITH KILHAM RAT VIRUS. M.A. Littlefield-Chabaud, J.J. England+* G.F. Amborski++*, J.K. Daniloff Dept. of Anatomy and Fine Structure, Department of Microbiology and Parasitology++, LSU School of Veterinary Medicine, Louisiana Veterinary Medical Diagnostic Laboratory+, Baton Rouge, LA 70803-8408

Normal cerebellar histogenesis in the mammalian brain occurs in two epochs: although most neurons are generated early in utero, the granular cells divide and organize at or after birth. Most activity is complete by days 16-19. Kilham Rat Virus (KRV) of the Parvoviridae family has a predilection for rapidly dividing cells. The goal of this series of studies was to quantitate and describe in detail the direct effects of KRV on the developing cerebellum.

Five-day-old Sprague-Dawley rats (n=8) were injected intracerebrally with either 0.03 ml RPMI-1640 containing 300-500 plaque-forming units of KRV or 0.03 ml RPMI-1640. Cerebella were collected at post-injection days 10 and 30 and compared to normal control cerebella. Morphometric quantitation of the relative areas of each major region was performed (Bioquant System IV, Nashville, TN).

Preliminary results indicated the virus caused significant cerebellar hypoplasia at post-injection days 10 and 30 compared to normal and media-injected rats. Results will be compared with data on the normal development of the cerebellum and its interconnections. Supported by LA-SVM 862.

MAJOR HISTOCOMPATIBILITY COMPLEX ANTIGENS IN THE CNS OF THE VIRALLY INFECTED RAT. D.L. Weinstein, D.G. Walker and P.L. McGeer, Kinsmen Laboratory, Dept. of Psychiatry, University of British Columbia, Vancouver, B.C., V6T 1W5, Canada

The present study was designed to determine major histocompatibility complex (MHC) expression in rat CNS after intraneuronally introduced virus. Under anesthesia, rats received injections of 5 µl of Herpes simplex virus type I (HSVI) containing an estimated 27,500 PFU into the sclera of one orbit. On day 6, the animals were sacrificed and the brains fixed. Immunohistochemistry with monoclonal antibodies against rat MHC class I and class II antigens and polyclonal antibodies against HSVI and glial fibrillary acidic protein (GFAP) was carried out in both single and double staining procedures. Positive staining for HSVI was observed in the ipsilateral sensory nucleus of the fifth nerve as well as in punctate areas of the brainstem, thalamus and deep structures of the cerebellum. Most of the positively staining cells had the morphology of leukocytes although a few neurons were clearly outlined. In serial sections class II positive staining of non-neuronal cells was seen in areas positive for HSVI and did not overlap with GFAP-positive cells. The class II positive cells had the morphology of leukocytes, suggesting that, at these early time periods, CNS tissue was not expressing class II MHC antigens in response to the infection. LIMB ROTATION DEPRESSES SPINAL CORD REFLEX EXCITABILITY IN NORMAL HUMAN SUBJECTS. D.A. Lake. Dept Physical Therapy, Northeastern University, Boston, MA 02115.

Rhythmical rotation of the extremities is a common therapeutic technique used in the treatment of spasticity in stroke patients. The effects of limb rotation on the electrically evoked stretch reflex, H-reflex, were studied in 15 normal male and female subjects. Subjects were positioned supine on a low treatment table and asked to relax. Silver cup recording electrodes were placed on skin above the soleus. Monophasic (DC) square-wave pulses (0.2 ms duration, 1/sec frequency) were delivered to the tibial nerve in the popliteal fossa by a clinical bipolar electrode for identification of optimal stimulation sites. The clinical electrode was then replaced by two 1 inch square carbon impregnated rubber electrodes which were taped and straped to provide a stable source of stimulation while the lower limb was being rotated. The evoked responses were recorded onto magnetic tape for later analysis. H-reflexes were evoked prior to the beginning of rotation, 1, 2 and 3 minutes after rotation had commenced, and 30 sec, 1 and 2 minutes after the termination of rotation.

One minute of rotation of the lower extremity produced an average of 52% depression in the H-reflex when compared with control levels. This depression was maintained throughout the duration of rotation. Upon the cessation of the rotation, the H-reflex returned to control levels within 2 minutes.

EFFECTS OF POSTURAL AND STIMULUS VARIABLES ON HUMAN LIP-MUSCLE REFLEXES. M.D. McClean. Dept. of Speech Pathology, Univ. of Toronto, Toronto, Ont. M5G 1L4 CANADA

Lip muscles display early and late excitatory reflexes (E1 & E2) at approximate latencies of 15 and 35 ms, and suppression responses (S) at 20-50 ms. Parametric analysis of these reflexes may enhance understanding of their neural organization and lead to improved methods for clinical evaluation of the trigeminal-facial system. In the present study the pattern and magnitude of lip-muscle reflexes were investigated using independent stimulation of the upper and lower lips during lip rounding and lower-lip depression, and lateral stretch of both lips during a lip-press posture. Subjects maintained background EMG levels of 10-20% of maximum while 100 ms step displacements were delivered at the midline of the lips with a flat stimulus probe. Stimuli were applied randomly at five levels of acceleration with an electromagnetic shaker, and signal averages of lower-lip muscle EMG were analyzed. During lip-press and rounding postures prominent E1 responses were noted, and these showed strong positive correlations ($r > .9$) with stimulus magnitude. E2 responses were more variable in their occurrence across subjects. The magnitudes of E1 and E2 were greater for lower-lip compared to upper-lip stimulation. S responses were most evident during the lower-lip depression gesture and showed larger magnitudes to upper-lip compared to lower-lip stimulation. COMPENSATION FOR MUSCLE YIELD AND LACK OF STIFFNESS REGULATION BY STRETCH REFLEXES. R.R. Carter*, P.E. Crago and M.W. Keith. Depts. of Biomedical Engineering and Orthopaedics, Case Western Reserve University, Cleveland, OH 44106.

The neuromuscular response to externally imposed adduction at the index finger metacarpal-phalangeal joint was recorded in normal subjects and decomposed into a passive component (measured with the muscle relaxed), an active mechanical component (estimated by electrically activating the first dorsal interosseus muscle) and a reflex component (calculated by subtracting the passive and active mechanical components from the total response). For large amplitude rotations, muscle yield was observed in the active mechanical component as an abrupt decrease in incremental stiffness to 22% to 70% of the small amplitude value. In contrast the total active stiffness (combined active mechanical and reflex stiffness) measured after onset of the reflex component differed from the pre-yield incremental stiffness by less than 9%. Thus, the reflex stiffness component of the stretch reflex provided excellent compensation for muscle yield. To investigate the stiffness regulation hypothesis, we employed a constant initial joint angle and rotational disturbance while modulating the initial torque level over the lower one-half of the available torque range. Both the mechanical component and reflex component increased with initial torque level, indicating that the reflex does not provide stiffness regulation.

521.4

MODULATION OF SOLEUS H-REFLEX EXCITABILITY WITH CHANGES IN HIP AND KNEE POSITION IN MAN. S.J. Sullivan, J. Pompura* and C.E. Chapman. Centre de recherche, Institut de réadaptation de Montréal; Concordia University; Université de Montréal, Montréal, CANADA.

The hypothesis that the facilitatory changes observed with controlled hip flexion in our previous studies were the result of afferent input resulting from stretch of the hamstrings group was investigated.

Soleus H-reflex recruitment curves were generated in 7 healthy subjects at one control (15° hip flexion) and two test positions: (1) hip flexion (40°) and (2) hip flexion (40°) plus knee flexion (36°). H-reflex testing followed a standard procedure (1ms pulse width, 0.1Hz). In position 1, Hmax increased in 3 subjects (10 - 26%), decreased in 1 (11%) and was unchanged in 3. In position 2, 4 subjects showed a marked decrease in Hmax (16 - 49%) and 1 showed an increase (18%). Only 1 of the subjects showing an increase in position 1 showed a decrease in position 2. The latter finding is not strongly supportive of the idea that hamstrings stretch contributed to the facilitatory effects of hip flexion alone on the soleus H-reflex. The pronounced inhibition seen in position 2 may be attributable to additional inhibitory inputs associated with the knee flexed position.

521.5

VIBRATION-INDUCED FACILITATION AND RECIPROCAL INHIBITION EFFECTS ON HUMAN SINGLE MOTOR UNIT CONTROL. J. Ives* and W. Kroll*(SPON: W. Abraham). Dept. of Exercise Science, Univ. of Massachusetts, Amherst, MA 01002.

The purpose of the present study was to assess changes in discrete volitional motor control when perturbed by facilitory and inhibitory reflexive input. Twelve (12) female subjects underwent standard single motor unit (SMU) control training of the tibialis anterior followed by two SMU control performance tests. EMG criteria measured were interspike interval (ISI), time to fire the SMU a specified number of times (TIME), number of extraneous motor unit potentials during SMU firing periods (ERRORS) and SMU rest periods (REST ERRORS). ISI and TIME were indices of specific SMU control while ERRORS and REST ERRORS measured ability to silence neighboring motor units. Treatment conditions consisted of applying tonic vibratory facilitation and reciprocal inhibition prior to performance testing. Stable baseline measures were taken on days 1 and 2 and treatment condition measures on days 3 and 4. The results from a 2-way repeated measures ANOVA revealed that reflexive facilitation increased ERRORS 433% and REST ERRORS 1638% ($p \leq .01$). The inhibition treatment increased ERRORS 388% ($p \leq .01$). Neither treatment significantly altered ISI or TIME. These results indicate that neither a facilitory or inhibitory reflex disrupted central activation of specific SMUs. The disruption of neighboring motor unit quiescence suggests that this inactivation is not due to central inhibitory command but relaxation of central activation.

PATELLAR TENDON REFLEX CHARACTERISTICS ARE ENHANCED BY A CONDITIONING ACHILLES TENDON REFLEX. D.M. Koceja*, J.M. Burke*, and G. Kamen. Motor Control Laboratory, Indiana University, Bloomington, IN. 47405.

Previous results in our lab demonstrated that a conditioning patellar tendon-tap reflex (PTR) produced a long-latency excitatory effect on the contralateral PTR. In this study, the PTR was conditioned by either an ipsilateral or a contralateral achilles tendon-tap stimulus in a group of normal college-age subjects (n=10). Paired tendon-tap reflexes were delivered with electromagnetic solenoids using conditioning intervals of 10, 25, 40, 55, 70, 85, 100, 115, 130 and 145 msec. Results indicated that a long-latency (> 50 msec) excitatory effect occurred for the PTR when conditioned by a tap to either the ipsilateral or contralateral achilles tendon, as shown for force impulse:

H-REFLEX MODULATION WITH THE GTO
M. Sabbahi, S. Olson*, M. Aldea*. Texas Woman's University School of Physical Therapy, 1130 M. D. Anderson Blvd., Houston, TX. 77030

The functional contribution of the Golgi Tendon Organs (GTO) in movement has been tested mainly in animal lower limb muscles. This study investigates the modulation of the H-reflex and presumably the motoneuron pool, during activation and deactivation of the GTO in flexor carpi radialis (FCR) muscles of human subjects. Normal subjects were tested using H-reflex of the FCR after electrical stimulation of the median nerve in the arm (0.2 pps, 1 MS at H-Max). Subject's hand was then loaded in extension using 2 pounds of weight and the peak-to-peak amplitude of the H-reflex was recorded. Two percent xylocain was then iontophoresed into the musculotendenous junction using 3 mA direct current for 20 min. H-reflexes were then recorded during unloaded and loaded conditions post anesthetic. Four H-reflexes were averaged at each phase and pre-test, post test comparison were carried out. Results showed that H-reflexes decreased by an average of 24% during loaded condition in 7 out of 8 subjects. This reflex inhibition was reversed after anesthetic was delivered to the GTO. During unloaded condition, H-reflex showed mild increase by an average of 8% in 5 subjects. Anesthetic iontophoresis resulted in substantial reduction of skin sensation under the electrode (2 cm diameter). Previous results showed >1 cm penetration of the anesthetic into the soft tissue using such treatment dose. These results imply that GTO of the flexor forearm muscles may cause inhibition of the homonymous motoneuron pool and this effect could be reversed by deactiviation using iontophoretic anesthesia. (Supported by NIH Grant #NS25297-01)

NONNOXIOUS SURAL NERVE STIMULATION EFFECTS ON TRICEPS SURAE HUMAN MOTOR UNITS. C.G. Kukulka, D.A. Brown* (SPON: C. Gisolfi). Physical Therapy Labs, The University of Iowa College of Medicine, Iowa City, IA 52242.

Experiments were done to evaluate the effects of nonnoxious electrical stimulation of the sural n on the discharging of human motor units from soleus (S) and lateral gastrocnemius (LG) muscles. Intramuscular motor unit recordings were made using bipolar fine wire electrodes. Single, 0.1 msec shocks were delivered at 3/s to the sural n at the ankle. Stimulation effects were evaluated by constructing poststimulus time and cumulative sum histograms. Stimulus intensities ranging from 1-5 times perception threshold (PT) were correlated with computer averaged evoked responses of the sural n. High linear correlations ($r \geq .09$) allowed representation of sural n input to the motoneuron pools in terms of PT as well as percentage of maximum evoked sural response. Complex excitatory/inhibitory changes were observed in 65 of 74 S spike trains and 13 of 15 LG trains. The predominant effects in S were inhibition-excitation-inhibition occurring between 38 and 137 msec poststimulation. Rarely (n=7), a short latency, mild excitation preceded this complex. In contrast to S, LG effects were of 2 types: a short latency inhibition between 40 and 60 msec (n=4) or inhibition-excitation between 70 and 110 msec (n=9). The results suggest that sural n afferent input may be disproportionately distributed to S and LG motoneurons in man. Supported by PHS Grant NS2499102

521.9

EVOCATION OF "EARLY" AND "LATE" COMPONENTS OF A CUTANEOUS REFLEX BY NON-PAINFUL STIMULI IN MAN. S. Nord and R. Durkovic. Neurol. Serv., VAMC; Depts. of Anat. and Physiol., SUNY Health Sci. Ctr., Syracuse, N.Y. 13210

It has been reported that the "early" (RII) component of a cutaneous reflex can be elicited by innocuous stimuli, whereas the "late" (RIII) component requires painful stimuli (e.g., Hugon, 1973; Willer, 1983). However, our preliminary experiments suggested that non-painful stimuli might produce both components. The present study focused upon this contradiction. Subjects were relaxed, normal adults. Surface EMGs were recorded via electrodes positioned over the short head of the biceps femoris muscle (SBi). Innocuous electrical stimuli were delivered in brief trains, one/min., to either the distal cutaneous distribution of the sural nerve or, percutaneously, to the retro-malleolar pathway of the sural nerve. Stimulation at each site generated SBi reflexes with both "early" and "late" components demonstrating that non-painful stimuli can elicit the "late" response under appropriate experimental conditions. Specifically, our data suggest that the low-threshold, longer latency component is consistently observed when intervals between stimulus presentations approach one min.. Notably, previous failures to observe this SBi response have occurred in studies which utilized much briefer interstimulus intervals (5-8s) but which were comparable to ours in other respects. Supported by NSF Grants BNS 8415917 and BNS 8808495.

521.10

EXTEROCEPTIVE REFLEXES IN MAN: STARTLING RESPONSES TO SHOCKING EXPERIENCES. R. Durkovic and S. Nord. Depts. of Physiol. and Anat., SUNY Health Sci. Ctr. and Neurol. Serv., VAMC, Syracuse, N.Y. 13210.

The present study was designed to survey the excitatory EMG reflex activity induced by the presentation of non-painful cutaneous or auditory (click) stimuli. Subjects were normal, relaxed humans in a supine position. Single clicks were delivered through padded earphones. Electrical stimuli, composed of brief trains of pulses, were delivered once each minute to various skin sites. Surface EMG recordings were obtained from electrodes overlying each of several different muscles.

Stimulation could induce both short and long latency reflex responses in muscles located relatively near the site of stimulation. In contrast, similar stimulation tended to trigger only the longer latency responses in muscles remote from the stimulation site. These findings are consistent with the following working hypothesis: "Early" reflex components have a local segmental organization, while "late" components result from suprasegmental activation organized in a pattern reminiscent of the "startle reflex" (e.g., Landis and Hunt, 1939). Supported by NSF Grants BNS 8415917 and BNS 8808495.

REFLEX FUNCTION: HUMAN II

522.1

THE ACTIVATION OF MOTOR UNITS IN REFLEX-INDUCED AND VOLUNTARY CONTRACTIONS IN HUMAN ARM MUSCLES. C.Gielen, E. van Zuylen*, J. Denier van der Gon*. Dept. of Medical and Physiol. Physics, Univ. of Utrecht, The Netherlands.

Motor-unit activity in human arm muscles was recorded with intramuscular electrodes during isometric contractions and during reflex activity elicited by torque perturbations in the elbow joint in flexion/extension and supination/pronation direction. Short latency responses to loading and unloading perturbations were found only in muscles that were stretched or shortened. However, changes in EMG activity at medium latency were also observed in muscles that were not stretched or shortened. Therefore, the medium latency reflex cannot be the result of a simple feedback mechanism that controls muscle length only.

During medium-latency reflex activity different types of motor-units were found in nearly all muscles, each with a different type of activation. The relative activation of these subpopulations in the medium latency reflex for torques in different directions counteracting the perturbation was the same as that observed during voluntary contractions in corresponding directions. The results demonstrate that the medium latency reflex reflects the coordinated activation of muscles which is necessary for an adequate response. The similar activation of motor units for voluntary and reflex-induced contractions suggests that the activation in both conditions is mediated by the same coordination center.

522.2

HUMAN FLEXOR REFLEX REVERSAL IN KNEE MUSCLES DURING CYCLING. D.A. Brown*, C.G. Kukulka, T. Cook*. Physical Therapy Education, The University of Iowa, Iowa City, IA 52242.

The human flexor reflex (HFR) in lower extremity muscles has been studied almost exclusively during static resting and static isometric conditions. In an attempt to characterize this reflex during a locomotive movement, subjects cycled at a constant workload while an electrical stimulus was delivered to the tibial nerve at the medial malleolus (0.1 ms rectangular pulses at 300/s for 25 ms). The EMG responses recorded in rectus femoris (RF) and biceps femoris (BF) at various phases of knee motion were compared to the mean EMG regularly occurring at these intervals with no stimulus present. Results indicate a pattern of inhibition-excitation-inhibition in RF during knee extension phases, and an excitation-inhibition-excitation pattern in BF during knee flexion. The peak amplitude of the excitatory responses are dependent on both the mean baseline EMG activity and the knee angle at which stimulation occurs. The observed patterns strongly support previous studies investigating phase dependent reflex reversal in animal and human subjects.

522.3

EVIDENCE FOR PHASE DEPENDENT CUTANEOUS REFLEX REVERSAL DURING WALKING IN HUMANS. J. F. Yang, R. B. Stein, Department of Physiology, University of Alberta, Edmonton, Alberta, Canada, T6G 2H7.

Phase dependent cutaneous reflex reversals in walking have been reported for some time in cats, but never demonstrated in humans. This study examines these responses in humans. Twin pulses of approximately four times sensory threshold were applied randomly to the tibial nerve, posterior to the medial malleolus, where the nerve is mostly cutaneous. An M-wave recorded from the abductor hallucis served as control. Responses were recorded from the ipsilateral tibialis anterior (TA), soleus (SO) and rectus femoris (RF). The walking cycle was divided into 16 parts; stimuli which occurred within one part were averaged together. The most prominent and consistent responses occurred at a latency of 70 to 90 ms in an active muscle. The responses were not observed in an inactive muscle. In the TA and RF muscles which are active in both the stance and swing phase of walking, a clear reversal in the direction of the response was observed: inhibition in the stance phase, excitation in the swing phase. These results suggest that a functionally appropriate reversal in the cutaneous responses does occur in the walking human.

522.4

CONSTANT ERRORS IN HUMAN FORCE ARE PREDICTED BY CONTRACTION-INDUCED PLASTICITIES IN THE STRETCH REFLEX. R.S. Hutton, A.C. Powers*, H.K. Kelsh* and S. Suzuki*. Dept. of Psychology, Univ. of Washington, Seattle, WA 98195.

Conditioning agonist muscle contractions cause post-contraction afterdischarge and increased stretch sensitivity in muscle spindle receptors. Under static conditions, the tonic stretch reflex is enhanced leading to non-volitional increments in muscle activity. Predictably, when human subjects estimate a previously learned criterion force (LCF) following a conditioning contraction, estimates of the LCF are overestimated compared to control values. The amplitude of these constant errors decreases over time as does the intensity of muscle spindle afterdischarge, and both are attenuated by muscle stretch (Hutton et al., J. Physiol., 393, 247-259, 1987). Since Ia afferents synapse with Ia reciprocal inhibitory interneurons, a maximum elbow extensor force (5 s duration) preceding 35 s estimates of a flexor LCF (2% max.) should induce underestimates in force due to afterdischarge-linked reciprocal inhibition from the extensors. This prediction was tested in 25 human subjects. Following an extensor conditioning force, estimates of the flexor LCF were consistently underestimated. The size of the underestimate was time dependent. Previous findings of an overestimate of a flexor LCF following a maximum flexor contraction were replicated. The direction of constant errors in human force can therefore be explained by known contraction-induced plasticities in muscle spindles.

522.5

VIBRATION-EVOKED RECIPROCAL INHIBITION BETWEEN HUMAN WRIST FLEXORS AND EXTENSORS. F.W.J. Cody* and T. Plant* (SPON: A.M. Smith) Dept. of Physiol. Sci., Univ. of Manchester, Manchester M13 9PT England.

Vibration stimuli (1, 2, 3 or 19 cycles, 0.7-1.3mm amplitude, 125Hz) were applied to the tendon of flexor carpi radialis (FCR) to evoke Gp Ia-dominated afferent discharges whilst the resulting reciprocal inhibition of its antagonist (extensor carpi radialis, ECR) was quantified as a reduction of asynchronous, on-going e.m.g. The protocol conformed to the Declaration of Helsinki.

The most marked and repeatable response, evident in 90% of trials from 16 subjects, was a reduction in ECR rectified e.m.g. activity commencing at about 40ms, lasting some 20ms and reaching a minimum of approximately 55% of the pre-stimulus level. In about 25% of trials a shorter latency (25ms), smaller (minimum of 70% pre-existing level) depression of e.m.g. was present. The amplitudes of both phases of inhibition increased in proportion to background e.m.g. for voluntary ECR contractions of 10-30% maximum. Neither phase was appreciably affected by changes in stimulus duration. Comparable patterns of reciprocal inhibition of FCR were observed, in 6 subjects, upon vibration of the belly of ECR.

Our findings, in the wrist musculature, of short-latency, reciprocal inhibition, probably mediated by Gp Ia, oligo-synaptic, spinal reflex action, and a later, more pronounced reduction in motor discharge agree with earlier descriptions from H-reflex studies (Cavallari, P. et al., Exp. Brain Res., 56, 574, 1984; Day, B.L. et al., J. Physiol., 349, 519, 1984). Two important differences were, however, noted:- (i) the overall duration of inhibition was far shorter and (ii) reciprocal inhibition increased, rather than decreased, during voluntary activation of the inhibited muscle.

MODULATION OF H-REFLEX FOLLOWING SURFACE SKIN ELECTRICAL STIMULATION, XYLOCAINE AND PLACEBO ANESTHESIA IN CONTROL SUBJECTS. A.Y. Belanger, A.B. Arsenault, M.J. Durand* and L. Fortin*. Research Center, Montreal Rehabilitation Institute, Montreal, Canada. H3S 2J4

The purpose of this study was to determine, in 12 subjects, the extent of soleus motoneuron excitability during conditions of increased (Electrical Stimulation, ES), decreased (Xylocaine Anesthesia, XA) and normal (Placebo Anesthesia, PA) cutaneous inputs. Skin ES was applied using a TENS unit, with the two pairs of electrodes placed respectively over the Achilles (S1 dermatome) and TA (L5) tendons. True and placebo anesthesia were respectively obtained after rubbing some Xylocaine (5%) and Vaseline ointment on the skin surface overlying the Achilles tendon. Sets of 10 H-reflexes (Hmax/2) were evoked (1 shock/30s) and averaged at different time intervals before, during and after the testing conditions (Hmax values were stabled throughout testing). The results, apart from showing a small (10%) H-reflex facilitation during Achilles tendon ES, revealed PA to cause the same gradual facilitatory response (up to 100% after 50 minutes) as that obtained during XA. This finding would appear to seriously challenge the view that reducing (via true anesthesia) neural activity from the skin to the soleus motoneurons significantly increases their excitability. We postulate that the elicitation of consecutive H-reflexes per-se (1 every 30s for minutes) facilitated the H-reflex over time.

DILUTE NOVOCAIN BLOCK OF THE STRETCH REFLEX IN HUMANS DURING STRETCH-SHORTENING CONTRACTIONS. H.A. Kilani[1]*, S.S. Palmer, M.J. Adrian*, and J.J. Gapsis[2]*. [1]Faculty of P.E., Univ. of Jordan; Dept. of Kinesiol.,[2]Div. of Rehab. Educ.Servs., Univ. of Illinois at Urbana-Champaign,IL 61801

Intramuscular injection of 1% Novocain (4-10cc) was used to block the stretch reflex of vastus lateralis (VL) to investigate stretch reflex contribution to stretch-shortening contractions with either tonic or dynamic pre-stretch. Six male athletes performed squat-jump relaxed (SJR, from seated on a chair), squat-jump tension (SJT, from knee flexion), squat-jump hop (SJH, on one leg), counter-movement jump (CMJ, with fast prestretch), counter-movement hop (CMH, on one leg), and drop jump (DJ, from 50 cm high box) trials before and after injection. Ground reaction forces were measured; EMG from VL was rectified and integrated (IEMG). Ten IEMG responses to tendon tap were averaged before and after injection. Reflex amplitude decreased 52-87%. Repeated measure ANOVA was used to analyze jump height (H), maximum force, IEMG, and vertical velocity (V). Since no change occurred in SJR variables, muscle function without prestretch was not compromised. Significant decreases occurred in both tonic /H - SJH(7%); V - SJH(5%)/ and dynamic /H - CMH(13%), DJ(10%); V - CMH (7%); IEMG - CMJ(20%), CMH(25%)/ prestretch conditions. Two leg tests may include some contralateral leg compensation. The stretch reflex contributes more to enhanced jump height during dynamic prestretch than tonic pre-stretch.

522.8

DEVELOPMENTAL AND AGING ASPECTS OF HUMAN ORAL-MOTOR REFLEXES. C.M. Weber, A. Smith, M. Denny*, and J. Newton*. Dept. Audiology and Speech Sciences, Purdue University., W. Lafayette, IN 47907.

The activity of human jaw-closing muscles is extremely sensitive to modulation by sensory feedback arising from low-threshold intraoral mechanoreceptors, and reflex responses of jaw-closing muscles elicited by mechanical stimulation of sites on the palate and tongue show a striking spatial organization (Smith et al., Exp. Neurol., 90:489-509). The aim of the present investigation was to explore the influence of developmental and aging processes on the nature of these reflex responses previously described for young adults. The patterns, latencies, and amplitudes of oral-motor reflex responses of children (7-8 years) and elderly adults (70-80 years) were examined.

Reflex responses in jaw-closing muscles were elicited with innocuous mechanical stimuli applied to sites on the palate and tongue dorsum. During stimulation, subjects maintained a constant isometric biting force. Reflex responses were measured as changes in biting force and in activity recorded from bilateral masseter muscles.

The complexity in patterns and spatial organization of oral-motor reflex responses elicited in children and elderly subjects were very similar to those previously described for young adults. However, there do appear to be subtle age-related effects on patterns, latencies, and amplitudes of responses for given stimulation sites.

522.9

TENDON TAP REFLEX RESPONSES AS INFLUENCED BY MOVEMENT IMPAIRMENT. N.J. Lambert*, W.P. Kroll*, and L.D. Abraham. Motor Control Lab, Univ. of Mass., Amherst, MA 01003.

Patellar tendon tap response to a maximum tap force were compared in an able-bodied group (AB,n=10) and a spastic group (SP,n=10) with respect to EMG latencies, peak to peak amplitude (AMP) of the largest spike, and muscle force (FORCE). SP subjects consisted of spinal cord injured with no voluntary movement (SCN,n=3) and impaired movement (SCM,n=3), or with cerebral palsy and impaired movement (CPM,n=4). Latencies from the tendon tap to the appearance of the muscle action potential (INITIAL), to the first peak of the largest spike (FIRST), and to the second peak of the largest spike (SECOND), were stable over six trials on each of two test days as indicated by intraclass R's of greater than .90. Latency differences were observed between the groups for INITIAL ($p<.01$; AB, x=21.4 msec; SP, x=18.6 msec) and FIRST ($p<.05$; AB, x=29.2 msec; SP, x=23.8 msec) measures. Latency differences may in part be due to differences in limb length. AMP and FORCE measures were also stable with intraclass R's of greater than .86. Differences between groups in AMP ($p<.01$; AB, x=267 uv; SP, x=786 uv) and FORCE ($p<.05$: AB, x=16.7 N; SP, x= 33.0 N) were also observed. Responses were largest for the SP subjects with impaired voluntary movement for AMP (CPM, x=1478 uv; SCM, x=741 uv; SCN, x=264 uv), and FORCE (CPM, x = 43.4 N; SCM, x=38.0 N; SCN, x=15.3 N) measures. The latter results indicate that the greatest spasticity occurs in subjects with impaired movement.

RELATION BETWEEN PROBE CONTACTOR CONFIGURATION AND THE MECHANICALLY EVOKED PERIORAL REFLEX. S.M. Barlow, Speech-Orofacial Physiology Laboratory, Boys Town National Institute, Omaha, NE 68131.

Recent evidence suggests that execution of fine motor behaviors by orofacial structures is dependent on peripheral inputs originating from a number of mechanoreceptors located within skin and muscle. These studies also have shown that a number of factors may influence the magnitude and distribution of afferent mediated processes, including the nature of peripheral input.

The purpose of the present investigation was to characterize the reflex sensitivity of perioral muscles to mechanical stimulation involving a series of contactor probes varying in size and configuration. A linear motor was used to deliver taps, with displacements ranging from 50 to 1500 microns, to hairy and glabrous skin of the lower face in humans. Several types of electrodes were used, including a highly selective intramuscular 2-conductor hook-wire for motor unit recordings, and 80 micron intramuscular hook-wire and miniature Ag/AgCl surface disks for recording gross EMG. Recording sites in the lower face included the medial and lateral segments of the orbicularis oris inferior, orbicularis oris superior, and mentalis. Young adult subjects were coupled to a specially designed transducer that allowed real-time monitoring of lip force during the presentation of mechanical stimuli to perioral skin. This was a necessary control since motoneuron activity (facial nucleus) is related to reflex magnitude. Preliminary results suggest that the threshold of the early component of the perioral reflex (14 to 20 millisecond latency) is inversely related to the probe contactor array size. Moreover, the distribution of the mechanically evoked perioral response is generally ipsilateral and confined to the muscles proximal to the stimulated skin.

523.1

DESENSITIZATION OF THE ALPHA-2 ADRENERGIC RECEPTOR IN HT29 CELLS. S.B. Jones* and D.B. Bylund (SPON: J.L. Lewis), Department of Pharmacology, Univ. of Missouri, Columbia, MO 65212.

The alpha-2 adrenergic receptor is coupled in an inhibitory manner to adenylate cyclase. Preincubation with an alpha-2 adrenergic agonist would be expected to result in an attenuation of inhibition upon a subsequent exposure of cells to that agonist. HT29 human colon adenocarcinoma cells have alpha-2 adrenergic receptors which are negatively coupled to adenylate cyclase. Utilizing the [^{3}H]adenine prelabelling technique, we preincubated cells for 30 min with norepinephrine and then stimulated with forskolin and various concentrations of UK14,304, an alpha-2 agonist. Preincubation with norepinephrine resulted in a rightward shift in the dose response curve to UK14,304 resulting in a 20-fold increase in the EC_{50} for UK14,304 (3 to 60 nM). Because preincubation of HT29 cells with norepinephrine results in a 10-fold increase in forskolin-stimulated cyclic AMP production, we repeated the experiment utilizing VIP in the stimulation phase of the assay instead of forskolin. Norepinephrine preincubation again caused a dose-dependent rightward shift in the dose response curve to UK14,304 indicating desensitization of the alpha-2 adrenergic receptor in HT29 cells. (Supported by NIH GM37664.)

523.2

ALPHA$_2$-ADRENERGIC RECEPTORS DOWN-REGULATION BY ALPRAZOLAM. Tyrone Lee. Psychopharmacology Unit, Clarke Institute of Psychiatry, Toronto, Canada M5T 1R8.

Recent reports have shown that alprazolam, a triazolobenzodiazepine, is effective in treating depressed patients with potency equivalent to that of other tricyclic antidepressants. In our earlier attempt to screen for drug action on various receptors in the CNS (Lee et al., Soc. Neurosci. Abst. 12:1080, 1986), alprazolam was found to reduce α_2-adrenergic receptor density. The present report investigates the dose-effect relationship of this action.

Six groups of male Wistar rats of 12 each were injected with daily doses of either saline (1 ml/rat) or desipramine (5 mg/kg) or alprazolam (1, 2.5, 5, 10 mg/kg) for 21 days. Brain α_2-adrenergic receptor density was determined by Scatchard analysis using ^{3}H-clonidine and phentolamine. The results are as follows:

	Bmax (fmoles/mg protein)	% Change
Saline Control	159 ± 6	0
Desipramine (5 mg)	142 ± 4*	-11
Alprazolam (1 mg)	141 ± 5@	-12
(2.5 mg)	131 ± 5¢	-18
(5 mg)	139 ± 5*	-13
(10 mg)	140 ± 4*	-12

¢ = $P < 0.01$; * = $P < 0.02$; @ = $P < 0.05$.

It is concluded that alprazolam significantly reduced the density of the α_2-adrenergic receptors at all doses attempted in this study. (Supported by the Clarke Institute Research Fund.)

CYCLIC AMP AND ADENOSINE DIFFERENTIALLY REGULATE THE EXPRESSION OF ALPHA-1 RECEPTORS IN DDT-1 CELLS. J.B. Schachter and B.B. Wolfe. U. PA Sch. Med., Phila. PA 19104.

We have observed that increases in [cAMP] induce an increase in the number of alpha-1 adrenergic receptors (α_1-R) in the DDT-1 smooth muscle cell line. α_1-R number, measured by the binding of ^{3}H-prazosin, reached 30 to 80% above control after 20 hours of drug treatment. The appearance of new receptors correlated with an increase in α_1-R stimulated turnover of inositol phosphates (PI).

Adenosine can inhibit cAMP production via A_1 receptors. We have observed that A_1 agonists downregulate α_1-R in DDT-1 cells by 20 to 30%. Conversely, A_1 antagonists upregulate α_1-R by 20%, suggesting that endogenous adenosine tonically downregulates α_1-R.

Since cAMP upregulates α_1-R and since A_1 receptors are negatively coupled to cAMP production adenosine could have been downregulating α_1-R by decreasing the basal [cAMP]. However, downregulation of α_1-R by adenosine agonists still occurred in the presence of 8-bromo cAMP. As an alternative mechanism, acute administration of A_1 agonists potentiated PI turnover in these cells. Thus, although A_1 receptors do inhibit cAMP production and cAMP does regulate α_1-R number, adenosine may heterologously downregulate α_1-R by enhancing the activity of a feedback mechanism involving PI and diacylglycerol. Supported by GM31155.

ESTROGENS MODULATE STIMULATION OF PHOSPHOINOSITIDE HYDROLYSIS BY NOREPINEPHRINE (NE) IN RAT BRAIN SLICES. A. Favit*, L. Fiore* and P.L. Canonico (SPON: C. Bethea). Institute of Pharmacology, Catania Univ. Sch. of Med., Catania, Italy.

Estrogen treatment modified stimulation of inositol phospholipid (PI) hydrolysis in slices prepared from rat hippocampus, corpus striatum and cerebral cortex. This effect was sex-dependent and required repeated injections of the steroid. In ovariectomized female rats, a 7-10 day treatment with estradiol benzoate (2 ug/animal subcutaneously, once every two days) [^{3}H]inositol monophosphate [^{3}H]InsP production in response to NE in hippocampal slices, while an increased responsiveness was found in the cerebral cortex. No effect was observed after a single injection of estradiol benzoate or after in vitro addition of 17-beta-estradiol to brain slices. In chronically treated male rats, the PI response to NE was increased in the hippocampus with no change in the cerebral cortex. The most dramatic changes induced by repeated estrogen treatment were observed in the corpus striatum, where the stimulation of [^{3}H]InsP production by NE was drastically reduced in both sexes. We are currently investigating whether this effect of estrogens at striatal level may be correlated to the antidyskinetic properties of the steroid.

MELATONIN'S INTERACTION WITH β-RECEPTORS IN RAT PINEAL. T. Warcholak* and L.P. Niles (SPON: G.M. Brown). Department of Neurosciences, McMaster University, Hamilton, Ontario, Canada L8N 3Z5

Binding studies in our lab have suggested an interaction between norepinephrine and [^{3}H]melatonin binding sites in rat hippocampus (1). In order to clarify this issue, the effects of melatonin on the binding of the β-adrenergic antagonists, [^{125}I]iodocyanopindolol ([^{125}I]CYP) and [^{3}H]dihydroalprenolol ([^{3}H]DHA), were examined.

Saturation studies indicate that melatonin does not alter [^{3}H]DHA binding in rat brain. When incubated with homogenates from rat pineal, melatonin enhanced [^{125}I]CYP binding up to 50% above control values. This effect was dose-dependent ($EC_{50} \approx 5 \times 10^{-9}$ M), in agreement with previous studies in rabbit pineal (2). Preliminary findings suggest that 100 nM melatonin significantly enhances the affinity of β-adrenergic sites in rat pineal. Control: K_D = .20 nM, Bmax = 1090 fmol/mg protein; Melatonin: Kd = .11 nM; Bmax = 930 fmol/mg protein.

Additional studies are required to confirm these findings and to determine the possible mechanism(s) involved in mediating melatonin's effects.

BETA-2-ADRENOCEPTOR SELECTIVITY OF A PROBABLE IRREVERSIBLE CARBOSTYRIL-BASED BETA-AGONIST. S.P. Baker, J. Pitha*, P. Posner* and K.M. Standifer. Depts. of Pharmacology and Physiology, Univ. of Florida, College of Med., Gainesville, FL 32610 and GRC-National Institute on Aging, Baltimore, MD 21224.

Previous studies suggest that a bromoacetamido congener of 8-hydroxycarbostyril (C-Br) is a potent beta-agonist which may bind to the beta-adrenoceptor in an irreversible manner. In the present study, the effects of *in vivo* administration of C-Br on the beta-adrenoceptor of several tissues was determined. Similar to isoproterenol, C-Br (0.1 and 5 mg/kg) stimulated rat heart and lung ornithine decarboxylase activity which was blocked by propranolol. Three hours after an i.p. or s.c. injection of C-Br (0.5-10 mg/kg), there was a dose-dependent loss of beta-adrenoceptors in the lung and spleen, the maximal loss being in the range of 75-85%. In contrast, the maximal loss of receptors in the heart and submaxillary gland was 15-25% and no receptor loss was detected in the cerebral cortex even at the highest dose. Competition assays using [^{125}I]iodocyanopindolol and the highly selective beta-antagonist CGP-20712A showed that the majority of receptors in the heart and submaxillary gland are beta-1 whereas the majority in the lung and spleen are beta-2. After treatment with C-Br (5 mg/kg), the competition assays showed that the loss of receptors in the 4 tissues was mainly of the beta-2 subtype. The selectivity of receptor loss was further confirmed by C-Br pretreatment of isolated membrane preparations from the tissues. The data suggest that C-Br is a beta-agonist *in vivo* with a high degree of irreversible selectivity for the beta-2 subtype. In addition, C-Br may not be able to cross the blood brain barrier. Supported by NIH grants HL32099 and GM34905.

523.7

DESENSITIZATION OF THE BETA-ADRENERGIC SYSTEM WITH AN IRREVERSIBLE AGONIST IN DDT_1-MF_2 CELLS. K.M. Standifer, J. Pitha*, and S.P. Baker. Dept. of Pharmacology, University of Florida College of Medicine, Gainesville, FL 32610, and GRC-National Institute On Aging, Baltimore, MD 21224.

We recently reported on the characterization of a bromoacetamido congener of 8-hydroxycarbostyril (C-Br). Our results showed the compound to be a beta-agonist that may bind irreversibly and produced sustained activation effects *in vitro* (Soc. Neurosci. Abstr. 13:148, 1987). In the present study, the effects of C-Br were investigated using the intact cultured cell system DDT_1-MF_2. Competitive binding studies using [^{125}I]iodocyanopindolol (ICYP) in the presence of 100 µM Gpp(NH)p showed that C-Br was 16 times more potent than (-)isoproterenol (iso). Measurements of cAMP accumulation in intact cells revealed that C-Br is 9 times more potent than iso, but equally efficacious. A time course of cAMP accumulation revealed that both iso and C-Br induced a cAMP peak level at 3 min followed by a similar decline, which nears basal levels by 60 min. Addition of propranolol at 3 min resulted in a rapid drop of cAMP to basal levels in the iso-induced system, but had no effect on the C-Br induced one. A time course of receptor loss with 10 µM iso or 1 µM C-Br treatment of intact cells was measured with [^{3}H]CGP-12177. Both iso and C-Br induce a time-dependent loss of receptors as measured on the cell surface. Cells assayed 24 hr later revealed that binding sites from iso treated cells had nearly returned to control levels, whereas the C-Br treated cells still showed an 80% loss of sites.

These results imply that C-Br, like iso, causes a desensitization in intact cells. Treatment of cells with iso for 60 min causes a redistribution of receptors, while treatment with C-Br results in loss of binding sites that has not reversed by 24 hr.

523.8

REGULATION OF SUBTYPES OF CENTRAL BETA ADRENOCEPTORS (BARs) AFTER CHRONIC INTRACEREBROVENTRICULAR INFUSION OF ISOPROTERENOL IN RATS **C. Gambarana*, G.A. Ordway*, & A.Frazer (Spon., D. Brunswick). V.A. Med. Ctr. & Univ. of Pa. Sch. of Med., Phila., PA 19104.**

Isoproterenol (ISO) causes a time-dependent reduction in the density of either beta-1 or beta-2 receptors when added to tissue preparations in vitro. To determine whether a similar phenomenon would occur in vivo with brain BARs, ISO was infused into the lateral ventricle of rats (300g) for 7 days at doses of either 5 ug or 15 ug/hr. Control rats received infusions of 0.9% NaCl. These infusions were done in rats treated at birth with either 6-hydroxydopamine (6-OHDA) or saline (sham-lesioned). Subtypes of BARs were measured in 23 regions by quantitative autoradiography (Proc. Natl. Acad. Sci. 81:1585, 1984). Neonatal treatment with 6-OHDA caused a significant increase of beta-1 receptors in 16 regions and a significant elevation of beta-2 receptors in 14 areas. In sham-lesioned rats ISO reduced significantly the binding of ^{125}I-Iodopindolol (IPIN) to beta-2 receptors in more regions (16) than the binding of the ligand to beta-1 receptors (2 regions). A similar result occured in the 6-OHDA treated rats as ISO reduced binding of the ligand to beta-2 receptors in 16 areas and to beta-1 receptors in 8 regions. The magnitude of the reduction that ISO caused in beta-2 receptors was greater than the reduction in beta-1 receptors in sham-lesioned rats and this tended to occur also in 6-OHDA lesioned rats. Even in rats lesioned with 6-OHDA, chronic infusion of ISO has a greater effect on the density of central beta-2 than on beta-1 receptors. **(Supported by Research Funds from the VA and USPHS grant MH29094).**

DMI TREATMENT DOES NOT DECREASE NE STIMULATED ADENYLATE CYCLASE ACTIVITY IN RAT CORTICAL SLICES FROM LONG-TERM NE DEPLETED ANIMALS. M.W. Dudley and B. Baron. Merrell Dow Research Institute, Cincinnati, OH 45215

β-Receptor (β-rec) density in cortical membranes and cAMP production in cortical slices were measured 35 days after treatment with xylamine (XYL). XYL (20 mg/kg) produced a sustained selective ≈50% decrease in cortical NE, DHPG and MHPG. Presynaptic markers indicated no loss of neuronal integrity or number. Dose-response curves with the non-selective agonist NE on cAMP formation showed the loss of NE antagonized the normal desipramine (DMI) induced (10 mg/kg, days 21-34) decrease in maximum response. The inclusion of prazosin (1 µM) or phentolamine (5 µM) in the NE dose-response study in these same tissues resulted in the expected decrease in maximal cAMP levels. Neither prazosin nor phentolamine had an effect on the NE dose response in control or the NE-depleted animals. The loss of NE did not affect the number or the selective agonist affinity for α_1- or α_2-receptors. The loss of NE did not effect basal β-rec number or the dose response to stimulation of cAMP formation by the selective β-agonist isoproterenol (ISO). DMI significantly decreased β-rec number and the maximum response to ISO on cAMP formation in control and NE-depleted animals. Recently published data has shown that central α-receptors can modulate β-rec adenylate cyclase activity. A chronic NE deficit may effect the coupling of α-receptors to their second messenger systems which may be important in the postsynaptic effect of antidepressant treatment.

523.10

ONTOGENY AND CHRONIC ANTIDEPRESSANT REGULATION OF β_1- AND β_2-ADRENERGIC RECEPTOR MESSENGER RNA IN RAT BRAIN. R.S. Duman and J.F. Tallman, Depts. of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06508.

Previous studies have characterized the ontogeny and chronic antidepressant regulation of ß-adrenergic receptors (βAR) by ligand binding analysis. However, little is known about βAR regulation at the level of gene transcription and translation. In the present study we examine mRNA levels for both the β_1AR and β_2AR subtypes in rat brain by hybridization blot analysis using cDNA clones specific for each adrenergic receptor subtype.

During early postnatal development (days 1-7) the density of βAR binding sites is very low (< 25% of adult) but then increases to adult levels by day 16. β_1AR and β_2AR mRNA levels exhibit a similar pattern of development except that β_1AR mRNA is expressed at relatively higher levels than β_2AR mRNA during the early time points. These results suggest that βAR receptor binding sites during days 1-7 are primarily of the β_1AR subtype.

Chronic imipramine administration (2-3 weeks) results in a decrease in the number of β_1AR but not β_2AR binding sites. Preliminary studies indicate that chronic imipramine treatment influences mRNA levels of both βAR subtypes; in contrast to the decrease or no change in binding sites, both β_1AR and β_2AR mRNA levels are increased by this treatment. The results suggest that chronic antidepressant treatment increases the synthesis and turnover of βAR binding sites or blocks the translation and expression of functional receptor binding proteins.

523.11

ELECTROCONVULSIVE SHOCK (ECS) DECREASES BETA-ADRENERGIC RECEPTOR BINDING DESPITE SEROTONIN LESIONS. C.A. Stockmeier and K.J. Kellar. Department of Psychiatry, Case Western Reserve University School of Medicine, Cleveland, OH 44106; Department of Pharmacology, Georgetown University School of Medicine, Washington, DC 20007.

Repeated daily administration of ECS causes a decrease in the number of antagonist-labelled beta-adrenergic receptors in rat cortex (Bergstrom and Kellar, 1979). It has been proposed that serotonin axons play a critical role in this process (Nimgaonkar et al., 1985). We examined the influence of 10 days of repeated daily ECS on [^{3}H]dihydroalprenolol binding sites for which isoproterenol has high and low affinity in control rats and in rats which received an injection of 5,7-dihydroxytryptamine (5,7-DHT) into the dorsal and median raphe nuclei. In competition experiments in cortex, ECS decreased the number of high-affinity binding sites, but did not alter the K_i of the high- or low-affinity binding sites or the number of low-affinity sites. Extensive lesions of serotonin neurons with 5,7-DHT resulted in a large increase in the number of low-affinity binding sites. Repeated ECS still resulted in a decrease in the number of high-affinity binding sites in rats with lesions of serotonin neurons, and the decrease was similar to that seen in rats without lesions. Hence, ECS does not require intact serotonin neurons to decrease the number of high-affinity beta-adrenergic receptors in rat cortex. Supported by NS24523, MH41819 and MH41684.

PROLONGED ELECTROSHOCK CHANGES THE COUPLING BETWEEN α- AND β-ADRENOCEPTORS IN RAT BRAIN. A. Pilc, I. Nalepa*, J. Vetulani* and S.J. Enna[1]. Institute of Pharmacology, Polish Academy of Sciences, Krakow, Poland and [1]Nova Pharmaceutical Corp., Baltimore, Md. 21224.

The cyclic AMP response to β-adrenergic agonists is greatly enhanced by α-adrenergic stimulants suggesting a functional interrelationship between these receptor systems in brain. Chronic administration of antidepressants diminishes this receptor interaction, indicating an association with the response to this drug class (Pilc, A. and Enna, S.J., Life Sciences 37: 1183, 1985). The present study was undertaken to examine whether electroshock, the most efficacious antidepressant therapy, modifies this coupling as well. For the study, rats were exposed to electroshock once daily for 7 consecutive days after which cyclic AMP and inositol phosphate (IP) accumulation were examined in rat brain cerebral cortical slices using prelabeling techniques. Whereas electroshock treatment had no effect on isoproterenol-stimulated second messenger production or on norepinephrine-stimulated IP accumulation, it significantly reduced the cyclic AMP response to norepinephrine alone and to isoproterenol in the presence of 6-fluoronorepinephrine, an α-adrenoceptor agonist. The results suggest that antidepressants modify the functional coupling between β-adrenoceptors and an α-adrenergic site distinct from that associated with inositol phosphate production.

523.13

HUMAN LYMPHOCYTE BETA ADRENERGIC RECEPTOR DENSITY - POSSIBLE RELATIONSHIP TO PANIC-AGORAPHOBIC SYMPTOMS IN DEPRESSED WOMEN.

J. Magliozzi, D.W. Gietzen, R. Maddock* and A. Doran*. Dept. Psychiatry Sch. Med. Univ. Calif., Davis, CA 95616

To investigate the relationship between lymphocyte β-adrenergic receptor density (BMAX), binding affinity (KD) and psychopathology in depressed outpatients, both were utilized in a multivariate regression model to predict pretreatment scores of the Hamilton Depression Rating Scale (HAM 17), Beck Depression Inventory (BECK), Sheehan Patient Rated Anxiety Scale (SPRAS), State-Trait Anxiety Inventories (X1 and X2) and Chambliss' Accompanied (MOBACC) and Unaccompanied (MOBAL) Mobility Inventories. Forty-six outpatients with major depression, unipolar type (DSM-III-R), (20 females, 26 males) participated. Binding was performed on partially purified lymphocyte membranes using the antagonist ligand 125[I]-iodocyanopindolol (ICYP).

In female patients, BMAX negatively associated with scores on both Mobility Inventories (MOBAL: b'=-0.722; p=0.043; MOBACC: b'=-0.913; p=0.002; Lambda=0.181; p<0.005), but was of no predictive value towards the other measures. In males, neither BMAX nor KD predicted scale scores. These results provide preliminary evidence of an assocation between lowered lymphocyte β-receptor BMAX and severity of panic- agoraphobic symptoms in female depressed outpatients.

INTRACEREBRAL ADMINISTRATION OF ADENOSINE TO THE MEDIAL PREOPTIC AREA ENHANCES SLEEP IN RATS.

S.R. Ticho*, R.M. Virus and M. Radulovacki. Dept. of Pharmacology, University of Illinois College of Medicine, Chicago, IL 60612.

To assess the role of adenosine in the medial preoptic area in the sleep-wake cycle of the rat, we have intracerebrally administered adenosine at doses of 5, 25 and 50 nmoles. All doses significantly increased total sleep by 27%, 38% and 28%, respectively, during the 6 hr polygraphic recording period. Analysis of the various sleep states revealed that the enhancement in total sleep was due to a proportional increase in SWS_1 ($p<0.01$), SWS_2 ($p<0.01$) and REM ($p<0.01$) sleep. In addition, doses of 5 and 25 nmoles significantly decreased sleep latencies for all three sleep stages ($p<0.01$). These observations support the hypothesis that adenosine in the medial preoptic area may be involved in the regulation of sleep in rats. Supported by FED-AFOSR contract 85-0349 to MR.

CHARACTERISTICS OF ADENOSINE A1 RECEPTORS AND ADENOSINE UPTAKE SITES IN THE BRAIN OF NARCOLEPTIC DOGS.

M.Hawkins*, S.O'Connor, E.H.Chen*, S.S.Bowersox, W.C.Dement and M.Radulovacki. Depts. Pharmacology and Epidemiology-Biometry Program, Univ. IL. Coll. Med., Chicago, IL 60612 and Dept. Psychiatry, Stanford Univ. Sch. Med., Stanford, CA 94305.

In order to assess the role of the adenosinergic system in narcolepsy we have examined [^{3}H]R-PIA binding to adenosine (ADO) A_1 receptors and [^{3}H]NBI binding to ADO uptake sites in cerebral cortical membranes isolated from 5 normal and 5 narcoleptic canine brains. Scatchard analysis of [^{3}H]R-PIA binding in sigmoid and coronal gyrus membranes isolated from normal and narcoleptic dogs revealed a single class of high affinity A_1 receptor sites. Our preliminary data also suggest a trend for A_1 receptor upregulation in both cortical gyri of narcoleptic dogs. This is of interest since ADO A_1 receptor upregulation has been found following REM sleep deprivation in the rat brain (Yanik et al., Br. Res., 402:362,1987). Supported by FED-AFOSR-85-0349 to M.R. and NIH NS-19572 to W.C.D.

LOCALIZATION OF A D SLEEP INDUCTION SITE WITH SHORT LATENCY BY MICROINJECTION OF CARBACHOL IN A HEAD-RESTRAINED CAT.

K. Yamamoto,* A. Mamelak,* J. Quattrochi and J.A. Hobson. Laboratory of Neurophysiology, Harvard Medical School, Boston, MA 02115.

In an attempt to identify a neuroanatomical region which can be chemically stimulated to induce D sleep with very short latency, four cats were placed in a chronic stereotaxic apparatus and microinjected with carbachol (4ug/250nl) using a movable microinjector assembly (Yamamoto et al. 1988). The time from injection until the first D epoch was scored and correlated with injection site. Our results indicate that shortest latencies were found when carbachol was injected in the rostral extent of the anterodorsal pons, a region contiguous with nucleus cuneiformis, central gray, and mesencephalic tegmentum. A map of latency vs. injection coordinate indicates this D induction site is highly localized, since injections greater than 0.5 mm away from this site yield significantly longer (>8 min.) latencies. These results suggest that this region represents a near optimal intersection of multiple neuronal networks involved in D-sleep generation, such that many networks are simultaneously activated by the diffusion of carbachol. Supported by MH 13923.

EFFECTS OF LY53857, A SELECTIVE 5HT-2 ANTAGONIST ON SLEEP IN THE RAT.

R.H. Pastel. Physiology & Behavior Branch, Dept Medical Neuroscience, WRAIR, Washington, DC 20307.

Recently, we have studied the effects of 3 5HT-2 antagonists (Ritanserin, ICI 169,369 & ICI 170,809) on sleep in the rat (1,2). All three suppressed REM and increased REM latency. Neither ICI compound had an effect on NREM, but Ritanserin disrupted NREM. Others have reported an increase in NREM following ritanserin (3). The present study examines the effects of LY53857, another selective 5HT-2 antagonist. Four male S.D. rats were given saline (ip) and 24 hr later LY53857 (1 mg/kg, ip). Injections were at light onset and sleep was measured for 6 hr after injection. NREM sleep was increased in hr 2-4 after injection and REM was decreased from hr 2-5 following injection. NREM latency was not changed, but REM latency was increased. A decreased number of REM periods was also noted. The present study supports previous findings of REM suppression and increased REM latency following administration of 5HT-2 antagonists. However, the effects of 5HT-2 antagonists on NREM sleep are not consistent. We and others (3) have found an increase in NREM sleep, but in previous studies (1,2) we have found no change in or a disruption of NREM. The role of 5HT-2 receptors in sleep mechanisms is still not resolved.

INFECTIOUS CHALLENGE ALTERS SLEEP IN RABBITS. L.A. Toth and J.M. Krueger. Depts. Comparative Medicine and Physiology, Univ. Tennessee, Memphis, TN 38163.

We recently described altered sleep in rabbits after inoculation with Staph. aureus, a gram-positive bacteria (Neurosci. Abstr. 13: 261, 1987). We now report that sleep is also altered in rabbits inoculated with E. coli, a gram-negative bacteria, and Candida albicans, a fungal organism. E. coli increased both slow-wave sleep (SWS) and EEG slow-wave amplitudes (SWA) for the first 4 h postinoculation (PI). SWA were then decreased for the next 20 h. Similar effects occurred if heat-killed E. coli were injected. In contrast, Candida enhanced both SWS and SWA from 6-18 h PI and decreased these parameters from 24-48 h PI. Sleep was not altered after inoculation with heat-killed Candida. Both E. coli and Candida inhibited REM sleep. Sleep responses induced by Candida and Staph. inoculations are similar and may be related to immune stimulation of the host. The more rapid effects produced by E. coli may be related to the presence of heat-stable endotoxin in the cell wall of this organism. (Supported by ONR-N00014-85-K-0773 and NIH-NH25378)

RATES OF CEREBRAL GLUCOSE UTILIZATION IN THE RAT ARE HIGHER DURING REM THAN DURING SWS. P. Ramm. Dept. of Psychology, Brock University, St. Catharines, Ont. L2S 3A1

Rates of cerebral glucose utilization (CGU) are lower during SWS than during wakefulness (Ramm, P. and Frost, B.J., Brain Research, 365:112, 1986). We have investigated links between CGU and REM. Twenty rats received recording electrodes, and cannulae in the femoral artery and vein. Four days after surgery, the freely-moving animals were REM-deprived for 48 hr. They were then returned to their home cages, where they received intravenous injections of [14C]2-deoxyglucose ([14C]2-DG). During the next 45 min, EEG and EMG recordings were made and arterial blood samples were taken. The animals slept quite normally during the [14C]2-DG incubation period, and many showed elevated levels of REM. Following the incubation period, the brains were extracted, cut, and autoradiographs were prepared. Rates of regional cerebral glucose utilization were calculated by computer densitometry.

Higher rates of CGU were associated with high levels of REM sleep (r_{xy} = 0.64, $p < .05$). Lower rates of CGU were associated with high levels of SWS (r_{xy} = -0.58, $p < .05$). As SWS and REM are differentially linked to fundamental life processes (metabolism), they may also be functionally different.

VIP-INDUCED REM SLEEP ENHANCES LEARNING IN PCPA PRE-TREATED RATS. O. Prospéro-García*, A. Jiménez-Anguiano*, F. Gil-Holguín*, S. Alvarez-Gallegos*, F. Bermúdez-Rattoni and R. Drucker-Colín. (SPON: J. Velázquez-Moctezuma). Depto. de Neurociencias, Instituto de Fisiología Celular, UNAM. México.

REM sleep has been involved in learning processes. Since it has been shown that VIP has REM sleep-inducing properties in rats and cats, we decided to test the effects of VIP on a learning task (passive avoidance) in parachlorophenylalanine (PCPA) pre-treated rats. In this study, we used male Wistar rats (180-210 g). They were implanted for standard sleep-wake cycle recordings. Additionally, a stainless steel cannula (22 gauge) was implanted into the IV ventricle. Rats were treated with 2 i.p. injections of PCPA, 24 h. apart. Twenty-four hours after the 2nd injection of PCPA, rats were placed in a step-through apparatus to train them. Immediately following acquisition, the rats received an intraventricular injection of either saline (5 ul) or VIP (200 ng). After this treatment, rats were recorded for 24 hrs. Upon completion of the recording period, a retention test was performed. It was found that VIP significantly increased total time of REM sleep as compared to saline (54.82 $\pm$ 8.78 min vs 5.55 $\pm$ 1.46 min). Whereas passive avoidance tests showed that VIP group had a prolonged step-through latency with respect to saline group (342.5 $\pm$ 96.5 sec vs 28.5 $\pm$ 16.5 sec). These results strongly suggest that VIP-induced REM sleep enhances learning in rats.

524.8

MEDIAL RETICULAR FORMATION (MRF) UNIT ACTIVITY DURING AUDITORY STIMULATED REM SLEEP PERIODS. G. Arankowsky*, D.J. McGinty and R. Drucker-Colín. (SPON: Graciela Meza). Depto. de Neurociencias, Instituto de Fisiología Celular, UNAM, México, D.F.

It has been reported that auditory and somatic stimulation during rapid eye movement (REM) sleep is capable of increase REM sleep duration. The present work attempts to determine whether changes in MRF unit activity are related with this phenomenon. Two cats were implanted under pentobarbital anesthesia with electrodes for conventional polysomnographic recording. Also, two barrel microdrives each housing six microwires were targeted into the MRF. The sleep-waking cycle was recorded alternating control REM sleep periods with auditory stimulated ones (2 KHz, 90 dB, every 20 sec) and the units discharge rate was determined. 17 Cells were recorded; while 7 units (41%) were not responsive to stimulation; 10(58%) were responsive to the stimulus. 7 Of these did not show changes in their discharge rate when comparing control vs stimulated periods. Three cells increased the mean discharge rate during stimulated periods ($p < 0.05$):

Control (Sp./9 sec)	Stimulus (Sp./9 sec)
5.12 $\pm$ 1.5	8.51 $\pm$ 2.00
32.2 $\pm$ 15.6	39.3 $\pm$ 12.05
5.5 $\pm$ 2.0	9.0 $\pm$ 4.0

Our results suggest that REM sleep enhancement due to sensory stimulation could be mediated by an increase in the excitability levels of the MRF.

BIPHASIC ACTION OF IBOTENIC ACID INJECTION INTO MEDIALIS DORSALIS THALAMIC NUCLEUS ON SLEEP BEHAVIOR AND EEG PATTERNS IN CATS. G. Marini*, I. Gritti and M. Mancia (SPON: European Brain and Behavior Society) Ist. Fisiologia Umana II & *ITBA via Mangiagalli 32-Milano-Italy

The medialis dorsalis thalamic nucleus (MD) has recently been suggested to subserve a role in inducing and maintaining sleep on the basis of both clinical and experimental studies. In order to further investigate its role in the control of brain waves and behavioral sleep, very localized chemical lesions were placed into MD by means of cell-selective neurotoxin ibotenic acid (IBO) injections. Five adult cats were implanted for chronic sleep recordings, under general anesthesia, according to standard techniques. One week later, under ketalar anesthesia, a Hamilton microsyringe needle was guided stereotaxically into the intermediate-lateral portion of MD and IBO (50µg/µl, 1-2µl) was slowly injected. Polygraphic recordings were made in pre- and post-lesioned unrestrained animals. The location of the lesion was histologically confirmed. Immediately after the IBO microinjections a behavioral hypersomnia lasting 8-28 hrs was observed. Quantitative spectral analysis done in 2 animals during this state revealed a sudden significant ($p<0.05$) increase in the 6-12 Hz activity followed by a gradual reduction up to a transient suppression. After unilateral IBO MD-injections in one animal, a remarkably long-lasting asymmetry was observed in the spindle activity (reduced in the lesioned side). Subsequently, the spindle activity recovered and EEG desynchronization and hyposomnia (residual sleep was light and fragmented) gradually developed in all animals. These results fit in nicely with the hypothesis that subsets of MD neurones play a role in synchronizing electrocortical activity and support the excitotoxic hypothesis of glutamate analogues.

QUISQUALIC ACID LESIONS OF THE VENTROMEDIAL MEDULLARY RETICULAR FORMATION: EFFECTS UPON SLEEP-WAKEFULNESS STATES. C.J. Holmes, H.H. Webster*, S. Zikman* and B.E. Jones. Department of Neurology & Neurosurgery, Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada H3A 2B4.

Since the classical neurophysiological studies of Magoun and Rhines, it has been assumed that the motor inhibition occurring during paradoxical sleep (PS) depends upon neurons in the ventromedial medullary reticular formation (VMRF) which project to the spinal cord. To test this assumption, we have selectively destroyed neurons in this area with stereotaxic injections of quisqualic acid (90ug) in cats implanted with standard electrodes for EEG, EMG, PGO and EOG. The animals were recorded 24 hours per day one week prior to and one month subsequent to the lesion.

The daily time spent in waking, slow wave sleep and PS was not greatly altered, but neck muscle tonus was significantly increased in PS during the full month of recording following the lesions. This increased tone was associated with whole body movements, including vigorous movements of the limbs. Histological analysis of the tissue revealed extensive cell loss in the VMRF. These results support the contention that the cells of the ventromedial medullary reticular formation contribute to muscle atonia during paradoxical sleep in the cat. (Supported by MRC of Canada)

CHOLINERGIC NEURONS FROM THE DORSAL PONS PROJECT TO THE MEDIAL PONS. P.J. Shiromani, D.M. Armstrong, and J.C.Gillin. San Diego VAMC & Univ California, San Diego Dept Psychiatry & Neuroscience (DMA), La Jolla, CA,92161

Infusions of cholinergic agonists into the medial pons readily triggers REM sleep. However, since there are no cholinergic cells in the medial pons, a cholinergic input is required to depolarize the medial pontine neurons important for physiologic REM generation. We examined the cholinergic input to the medial pontine area.

Four cats were deeply anesthetized and stereotaxic microinjections of WGA-HRP (5%;0.1ul-0.05ul) were made into the medial pons. 48 hrs later the cats were administered Nembutal and perfused. 40 um thick sections were processed for HRP using TMB as the chromagen. The same sections were then placed in a polyclonal antibody to ChAT (provided by L. Hersh) which determined whether the HRP labelled neuron was cholinergic.

We observed numerous HRP- and ChAT-labelled cells scattered throughout the peribrachial region and lateral dorsal tegmental (LDT) region. Estimates based on gross examination of the area suggest that less than 20% of the cholinergic cells in the LDT and peribrachial region were double-labelled.

These results demonstrate a cholinergic input from the pedunculopontine region and we suggest that REM sleep occurs when acetylcholine from these neurons depolarizes the medial pontine cholinoceptive neurons.

EFFECTS OF TONE INTENSITY ON PGO WAVES. W.A.Ball*, W.K. Hunt*, R.J. Ross, and A.R. Morrison. Lab. of Anatomy, Sch. of Vet. Med., U. of Pa., Phila., PA 19104.

Tones elicit PGO waves in both slow wave sleep (SWS) and paradoxical sleep (PS); rapid habituation of the effects occurs in SWS, but less change is observed in PS (Ball, W.A. et al, Sleep Res., 17:1988). In the early trials, however, tones elicit PGO waves more readily during SWS than PS. We tested the effects of tone intensity on this initial difference.

Six cats were implanted with standard lateral geniculate, electroencephalogram, electrooculogram, and electromyogram electrodes. Tones (1000 Hz, 90 msec square wave) were presented as blocks of 5 different intensities (60, 70, 80, 90, and 100 dB), each block tested in up to 8 sessions in each state. FM recordings were made for off-line computer analysis.

In SWS tones elicited PGO waves more often than in PS ($p<.01$) at all intensities and tended to have shorter mean latencies to peak ($p<.04$, 83 vs.101 msec.). From 60 to 100 db, PGO waves elicited in PS and SWS became 1) more frequent ($p<.01$) 2) 17 and 42 % greater in amplitude in PS and SWS respectively ($p<.01$) and 3) reduced in latency (96 and 85 msec at 60 and 100 db, $p<.05$).

Thus, external stimuli are less likely to elicit PGO waves during PS. We speculate there may be sensory gating or ceiling effects in the activity of PGO generating sites. Supported by 1-RO1-MH42903-01 and F32-MH-09584-01.

SUPPRESSION OF MUSCLE TONE PRODUCED BY ELECTRICAL STIMULATION AT THE PONTO-MESENCEPHALIC JUNCTION. Y. Y. Lai and J. M. Siegel. Sepulveda VAMC, UCLA School of Medicine, Sepulveda CA 91343

Stimulation of the medial medulla and dorsolateral pons produce a suppression of muscle tone. These regions have been implicated in the loss of muscle tone in REM sleep and in cataplexy. In the present study, we report that stimulation of the dorsolateral portion of the reticular formation at the ponto-mesencephalic junction also produces bilateral inhibition of muscle tone. Studies were performed on 4 unanesthetized decerebrate cats. Trains of cathodal pulses (100 Hz, 0.2 ms, 10-100 μA) were delivered through stainless steel monopolar microelectrodes to the area between A2.0-P1.0, L 0-5.5, H+2.0 to H-9. Bilateral recordings were made from neck muscles (occipitoscapularis, splenius, and biventer cervicis). We found that stimulation between A2.0-A0.0, L3.0-5.0, H0 to -2.5 produced bilateral inhibition of muscle tone at very low stimulation intensity thresholds (15-50μA). This area corresponds to the lateral portion of the cholinergic pedunculopontine tegmental nucleus, and is just rostral to the pontine cholinoceptive region known to trigger atonia. Cell bodies or axons in this area may participate in generating the atonia of REM sleep and cataplexy, or may help regulate postural tone in waking.

524.14

RECEPTORS MEDIATING SUPPRESSION OF MUSCLE TONE PRODUCED BY GLUTAMATE IN DORSOLATERAL PONS AND MEDIAL MEDULLA. J. M. Siegel and Y. Y. Lai. Sepulveda VAMC, UCLA School of Medicine, Sepulveda CA 91343

We have previously reported that suppression of muscle tone can be produced from three brainstem sites implicated in REM sleep atonia. Acetylcholine [Ach] microinjected into the dorsolateral pons [DLP], or nucleus paramedianus of the medulla [NPM], and glutamate in DLP or nucleus magnocellularis of the medulla [NMC] produce atonia in the decerebrate cat. Gamma-D-glutamylglycine [DGG], an NMDA and kainate receptor antagonist, blocked the glutamate-induced muscle inhibition in DLP and NMC. L-glutamic acid diethyl ester [GDEE], an NMDA and quisqualate receptor antagonist, blocked or attenuated the glutamate effect on muscle activity in both DLP and NMC. However, DL-2-amino-5-phosphonovaleric acid [APV], a highly specific NMDA receptor blocker, did not block the glutamate-induced atonia in DLP or NMC. Both Ach and its agonist, carbachol, induced muscle atonia in DLP and NPM but not in NMC. Microinjected atropine blocked the Ach effect on muscle activity at both sites. Agonist studies confirmed the antagonist findings. NMDA injection into either DLP or NMC produced excitatory effects on muscle activity. In contrast, kainic and quisqualic acid induced bilateral inhibition. We conclude that non-NMDA and muscarinic receptors mediate DLP atonia. Non-NMDA receptors mediate NMC atonia. Muscarinic receptors mediate NPM atonia.

524.15

CHANGE IN PONTINE UNIT RESPONSE TO AUDITORY STIMULI AFTER REM SLEEP DEPRIVATION. B. N. Mallick*, H. Fahringer, M. F. Wu and J. M. Siegel (SPON: R. Szymusiak). Sepulveda VAMC, Sepulveda CA 91343, UCLA Sch. Med., Los Angeles CA

While the behavioral changes resulting from REM sleep deprivation have been extensively analyzed, the neuronal substrates of these changes are unknown. In the present study, we have taken advantage of the extraordinary stability of the microwire recording technique to analyze changes in unit activity during REM deprivation. We have studied 8 cells in the dorso-lateral pontine reticular formation, an area critical for REM sleep control. Units were recorded continuously for at least 40 hours during baseline, deprivation and recovery periods. Post-stimulus histograms of response to 102-105 db tones, were computed. During predeprivation periods, stimuli produced an inhibition of discharge with a latency of 20-40 msec. REM deprivation produced a reduction in the evoked inhibition ($p<0.002$, F test). Responses returned to baseline levels after 20 hours of recovery sleep. Discharge rate did not change during deprivation. Clonidine administration produced a similar reduction in evoked auditory inhibition. Recent studies have shown that REM sleep deprivation produces downregulation of norepinephrine receptors. This downregulation/desensitization is hypothesized to mediate the present effect and may underlie many of the behavioral and physiological effects of REM deprivation.

524.16

LATERAL GENICULATE SPIKES, MUSCLE ATONIA AND STARTLE RESPONSE ELICITED BY AUDITORY STIMULI AS A FUNCTION OF STIMULUS PARAMETERS AND AROUSAL STATE. M.-F. Wu, B. N. Mallick* and J. M. Siegel. Neurobiology Res., VAMC, Sepulveda, CA 91343 and UCLA Med. Ctr, Los Angeles, CA 90024.

The occurrence of ponto-geniculo-occipital (PGO) waves has been associated with phasic suppression of both muscle tone during non-REM sleep and monosynaptic reflexes during REM sleep. However, muscle excitation and reflex enhancement in association with PGO waves have also been noted. In the present study, we have systematically examined the effect of auditory stimuli on PGO and EMG as a function of stimulus intensity and arousal state. Clicks from 65 to 115 dB were presented. EMG responses were averaged and peak-to-peak LGN PGO amplitudes measured. We found that stimuli >95 dB produce temporally separated EMG suppression and excitation, with the excitatory response maximal in waking, while the inhibitory response was maximal in the pre-REM period. <75 dB stimuli mainly produced muscle suppression. PGO waves could be elicited with both low and high intensity stimuli, with the amplitude proportional to intensity. PGOs evoked by equal intensity stimuli were of progressively larger amplitudes in waking, non-REM, REM and pre-REM. These findings demonstrate that the amplitude of PGO waves and the direction and amplitude of EMG responses to auditory stimuli, are a function of both stimulus intensity and behavioral state.

524.17

EFFECT OF REM SLEEP DEPRIVATION IN THE DEPTH PERCEPTION ON THE VISUAL CLIFF IN RATS OF 30 AND 60 DAYS. Cintra, L., Díaz-Cintra, S., Labastida, P*., Galván, A*. and Ortega A*. Dept. of Physiology Inst. Inv. Biomédicas, UNAM, México, City, C.P. 04510.

This study was performed to know the effect that REM sleep deprivation (RSD) by the platform method, produces in the depth perception on the visual cliff apparatus in rats of 30 and 60 days. For the visual cliff procedure, rats were REM sleep deprived by 48h and at the same time two trials of 3 min each were performed at 12h intervals; as well as in the recovery day. Vigilance states of animals implanted in the occipital cortex and neck muscles, were EEG recorded during 24h of control day and during the recovery day after 48h of RSD. No significant differences were found at 30 days between sleep deprived (SD) rats and control (C) rats however, the SD rats at 60 days showed preferences for the deep side (DS). When we compared each group by age, was clear that SD rats of 30 days preferred the shallow side (SS) and 60 days animals the DS; C rats showed no differences. REM sleep presented a significant increment on both ages during the recovery day in the 12h rest phase and slow wave sleep, increased significantly during activity phase at 30 days, and REM sleep at 60 days; 24h analysis revealed a significant decrease in waking in both ages and significant increase in REM at 60 days. These results agree with the hypothesis that 48h of RSD, affects during this period the visual depth perception in rats, due to alterations in the visual and motor systems.

524.18

RESPIRATORY DISTURBANCE INDEX CHANGES WITH AN ANTERIOR MANDIBULAR POSITIONING DEVICE FOR OBSTRUCTIVE SLEEP APNEA. G.T. Clark, D. Arand* and E. Chung* (SPON: M.C. Carter). UCLA Dental Research Inst. & Sleep Disorders Clinic, Neuropsychiatric Inst., Los Angeles, CA 90024.

Several case reports have indicated that dental devices have a potential effect in the reduction of obstructive sleep apnea (OSA) problems. This study utilized an anterior mandibular positioning appliance in OSA patients and evaluated the changes in their respiratory disturbance index (RDI). The RDI is calculated by dividing the total sleep time into the total number of oxygen desaturations. The amount of movement induced by the appliance was 60-80% of the mandible's maximum protrusive distance (5-7mm) measured from maximum intercuspation. The RDI levels were determined during all night polysomnographic studies. To date, 5 diagnosed OSA subjects have completed all phases of the protocol which involved a pre-appliance sleep study, a 1-month post-appliance sleep study, and a 6-month post-appliance clinical examination. All 5 subjects showed a clear decrease and the mean and s.d. for the RDI level pre-appliance was 28.3 ± 7.3 and 4.24 ± 1.93 post-appliance. The 6-month clinical examination data clearly indicates no adverse change in jaw function (range of motion, joint sounds or muscle tenderness) and patients continue to be fully compliant with the prescribed all night use of the appliance.

524.19

SLEEP-ONSET CRITERIA IN THE DETERMINATION OF EXCESSIVE DAYTIME SOMNOLENCE. C. P. Browman. Sleep Disorders Center, Humana Hospital-Audubon, Louisville, KY 40217.

Sleep onset on the multiple sleep latency test (MSLT) was determined using a single epoch of stage 1, three consecutive epochs of stage 1, and a single epoch of stage 2 or REM sleep for 21 patients (mean age 38.0 yr) with narcolepsy and 21 patients (mean age 38.0 yr) with obstructive sleep apnea (mean apnea index of 64.3). Five MSLT procedures were from 10:00 to 18:00. The resulting polysomnogram was scored in 30 sec epochs. For patients with narcolepsy, mean sleep latency in min using one epoch of stage 1 was 3.07±0.35, using three epochs of stage 1 was 3.37±0.37, and one epoch of stage 2 or REM was 5.97±0.55 (p<.001). The respective values for patients with sleep apnea were 3.61±0.54, 4.36±0.61, and 8.46±0.85 (p<.001). Measures of sleep latency were interrelated for patients with narcolepsy (r=.969 to .701, p<.001) and for patients with sleep apnea (r=.894 to .751, p<.001). The obstructive apnea prevented or delayed sleep onset 18.14% of trials using one epoch of stage 1, 24.76% using three epochs of stage 1, and 27.62% using one epoch of stage 2 or REM criteria for patients with sleep apnea. A single epoch of any stage of sleep is an appropriate measure of sleep latency for narcoleptics although a modified scoring system should be developed for sleep apneics and other patients to account for the pathology-related interruptions.

EEG: CHAOS AND QUASIPERIODICITY. H. Stowell. ERBP Lab., 120 Nature Creek, Milledgeville GA 31061.

The mass-action of cooperating/competing neural networks interests artificial-intelligence (AI) and neurocomputing engineers (Denker, J.S., AIP Conf. Proc. 151. AIP, New York 1986). The mass-action of one mammalian sensory nucleus, the olfactory bulb, now approaches intelligibility in terms of nonlinear dynamics (Freeman, W.J. et al., Behav. Neurosci., 100: 753; 101: 393, 766, 1986-7). Is it useful to examine human EEG in similar terms (Stowell, H. Int. J. Neurosci., 32: 861; 34: 117; 35: 111, 1987)? Though it remains impossible to discard the hypothesis that extracellular slow waves of the brain reflect noise irrelevant to information processing, some progress appears in frequency analysis of time-domain event related brain potentials (ERBP), showing that: (i) Synchronization of "averaged evoked EP" reflects a transient perturbation of ongoing EEG, constraining its possible phases (Sayers, B.McA. et al., Nature, 274: 481, 1974); (ii) Similar phase order occurs in the 300 ms before a familiar stimulus and, under specifiable conditions of subjective time-frame, at the expected times of absent pattern elements during subjective discrimination of acoustic rhythms. Progress in testing the hypothesis of a functional EEG will need powerful algorithms with massive data processing (Gevins, A.S. et al., Science, 235: 580, 1987) and support from AI (Cohen, M.S. & Julian, W.H. Neural Networks with a Hopf Bifurcation: Slowly Modulated Waves. Personal communic. from CRL, Las Cruces NM, 1987).

EEG FACTOR SCANS. R. Gussio*, K.L. Marquis*, G.G. Buterbaugh and G.A. Young. Department of Pharmacology and Toxicology, University of Maryland School of Pharmacy, Baltimore, MD 21201.

Attempts to quantify EEG are typically accomplished by period amplitude analysis, Fourier analysis, etc. Data from these analytical techniques are usually subjected to univariate statistical evaluations which are limited by their inability to statistically control multidimensional data sets. Therefore, we combined the powerful features of single case design, derived power spectral parameters, factor analysis and computerized three dimensional graphics in the development of EEG factor scans. Frontal-parietal cortical EEG recordings were collected during sleep-awake cycles, drug-induced states and status epilepticus in rats. Quantitatively and qualitatively unique EEG factor scan patterns were generated from each of these CNS states. As an example, the relatively selective mu and kappa agonists morphine and ethylketocyclazocine were distinquished by the patterned loadings of several factors which are independent from the relative distribution of power spectral amplitudes within descrete frequency bands. These results illustrate the sensitivity of this novel assay. We predict that EEG factor scans will have utility in the classification of disparate groups of CNS active agents and pathological states. AGGREGATE CULTURES OF RAT FETAL DOPAMINE (DA) NEURONS PRODUCE BEHAVIORAL EFFECTS IN PARKINSONIAN RATS. J.F. Loring, R.E. Strecker, B. Boss, R. Miao*. Hana Biologics, 850 Marina Village Parkway, Alameda, CA 94501

Neural grafts of freshly dissected DA-rich fetal ventral mesencephalon (VM) restore function in rats made parkinsonian by 6-OHDA treatment. If graft therapy for Parkinson's disease is to be successful, it may become important to maintain the tissue in culture before grafting. However, it is likely that neurons that grow processes onto planar substrata suffer damage during dissociation required to remove them from culture dishes for grafting. To avoid this problem, we have used aggregate tissue culture methods, which allow cultured DA-rich neuronal tissue to be grafted after only one initial dissociation procedure. Donor tissue was dissected from the VM of 13 day old rat fetuses and prepared for aggregate culturing by a modification of the method of Hemmendinger et al. (PNAS 78:1264-1268; 1981). Cells were cultured 9 days in rotating flasks. The cells formed many small balls (175-300 um dia.) each estimated to contain over 5,000 cells. Forty such balls were injected via a 22 G needle into the DA-denervated striata of host parkinsonian rats. Six weeks post grafting 7 of 11 rats exhibited behavioral signs of a functional graft, as shown by both reduction in amphetamine-induced ipsilateral rotation and increase in contralateral rotations. One rat sacrificed at 3 weeks post grafting had over 400 surviving dopaminergic neurons, judged by tyrosine hydroxylase (TH) immunohistochemistry. TH-positive fibers extended from the transplant site into the host striatum. These results suggest that aggregate culture methods are a promising means to maintain and deliver fetal neurons for graft therapy.

ENCAPSULATED EMBRYONIC MOUSE MESENCEPHALIC TRANSPLANTS ALLEVIATE EXPERIMENTAL PARKINSONISM IN RATS. P.Aebischer*, S.R. Winn*, D. Ross (SPON: J. Parmelee). Artificial Organ Laboratory, Brown University, Providence, RI 02912.

Embryonic mesencephalic xenotransplants alleviate experimental parkinsonism, however they are rejected over time. We are studying the ability of cografts of mesencephalon and striatum immunoprotected by a permselective membrane to affect experimental parkinsonism. A polymeric membrane with a molecular weight cut-off of 50,000 daltons provides immunoprotection by allowing nutrients, growth factors and neurotransmitters to freely diffuse through the membrane while preventing the invasion of immunoglobulins and cells. Polyvinyl chloride acrylic copolymer permselective tubes, ID 600 µm, were loaded with E14 mouse cografts and capped with a compatible polymer glue. The polymer capsules were then placed stereotaxically in the striatum of 6-hydroxydopamine lesioned rats. Rats implanted with empty polymer capsules served as controls. Motor asymmetry was assessed under amphetamine (5 mg/kg) stress.Cohorts of 6 animals were observed for at least 8 weeks. A significant decrease in rotational behavior was observed in 5 of the 6 encapsulated cografts whereas no decrease was observed with empty polymer capsules. Upon retrieval intact neuron-like cells were observed within the polymer capsules up to 3 months of implantation. Tissue reaction to the polymer capsule was minimal. These results indicate that synaptic contact is not required in order to reduce the symptomatology of experimental parkinsonism. Whether the effects observed are due to dopamine release or host regeneration induced by growth factors released from the transplants is not known.

525.3

INTRASTRIATAL IMPLANTATION OF AN ENCAPSULATED L-DOPA RELEASING POLYMER REVERSES EXPERIMENTAL PARKINSONISM IN RATS. S.R. Winn *, A.N. Salessiotis *, P.Aebischer * (SPON: N. Knuckey). Artificial Organ Laboratory, Brown University, Providence RI 02912.

Parkinson's disease is characterized by a deficit of dopamine within the striatum. We are investigating the feasibility of implanting a polymeric substrate which releases L-DOPA to reverse experimental parkinsonism. Films of poly[ethylene vinyl acetate] containing 10% by weight of L-DOPA were cast, shaped into cylinders, and encapsulated within permselective acrylic copolymer tubes with a nominal molecular weight cut-off of 50,000 daltons. The tubes were sealed with a compatible polymer glue and implanted stereotaxically in the striatum of 6-hydroxydopamine lesioned rats. Cohorts of 3 animals received L-DOPA loaded capsules; controls received capsules loaded with substrate alone. Rotational behavior was observed under amphetamine challenge (5 mg/kg). Immediately following transplantation, animals with L-DOPA loaded capsules spontaneously rotated contralateral to the lesioned side. At 2 to 4 days post-transplantation, net rotational asymmetry under amphetamine stress was reduced 100% to that of pre-transplant rotational values. One week post-transplantation, rotational behavior in animals with the L-DOPA containing capsules returned to pre-transplant values. No changes in post-transplantation rotational asymmetry were observed in control animals. The present study shows that intrastriatal release of L-DOPA suspended in a hydrophobic polymer is able to reverse experimental parkinsonism in rats. Controlled release of neurotransmitters or macromolecules from a polymeric substrate may provide an alternative method of treatment for neurological disorders

525.4

XENOGRAFTS OF FETAL PIG DOPAMINE (DA) NEURONS SURVIVE AND FUNCTION IN BOTH CYCLOSPORIN A (CyA)-IMMUNOSUPPRESSED AND IMMUNODEFICIENT NUDE RATS. R.E. Strecker, T. Huffaker*, B.Boss, J.F. Loring, A. Morgan*, M. Spence*, A. Xuan*, and R. Miao*. Hana Biologics, 850 Marina Village Parkway, Alameda, CA 94501.

Fetal pig CNS is an attractive model system to use for the development of a graft therapy for Parkinson's disease since, relative to rats, the developmental time course of the pig more closely approximates that of the human embryo, and pig DA neurons can be expected to innervate a larger brain area than rat neurons. Longterm survival of CNS xenografts in rats has been shown to require immunosuppression with CyA, a time-consuming and expensive procedure. Hence, we tested whether fetal pig CNS grafts would survive in both nude rats and immunosuppressed normal rats. DA-rich cell suspensions of freshly dissected embryonic day 21 fetal pig ventral mesencephalon were grafted into the right striatum of 20 CyA-immunosuppressed and 8 nude rats. All rats had previously been made unilaterally parkinsonian with 6-OHDA. At 9 weeks post-grafting 15 of 20 CyA-treated rats exhibited behavioral effects of the grafting, as shown by a reduction of amphetamine-induced rotation, with complete reversal of rotation by 14-17 weeks. Cessation of CyA treatment resulted in behavioral signs of graft rejection within 4 to 9 weeks. Control grafted rats (N=9) showed no change in rotation. Large numbers of DA neurons (identified by tyrosine hydroxylase immunohistochemisry) were found in functional grafts. Grafted nude rats showed a similar reduction in amphetamine-induced rotation, which remained stable for at least 18 weeks, indicating that the nude rat model is a useful alternative to CyA injections in CNS-xenografting experiments.

525.5

DISPLACEMENT OF MPP^+ FROM ITS BINDING SITES AND INHIBITION OF MAO-A ACTIVITY BY DEBRISOQUIN AND SOME ANALOGUES IN MOUSE BRAIN. M.Del Zompo, S.Ruju*, R.Maggio*, M.P.Piccardi*, G.U.Corsini*. Dept. Neurosciences, Clin. Pharmacol., Univ. of Cagliari, Italy.

Self-administration of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) causes irreversible parkinsonian symptoms in man. It has been proposed that MPTP is effective by conversion via oxidation to an active metabolite, 1-methyl-4-phenyl-piridine (MPP^+). Several findings suggest that type B monoamine-oxidase (MAO-B) is responsible for the oxidation of MPTP to MPP^+. We have previously shown that ^3H-MPP^+ binds saturably and with high affinity to mouse brain membranes. Successively, an adrenergic neuron blocking agent, debrisoquin, was found to compete with ^3H-MPP^+ for its binding sites with a IC50 of 15± 2 uM. In order to better characterize this property, several analogues of debrisoquin have been tested. The relative structure required to inhibit MPP^+ binding sites has been evaluated.The derivative with a tiocarbamydic group at the position R4 is essential for the affinity for the ^3H-MPP^+ binding sites. Moreover these analogues have been tested to determine MAO inhibiting activity, being debrisoquin a potent intraneuronal MAO-A inhibitor. A correlation between these structure requirements for binding sites and MAO inhibition capacity has been evaluated.

EFFECTS OF MPTP ON THE FINE STRUCTURE OF NIGRAL NEURONS OF DOG: POSSIBLE EVIDENCE OF CALCIUM LOADING. V.O.F. Warrington*, S.C. Rapisardi and J.S. Wilson, Dept. Anatomy, Howard Univ., Washington, D.C., 20059.

For the last several years, we have been systematically studying the spatial and temporal evolution of degeneration induced by MPTP in the nigrostriatal system of dog. This is our first report of fine structural changes. Two dogs received a single injection of MPTP (3mg/kg; i.v.) and were sacrificed 1 and 4 days later. A third dog received an injection of saline and served as a control. The brains were stereotaxically blocked into 5 mm slabs, and cores of tissue were taken with a 18 guage needle from the medial pars compacta of the substantia nigra. The locations of cores were verified histologically using immunostaining for tyrosine hydroxylase. Cores were processed for conventional electron microscopy.

In the MPTP treated animals, major changes were seen in the rough endoplasmic reticulum (RER) and mitochondria. In single sections from the normal animal, the RER appeared as small rectangular stacks which occupied approximately 5.0% of the total area of the soma. The longest continuous membrane with bound ribosomes in each array averaged 0.0014 mm. In the one day survival animal, the RER appeared in very long, uninterrupted ribbon-like arrays (longest average length/array=0.014mm) which occupied approximately 18.3% of the total area of the soma. In the four day survival animal, the RER was disrupted and only small fragments of membrane bound ribosomes were observed.

Mitochondria demonstrated a tremendous swelling in the MPTP treated animals changing their average area from 8.2xE-8 in the normal animal to 1.6xE-7 and 6.2xE-7 in the 1 and 4 day survival animals, respectively. Although the mitochondrial matrix remained electron lucent, their cisternae were completely disrupted in the longer survival animal.

Similar mitochondrial changes have been reported in other pathological models in which the neurotoxic effects are thought to be the consequence of calcium overload such as kainic acid poisoning, cerebral ischemia and seizure. We have recently reported that incubation of mouse brain slices in calcium-free medium blocked MPTP's toxic effects (Wilson, Neurosci. Abst., 12:1309, 1986). These results provide further support that intracellular calcium accumulation may play an important role in MPTP's toxicity. NIH-MBRS 2S06-RR-08016-16.

MPTP PRODUCES A MOSAIC PATTERN OF TERMINAL DEGENERATION IN DOG:FURTHER EVIDENCE FOR SUBCOMPONENTS OF THE NIGROSTRIATAL SYSTEM.

B.H. Turner, J.S. Wilson and J.C. McKenzie*, Dept. Anat., Howard Univ., Washington, D.C. 20059.

We have previously reported that MPTP, a toxin specific to the dopaminergic nigrostriatal pathway, produced a mosaic-like pattern of terminal degeneration in the caudate nucleus (Cd) of dog (Brain Res. 423:329-332, 1987). The purpose of this study was to determine if this mosaic-like pattern corresponded to the striosome/matrix compartments as defined by acetylcholinesterase (AChE) staining. We found that in the normal dog both AChE and tyrosine hydroxylase (TH) histochemistry defined a matching mosaic organization of the Cd nucleus that was similar to that described in other species. A single injection of MPTP (3.0 mg/kg; i.v.) produced a mosaic pattern of terminal degeneration in the Cd nucleus which was most pronounced at 8 to 10 days survival. Comparing sections stained for terminal degeneration by the Fink-Heimer method with adjacent sections stained for AChE and TH revealed that heavy degeneration was limited to the matrix while only light degeneration was found in the striosome. At no survival times examined thus far (1-14 days) has heavy terminal degeneration been observed in the striosome compartment. This may be because the dopaminergic projection to the striosome 1) may have a higher toxic threshold to MPTP, 2) may be less dense or 3) may be more difficult to stain with silver degeneration methods. These data provide further evidence that the nigrostriatal system is composed of parallel projections to the striosome and matrix. Supported in part by NIH-MBRS Grant 2S06 RR 08016-16.

MPTP CAUSES AN ACUTE DECREASE IN DOPAMINE (DA) LEVELS IN MOUSE BRAIN SLICES. J.A. Wilson, T.J. Doyle*, J.G. Gleason*, & Y.S. Lau. Depts. of Physiology & Pharmacology, Creighton Univ. School of Medicine, Omaha, NE 68178.

MPTP causes a Parkinson's disease like decrease in DA levels in man and certain other animals. It can selectively kill neurons originating in the substantia nigra, but in some animals, recovery occurs indicating that the lesions were not permanent. The cause of this acute decrease in DA content by MPTP is not well known. Both MAO inhibitors (pargyline) and DA uptake inhibitors (GBR-12909) can prevent the toxic effects. We investigated the effects of MPTP on DA content in mouse brain slices. Comparison of control brain slices with MPTP treated brain slices shows that a 20 min. application of 300 μM MPTP causes a significant reduction in DA content. Treatment with either pargyline, GBR-12909, or low Ca^{++}-high Mg^{++} alone causes no change in DA content; however, co-application of these compounds with MPTP results in DA levels significantly lower than control levels and not different from the DA levels of slices treated only with MPTP. The MPTP induced decrease in DA content could be prevented by γ-hydroxybutyrate (a DA release inhibitor). We interpret these results to indicate that MPTP induced depletion of DA *in vitro* is not causally related to MPTP's ability to selectively lesion DA neurons.

THE NEUROPATHOLOGY OF 1-METHYL-4-PHENYL-1,2,3,6-TETRAHYDRO PYRIDINE: HOW IMPORTANT IS MITOCHONDRIAL DAMAGE?

J.D. Adams, Jr.* (SPON: C.G. Wong). School of Pharmacy, Univ.Southern Calif., Los Angeles, CA 90033.

1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) is a neurotoxin which destroys dopaminergic neurons in the mouse substantia nigra. In vitro evidence indicates that MPTP is a mitochondrial toxin which inhibits the electron transport chain. However, there is also a possibility that MPTP acts through the generation of oxygen radicals which are toxic to mitochondria as well as most other cell organelles. This study found that the primary lesion produced by MPTP was damage to astrocytes. Both the protoplasmic and fibrous astrocytes were affected. At the subcellular level, endoplasmic reticula were more affected than mitochondria at early time points. This study has demonstrated that MPTP is not exclusively a mitochondrial toxin. All animals were cared for in accordance with NIH guidelines. At no time during this study did animals suffer. This research was supported by NIH grant NS23515.

525.10

EFFECTS OF SELECTIVE D_1 AND D_2 RECEPTOR BLOCKADE ON LEVODOPA-INDUCED REGIONAL GLUCOSE UTILIZATION CHANGES.

J.M. Trugman, M.R. Johnson*, and G.F. Wooten. Dept. of Neurology, Univ. of Virginia, Charlottesville, VA 22908.

Following systemic L-dopa administration to rats with unilateral 6-hydroxydopamine substantia nigra lesions, regional cerebral glucose utilization (RCGU) increases 2-3 fold in the ipsilateral entopeduncular nucleus (EP) and substantia nigra pars reticulata (SN_r) and decreases in the ipsilateral lateral habenula (LHN) (Brain Res. 379:264). In this study we have examined the effects of selective D_1 and D_2 receptor blockade on dopa-induced RCGU changes. Lesioned rats were administered haloperidol 3 mg/kg i.v. or SCH 23390 1 mg/kg i.v. (to block D_2 or D_1 receptors, Brain Res. 415:90), followed 1 hour later by L-dopa methyl ester 25 mg/kg i.v. and [^{14}C]2-deoxyglucose 10 μCi/100 g i.v. SCH 23390 nearly completely blocked (90%) the dopa-induced RCGU increase in the EP and SN_r. Haloperidol also effectively attenuated the RCGU increase by 70%. Neither drug blocked the effects of dopa on RCGU in the LHN. Both haloperidol and SCH 23390 markedly attenuated dopa-induced rotational behavior. We conclude that dopamine formed following decarboxylation of L-dopa stimulates both D_1 and D_2 receptors in vivo. While D_1 stimulation appears necessary, both D_1 and D_2 receptor occupancy contribute to the marked RCGU increase in EP and SN_r following L-dopa.

525.11

L-DOPA-INDUCED ROTATIONAL BEHAVIOUR IS DEPENDENT ON BOTH STRIATAL AND NIGRAL MECHANISMS.

G.S. Robertson and H.A. Robertson* Dept. of Pharmacology, Dalhousie University, Halifax, N.S. Canada B3H 4H7

Recent evidence suggests that the therapeutic action of L-Dopa may result in part from its ability to increase dopamine (DA) levels in the substantia nigra (SN). Moreover, when striatal (ST) levels decline, elevated DA levels in the SN may be able to maintain L-Dopa-induced circling behaviour by activating D_1 DA receptors in the SN. In order to test this possibility, the effects of L-Dopa on DA levels in the SN and intranigral administration of the D_1 antagonist SCH 23390 on rotation were determined in an animal model of Parkinson's disease. Rats unilaterally lesioned in the SN with 6-hydroxydopamine (6-OHDA) that turned at least 900 times (4 h period) after a carbidopa and L-Dopa (25 mg/kg, i.p. each) treatment were included in the study. One h after this treatment, DA was elevated in the striatum and the SN ipsilateral to the 6-OHDA lesion relative to vehicle controls. However, at 2 and 3 h the DA content in the ipsilateral ST was reduced by half while the levels in the 6-OHDA-lesioned-SN were the same as that at 1 hour. Interestingly, the infusion of 1.5μg SCH 23390 in 1μl of water into the lesioned SN 20 min prior to the L-Dopa injection was able to abolish rotation that would normally have occured 2 h after L-Dopa. These results suggest a time-dependent interplay between ST and SN in the regulation of L-Dopa-induced rotation. (Supported by the Parkinson's disease foundation of Canada and the MRC).

CROSS REACTIVITY OF BRAIN REACTIVE AUTOANTIBODIES. C.S. Madsen* and S.A. Hoffman (SPON: D. Glanzman). Dept. of Microbiology, Arizona State University, Tempe, AZ 85287.

Autoantibodies to brain membrane antigens have been demonstrated in patients and in murine models of SLE. We have been characterizing the nature and specificity of these autoantibodies to determine what role, if any, they play in the neuropsychiatric manifestations of autoimmune disease. In this study we used absorption, gel electrophoretic and immunoblot techniques to examine the degree to which these autoantibodies bind uniquely to brain membrane proteins as opposed to being cross reactive with membrane antigens of other organs. Aliquots of sera from mice were absorbed with dissociated cells of brain, liver, kidney and spleen from the animal the sera was collected. These, as well as unabsorbed sera, were reacted against integral brain membrane protein of a non-autoimmune mouse strain (Balb/C). The membrane proteins were isolated by detergent extraction and phase separation, separated on SDS polyacrylamide gels under non-dissociating conditions and transferred onto nitrocellulose membrane. Sera incubated with the blot and stained with anti-mouse Ig antibody indicate that autoantibodies to brain specific as well as cross reactive antigens can be found. The data and their implications for CNS involvement in autoimmune disease will be discussed.

A BRAIN SPECIFIC ANTIGEN IS RECOGNIZED BY ANTIBODIES IN THE SERUM OF PATIENTS DISPLAYING CNS-SLE. Daniel Rosenbluth*, D.S. Kohtz*, M. Horowitz*, H. Spiera* and S. Puszkin* Departments of Pathology & Medicine, Mount Sinai Sch. of Med., C.U.N.Y., New York, N.Y. 10029

An antibody was identified in the serum of a patient with Systemic Lupus Erythematosus (SLE) and CNS manifestations which specifically bound to a brain synaptic plasma membrane antigen. This antigen (Lp50), which appears to be an integral brain membrane glycoprotein, was not detected in extracts of cardiac and striated muscle, liver, kidney or pancreas. The serum was screened by Western blotting with LP50 purified from brain synaptic plasma membrane. Serum samples from 33 patients with connective tissue disorders including rheumatoid arthritis, polymyositis, scleroderma, vasculitis, and SLE were tested. Eleven of 21 patients who showed antibody reactivity with Lp50 had CNS disease manifested by depression, psychosis or seizures. The 12 remaining patients and 3 normal controls did not express anti-Lp50 antibodies, and had no apparent clinical CNS manifestation of disease. The physiological significance of the Lp50 antigen, and whether the antibody identified is an etiologic factor in, or just a marker of CNS disease is under further study.

IMMUNOCYTOCHEMICAL FEATURES OF ARGYROPHILIC GRAINS, A PATHOLOGICAL ALTERATION CHARACTERIZING AN ADULT ONSET DEMENTIA DIFFERENT FROM ALZHEIMER'S AND PICK'S DISEASE H.Braak, E.Braak, I.Grundke-Iqbal* and K.Iqbal*. Dept.Anat. J.W.Goethe Univ. D-6000 Frankfurt 70, FRG, *Inst.for Basic Res. in Dev. Disabilities, Staten Island, NY 10314, USA

Brains of ten individuals afflicted with adult onset of dementia showed no neurofibrillary tangles, neuritic plaques, neuropil threads or amyloid deposits but did show argyrophilic grains scattered throughout the neuropil of some cortical areas. The grains were best demonstrated with the Gallyas silver technique for neurofibrillary changes. Most of them were spindle-shaped and reached a length of up to 9 µm and a diameter of up to 3 µm. They were quite numerous in sector CA 1 of the Ammon's horn and in layer III (pre-ß) of the entorhinal cortex. In paraffin sections, they showed immunostaining with Alz-50 and antibodies raised against paired helical filaments and a bovine-tau protein (avidin-biotin-complex-technique). No immunostaining was achieved with antibodies raised against amyloid and ubiquitin.

Some sections were processed using the chromogen 4-chloro-1-naphthol. After documentation of the immunoreactive structures the chromogen was de-stained by ethanol. The sections were then re-stained according to the Gallyas technique and showed the same structures as in the previous immunostaining.

STRUCTURAL AND FUNCTIONAL STUDIES OF THE SCRAPIE-AGENT PROTEIN. G. Bablanian, D. Windsor, P.E. Bendheim and D. Bolton. Dept. of Molecular Biology, NYS Institute for Basic Research, Staten Island, NY 10314.

Scrapie is a neurodegenerative disease of animals and is a model for the human diseases kuru, Creutzfeldt-Jacob disease and Gerstmann-Straussler syndrome. The physical properties of the scrapie agent are not known, however, a 33-37 kDa modified host protein (Sp33-37) derived from infected hamster brain is essential for disease production in lab animals. A smaller form of this protein (PrP 27-30) is produced from Sp33-37 by partial proteolysis. Chemical modification of specific amino acid residues under mild reaction conditions was used to probe the protein structure and function. The modified protein was detected using polyacrylamide gel electrophoresis and immunoblotting with polyclonal antiserum to PrP 27-30 and a monoclonal antibody, 3F4. 3F4 did not bind to the scrapie protein after cleavage at methionine residues or following modification with diethyl pyrocarbonate (DEP). Modification with succinic anhydride, *N*-succinimidyl 3-(4-hydroxyphenyl)propionate and chloramine-T did not reduce 3F4 binding. Infectivity was reduced by modification of histidine with DEP and restored after reversal with hydroxylamine, implicating histidine as an active site residue. 3F4 binding was not restored by hydroxylamine treatment. Possible sites for the monoclonal epitope are suggested from the sequence predicted from cDNA clones of Sp33-37. NIH Grant NS23948

IMMUNOPEROXIDASE LOCALIZATION OF CYTOSKELETAL PROTEINS IN SPINAL CORD OF THE MOTOR NEURON DEGENERATION (Mnd) MOUSE. **J.E. Mazurkiewicz*, L. Callahan* and A. Messer (SPON: D.A. Poulos). Dept. of Anat., Cell Biol. & Neurobiol., Albany Med. Col. and Wads. Ctr. for Labs & Res, NYS Dept. Health and Sch. of Public Health Sciences, SUNYA, Albany, NY 12208.**

We recently reported the presence of phosphorylated neurofilament (pNF) epitopes in the cell soma of spinal motoneurons of the Mnd mouse (JCB 105:316a, 1987). The monoclonal antibody we used was axon-specific; the cell body of a normal motoneuron is negative. Additional analyses of cords from animals which exhibited different degrees of symptomology showed that while only mutants contained somatic pNF, there was no apparent correlation between the number of pNF positive cell bodies and the severity of disease at the time of fixation. This may not be surprising since there is a continuous loss of spinal motoneurons with time of progression of the disease which could result in the prior disappearance of degenerating (pNF-positive) soma. Alternatively there may be an underlying Mnd neuronal alteration which is several steps removed from the symptomology. The microtubule associated protein Tau is also enriched in axons, and might also have shown an anamolous distribution in Mnd spinal motoneurons. Using an antibody to Tau-1, its localization was similar in normal and Mnd spinal motoneurons: predominantly axonal. However, in Mnd spinal cord there were a few more positive neuronal cell bodies. In addition, a large number of Tau-positive cells were observed in both gray and white matter in Mnd and normal spinal cord. The cells were small and round, and distributed throughout the tissue. A tentative identification as glia is consistent with their size, number and location. Using cell specific markers, work is in progress to positively identify these cells.

Effects of age on the development of Huntington's-like symptoms using endogenous neurotoxin 1-Pyroglutamic acid in rats. Jennie C. Johannesen* and Richard E. Musty University of Vermont Burlington, VT 05403

A recent study has shown that 1-pyroglutamic acid, a major intermediate in the gamma-glutamyl metabolic cycle, mimics the symptoms of Huntington's Chorea when injected unilaterally into the caudate of mice (Rieke, Scarfi & Hunter, 1984).

We examined the effects of age on the development of Huntington's-like symptoms by performing bilateral injections of 1-PGA into the caudate of 6 month old and 2 year old male Wister rats. Several behavioural measures were taken, including two tests of muscle strength, a measure of aggression and general behavioural observations. In addition, the rat's footprints were examined in a straight runway to check for signs of ataxia, or gait disturbance.

We found several significant differences between young and old rats in response to bilateral lesions. Younger animals displayed significantly increased aggression while older animals displayed more ataxias & general gait disturbances. In addition, the majority of the older rats demonstrated a significant loss of muscle strength following injection. These results suggest that the neurotoxic effects of 1-PGA become more pronounced with age. This may prove helpful when examining the slow progressive degeneration of neural tissue in Huntington's patients.

IMMUNOLOGICAL REACTIONS IN CHRONIC DEGENERATIVE NEUROLOGICAL DISEASE. S. Itagaki*, P.L. McGeer, S.-G. Zhu*, H. Akiyama*, and E.G. McGeer (SPON: J. Weinberg) Kinsmen Lab, Dept Psych Univ of British Columbia, Vancouver, B.C., Canada, V6T 1W5

Many chronic degenerative neurological diseases are characterized by the appearance of a low grade inflammatory response in regions selective for particular disease. Alzheimer's, Pick's, Parkinson's and Huntington's disease, amyotrophic lateral sclerosis, Shy-Drager syndrome, progressive supranuclear palsy, and Parkinsonism-dementia of Guam are examples. The most prominent immunological finding in these diseases is reactive microglia positive for the MHC Class II glycoprotein HLA-DR, which is essential for presentation of foreign antigen to T-lymphocytes. Reactive microglia are also weakly positive for leucocyte common antigen (LCA). LCA positive round cells can be found in vessels and in the matrix of affected areas. Subpopulations of these cells, which can be identified by markers for lymphocytic subsets include T-cytoxic suppressor and T-helper/inducer cells. Reactive astrocytes, also present in these conditions, are a separate population from the microglia as shown by double immunostaining for glial fibrillary acidic protein and HLA-DR. The results suggest that cell-mediated immune responses occur in many diseases where such involvement has not previously been suspected. HLA-DR staining may be a valuable addition to standard neuropathological methods.

ASTROCYTES APPEAR DISTINCT FROM HLA-DR-POSITIVE CELLS IN MULTIPLE SCLEROSIS PLAQUE REGIONS. E.A.Boyle, S.Itagaki and P.L.McGeer, Kinsmen Lab, Dept Psychiatry, Univ. of British Columbia, Vancouver, B.C. Canada. V6T 1W5.

It is believed that many cell-mediated immune responses depend on antigen presentation in conjunction with HLA-DR. Yet it is still unresolved which cells carry out this function in multiple sclerosis (M.S.). We have performed double immunostaining on paraformaldehyde-fixed M.S. plaques using a monoclonal antibody against HLA-DR as the putative antigen-presentation marker, and a polyclonal antibody against glial fibrillary acidic protein (GFAP) as a marker for reactive astrocytes. Other pathological features were confirmed with Luxol Fast Blue for demyelination and a monoclonal antibody against leukocyte common antigen for perivascular cuffs. Examination of stained sections showed that HLA-DR is vigorously expressed in the inflamed margins of the plaques by cells showing the typical morphology of mature macrophages and some leukocytes and, near their edges, by reactive microglia. GFAP-positive astrocytes are frequently seen in the vicinity, but we have been unable to obtain convincing evidence that they overlap with HLA-DR-positive cells. Our evidence suggests that astrocytes display HLA-DR weakly, if at all, in M.S. plaques, and that macrophages and microglia constitute the overwhelming majority of HLA-DR-positive cells.

A PRIMATE MODEL OF HUNTINGTON'S DISEASE: UNILATERAL EXCITOTOXIC LESIONS OF THE CAUDATE-PUTAMEN AND NEURAL TRANSPLANTATION IN THE BABOON. O. Isacson, P. Hantraye*, D.Riche* and M.Maziere*. Dept. of Anatomy, University of Cambridge, Cambridge CB2 3DY, England and Frederic Joliot Hospital, Dept of Biology, CEA, Orsay 91406, France.

In the rat, many of the neuropathological and neurochemical features of Huntington's disease (HD) can be replicated by intrastriatal infusion of excitotoxins such as ibotenic acid. We have developed a lesion model of HD in the primate by excitotoxic lesions of the caudate-putamen complex (CPU) in order to test treatment strategies such as neural transplantation and pharmacological interventions. Ten monkeys received stereotaxic unilateral infusion of ibotenic acid into the right CPU, while 4 unoperated animals served as controls. Three animals received stereotaxic implantation of fetal cell suspensions prepared from striatal rat primordia into the lesioned CPU. These monkeys were treated with the immunosuppressant drug cyclosporine. Two to 35 weeks after the lesion the animals were assessed in their home-cages for spontaneous behaviours and motor abnormalities induced by various doses of the dopamine agonist drug apomorphine (0.5, 1.0 and 2.0 mg/kg). Behavioural studies indicated few spontaneous abnormalities following the unilateral ibotenic acid lesion, but injection of the dopamine agonist drug induced dramatic dyskinesias and motor stereotypies in the lesioned animals, while controls were either not affected or showed mild stereotypic motor behaviours. In vivo PET studies indicated clear lesion-induced changes in the CPU, such as reduction of dopamine receptor binding. Anatomical and histological analysis showed striatal lesions that corresponded closely to the anatomical distribution of CPU damage seen in HD. Results in progress describing the effects and survival of the transplants will be presented at the meeting.

REGULATION OF AUTONOMIC FUNCTION III

LIGHT AND ELECTRON MICROSCOPICAL OBSERVATIONS OF ACETYLCHOLINESTERASE REACTION IN DEVELOPING RAT RETROPERITONEAL PARAGANGLIA. Liisa Eränkö, Marketta Ahonen and Nils Bäck. Department of Anatomy, University of Helsinki, Finland.

The main retroperitoneal paraganglia of the newborn rat consists of different kinds of catecholamine cells; one with moderate immunofluorescence of tyrosine hydroxylase (TH) and dopamine beta-hydroxylase (DBH) resembling sympathetic nerve cells; another with bright fluorescence to TH and DBH. The latter type are smaller and are considered as paraganglion type cells.

The developing paraganglion cells initiated catecholamine synthesis on the 13th prenatal day. At this stage, some of these cells showed AChE reactivities. During later development, two subpopulations of cells were distinguished. One showed intense TH immunoreactivity but no AChE reactivity. The other was moderately reactive to TH and showed intense AChE staining. Electronmicroscopically these two cell populations were clearly distinguished. AChE reactivity was observed only in the neuron-like cells, in which the reaction was mainly located in the endoplasmic reticulum.

BULLFROG AUTONOMIC GANGLION CELLS HAVE LOCAL AXON COLLATERALS. C.J. Forehand and L.M. Konopka*. Dept. of Anatomy and Neurobiology, Univ. Vermont Col. Med., Burlington, VT 05405.

Autonomic ganglia in the frog are traditionally described as simple relay stations. However the variety of peptides found in ganglion cells and their preganglionic inputs suggests that these ganglia may be more complex. In an effort to define the microenvironment of identified cells after studying their responses to particular peptides, we began to label the cells by intracellular injection with HRP. We found that the morphology of both sympathetic lumbar chain cells and parasympathetic cardiac ganglion cells in the frog is more complex than the simple unipolar description normally given.

Most HRP-labeled cardiac ganglion cells (located in the interatrial septum) had extensive axon collaterals arising from the axon within 30 um of the cell bodies. These local collaterals were in addition to the main axonal projection into the cardiac muscle and contained numerous synaptic bouton-like swellings. Local axon collaterals, though less extensive than those on cardiac ganglion cells, were also present on 30% of the cells in lumbar sympathetic ganglia. The cells with local axon collaterals were a subset of the total population of ganglion cells based on size: The largest cells did not have axon collaterals. (PHS RO123978 & NSF BNS 8605611)

UNEXPECTED AUTONOMIC NERVOUS SYSTEM CONNECTIONS REVEALED BY THE HORSERADISH PEROXIDASE METHOD. J.C. Liu,* K.-P. Shaw and J.I. Yau.* (SPON:C.Y. Wen) Dept. Biol. Anat., Natl. Def. Med. Ctr., Taiwan, R.O.C.

New autonomic nervous system connections from the contralateral superior cervical ganglion (SCG) and middle cervical ganglion (MCG) to SCG were demonstrated by applying the Horseradish peroxidase (HRP) retrograde tracer technique. HRP was injected into the unilateral SCG in 12 cats. After survival times of 2 or 3 days, the animals were sacrificed and their spinal cord, brain stem and sympathetic ganglia were processed to visualize HRP labeling by using the tetramethyl benzidine method. Labeled neurons were found not only in ipsilateral T1-T5 spinal cord segments, MCG and Stellate ganglion, but also within the contralateral SCG and MCG. Lesions in the sympathetic chain caudal to the SCG injection site prevented spinal cord labeling, but not contralateral SCG and MCG labeling. Thus the contralateral pathway utilizes a rostral course. In conclusion, the presence of the contralateral projection to the sympathetic cervical ganglion challenges the principle of the two-neuron-chain peripheral autonomic nervous system. (Grant NSC 77-0412-B016-32, Taiwan, R.O.C.)

ORIGINS OF THE RENAL INNERVATION IN THE MONKEY, *MACACA FASCICULARIS*. S. F. Echtenkamp, C. F.Marfurt, and M. Jones*. Departments of Anatomy and Physiology, Indiana University School of Medicine, Northwest Center for Medical Education, Gary, IN 46408.

The origins of the renal afferent and efferent innervations in five monkeys were studied by using the retrograde transport of horseradish peroxidase (HRP). The cut ends of the right renal nerves were soaked for one hour in a solution of 15% HRP and 2% HRP-WGA and the animals were sacrificed 72-96 hours later. Labeled sensory neurons (196-543 per animal) were found in ipsilateral dorsal root ganglia (DRG) T8-L4, with the majority (57%) located in DRG T13. Ninety-two percent of the labeled afferent perikarya were found between T12 and L1. The labeled DRG cells ranged from18-64um in diameter, with a mean of 32.4um. Labeled cells were never seen in any contralateral DRG, and with a single exception in one animal, no labeled neurons were observed in the nodosal ganglia. The contributions to the renal efferent innervation from the prevertebral and paravertebral (sympathetic chain) ganglia varied considerably from animal to animal. Collectively, 57.4% of the total sympathetic innervation (5,574-14,565 cells per animal) arose from topographically organized areas of the ipsilateral prevertebral (coeliac, adrenorenal, and renal) ganglia, whereas 42.6% arose from ipsilateral sympathetic chain ganglia (T10-L3). The majority of labeled sympathetic chain cells (97%) were located in T13-L3, and of these 69% were found in L1 and L2. No labeled neurons were found in any contralateral prevertebral ganglia and only rarely (4 cells in one animal) were any cells observed in the contralateral sympathetic chain ganglia. These results reveal for the first time the origins of the renal afferent and efferent innervations in a primate. (Supported by NIH grants HL37223 to S.F.E. and 507RR5371 to C.F.M.)

527.5

APPARENT PLASTICITY OF AUTONOMIC NERVES: STIMULATION OF THE HYPOGASTRIC NERVES ELICITS INCREASES IN PENILE PRESSURE AFTER CHRONIC INTERRUPTION OF THE SACRAL PARASYMPATHETIC OUTFLOW. M.P. Olmsted*, G. Walton* and W. G. Dail. (SPON: E. Reyes) Dept. of Anatomy, Univ. of New Mexico, Sch. of Med., Albuquerque, NM 87131.

Investigations have previously documented that preganglionic fibers in the pelvic nerve and hypogastric nerve may participate in erection in mammals. The effects of stimulation of autonomic nerves on pressure in the corpora cavernosa penis (CCP) were studied in intact rats and in rats in which the pelvic nerves were unilaterally or bilaterally transected one to six weeks earlier. An increase in penile pressure in control animals occurred with stimulation of the pelvic nerve and with stimulation of postganglionic fibers from the pelvic plexus. A more consistent rise in pressure occurred with stimulation of postganglionic fibers. However, no increase in penile pressure was obtained even with bilateral stimulation of the hypogastric nerves. One week following interruption of the pelvic nerve, stimulation of the hypogastric nerve resulted in a small but significant rise in pressure in the CCP (average rise of 13mm Hg). In animals with bilateral interruption of the pelvic nerve, stimulation of either hypogastric nerve elicited an increase in pressure while in the unilaterally lesioned group, tumescence occurred only after stimulation on the lesioned side. It is hypothesized that chronic interruption of the pelvic nerves is a stimulus for compensatory changes in the penile vasodilator pathway of the hypogastric nerves. A similar mechanism may underlie the preservation of penile erection in injury to the terminal portion of the spinal cord in man. Supported by NIH RO1NS1983-5 and RR08139-12.

527.6

AUTONOMIC INNERVATION OF THE ANOCOCCYGEUS MUSCLE OF THE RAT. W. G. Dail, D. S. Trujillo*, Y. Carrillo*, N. Minorsky, D. de la Rosa* and G. Walton*. Dept. of Anatomy, Univ. of New Mexico, Sch. of Med., Albuquerque, NM 87131.

The anococcygeus muscle of the male rat is often used as a model to investigate neural control of smooth muscle. Norepinephrine is an excitatory neurotransmitter to this muscle, yet relatively little is understood of the nature of the inhibitory neurotransmitter and the location of ganglionic synapses. To investigate these questions, ganglion cells were located by injection of the retrograde tracer fluorogold into the anococcygeus. In addition, the anococcygeus muscle was stained for the presence of nerves containing acetylcholinesterase (AChE) and fibers immunoreactive for vasoactive intestinal polypeptide (VIP). Labeled ganglion cells were found in the lumbosacral sympathetic chain (average of 120), the pelvic plexus (aver. 300) and the inferior mesenteric ganglion (aver 15). Neurons in the pelvic plexus were found in the major pelvic ganglion and all along the main penile nerve to the anococcygeus muscle. Some ganglion cells were present in the anococcygeus muscle. The anococcygeus muscle has a rich plexus of AChE positive fibers and a somewhat less dense innervation by VIP-IR fibers. Immunocytochemistry of identified neurons indicates that the pelvic plexus is one source of the VIP innervation of the anococcygeus. Previous studies have failed to find an AChE+ innervation of this muscle. The presence of AChE+ fibers and VIP-IR fibers raises the possibility that acetylcholine and VIP may participate in the innervation of the anococcygeus muscle. Supported by NIH grant RRO8139-12.

527.7

AFFERENTS IN THE PELVIC VISCERA OF FEMALE RATS LOCALIZED BY ANTEROGRADE TRANSPORT OF HRP. D. M. Nance, J. Burns*, C. M. Klein* and H. W. Burden. Dept. of Anat., Dalhousie Univ., Halifax, Nova Scotia, B3H 4H7, Canada, and Dept. of Anat. & Cell Biol. East Carolina Univ. School of Med., Greenville, N.C. 27858.

Innervation of the female reproductive system provides an important signal for several neuroendocrine reflexes in the rat. Afferent feedback from the gonads may be involved in the control of the gonads and pituitary hormone release. Retrograde tract tracers indicate that the ovary receives an afferent input from thoraco-lumbar dorsal root ganglia (DRG). Diffusion following injections into the ovary or related nerves may overestimate the extent of afferent innervation. We re-examined the afferent input to pelvic viscera by means of the antero-grade transport of HRP from thoracic, lumbar and sacral DRG and tested the effects of unilateral removal of the DRG on the substance P (SP) containing fibers in the ovary, oviduct and uterus. The T_{13} and L_1 DRG provide innerva-tion to the uterine horn, oviduct and ovary and the L_6 and S_1 DRG provide af-ferent fibers to the cervix ,vagina, bladder and rectum. Innervation of the oviduct was more extensive than the uterus and only 2 /14 injections into the T_{13} and L_1 DRG produced labeled fibers in the ovary, but labeled fibers were seen in the ovarian bursa. Injections into the L_6 and S_1 DRG produced many labeled fibers in the cervical portion of the uterus, vagina, base of the bladder and rectum. Innervation of the vagina was greater than the cervix. Relative distribution of SP-like fibers was: oviduct > uterine horn > ovary. Removal of the T_{13} and L_1 DRG eliminated or reduced the number of SP-like fibers from these viscera on the same side as the surgery. Thus, cranial structures receive a modest and diffuse afferent supply from the thoraco-lumbar DRG and the caudal part of the reproductive tract, bladder and rectum receive an extensive afferent supply from the lumbo-sacral DRG. There is a modest afferent input to the ovarian bursa and surrounding tissue, but a limited number of afferent fibers enter the gonad. Supported by M.R.C. of Canada.

527.8

DISTRIBUTION AND CHARACTERIZATION OF PELVIC NEURONS WHICH PROJECT TO THE BLADDER, COLON OR PENIS IN RATS. A.M. Booth, J.R. Keast, C.R. Murray* and W.C. de Groat. Dept. Pharmacology, Univ. Pittsburgh, Pittsburgh, PA 15261.

The distributions of pelvic neurons which supply three organs of male rats were defined by using retrogradely transported dyes, injected into the bladder, colon or penis and removing the major pelvic ganglia (MPG) 3 days to 6 weeks later. For each organ there was a different distribution of labelled neurons: those supplying the bladder were located throughout the MPG, those to the colon located mainly dorsally, close to the entrance of the pelvic nerve and those to the penis mainly found near or within the penile nerve. Immunoreactivity for vaso-active intestinal peptide (VIP), neuropeptide Y (NPY), tyrosine hydroxylase (TH), leu-enkephalin (LENK), somato-statin (SS) or cholecystokinin (CCK) was identified in dye-labelled neurons and their surrounding nerve terminals. There were unique features for each neuronal population. Many colon and bladder neurons, but very few penis neurons, contain TH or NPY; most penis neurons, but very few colon or bladder neurons, contain VIP; some colon neurons contain LENK, but LENK was rarely seen in bladder or penis neurons; SS or CCK were found in nerve terminals around many bladder or colon neurons, but were rare around penis neurons. These features may indicate differences in neurotransmission to each organ. (J.K. is supported by an NH&MRC C.J. Martin Fellowship.)

REORGANIZATION IN CAT PELVIC PLEXUS FOLLOWING PARASYMPATHETIC PREGANGLIONIC DENERVATION. S. Smerin, A.M. Booth, M. Kawatani & W.C. de Groat. Depts. of Pharmacol. & Behav. Neurosci. Univ. of Pittsburgh, Pittsburgh, PA 15261

Chronic resection of the parasympathetic preganglionic innervation to the pelvic plexus results in the evolution of new patterns of urinary bladder (UB) activity and neural firing on UB postganglionic nerves in response to pelvic (PN) or hypogastric (HGN) nerve stimulation. These patterns include: 1) sustained UB contractions evoked by stimulation of the HGN, and 2) increased asynchronous neural activity in UB postganglionic nerves following a tetanizing stimulus to the lesioned PN. Conventional in vitro intracellular recording techniques were used to examine the synaptic correlates of these events more than one year after resection of the sacral dorsal and ventral roots in the adult cat. Lucifer Yellow was injected into most cells to examine their morphology.

These recordings revealed: 1) a high percentage of cells without synchronously evoked fEPSPs, 2) fewer inputs to innervated cells that were of abnormally long latency and large amplitude, 3) an evoked asynchronous discharge in the majority of cells, 4) different thresholds for fEPSPs and asynchronous discharge, and 5) abnormal cell morphology. These results confirm significant synaptic reorganization within bladder ganglia of the cat following partial denervation.

INFLUENCE OF SACRAL AFFERENT INPUT AND RECURRENT INHIBITION ON PONTO-SPINAL MICTURITION PATHWAYS. B. Mallory, M. Kruse, J. Roppolo, H. Noto and W. deGroat. Depts. of Pharmacol. & Behav. Neurosci., Center for Neurosci., Univ. of Pittsburgh, Pittsburgh, PA 15261.

We have assessed the effect of inputs that are known to influence spontaneous contractions of the urinary bladder (C-UB) on C-UB elicited by electrical stimulation (ES) of the pontine micturition center (PMC). ES of the proximal cut S2 ventral root (2V, 20 Hz, 0.05 msec) or mechanical stimulation of the rectum inhibited both spontaneous C-UB and C-UB elicited by PMC stimulation. However perigenital (PG) stimulation which inhibited spontaneous C-UB, facilitated C-UB elicited by PMC stimulation. Section of dorsal roots L7 through S3 abolished spontaneous C-UB but abolished neither the C-UB nor the relaxation of the external urethral sphincter (EUS) elicited by ES of the PMC (90-100 uA, 0.3 msec, 300 msec trains at 50 Hz). C-UB elicited by PMC stimulation in the deafferented animal, were not affected by neuromuscular blockade but were abolished by section of the sacral ventral roots. We conclude that the UB/EUS synergy during micturition is organized within the CNS independent of sacral afferent input and that recurrent inhibitory, rectal inhibitory and PG facilitatory inputs modulate the descending PMC pathway whereas PG afferent inhibitory input likely acts on the afferent arc of the spinobulbospinal micturition reflex.

527.11

ULTRASTRUCTURAL ANALYSIS OF ENKEPHALINERGIC TERMINALS IN PARASYMPATHETIC GANGLIA (PSG) INNERVATING THE URINARY BLADDER OF THE CAT. M. Kawatani, S. Shioda*, Y. Nakai*, C. Takeshige* and W.C. de Groat. Depts. Physiol. and Anat., Showa Univ., Tokyo, and Depts. Pharmacol. and Behav. Neurosci., Univ. Pittsburgh, Pittsburgh, PA 15261.

Previous studies revealed that leucine-enkephalin (LENK) was present in sacral preganglionic neurons (SPGN) which innervate the urinary bladder and in varicosities surrounding postganglionic neurons in bladder PSG. The varicosities were eliminated after sacral ventral root transection indicating that they were terminals of SPGN. Present studies examined the ultrastructural characteristics of LENK terminals in the PSG. Experiments were conducted in 7 adult cats using standard EM-immunohistochemistry. LENK was identified only in axons and terminals in PSG. LENK positive terminals exhibited large dense core vesicles and small clear spherical vesicles. LENK-IR was primarily associated with the large dense core vesicles. The average size of the large dense core vesicles was 105 nm whereas small clear vesicles averaged 50 nm. LENK terminals made synaptic contact with the dendrites and soma of the principal neurons. Axo-axonic contacts were identified in few cases. The synapses were of the symmetrical type. These observations suggest that LENK is a co-transmitter with acetylcholine in the sacral preganglionic outflow of the cat.

527.12

THE EFFECTS OF SUPERFICIAL CERVICAL SPINAL STIMULATION ON SYMPATHETIC PREGANGLIONIC NEURONS. L.P. Schramm, M.P. Gilbey, and J.P. O'Reilly*. The Johns Hopkins School of Medicine. Baltimore, MD 21205

Experiments were conducted to determine whether superficial cervical stimulation inhibits glutamate-elicted activity of otherwise silent sympathetic preganglionic neurons (SPN), indicating the direct impingement of the dorsal spinal sympathoinhibitory system (DSSS) on SPN. Three-hundred gram, male, Sprague-Dawley rats were anesthetized with chloralose and prepared for recording from SPN at the T2-T3 levels. These neurons were identified by antidromic stimulation from the cervical sympathetic chain. Recordings were made through one barrel of a three-barrel electrode from which glutamate could be iontophoresed. Stimulus-elicited inhibition of sympathetic activity was manifested by depressor responses or by decreases in renal nerve sympathetic activity. Of the 20 SPN recorded, 16 exhibited activity only during glutamate iontophoresis. Very low (but not higher) rates of glutamate-elicited firing could be inhibited by cervical stimulation in 6 of these otherwise-silent SPN. Inhibition was well-sustained in 3 of these neurons, but lasted only a few seconds in 3. Glutamate-elicited activity in the remaining 10 SPN was either unchanged or increased by cervical sympathoinhibitory stimulation. Cervical stimulation elicited well-sustained inhibitions of action potentials of all 4 spontaneously active SPN. Because inhibition of SPN by cervical stimulation appeared to be very weak, we tentatively conclude that this inhibition acted by reducing subthreshold excitation of glutamate-excited SPN, not by directly inhibiting them. Whether inhibition of SPN generating abdominal sympathetic activity will be more powerful remains to be tested.
Supported by NIH Grant HL16315.

527.13

AN EXTRACELLULAR STUDY OF THE RESPONSES OF LUMBAR SYMPATHETIC PREGANGLIONIC NEURONES TO NOXIOUS STIMULATION OF THE SKIN IN THE CAT. M.P. Gilbey, J.F.R. Paton* and I.M. Clark*, Department of Physiology, Royal Free Hospital Medical School, Rowland Hill Street, LONDON NW3 2PF, U.K.

Response patterns of lumbar sympathetic preganglionic neurones (SPN) to noxious stimulation of the skin have been studied previously using single fibre recordings (Janig, W., Rev. Physiol. Biochem, Pharmac., 102, 119-213, 1985). In this study extracellular recordings from SPN have been made as the technique permits cells to be driven pharmacologically (Gilbey, M.P. et al, J. Physiol. 378 : 253-265, 1986) and therefore inputs to 'silent' SPN as well as those having ongoing activity can be studied.

Forty six neurones have been studied in chloralose anaesthetized cats. These were identified antidromically by stimulation of the lumbar chain between L5 and L6 ganglia. Of 6 glutamate-activated SPN tested for their response to noxious input (heat 50-60°C), 2 ceased to discharge, one had a slightly decreased discharge during the stimulus and a rebound excitation, and 3 were unaffected. One neurone having ongoing activity was unaffected by the stimulus.

These results show that the discharge of glutamate-activated SPN can be influenced by noxious stimulation of the skin.
Supported by the British M.R.C. and British Heart Foundation*.

Enkephalinergic Projections from Brainstem to the Spinal Cord. MA Romagnano, R Harshbarger, CB Saper, and RW Hamill. Neurology Dept., Univ. of Rochester/Monroe Community Hosp., Rochester, NY, 14603 and Dept. Pharm. & Physiology, Univ. of Chicago, Chicago, Il, 60637.

In the rat, enkephalinergic (Enk) fibers in the spinal cord are found in a ladder-like pattern corresponding with preganglionic sympathetic nuclei. These Enk fibers are of both supraspinal and intraspinal origin. We combined immunohistochemistry for Enk in the brainstem with retrograde transport of FB unilaterally injected into the intermediolateral cell column at the junction of spinal levels T2 and T3.

Double-labeled neurons are found ipsilaterally and contralaterally in many areas of the brainstem previously shown to project to the spinal cord including the rostroventrolateral medulla (C1 area) and the region dorsal to the inferior olive (B3 area). In the pons and midbrain double-labeled neurons are located in the same regions as noradrenaline cells and fiber pathways. These double-labeled cells are the source of brainstem Enk projections to the spinal cord and may represent the origin of an opioid influence on autonomic functions.

527.15

IDENTITY OF VAGAL AFFERENTS AND EFFERENTS IN RELATION TO NEURONS CONTAINING ENKEPHALIN-LIKE IMMUNOREACTIVITY. J. Chan, L. Velley, T.A. Milner, S. Morrison, and V.M. Pickel. Div. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

Immunoautoradiographic localization of an antiserum directed against Met^5-enkephalin was examined in relation to sensory and motor components of the rat dorsal vagal complex. The afferents and efferents were identified by anterograde and retrograde transport of horseradish peroxidase applied in a cuff around the proximal end of the vagus nerve sectioned at the cervical level. By light microscopy, enkephalin-like immunoreactivity (ELI) was seen as silver grains diffusely distributed throughout the neuropil and in isolated perikarya located within the medial nuclei of the solitary tract (m-NTS). Portions of the m-NTS containing ELI also contained extensive anterograde labeling of vagal afferents. Conversely, the motor nuclei of the vagus contained retrogradely labeled perikarya and proximal processes. Motor neurons were surrounded by silver grains indicative of ELI. By electron microscopy, ELI was associated principally with large dense core vesicles in axon terminals. Terminals containing ELI were detected in both sensory and motor portions of the vagal complex as identified by anterograde labeling of axon terminals or retrograde labeling of perikarya and dendrites. These results suggest that opioids may be important modulators of both sympathetic and parasympathetic reflexes involving the dorsal vagal complex. (Supported by NIH grants MH00078 and HL18974 (VMP) and INSERM 856024 (LV)).

527.16

INNERVATION OF THE DORSAL MOTOR NUCLEUS OF THE VAGUS IN THE CAT: IMMUNOCYTOCHEMICAL AND RETROGRADE TRACING EVIDENCE FOR PROJECTIONS FROM HINDBRAIN, BUT NOT FOREBRAIN NUCLEI. R.A. Gillis* E.K. Friedman* W.P. Norman and P.J. Hornby*. Depts of Pharmacology and Anatomy, Georgetown University. Washington, DC.

It is well documented that a number of forebrain and hindbrain nuclei project to the dorsal vagal complex [i.e. the area postrema (AP), nucleus tractus solitarius (NTS) and dorsal motor nucleus of the vagus (DMV)]. Use of immunocytochemistry and antibodies to thyrotropin-releasing hormone (TRH), neuropeptide Y, neurotensin, oxytocin and substance P reveals differences in the distributions and densities of these neuropeptides in the nuclei of the dorsal vagal complex. Specifically, a marked density of TRH puncta is noted within the DMV, whereas few TRH puncta are observed in the NTS and AP. The region of the DMV with the most dense TRH innervation is 1-3mm rostral to the obex and contains vagal neurons projecting to the stomach. Microinjection or iontophoresis of HRP-WGA (10%) or fluorogold (2%) into the "gastric" region of the DMV, results in labelled cell bodies in the ventrolateral medulla and raphe nuclei but not in the paraventricular nucleus of the hypothalamus (PVN), although microinjections which spread into the NTS did label cells in the PVN. These data suggest that TRH projections to the DMV arise from neurons in the raphe nuclei and not the PVN. A role of these projections in control of gastric motility is supported by the fact that microinjection of 100-200nl of 0.5M glutamate into the raphe obscurus results in an increase in gastric motility. (Supported by NIH grant AM 29975)

527.17

IDENTIFICATION OF THE TERMINALS OF VAGAL EFFERENT FIBERS AND THEIR APPARENT TARGET NEURONS IN THE RAT GUT. A. L. Kirchgessner and M. D. Gershon. Dept. of Anatomy & Cell Biology, Columbia Univ. P&S, New York, NY 10032

Although the intrinsic innervation of the bowel is independently capable of mediating reflexes, the gut receives a CNS innervation from the dorsal motor nucleus of the vagus (DMX). Since the number of efferent vagal fibers is small, it is not clear how the vagus affects enteric activity. The current experiments were undertaken as a partial test of the hypothesis that the CNS innervates a small number of command neurons in enteric ganglia. The anterograde tracer, *Phaseolus vulgaris* leucoagglutinin (PHA-L), was iontophoretically injected into the DMX and 10-21 days later, PHA-L was immunocytochemically visualized in the bowel. Varicose vagal efferent fibers, labeled by PHA-L, were found in the myenteric plexus as far distally as the ileo-colic junction. These axons were relatively rare, entered a minority of myenteric ganglia, and contacted a small proportion of the neurons. Vagal efferent fibers were most numerous in the gastric antrum and became progressively more sparse distally. Possible target neurons were neurochemically identified by simultaneously demonstrating the immunoreactivities of VIP, enkephalin, galanin, 5-HT, and tyrosine hydroxylase (TH) along with that of PHA-L. Vagal terminals appeared to contact VIP+ and 5-HT+, but not galanin+ or enkephalin+ neurons. Vagal efferents were galanin+, but TH-; therefore, some vagal preganglionic fibers probably contain galanin; however, TH-containing axons in the vagus nerve are likely to be of sympathetic origin. Following injections of Fluoro-Gold (FG) into the stomach, a subset of cells in the DMX labeled by retrograde transport of FG were galanin+. Galanin+ terminals also encircled FG-labeled DMX cells. These observations are consistent with the hypotheses that the vagus nerve innervates a small number of command neurons in the myenteric plexus, that some of these neurons contain VIP or 5-HT, and that galanin may be a modulator of CNS control of the bowel. 527.18

SYNAPTIC ORGANIZATION OF VAGAL AFFERENTS AND EFFERENTS IN THE MEDULLA OBLONGATA. M. Kalia. Department of Pharmacology, Thomas Jefferson University, Philadelphia, PA 19107.

Vagal afferent fibers terminate in the nucleus of the tractus solitarius (nTS) with a distinct viscerotopic and modality-specific organization (Kalia & Mesulam, '80). Intraaxonal injections of HRP into functionally identified pulmonary afferents have revealed striking features of these terminals in the nTS (Kalia & Richter, '85). This study focuses on vagal afferents terminating in all the subnuclei of the nTS and determines the nature of their terminations. In addition, neurons in the dorsal motor nucleus of the vagus (dmnX) were studied in order to examine terminations on their dendrites and somata. Adult cats and rats were anesthetized and the right nodose ganglion was injected with cholera toxin-horseradish peroxidase conjugate. Following a 48-hour survival period, the animals were perfused and serial vibratome sections of the medulla oblongata were reacted for electron microscopy using tetramethyl benzidine-ammonium molybdate at pH 6.6, followed by slow osmication, pH 5.5 (Ralston, et al, '87). The nTS-dmnX complex was examined at each rostrocaudal level for reaction product under the light and electron microscope. Axon terminals of vagal afferents established contact with large dendrites, including dendritic shafts and spines. In addition, axo-axonal contact with axon terminals containing pleomorphic vesicles were found. Somata of dmnX neurons were surrounded by medium-sized dendrites, however, no contact with these unlabeled dendrites was found in the sample examined. Dendrites of dmnX cells were contacted frequently by axon terminals. (Supported by USPHS HL30991, HL33632, HL40270.)

SUBSTANCE P AND GABA CONTRIBUTE TO THE CONTROL OF AUTONOMIC FUNCTION BY LAMINA I-II NEURONS OF TRIGEMINAL N. CAUDALIS. D.A. Bereiter, A.Benetti* and D.S.Gann Depts. Surgery & Neurobiology, R.I.Hospital/Brown Univ., Providence, R.I. 02902.

Excitation of neurons, by L-glutamate, within specific laminae (I-II or V-VI) of trigeminal n. caudalis (Vc) evokes endocrine and autonomic responses consistent with the activation of nociceptors from orofacial regions. To assess the effects of putative neurotransmitters within Vc on these reflex responses, microinjections (40 or 160nl) of substance P (SP), a GABA antagonist (bicuculline,BMI), or a GABA agonist (muscimol) were directed at various laminae of Vc in cats anesthetized with chloralose, paralyzed with gallamine triethiodide. Arterial pressure, heart rate, and expiratory CO2 were monitored continuously. Adrenal catecholamine (CA) secretion was assessed from adrenal vein plasma samples by HPLC with EC and peripheral venous plasma ACTH was measured by RIA. SP (36pmol) evoked increases in adrenal CA secretion, in ACTH, in arterial pressure, and in heart rate by +1min after injections into lamina I-II of Vc, whereas injections into more ventral laminae of Vc had no significant effects. BMI (62pmol) increased CA secretion and arterial pressure by +1min, whereas muscimol (280pmol) caused a delayed decrease in CA secretion and in arterial pressure after lamina I-II injections. BMI or muscimol did not affect significantly the release of ACTH regardless of the laminar site of injection within Vc, whereas injections of BMI or muscimol into more ventral laminae of Vc had no consistent effects on CA secretion, on arterial pressure or on heart rate. SP-evoked changes in CA secretion were not correlated with changes in adrenal blood flow, whereas BMI- and muscimol-evoked changes in CA secretion were well correlated ($P<.01$) with changes in adrenal blood flow. The data indicate an excitatory input to lamina I-II neurons by SP in the control of adrenal CA secretion and in the release of ACTH by Vc, consistent with a possible role in nociception. GABA may exert a tonic inhibitory influence on lamina I-II neurons that contribute to the reflex control of adrenal CA secretion. The identity of putative neurotransmitters that affect autonomic function via lamina V-VI neurons of Vc remain unknown. Supported by NIH #'s NS26137(DAB) & DK26831(DSG).

THE HUMAN INTERMEDIATE RETICULAR NUCLEUS (IRt). G. Paxinos, I. Törk*, G. Halliday* and W.R. Mehler. Schools of Psychology and Anatomy, Univ. New South Wales, Kensington, Australia 2033, and Dept of Anatomy, Univ. Calif. at San Francisco, Calif. 94143.

The IRt has recently been identified in the rat as a zone between the gigantocellular and parvocellular reticular nuclei which contains some large, as well as medium and small cells and is more reactive for acetylcholinesterase (AChE) than its neighbors (Paxinos and Watson, *The Rat Brain in Stereotaxic Coordinates*, Academic Press, Sydney, 1986). We now delineate the boundaries of this nucleus in the human on the basis of chemoarchitecture. The nucleus has the shape of an arc with a lateral concavity and nestles the ambiguus and retroambiguus nuclei. It commences at the pyramidal decussation and continues until the facial nucleus, and separates the dorsal from the ventral medullary reticular nuclei as well as the gigantocellular from the parvocellular reticular nuclei. Substance P positive cells and fibers are found throughout this nucleus. Catecholamine cells and fibers are also found in IRt but they are more prominent in the part ventrolateral to the ambiguus nucleus. Dorsally, outlying tyrosine hydroxylase positive cells of this nucleus are found in the cell poor zone that caps the medial pole of the dorsal motor nucleus of vagus. 5-Hydroxytryptamine containing cells are found intermingled with catecholamine cells mainly in the caudal part of IRt. This suggests that the autonomic regulatory centers localized in the ventrolateral medulla are part of a larger zone extending dorsomedially.

527.21

ANATOMICAL EVIDENCE THAT AUTONOMIC AND VISCERAL AREAS CONVERGE ON PARAGIGANTOCELLULARIS, A MAJOR AFFERENT TO LOCUS COERULEUS. *E.J. Van Bockstaele, V.A. Pieribone, G. Aston-Jones and M.T. Shipley*[1], Dept Bio & Cntr Neural Sci., New York Univ., NY 10003; [1]Dept. Anat. Cell Bio, U. Cincinnati Col. Med.,OH 45267

Recent investigations have found that the paragigantocellularis (PGi) in the ventrolateral medulla is broadly influential, being both a major afferent to the nucleus locus coeruleus (LC) and a key element in regulating the sympathetic nervous system. While previous studies have investigated afferents to PGi, we have re-examined this issue so as to focus on areas of PGi that project to LC, using recently developed, more sensitive transport techniques.

Wheat germ agglutinin-conjugated horseradish peroxidase (WGA-HRP) or fluoro-gold (FG) was iontophoretically injected into PGi and retrogradely labeled cells were identified in rat. WGA-HRP and FG yielded similar results, and in all WGA-HRP cases ipsilateral LC contained anterograde labeling. Our results confirm some previous findings, including projections from the nucleus of the solitary tract (NTS), A1 area, gigantocellularis, lateral parabrachialis, periaqueductal gray and lateral hypothalamus. However, projections not previously reported were also identified, including lumbosacral cord, medullary reticular field, contralateral PGi, A5 area, supraoculomotor nuc., Kolliker-Fuse nuc. (reported in cat and rabbit) and medial prefrontal cortex. Topography for these afferent terminations was investigated by varying injection placements within PGi. Retrogradely labeled cells in hypothalamus and medial prefrontal cortex occurred primarily after caudal injections in PGi. In addition, retrograde labeling in caudal NTS (commissuralis level) was most prominent following caudal PGi injections while those in rostral PGi revealed retrogradely labeled neurons in more rostral NTS areas. The present findings indicate that many areas afferent to PGi are implicated in autonomic and visceral regulation. Further studies will determine whether such afferents regulate the subset of PGi cells that project to LC; if so, these pathways may globally disseminate information pertaining to visceral and autonomic function by coordinating these functions with LC activity. CATECHOLAMINERGIC CELLS OF THE VENTROLATERAL MEDULLA AND NUCLEUS OF THE SOLITARY TRACT INNERVATE THE CENTRAL NUCLEUS OF THE AMYGDALA IN THE RAT. A.M. Zardetto-Smith and T.S. Gray. Dept. Anat., Loyola Univ., Maywood IL 60153.

The central nucleus of the rat amygdala mediates the visceral and somatic responses associated with various adaptive behaviors, such as fear and the defense reaction. The nucleus of the solitary tract (NTS), the site of first synapse for cardiovascular afferent fibers, projects to the central nucleus. In this study, the possibilty that catecholaminergic neurons in the NTS innervate the central nucleus was examined using the combined retrograde tracer (Fluoro-Gold) and immunohistochemical (tyrosine hydroxylase) technique. Retrogradely labeled tyrosine hydroxylase-immunoreactive cells were observed in both the NTS and ventrolateral medulla. These results demonstrate that catecholaminergic neurons in both the ventrolateral medulla and NTS innervate the central nucleus. Central catecholamine neurons, the NTS and ventrolateral medulla have each been implicated in the autonomic control of blood pressure. The catecholaminergic projections from the NTS and ventrolateral medulla may convey cardiovascular interoceptive information to the central nucleus. Studies are in progress to determine if the catecholaminergic innervation of the central nucleus arises from the adrenergic (C1/C2) or noradrenergic (A1/A2) group of catecholamine neurons within the brainstem. (Supported by Sigma Xi Grants-in Aid of Research and NIH NS 20041).

STATIC MUSCULAR CONTRACTION ALTERS THE DISCHARGE FREQUENCY OF NEURONS IN THE ROSTRAL VENTROLATERAL MEDULLA IN CATS R.M. Bauer*, G.A. Iwamoto and T.G. Waldrop* (Spon: J.A. McMillan) Depts. of Physiology and Vet. Biosciences, University of Illinois, Urbana, IL.

The areas in the central nervous system which modulate the sympathoexcitatory responses to muscular contraction are not well understood. Recent studies from this laboratory have demonstrated that the reflex arterial pressure response to muscular contraction can be attenuated after bilateral microinjections of a glutamate antagonist into the rostral ventrolateral medulla (RVLM). The purpose of the present study was to determine if static contraction of hindlimb muscles alters the extracellular single unit activity of neurons in the RVLM. In anesthetized cats, contraction elicited by stimulation of L7 and S1 ventral roots evoked increases in arterial pressure, heart rate and minute volume. The majority (90%) of cells (n=50) recorded from within the RVLM (2.0 mm rostral and 3.75-4 mm lateral to obex and 4.7-5.5 mm below the dorsal surface) responded to contraction with a sustained 70% or greater increase in firing rate. The firing frequency of neurons recorded from sites dorsal and lateral to the RVLM were not altered significantly during contraction. These findings suggest that the reflex increases in cardiorespiratory activity evoked by muscular contraction involve neurons in the RVLM. (Supported by Am. Heart Assoc.)

ELECTROPHYSIOLOGICAL CHARACTERIZATION OF ANGIOTENSIN ACTIONS IN THE AREA POSTREMA. S. Papas* and A.V. Ferguson, Dept. of Physiology, Queen's University, Kingston, Ontario, Canada.

The area postrema (AP) is a midline circumventricular organ located on the dorsal surface of the caudal medulla in the rat, overlying the nucleus of the solitary tract (NTS). It sends major projections to the NTS and the parabrachial nucleus (PBN) and contains a high concentration of angiotensin II (AII) receptors. In many species, the AP is thought to centrally mediate AII's effects on the cardiovascular system. In this study, electrophysiological techniques were used to investigate the effects of systemic AII on neuronal activity in the AP and NTS, and to examine connections between the AP and the PBN.

Recordings were obtained from neurons in the AP and NTS of anesthetized male rats and the effects of iv AII (100ng-500ng), or PBN stimulation on the activity of these neurons were examined. A total of 57 cells were recorded from in the AP. Of the 9 cells tested with systemic AII, activity was enhanced in 67% and unaltered in 33% of the neurons. Recordings were made from 30 cells in the NTS, of which 15 were tested with iv AII. The activity of 73% of the neurons was inhibited upon AII injection. Two cells (13%) exhibited a rise in activity and 13% were not affected. PBN stimulation affected the neuronal activity of 12 neurons out of the 21 cells tested. Five neurons (25%) were antidromically identified as projecting to the PBN region and 33% were orthodromically identified as projecting to the AP. These findings suggest that systemic AII exerts opposing effects on cells in the AP and the NTS. Further experiments will elucidate both the mechanism of this action and the effects of AII on neurons projecting from the AP to the PBN. Supported by the MRC of Canada.

THE SALIVATORY NUCLEI OF *MACACA FASCICULARIS*. A.R. Eden, K.J. Chandross*, J.T. Laitman* and P.J. Gannon. Departments of Otolaryngology and Anatomy, Mount Sinai School of Medicine, New York, NY 10029.

The distribution of neurons representing the superior and inferior salivatory nuclei (SSN, CN VII; ISN, CN IX) of adult macaques was determined using HRP tract tracing methods. The tympanic and chorda tympani nerves (TN, n=7; CTN, n=4) were transected in the middle ear and cannulated with a HRP (30%) filled tube. The greater petrosal nerve (GPN, n=5) was cannulated distal to the facial hiatus. After perfusion fix, 40um frozen-cut brainstem sections were processed using standard HRP-TMB methods. Labelled cells were quantified by two separate observers.

Results showed that for the **TN**, three distinct groups of neurons were labelled ipsilaterally. The largest group, situated along the dorsolateral margin of the medullary reticular formation, extended from the level of the caudal pole of nucleus ambiguus (NA) to the caudal superior olive. A scattered group of labelled cells was present around the caudal pole of NA. A medium-sized group was situated around the dorsal margin of the facial nucleus (FN). For the **CTN**, two ipsilateral cell groups were labelled. One group was located outside the dorsal boundary of the FN. The other group was located 1.3mm dorsomedial to the FN. The two groups merged rostrally to form a large dorsoventrally scattered chain of cells. For the **GPN**, two cell groups were labelled ipsilaterally. The larger group was located along the lateral margins of FN. A small column of cells was present 1.2mm dorsomedial to FN. A few scattered cells bridged the two groups.

This study demonstrated what may be numerous subnuclei of the inferior and superior salivatory nuclei. There is some overlap of cell groups for the three nerves, both around the margin of FN and more dorsally. The diversity and number of cell groups suggest that functions other than lacrimation, salivation and nasal mucous secretion may be subserved. Current studies focus on a potential common role of ISN and SSN components in middle ear function by chemoreceptor modulation. (Supported by NIH Grant NS22685)

527.26

THE TYMPANIC PLEXUS OF *MACACA FASCICULARIS*. P.J. Gannon, J.T. Laitman* and A.R. Eden. Departments of Otolaryngology and Anatomy, Mount Sinai School of Medicine, New York, NY 10029.

The tympanic plexus (TP) of the middle ear is the crossroads of three cranial nerves (CN VII, IX and X) and the autonomic nervous system. This study investigates the anatomy of the TP and the relations of a little known intrinsic component, the glomus/ganglion (G/G) cells associated with the tympanic (TN) and caroticotympanic (CTN) nerves.

In five adult animals the superior cervical ganglion (SCG) was ablated unilaterally, then the head and neck fixed by transcardiac perfusion at 7, 20, 30, 42 and 48 days. Two unoperated animals were used as controls. After 1 week post-fix the middle ear was flooded with 2% osmium tetroxide for 30min to distinguish neural elements of the TP against the promontory mucosa. After drawing and photography, TP components were dissected and processed for EM. In four animals the TN was present bilaterally as a large single nerve traversing the promontory. In three other animals a hypotympanic branch of the TN was present unilaterally. In all animals, several CTN coursed from the region of the carotid artery to join the TN. Often associated with this nerve junction were large delta-shaped G/G cell clusters. These clusters were also present at many locations throughout the TP, mostly associated with CTN. Ultrastructural analysis showed degenerating terminals synapsing on, and in close association with, these cells *bilaterally*. Degenerating myelinated and unmyelinated axons were also present in the TN and CTN bilaterally. Not all CTN axons were degenerated, suggesting a source other than SCG. Although G/G cells were associated with numerous mucosal blood vessels, no fenestrated endothelia were observed. The large G/G cells (35um) showed many somatic extensions with multiple synaptic relations, a large spherical nucleus with a single nucleolus, abundant cytoplasmic organelles, and some dense cored vesicles. They are enveloped by satellite cells with thin tortuous cytoplasmic processes, an elongated nucleus with dark clumped chromatin, and a dark organelle-poor cytoplasm.

The potential role of TP elements in subserving a middle ear aeration reflex analogous to that seen in the lower respiratory tract is the focus of present studies.

527.27

DISTRIBUTION OF VASOPRESSIN AND VASOACTIVE INTESTINAL POLYPEPTIDE IN CANINE PARAVENTRICULAR AND SUPRAOPTIC HYPOTHALAMUS. C.H. Block and H. Vilsack*. The Research Institute of the Cleveland Clinic Foundation, Cleveland, OH 44195

From initial anatomical studies, vasopressin (VP) and vasoactive intestinal polypeptide (VIP) are co-distributed in the paraventricular (PVN) and supraoptic (SON) nuclei of the canine hypothalamus (Block, 1987). However, in the normal Sprague-Dawley rat, VIP-containing cell bodies are not found in the PVN, while in the colchicine-treated homozygous Brattleboro and lactating or adrenalectomized rat, VIP immunoreactivity within perikarya of the PVN is evident (Mezey, 1986). Since the PVN and SON are significant hypothalamic regions for fluid regulation and control of pituitary and autonomic functions in the dog, the distributions of the neuropeptides, VP and VIP were examined in the canine brain.

Eight male mongrel dogs (2-6 kg body weight), 4 pretreated with colchicine, were perfused with Zamboni's fixative and brain tissue was processed for localization of VP and VIP using single- and dual- immunocytochemistry.

At the level of the optic chiasm, two distinct populations of cells containing VP- and VIP-immunoreactivity were observed in the periventricular-PVN. Additionally, many VP cells were found throughout the SON, whereas VIP-containing cells were localized to the medial SON. At mid-anterior-posterior levels of the PVN, a dense population of cells containing VP were visualized throughout the posterior magnocellular division, while VIP-containing cells were found primarily in the lateral aspect of the posterior magnocellular division of PVN. Double-stained neurons, containing VP and VIP, were scattered in the posterior magnocellular division and accessory PVN, and in the caudal aspect of the medial-SON and infundibular region.

These studies indicate a coincidence and overlap of VP- and VIP-containing cell populations in the PVN and SON of the dog. Since studies conducted in the rat suggest that VIP may participate in the release of prolactin and VP, it is plausible that, in the dog, VIP may also contribute to release of VP and fluid regulating mechanisms.

OLFACTORY INPUT TO AMYGDALOID NEURONS PROJECTING TO THE DORSAL MEDULLA. M.D. Cassell* and L. Modarressi*. (SPON: J. West). Dept. Anat., Univ. of Iowa, Iowa City, IA 52242.

The taenia tecta (TT) appear to be the main source of olfactory inputs to the central amygdaloid nucleus (Ce). The TT projection in the rat terminates in the medial Ce and is in a position to influence Ce neurons projecting to the medulla. We have therefore examined the post-synaptic relationships of TT terminals in the rat Ce at the ultrastructural level. Unilateral electrolytic lesions of the TT were made in 12 rats, 6 of which received concurrent injections of 1.5% HRP-WGA into either the NTS or parvicellular reticular formation. Peroxidase activity was detected using Co-Ni/DAB intensification of TMB chromagen. At 48 hr post-lesion, degenerating terminals were observed in the medial Ce on perikarya (12%), small (<500 nm dia) dendrites (36%) and large (>500 nm dia) dendrites (52%). No axo-spinous contacts were observed. Degenerating terminals on large dendrites were usually clustered into groups of 2-4 terminals per dendrite profile. Similar patterns of degeneration were observed on HRP labelled perikarya and large dendrites. Control injections of HRP into medulla alone produced degenerating and labelled terminals in the ventrolateral Ce but not observed in contact with retrogradely labelled neurons. The present results provide evidence of a polysynaptic route through the Ce by which olfactory influences on autonomic functions may be mediated.

527.29

CALCITONIN GENE- RELATED PEPTIDE IMMUNOREACTIVE INNERVATION OF THE INSULAR CORTEX OF THE RAT. Y. Yasui*, D.F. Cechetto, and C.B Saper, (Spon: P.A. McGrath) Depts. of Pharm. & Physiol.Sci. and Neurology, Univ. of Chicago, Chicago, IL 60637 and Robarts Res. Inst., Univ. Western Ont., London, ONT

Calcitonin gene-related peptide-like immunoreactive (CGRPir) innervation of the insular visceral sensory cortex (IC) in the rat is thought to originate from the ventroposterior parvocellular (VPpc) visceral relay nucleus in the thalamus. We re-examined this putative projection, using immunohistochemistry for CGRPir combined with retrograde transport of the fluorescent dye, Fluoro-gold (FG).

Only modest numbers of CRGPir fibers were seen in the dysgranular and agranular IC, and fewer still were found in the granular IC. However, the density of CGRPir innervation increased caudally along the rhinal fissure, in the adjacent perirhinal cortex. Following injections of FG into the granular or dysgranular IC, numerous retrogradely labeled neurons were seen in the VPpc, but few if any of these were CRGPir. On the other hand, injections of FG into the perirhinal cortex retrogradely labeled numerous CGRPir neurons in the posterior thalamic complex.

We did, however, observe that the VPpc was heavily invested with CGRPir terminals. Injections of FG into the VPpc retrogradely labeled CGRPir cell bodies in the parabrachial nucleus. Additional CGRPir cell bodies in the parabrachial nucleus were retrogradely labeled by injections of FG into the IC. CCRP may be a neuromodulator in the ascending visceral sensory pathway from the parabrachial nucleus to the VPpc and the IC, but not between the latter structures.

527.30

EFFERENT PROJECTIONS FROM THE INFRALIMBIC CORTEX. K.M. Hurley and C.B. Saper, Dept. of Pharm. & Physiol. Sci., University of Chicago, Chicago, IL 60637.

Electrical stimulation of the infralimbic cortex (ILC) decreases blood pressure and inhibits gastric motility. We examined the efferent projections of ILC using the anterograde tracer PHA-L. Three efferent fiber bundles were observed. (1) A dorsal projection innervated the prelimbic and anterior cingulate cortices, then continued into the dorsal fornix and the dorsal subiculum. (2) Fibers in a lateral projection either extended caudally in the ventromedial portion of the internal capsule or laterally to innervate the dorsal piriform and insular cortices. (3) The largest group of labelled fibers took a ventral trajectory, entering the medial forebrain bundle (MFB) to innervate portions of the basal forebrain, hypothalamus, midline thalamus and ventral tegmental area. At the posterior hypothalamus, some MFB fibers coursed dorsomedially into the periaqueductal grey while others extended dorsolaterally into the central tegmental fields. Both pathways contibuted to terminal labelling in the parabrachial nucleus. Fibers descended through the medial and lateral portions of the medullary tegmentum and innervated the spinal trigeminal nucleus, rostral ventrolateral medulla, nucleus ambiguus and the ventrolateral, medial and commissural portions of the nucleus of the solitary tract. These efferent projections may provide the neuroanatomical substrates mediating the physiological responses observed during electrical stimulation of ILC.

527.31

SINGLE-UNIT ACTIVITY IN THE BED NUCLEUS OF THE STRIA TERMINALIS (BST): RESPONSES TO PERIPHERAL THERMAL AND BARORECEPTIVE INPUTS. W.B. MATHIESON, Q.J. PITTMAN AND W.L. VEALE. Dept. Med. Physiol., University of Calgary, Alberta T2N 4N1.

Arginine vasopressin (AVP), released from nerve terminals in the ventral septal area (VSA), acts as an endogenous antipyretic to control febrile hyperthermia (J. Physiol.387:163-172). A major source of this AVP is from neurons in the BST. To characterize the connectivity of these cells with their targets in the VSA, and the conditions under which they are activated, single-unit extracellular recordings were made from BST neurons in anesthetized rats. Afferent and efferent connections were identified by electrical stimulation of the med. amygdala and VSA. BST neurons received both inhibitory and excitatory inputs from the amygdala and VSA. Efferents to the VSA were identified by stimulus-evoked antidromic spike invasion. The response of BST neurons to changes in scrotal skin temperature or increases in BP was recorded to investigate if previously described thermoresponsive and baroresponsive neurons in the VSA get peripheral receptor input via this BST-VSA pathway. Although some units were sensitive to scrotal temperature or BP, the results suggest that the BST is not a major relay of these inputs to the VSA.

528.1

ANATOMICAL AND MORPHOLOGICAL STUDY OF EXTRAADRENAL CHROMAFFIN TISSUE IN YOUNG RABBITS, PRE- AND POSTSTRESS
J.A. Mascorro* and O.A. Galindez*. (SPON: J.T. Weber). Dept. of Anatomy, Tulane Med. School, New Orleans, LA.

The adrenal medulla possesses abundant catecholamines (CAMs) and peptides. While the role of the latter is not understood, it generally is agreed that CAMs are released from this endocrine gland in response to various stimuli. Abundant chromaffin tissue also exists in extraadrenal sites, but the function of these "paraganglion" cells is totally unknown. In order to determine if this tissue responds to stimulus as does the adrenal medulla, animals were subjected to a hypothermic environment known to affect the CAM-rich cells of the medulla. Tissues were anatomically mapped with potassium dichromate and then processed for fine structural study. Following mild (4 hrs. @4°C, 34°C rectal temp.) or more severe (10 mins. in 0°C ice bath, 15°C rectal temp.) hypothermic stress, medullary CAM granules readily showed changes ranging from partial to total depletion of the dense cores usually associated with CAM storage. Conversely, even the more severe hypothermia failed to affect the paraganglion granules to the same degree, as the granule core always was present. Occasionally, many granules were swollen and vacuolization was evident within the cytoplasm, nevertheless frank depletion was not noticed. Paraganglion cells may not respond to this stimulus, particularly when one considers that they do not receive nerve endings.

528.2

EFFECT OF MATERNAL HYPOXIA ON ENKEPHALIN AND CATECHOLAMINE LEVELS IN RABBIT PUP ADRENAL MEDULLA.
J Gingras*, R Rigual* C Unsworth*, O Viveros, W Long*, (Spon. M McNamara) Peds Dept, Duke, Durham 27710, UNC, Chapel Hill 27514, Burroughs Wellcome, RTP 27709

Maternal Hypoxia (MH) alters pre and postnatal opiate levels in rabbit brainstem (Dev. Neurosci. In Press). We hypothesized that MH would also alter pre and postnatal adrenal opiate levels. 12 pregnant animals were placed in environmental chambers at gestational day E10. Between days E14 and E28, 6 pregnant animals breathed 21% O2(C) and 6 pregnant animals breathed 14% O2(H). On E28, 3C and 3H animals were delivered by hysterotomy. The remaining animals kindled at term. H was discontinued on day E29. Pups were sacrificed on E28 and postnatal days P3, P7 and P21 and adrenal medullae removed for measurement of opiate and catecholamine levels (NE,DA,E). NE, DA, E content/mg protein were unaffected by MH. Opiate results are below (pmol/mg protein ± SD).

AGE:	Native(N)	Enkephalin H:C	Total(T)	Opioid Activity H:C
E-28	24±12	: 14±5	112±52	: 43±16
P-3	23±12	: 37±18	43±21	: 61±37
P-7	33±13	: 52±18	124±71	: 132±42
P-14	74±47	: 75±20	294±148	: 253±102
P-21	28±14	: 61±22	199±128	: 379±171

MH elevated N and T opioid activity in fetal adrenal medullae ($p<0.05$). MH reduced N and T opioid levels at P21 ($p<0.05$) and accelerated the timing of the postnatal enkephalin peak. MH alters the content, processing, maturational patterns of adrenal medullary enkephalins in offspring.

528.3

INTERACTIONS OF STRESS, SALT INTAKE AND EXERCISE ON ADRENAL AMINES IN THE BORDERLINE HYPERTENSIVE RAT (BHR).
E.F. O'Connor, R.H. Cox, S.K. Naylor* and J.E. Lawler. University of Tennessee, Knoxville, TN 37996.

The BHR (the F1 cross of SHR x WKY) has a marked sensitivity to tail shock stress and dietary salt intake. Since the adrenal medulla and its amine neurohormones are thought to play a permissive role in the development of hypertension, we examined adrenal amines (norepinephrine, NE, epinephrine, E, dopamine, DA, and serotonin, 5-HT) in BHRs given normal (N) or high salt (3% NaCl) diets and exposed daily to swimming, tail shock or neither. Our results (MN±SEM) are summarized below.

		NE(ug)	E(ug)	DA(ng)	HT(ng)
CONT	(N)	5.84(0.4)	25.6(1.1)*	219.73(40)	29.55(4)*
	(3%)	5.31(0.3)	19.8(1.4)	216.97(14)@	20.20(2)
SWIM	(N)	7.10(1.0)*@	24.3(1.5)	256.97(17)*	23.04(3)
	(3%)	6.51(0.5)	21.9(0.9)	175.42(9)	22.63(4)
STRS	(N)	5.00(0.3)	21.9(1.2)	155.25(11)@	22.04(3)
	(3%)	5.56(0.3)	22.8(2.1)	170.19(20)	20.47(3)

* indicates p 0.05 for comparisons between conditions
@ indicates p 0.05 for comparisons between diets.

Swimming had the greatest effect, resulting in an apparent increase in adrenal NE and DA. (Supported by HL19680, HL01395 and HL34878)

528.4

INCREASED ANGIOTENSIN II RESPONSES ARE NOT REQUIRED FOR POTENTIATION OF ADRENAL CATECHOLAMINE RESPONSES TO REPEATED HEMORRHAGE IN DOGS.
J.S.Cross*, M.P.Lilly*, E.J.DeMaria*, and D.S.Gann, (SPON: D.Carlson) Dept. of Surgery, Brown University/Rhode Island Hospital, Providence, Rhode Island, 02903

Potentiated adrenal catecholamine(CA) secretory responses have been described to the second of two paired hemorrhages(hem) in dogs. Angiotensin II (A-II) is an adrenal CA secretagogue and may be necessary for normal adrenal CA responses to hem. To study the role of A-II in the CA response to repeated hem, we prepared dogs (n=13) with splenectomy and adrenal vein and femoral artery and vein cannulas. Two days later under pentobarbital anesthesia, dogs were bled either 20%(H1) of measured blood volume (Evans blue dye), or 0% (H0, samples only). Shed blood was reinfused 30 min after H1. 90 min after the start of the experiment, all animals had 20% hem (0%/20%=H0/H02;n=6), (20%/20%=H1/H12;n=7). Adrenal venous and arterial plasma samples and hemodynamic measurements were taken at -5, 2, 4, 6, 8, 10, 15, 20, and 30min after each hem. CA were measured by HPLC and adrenal secretion rates of epinephrine and norepinephrine (E, NE) were calculated. A-II was measured by RIA (n=4 for H02); data were analyzed by ANOVA. Resting E, and NE were not different among groups, but resting A-II was greater before H12. NE response paralleled E.

Horm	Hem	n	Control	Δ at 10min	Δ at 20min	Δ at 30min
Δ E	H02	6	1.4±0.8	29.2± 9.9*	52.9±26.7*	18.1± 12.8*
(ng/min)	H1	7	2.5±0.7	15.3± 7.1*	33.5±14.1*	33.5± 16.2*
	H12 §	7	2.8±1.5	109.0±59.7*†	116.4±68.8*	120.3± 72.6*
Δ A-II	H02	4	103.9±23.7	119.1±28.3*	150.5±48.9*	237.0±121.3*
(pg/ml)	H1	7	80.3±17.6	170.8±23.2*	198.2±36.0*	208.3± 45.3*
	H12	7	168.0±50.8†	189.3±41.3*	156.8±36.5*	181.5± 32.0*

*$p<0.01$ from control †$p<0.05$ from H1. §$p<0.05$: H12 group vs. H1 group.

Hemodynamic responses in the three hem groups were not different. Maximal Δ E correlated with resting A-II ($p<0.0001$), but not with maximal Δ A-II. Thus the larger E responses to H12 were associated with higher resting A-II but not with greater change in A-II. These results could be explained by increased sensitivity of the sympatho-adrenal system to A-II, action of another factor, or a "permissive" role for A-II in CA responses to hem. Supported by NIH Grant # GM27946.

EFFECTS OF CHRONIC INSULIN TREATMENT ON ADRENAL CATECHOLAMINE SYNTHESIS AND RELEASE IN THE PITHED RAT.
K. Richter*, E. M. Stricker and R. R. Vollmer*. (SPON: R.J. Ertel). Dept. Behavioral Neuroscience, Univ. Pittsburgh, Pittsburgh, PA 15260

Hypoglycemia produced by repeated treatment with insulin results in increased adrenal medullary catecholamine (CA) synthesis as evidenced by an induction of tyrosine hydroxylase (TH). The relation between augmented TH activity and CA release in the adrenal medulla was examined in male Sprague-Dawley rats.

Rats were treated with protamine-zinc insulin (Lilly) at 12 hr intervals for 4 days (4-8 U/day, s.c.), causing a two-fold increase in adrenal TH activity. Adrenal CA release was assessed in pithed rats 16-18 hr after the final dose of insulin when blood glucose concentration and absolute adrenal CA content had returned to normal levels. Electrical stimulation of the thoracolumbar spinal cord (4-32 Hz) resulted in increments in blood pressure and plasma epinephrine and norepinephrine that were equivalent in insulin- and saline-treated rats. Unstimulated values were also equal. Insulin had no effect on clearance of epinephrine from the plasma. Similar results were obtained when the adrenal was field stimulated in situ at 8 Hz for 1 hr.

These findings suggest that the induction of TH that results from insulin-induced hypoglycemia is not associated with a change in the basal or neurally mediated adrenal CA release. (Supported by NIH Grant MH-29670 and NSF BNS-8518035.)

SECRETED MOLECULES OF DIFFERENT SIZES TAKE DIFFERENT ROUTES FROM THE ADRENAL MEDULLA.
S.W. Carmichael, G.M. Tyce, T.L. Yaksh,* D.T. O'Connor* and S.L. Stoddard. Depts. Anatomy, Physiology, and Neurosurgery, Mayo Clinic/Foundation, Rochester, MN 55905, Dept. Medicine, Univ. California, San Diego, CA 92161, and Dept. Anatomy, Indiana Univ., Fort Wayne, IN 46805.

Following an insulin-induced hypoglycemic insult, patients demonstrate a peak in plasma chromogranin A (CHR A) levels that lags behind the catecholamine (CA) peak by about 90 min (Clinical Res. 35:605A, 1987). From this observation we suggest that molecules of different sizes secreted from the adrenal chromaffin cell gain access to the circulation via different routes. Plasma and lymph were collected from cannulae placed in the left adrenolumbar vein and thoracic duct, respectively, in halothane-anesthetized cats (N=9). Blood glucose was determined in samples taken from the femoral vein. Insulin (1 U/kg; iv) was given after collection of baseline samples; additional samples were taken over 4 hr. In three cats, the adrenal glands were isolated from the circulation after 4 hrs and lymph collected for an additional 90 min. Free CA (MW=153-183) levels in adrenolumbar venous plasma greatly exceeded those in lymph. Neuropeptide Y (MW=4254) was found primarily in plasma, but was also present in lymph. CHR A (MW=48 kDa) was detected in approximately equal amounts in plasma and lymph. After the adrenals were isolated, CHR A levels dropped in lymph. We conclude that larger molecules secreted from the adrenal medulla may enter the circulation via the lymphatic system.

CHANGES IN ADRENAL BLOOD FLOW DISTRIBUTION DETERMINED BY NON-RADIOACTIVE FLUORESCENT MICROSPHERES M.S. Jasper*, P. McDermott*, D.S. Gann, and W.C. Engeland, Sect. of Neurobiology/Dept. of Surgery, Brown Univ./R.I. Hosp.,Providence, RI 02902

Changes in adrenal medullary and total cortical blood flow after hemorrhage (hem) have been described using radioactive microspheres (mcs). To assess changes in intracortical adrenal blood flow, a method was used based on microscopic detection of non-radioactive mcs. Injection of different colored fluorescent mcs permitted multiple determinations of blood flow. Pentobarbital anesthetized dogs (n=6) were prepared acutely with left ventricular and aortic catheters for injection and collection of 15 µm mcs, respectively. Adrenal denervation was done unilaterally by cutting the thoracic splanchnic nerve. Injections were made prior to and immediately after 18 ml/kg hem (duration 5-7 min.). Dogs were sacrificed with KCl and adrenals were removed, fixed and sectioned at 80 µm. Using fluorescence microscopy, mcs coated with fluorescent dyes were counted in each section. The number of mcs in the capsule (CAP), zona glomerulosa (ZG), inner cortex (IC), and the medulla (MED) was determined. Prior to hem, CAP received 10.2% , ZG received 65.4%, IC received 5.5%, and MED received 18.9% of adrenal blood flow. Denervation did not change this distribution. Following hem, in intact glands, the proportion of flow to the MED increased to 55.7%, while proportions to CAP, ZG, and IC decreased to 5.6, 35.1, and 3.5%, respectively. Distribution of intracortical blood flow did not change. In denervated glands, changes in all zones after hem were reduced. Since sinusoids in the IC are in series with ZG capillaries, the small proportion of mcs in IC may result from trapping of mcs in the ZG. To test this possibility, 5 and 8 µm mcs were injected. The ratio of IC spheres to total adrenal mcs increased inversely with sphere diameter, suggesting that blood flow determination with 15 µm mcs underestimates IC flow. These data show that whereas hem increases medullary blood flow in intact glands, neither hem nor denervation causes changes in distribution of intracortical blood flow. These findings support and extend work suggesting that the distribution of adrenal blood flow is influenced by adrenal innervation. Supported by NIH grants DK38951 and DK26831 .

INFLUENCE OF CAPTOPRIL ON NEURALLY-EVOKED CHANGES IN ADRENAL CORTICAL AND MEDULLARY SECRETION W.C. Engeland, P. Miller* and D. S. Gann, Sect. of Neurobiology/ Dept. of Surgery, Brown Univ./ R. I. Hosp., Providence, RI 02902

Angiotensin II (AII) stimulates the secretion of cortisol (F) from the adrenal cortex and the secretion of epinephrine (E) and norepinephrine (NE) from the adrenal medulla in dogs. Splanchnic nerve stimulation in dogs results in increased secretion of F, E and NE. To test the possible influence of AII generated by nerve stimulation on adrenal responses, neurally evoked secretion was assessed with or without blockade of AII converting enzyme by captopril. Dogs under pentobarbital anesthesia were hypophysectomized and prepared with an adrenal venous cannula; the thoracic splanchnic nerve was cut and placed in a stimulating electrode. Dogs infused with ACTH (2 and 10 ng/min) or with ACTH and captopril (2 µg/kg/min) underwent nerve stimulation (30V; 0.5 msec pulses) at 1 and 4 Hz. Adrenal venous E and NE were measured by HPLC-EC; F and 11-deoxycortisol (S) by HPLC-UV; and AII by RIA. At both doses of ACTH, nerve stimulation resulted in frequency dependent increases in mean arterial pressure (MAP), adrenal blood flow (ABF), arterial AII and secretion of E and NE; at 10 ng/min ACTH only, nerve stimulation at 1 and 4 Hz increased secretion of F and decreased secretion of S resulting in increases in the F/S ratio. Captopril reduced basal MAP and arterial AII and blocked neurally evoked increases in AII. With captopril nerve stimulation resulted in augmented increases in ABF, in adrenal vascular conductance (ABF/MAP) and in E and NE secretion but resulted in similar changes in F and S secretion relative to dogs without captopril. These data show that adrenal steroid and catecholamine responses to splanchnic nerve stimulation can occur after blockade of increases in arterial AII. These findings suggest that neurally-evoked changes in adrenal steroidogenesis occur independently of an intact renin-AII system. Also, the reduction of the vasoconstrictor activity of AII on the adrenal appears to augment the adrenal secretion of E and NE without increasing secretion of steroids. Supported in part by NIH grants DK38951 (WCE) and GM27946 (DSG).

PLASMA CORTICOSTERONE RESPONSES TO ELECTRICAL STIMULATION OF THE MEDIAL THALAMUS. J.D. Dunn and I. Calloway*. Dept. of Anat., Sch. Med., Oral Roberts Univ., Tulsa, OK 74171.

To pursue the possibility that the medial thalamus is involved in adrenocortical function, blood samples obtained prior to and following electrical stimulation of female rats were assessed for corticosterone (Cpd B) concentration. Rats were anesthetized with urethane ($1.3g \cdot Kg^{-1}$), tracheotomized, instrumented and positioned in a stereotaxic apparatus. ECG, HR, MAP, and hippocampal EEG were monitored and timed blood samples (0.2ml) were obtained from a tail artery. Blood samples were taken at 0.5 min. prior to and at 5, 10, 15 and 30 min. after initiation of stimulation (monophasic square waves, 100µA, 50HZ, 0.5 msec, 1 sec on/1 sec off for 30 min.). A change in plasma Cpd B was considered different from no change when the average of the 5,10,15 and 30 min. samples deviated by more than 10% from the pre-stimulus level.

Stimulation of all subdivisions of the dorsomedial nucleus produced an increase (+21%) in plasma Cpd B levels. Stimulation of the paratenial nucleus resulted in decreased (-16%) plasma Cpd B levels. In contrast no change in Cpd B levels were observed following sham stimulation or stimulation of other surrounding sites, including the medial habenular nucleus. Collectively these data support the hypothesis that the medial thalamus contains areas differentially involved in adrenocortical function.

INTRA-INDIVIDUAL VARIABILITY OF BASAL, PEAK, AND DELTA CORTISOL DURING REPEATED ACTH STIMULATION. R.G. Kathol, R.S. Jaeckle, J.F. Lopez*, W. Meller*. Departments of Psychiatry and Internal Medicine, University of Iowa Hospitals, Iowa City, IA 52242.

Six male controls were administered alpha $_{1-24}$ cosyntropin by intravenous bolus at 1600 hour on nine occasions with at least a two day interval between tests. Dosages of 250 ng, 1 ug, and 250 ug were each given on three occasions in random order while plasma samples were obtained at 0, 15, 30, 45, and 60 minutes after injection. Mean baseline, peak, peak time, and delta cortisol levels did not demonstrate carry-over effects from prior testing. The mean intra-individual coefficient of variation (CV) for baseline 1600 hour cortisol levels (mean--11.4 +/- 1.5 ug/dl) was 27%. The mean intra-individual CV for peak cortisol levels was 20%, 12%, and 13% for 250 ng, 1 ug, and 250 ug of ACTH respectively. Peak cortisol levels for the 250 ng, 1 ug, and 250 ug injections were 21.4 ug/dl, 23.3 ug/dl, and 24.9 ug/dl respectively. The mean intra-individual CV for delta cortisol levels was 61%, 38%, and 17% for the three dosages respectively. Peak time occurred at 33 and 35 minutes for the 250 ng and 1 ug injections respectively and at 50 minutes for the 250 ug.

These data suggest that longitudinal evaluation of adrenal responsivity to ACTH within an individual is best performed by measuring the peak response. Use of the submaximal 1 ug dose of ACTH allows assessment of increases as well as decreases in cortisol response without compromising within subject variability. Baseline cortisol levels are less consistent than peak response to ACTH for longitudinal monitoring.

AMPLITUDE MODULATION OF A BURST-LIKE MODE OF CORTISOL SECRETION GIVES RISE TO THE CIRCADIAN GLUCOCORTICOID RHYTHM IN MAN. JD Veldhuis, A Iranmanesh,* G Lizarralde,* ML Johnson.* Univ of Virginia School of Med, Charlottesville, VA 22908; Dept of Int Med, Veterans Administration Medical Center, Salem, VA 24153.

We examined mechanisms subserving the in vivo circadian rhythm of cortisol in man. Blood samples were drawn at 10 min intervals for 24 hr in each of 6 men to yield well defined episodic cortisol release profiles. A novel multiple-parameter deconvolution model was applied to discriminate number, amplitudes, and durations of all significant underlying cortisol secretory bursts, and simultaneously estimate the endogenous half-life of cortisol disappearance. These experiments disclosed delimited cortisol secretory bursts with a mean interpulse interval of 77±4.0 min. The amplitude of secretory bursts was 0.45±0.044 (mcg/dl/min) and half-duration (duration at half-maximal amplitude) only 16±0.61 min. We calculated an in vivo cortisol disappearance half-time of 73±5.3 min (range 62-97 min) and production rate of 142±14 (mcg/dl/day) (16±1.4 mg/day). Cortisol secretory burst frequency varied 2.2 fold over 24 hr, whereas secretory burst amplitude varied 6.6 fold. We conclude: the nyctohemeral pattern of cortisol variation can be accounted for by a model of amplitude-modulated burst-like cortisol secretion. This eliminates the need to postulate a tonic mode of cortisol secretion in man.

GLUCOCORTICOID REGULATION IN RESPONSE TO CHRONIC ETHANOL TREATMENT. R.L. Spencer, K. Kimura* and B.S. McEwen, Lab. of Neuroendocrinology, Rockefeller Univ., New York, NY 10021.

The response to an acute dose of ethanol (EtOH) resembles a stress response, characterized by a rapid rise in serum corticosterone (Cort). We examined the effect of chronic (1-3 wks) EtOH treatment on glucocorticoid regulation. In 1 experiment, male Sprague-Dawley rats were given EtOH (2.5-3.0 g/kg i.p., 20% v/v) twice per day (9AM and 4PM) for 18 days. The EtOH treated rats had signs of chronic pituitary-adrenal axis activation, with a significant decrease in body weight and thymus weight, and increase in adrenal/body weight relative to saline injected controls. There was, however, no change in glucocorticoid receptor (GR) Type I or Type II binding levels in the hippocampus (HC). EtOH treated rats also had elevated basal serum Cort levels at 8AM on day 19, but a blunted Cort response to 1 hr of restraint stress relative to control rats. In a second experiment with male Long-Evans rats, the same EtOH treatment paradigm produced a similar pattern of body and tissue weight changes, as well as a significant increase in GR Type I binding in the HC. These results indicate changes of glucocorticoid regulation in response to chronic EtOH treatment. Some of these changes may be adaptive and help to diminish the acute and long-term "stress" response to ethanol. Supported by MH41256 and AA05256.

VIP BINDING AND STEROIDOGENIC EFFECTS IN THE ADRENAL CORTEX. L.A. Cunningham and M.A. Holzwarth. Department of Cell and Structural Biology, University of Illinois, Urbana, IL 61801.

VIP-immunoreactive nerve fibers innervate the capsule and zona glomerulosa regions of the rat adrenal cortex. Previous studies demonstrated direct VIP stimulation of steroid secretion by rat adrenal capsule-glomerulosa tissue preparations perifused in vitro (Endocrinology 122(5), 1988). The present studies were undertaken to determine: 1) the distribution of adrenal VIP binding sites and 2) whether the steroidogenic effect of VIP is altered by the presence of ACTH or angiotensin II. Using in vitro autoradiography, VIP binding sites were found to be concentrated in the capsule and zona glomerulosa, the regions that receive most extensive VIP innervation. Specificity of ^{125}I-VIP binding in this region was demonstrated; binding of 0.75 nM ^{125}I-VIP was inhibited (65%) in the presence of unlabelled VIP (7.5 μM), was unaffected by ACTH (7.5 μM), and was decreased 20% by 7.5 μM angiotensin II. VIP stimulation of aldosterone, but not corticosterone, was enhanced by the humoral secretaguogue, ACTH;aldosterone secretion stimulated by 10^{-5} M VIP in vitro was enhanced 70-80% by concomitant stimulation with subthreshold concentrations of ACTH (10^{-13} or 10^{-12} M). VIP-stimulated steroid secretion was not affected by the presence of 10^{-10} or 10^{-9} M angiotensin II.

ONTOGENY AND HANDLING-INDUCED CHANGES IN HIPPOCAMPAL GLUCOCORTICOID AND MINERALOCORTICOID RECEPTORS IN THE RAT. V. Viau, A. Sarrieau, S. Sharma, and M.J. Meaney. Douglas Hospital Research Ctr., Dpet. Psychiatry, McGill Univ. Montreal, Canada H4H 1R3.

We report here on the developmental changes in ^{3}H RU 28362 (glucocorticoid receptor) and ^{3}H aldosterone (mineralocorticoid receptor) binding capacity in soluble fractions prepared from hippocampal tissue. ^{3}H RU 28362 bind was low on Day 3 of life (30% of that observed in adults) and increased towards adult values during the second and third weeks of life, a pattern virtually identical to that previously reported for dexamethasone binding. In contrast, ^{3}H aldosterone binding on Day 3 of life was only slightly less than that observed in adults and reached adult values by Day 7 of life. Postnatal handling, which has been shown to increase dexamethasone binding in hippocampus, resulted in a significant increase in ^{3}H RU 28362 binding capacity in hippocampus, but had no effect of ^{3}H aldosterone binding. These results confirm that handling selectively influences the glucocorticoid receptor system in hippocampus. (Supported by MRCC grants to MJM).

BEHAVIORAL AND NEUROENDOCRINE REGULATION OF MINERALOCORTICOID AND GLUCOCORTICOID ACTION. H. Coirini*, J. Schulkin* and B. McEwen, Lab of Neuroendocrinology, Rockefeller University and Dept. of Anatomy, University of Pennsylvania. (SPON: M. Tordoff)

During states of extracellular fluid and body sodium loss the mineralocorticoids (MIN) are elevated in the body and play a fundamental role in the retention and redistribution of body sodium. The hormone also generates a hunger for salt in the rat. The glucocorticoids (GLU) are to a much less degree elevated during body sodium depletion and are not natriorexigenic in the rat. While both hormones compete for the same receptor sites in several limbic brain regions, and there is a far greater number of GLU than MIN sites, these sites also show preferential binding. A MIN target is the preoptic area and hypothalamus; a GLU target is the hippocampus. In the present study we confirm and extend that MIN induced salt appetite in addition to body sodium depletion induced salt appetite is further elevated when combined with GLU. And we report that corticosterone administration increases the level of aldosterone binding to preoptic-hypothalamic, but not to hippocampal MIN receptors. One hypothesis is that elevating MIN receptors by GLU action in preoptic-hypothalamic tissue contributes to the natriorexigenic actions of the mineralocorticoids.

CHARACTERIZATION OF ^{3}H-RU 28362 BINDING TO TYPE II GLUCOCORTICOID RECEPTORS IN NEURONAL, LYMPHOID AND PITUITARY TISSUES. M.T. Lowy, Department of Psychiatry, Case Western Reserve University, Cleveland, OH 44106.

Glucocorticoid receptor (GR) abnormalities are present in the lymphocytes of depressed patients. However, it is not known if GR in lymphoid tissues are regulated in a manner similar to neuronal GR. To initially address this issue, type II GR were quantitated in neuronal (frontal cortex: FCX, hippocampus: HPC, and hypothalamus: HYPO), lymphoid (circulating lymphocytes: LYMP, thymus: THY and spleen: SPL) and pituitary (PIT) tissues in adrenal-intact and 1 day adrenalectomized (ADX) rats using the specific type II GR ligand ^{3}H-RU 28362.

^{3}H-RU 28362 binding was detectable in all tissues with the rank order of GR content in ADX rats being THY > FCX=SPL>HPC=PIT > HYPO > LYMP. The rank order of GR content in intact rats was THY > FCX=PIT=SPL > HPC > LYMP > HYPO. Tissues from intact rats generally had fewer GR compared to ADX rats. The dissociation constant (K_d) for the GR was similar (0.20 - 0.40 nM) in all tissues and in intact vs. ADX rats. Results from competition studies will also be presented.

These results document the presence of specific high affinity type II GR in neuronal, lymphoid and pituitary tissues.

STEROID-RECEPTOR INTERACTIONS IN THE DIFFERENTIAL DOWN-REGULATION OF TYPE I AND TYPE II ADRENOCORTICOSTEROID RECEPTORS IN MOUSE BRAIN. William G. Luttge and Mary E. Rupp*. Dept. of Neuroscience, Univ. of Florida Coll. of Medicine, Gainesville, FL 32610.

Previous work from our laboratory (Luttge and Rupp, STEROIDS, in press) revealed that adrenalectomy-orfadectomy (ADX) of female and male mice resulted in a dramatic bi-phasic up-regulation of Type I, and to a lesser extent, Type II adrenocorticosteroid receptors in mouse brain. Peak levels in maximal binding capacity were observed at 3-8 days post-surgery, followed by decreases to near intact levels by 16 days post-surgery. ALDO and CORT replacement therapy was found to be equally effective in supressing the increases in the binding capacity of both of these receptors. This equivalency is consistent with the equal affinity of ALDO vs. CORT for Type I receptors, but it is inconsistent with the much lower affinity of ALDO vs. CORT for Type II receptors. In an attempt to explain these data we hypothesized that ALDO may down-regulate Type II receptors via its interactions with Type I receptors which, in turn suppress the expression of the gene coding for Type II receptors. The present study offers the first indirect support for this novel hypothesis.

At 24 and 48 h post-ADX, adult female mice were given a single injection of one of the following: 1) Proplylene glycol, 2) ALDO, 3) CORT, 4) RU26752, 5) RU38486, 6) ALDO + RU26752, 7) ALDO + RU38486, 8) CORT + RU26752, or 9) CORT + RU38486. At 72 h post-ADX, mice were killed, brain cytosol prepared, and Type I ([^{3}H]ALDO + [^{1}H]RU26988 ± [^{1}H]ALDO) and Type II ([^{3}H]DEX ± [^{1}H]DEX) receptor binding capacity determined. Once again, ALDO and CORT were found to be equally potent in suppressing Type I and Type II receptor binding capacity. The antimineralocorticoid RU26752 was found to partially suppress Type I receptors and to have no effect on Type II receptors, whereas the antiglucocorticoid RU38486 had no effect on Type I receptors and a marked down-regulatory effect on Type II receptors. Since RU26752 also inhibited the down-regulatory actions of ALDO and CORT on both Type I and Type II receptors, we speculate that ALDO/CORT-Type I receptor interactions may at least in part mediate the down-regulation of Type II receptors.

Characterization of Glucocorticoid-Type II Receptors in Brain Cell Cultures. Yun-Chia Chou*, William G. Luttge, and Colin Sumners (SPON: W.A. Friedman). Depts. of Neuroscience & Physiology, Univ. of Florida Coll. of Medicine, Gainesville, FL 32610.

The purpose of this investigation was to study the properties of glucocorticoid-Type II receptors in brain cell cultures. Cytosol was prepared from primary cultures of neurons or glia and incubated with [^{3}H]DEXamethasone at 0°C. Free steroid was removed afterwards by gel filtration on G-25 columns. At a steroid concentration of 20 nM, [^{3}H]DEX-Type II receptor binding in cytosol prepared from both cultures reached equilibrium after 16 h incubation and was stable up to 48 h. The binding was saturable and specific. Scatchard analyses of [^{3}H]DEX binding revealed a single population of high affinity receptors in both cultures. Despite no significant difference in the dissociation constant, glia contained 5-20 times as many receptors as neurons. As neuronal cultures are maintained in medium containing plasma-derived horse serum (PDHS), whereas fetal bovine serum (FBS) is used for glial cultures, the potentially differential effects of these serums on receptor binding was examined. Incubation of glial cultures in FBS was found to significantly increase Type II receptor content when compared to incubations in PDHS. Switching cells from serum-supplemented to serum-free medium prior to cytosol preparation was also studied and found to reduce the association rate of [^{3}H]DEX-Type II receptor complexes while having no effect on the K_d or B_{MAX}.

These results demonstrate the presence of glucocorticoid-Type II receptors in brain cell cultures which are similar to those in brain and other tissues. Since glucocorticoids have profound influences on brain function, the use of neuronal and glial primary cell cultures should be an important model system for further research on the molecular mechanisms of glucocorticoid actions in brain. *(Supported by NIH grants HL-36645 and NS-24404)*

ACUTE EFFECTS OF CORTICOSTERONE ON RAT HIPPOCAMPAL PERIKARYA, M.M. Miller, E. Antecka,* R. Sapolsky, Department Obstetrics and Gynecology, McGill University, Montreal, Quebec, Canada, H3A 1A1; Department of Biology, Stanford University, Stanford, Ca., 94305.

This study was designed to identify effects of corticosterone (cort) on hippocampal neurocytoarchitecture using quantitative electron microscopy. Sections from regions CA3B, CA1, and dentate gyrus were examined in unstressed controls and cort-treated rats (20 mg/kg in sesame oil/day x 3 days); each dose produces cort levels in the upper physiologic range for 20 hrs. The density and surface area of Golgi and the number of Golgi stacks in cort-treated rats increased 25-35% in neurons of these regions ($p<.05$, ANOVA). In addition, the surface area of rough endoplasmic reticulum and numbers of cisternae increased (38-50%) in neuronal perikarya ($p<.001$, $p<.003$). Densities of mitochondria, multivesicular bodies, and lysosomes in perikarya were unaffected. These data suggest that high doses of cort not only increase protein synthesis, but also may alter subsequent processing by the Golgi and they agree with studies of Finch et al. (1987) showing a similar time course of cort induction of an array of hippocampal mRNAs. Supported by NIH HD 19431, NIH AG-06633, and FRSQ.

ACTIVATION OF SYNAPTIC PLASMA MEMBRANE CALCIUM-ATPASE BY GLUCOCORTICOIDS. P.Y. Sze and Z. Iqbal. Dept. of Pharm., Chicago Medical School, North Chicago, IL 60064

Synaptic plasma membrane (SPM) from rat brain is known to have specific binding sites for glucocorticoids. We have previously shown that binding of corticosterone (CS) to SPM promotes membrane binding of calmodulin (CaM). In this study, we report that exposure of the membrane to CS results in similar increases of the activity of calmodulin-dependent Ca-activated ATPase (CaM-Ca-ATPase; "Ca-pump" ATPase). Purified SPM was prepared from rat brain by sucrose-density gradient centrifugation of osmotically disrupted synaptosomes. The membrane was preincubated with CS (10 nM-1 uM) at 37C for 15 min or 0C for 1 hr. CaM-Ca-ATPase activity was determined in the presence of Ca-CaM and defined as (Ca+Mg)-ATPase activity sensitive to trifluoperazine. The steroid hormone produced a dose-dependent increase in the activity of the membrane enzyme; at 1 uM CS, the enzyme activity was more than doubled. The dose-response relationship parallels the specific binding of the steroid to the membrane. Deoxycorticosterone, which does not bind to SPM and which is ineffective in promoting CaM binding to the membrane, was without an effect on the enzyme activity. These data are in support of our hypothesis that the alteration of membrane binding of CaM by glucocorticoids leads to cascading alterations of membrane functions involving Ca-CaM. Membrane transduction of steroid hormone signals may very well involve Ca-CaM.

GENE EXPRESSION CHANGES IN DEVELOPING AND MUTANT CEREBELLAR PURKINJE CELLS. A. Messer, E.L. Wylen, J.A. Plummer-Siegard & M.C. Wilson. Wadsworth Ctr. for Labs. and Res., NYS Dept. of Healt & Sch. of Public Health Sci., SUNY, Albany, N.Y. 12201 & Res. Inst. of Scripps Clinic, La Jolla, CA. 92037.

Branks and Wilson (Mol. Brain Res, 1:1-16;1986) have described a cDNA clone, pMuBr3, which, in adult cerebellum, preferentially hybridizes to Purkinje cell soma in situ. In situ hybridization (^{35}S antisense RNA) studies of developing mouse cerebella show that at postnatal day(P)0 there is no label over the external granule layer (EGL) and heavy label over the developing molecular layer (ML) and Purkinje layer (PL). The P7 pattern is similar, uniformly heavy in the ML, plus light label over the developing internal granule layer (IGL). By P14 there is a significant shift, with the heaviest label over the PL, and much less in the ML. The adult has only scattered label in the IGL and ML, with very heavy label over the PL. The residual, abnormal Purkinje cells in the staggerer mutant show greatly reduced labeling, with somewhat more ML signal than controls. These results are consistent with a developmental shift from dendritic to somatic localization of the mRNA recognized by pMuBr3 in normal Purkinje cells, although the P0 pattern is so diffuse that additional factors must also be involved. Preliminary analysis by Northern blot suggests that total pMuBr3 mRNA increases greatly between P0 and P14, with some discordancy between the two reported transcripts. Studies of additional ages and mutants are in progress. Supported by NS17633 (AM) and NS23038 (MCW).

INDUCTION OF NOVEL SPECTRIN ISOFORM DURING PERIOD OF SYNAPTOGENESIS. J.C. Noszek*, R.B. Nelson, L.G. Davis and R. Siman (SPON: J. Schwaber). Medical Products Dept., The DuPont Co., Wilmington, DE. 19898.

The actin-binding structural protein brain spectrin (also called fodrin) exists in mammalian central neurons in two isoforms. The two share a similar, if not identical subunit (Mr~240kD, α-spectrin), and have immunologically distinct second subunits (Mr~235kD, β-spectrin and δ-spectrin). The $\alpha\beta$-isoform is present in undetectable levels before post-natal day (PND) 7, and is induced over the next two weeks by more than 20-fold. Here, we have examined the developmental appearance of mRNA encoding β-spectrin. We used a 1kb cDNA selected from a human reticulocyte library (Prchal *et al.*, PNAS *84*, 7468). A portion of the amino acid sequence predicted from the cDNA completely matches the known partial sequence of the erythrocyte β-subunit. The probe labels a single band of about 9.5kb on Northern blots of adult rat brain and two other tissues known to contain the $\alpha\beta$-isoform, cardiac and skeletal muscle. All brain regions examined contain the 9.5kb mRNA, with levels in cerebellum, the most enriched region, exceeding those of thalamus by about 8-fold. Similar to the β-spectrin polypeptide, the mRNA cannot not be detected in cerebral cortex before PND7, and rises until PND 24, an increase of more than 10-fold. In contrast, mRNA for another structural protein, actin, does not appreciably change over the same post-natal period. These results indicate that expression of the $\alpha\beta$-spectrin isoform is controlled primarily by the level of β-subunit mRNA, and suggest that synapse formation could signal the induction of β-spectrin gene expression.

GENE EXPRESSION IN RAT CEREBELLAR DEVELOPMENT. S-C. Lin* and M.R. Morrison-Bogorad. Depts. of Biochemistry and Neurology, UT Southwestern, Dallas, TX 75235.

We have examined the temporal expression of individual cerebellar mRNAs by plaque differential screening and by Southern analysis of clones from a 20 day rat fetal cerebellar cDNA library cloned in lambda-ZAP. Seven hundred plaques were screened by plaque differential hybridization to cDNA probes for fetal and adult cerebellar mRNAs; 8 plaques were selected for further analysis. Southern hybridization confirmed that four of these contained sequences highly enriched in fetal cerebellum. Northern analysis showed that two mRNAs, 0.7 and 1.8 kb in size, were expressed at high abundance in rat fetal cerebellum and cortex. The mRNAs were present in adult testis, were 30-60 fold reduced in adult cortex, and were not detected in adult cerebellum, liver or kidney. In a parallel series of experiments, cDNA was isolated from 500 individual plaques (pooled into 150 groups) using our modified rapid mini-isolation method. Southern analysis of the restricted DNAs showed that >90% of the inserts were detected by the fetal probe. Thus, this method can be used to screen mRNAs of low abundance. Most of the fetal cerebellar mRNAs were expressed at similar levels in the adult rat cerebellum. 20% were reduced several fold and 2% were increased in development. Five mRNAs were highly enriched in fetal cerebellum. Supported by NIH HD14886 and the Leland Fikes Foundation.

DEVELOPMENTAL REGULATION OF GAP-43 mRNA.
S. G. McElligott, L. G. Davis, and J. G. McElligott#
Medical Products Dept., E. I. du Pont Company, Wilmington, DE 19898 and #Dept of Pharmacology, Temple University School of Medicine, Philadelphia, PA 19140.

Growth-associated protein (GAP-43/B50/pp46/F1) has been implicated in axonal elongation, regeneration, and synaptic plasticity. This neuron-specific phosphoprotein is expressed at high levels during the first week after birth and decreases to lower levels in the adult brain. With the single cell resolution of in situ hybridization histochemistry, we determined the cellular location of GAP-43 messenger RNA (mRNA) during postnatal development in various brain areas. Regional differences in the ontogenetic pattern of this mRNA expression are observed. The densest hybridization signal is observed in the neocortex, thalamus, ventromedial hypothalamus, hippocampus, and amygdala from birth to postnatal day 7. At a cellular level, the expression in various neuronal cell types changes over the developmental time course. For example, at birth high levels of this mRNA are observed in neurons of the cortical plate and pyramidal layer of the hippocampus whereas in the later emerging granule cells of the dentate gyrus and intermediate zone of the cerebral cortex increased hybridization is observed only after postnatal day 7. Maximum expression of GAP-43 mRNA in these cell types coincides with periods of dendritic and axonal growth and synaptogenesis. The developmentally coordinated expression of GAP-43 mRNA supports a role for this protein in axonal elongation and synaptic growth.

IDENTIFICATION of mRNA SPECIES RAPIDLY INDUCED BY NGF TREATMENT OF PC12 CELLS. Jeffrey L. Twiss* and Gary E. Landreth (SPON. R. Hadley), Department of Neurology, Medical University of South Carolina, Charleston, SC 29425.

NGF rapidly stimulates the transcription of the protooncogene c-fos; this gene can be superinduced by pretreatment of the cells with protein synthesis inhibitors. In order to identify other NGF-induced mRNA species we constructed a cDNA library in lambda gt10 from PC12 cells treated with NGF for 30 min in the presence of anisomycin. The library contained 2 x 10^5 recombinants and was initially screened using a subtracted probe and rescreened twice by differential hybridization. Approximately 20 positive clones were identified. Ten of these have been further investigated. The mRNA levels were maximally elevated within 30 min (1 clone), 1 hr (5 clones), or 4-10 hrs (4 clones) following NGF treatment. The expression of three clones was NGF specific, while the mRNA levels of the other clones were also elevated by EGF and TPA.

We have independently identified several additional mRNA species whose abundance is decreased following NGF treatment. One such clone, 1N18, is suppressed after 30 min of NGF treatment, but subsequently rises to control levels after 1 h.

INDUCTION OF HEAT SHOCK (STRESS) GENES IN THE MAMMALIAN BRAIN ANALYZED BY IN SITU HYBRIDIZATION. T.E. Masing and I.R. Brown. Department of Zoology, University of Toronto, Scarborough Campus, West Hill, Ontario, Canada M1C 1A4.

Studies in this laboratory have described striking regional differences in the expression of genes encoding 70 kDa heat shock proteins (hsp70) in the rabbit brain (Sprang and Brown, Molec. Brain Res. 1987, 3: 89-93). This previous work utilized frozen sections (ten microns) for in situ hybridization. To identify the types of neuronal and glial cells which are engaged in the expression of hsp70 genes we have now carried out in situ hybridization utilizing plastic (methacrylate) embedded tissue (sectioned at three microns) which permits increased cellular resolution. The patterns of expression of hsp70 genes have been analyzed in the retina, cerebellum, hippocampus and neocortex of control and hyperthermic rabbits using labeled antisense RNA probes (length 255 nucleotides) transcribed from a mouse hsp70 genomic clone (Perry and Moran, Gene, 1987 51: 225-234). Constitutive expression of an hsp70 gene was noted in several neuronal cell types. Induction of hsp70 mRNA was dramatic in glial cells in fibre tracts throughout the brain and was also apparent in several neuronal cell populations. (Supported by grants from the Medical Research Council of Canada).

NUCLEOCYTOPLASMIC TRANSPORT OF RECENTLY SYNTHESIZED RNA BY NEURONS IN HIPPOCAMPAL SLICES IS TEMPERATURE SENSITIVE

R. Kleiman*, L. Davis, G.A. Banker[1], and O. Steward (SPON: L. Phillips). Dept. of Neuroscience, and the Neuroscience Program, Univ. of VA, Charlottesville, VA 22908. [1]Dept. of Anatomy, Albany Medical College, Albany, N.Y.,12208.

In the course of studies of dendritic transport of RNA by hippocampal neurons in slices maintained in vitro, we have found that nucleocytoplasmic transport of recently synthesized RNA is virtually eliminated when slices are maintained at room temperature. Hippocampal slices prepared from 21-26 day old Sprague-Dawley rats were incubated with ^{3}H-uridine (.3mCi/ml) for one hour at room temperature (about 27°C) or at 37°C. Following the one hour labeling period, all slices were rinsed in aerated Ringer's solution with an excess of unlabeled uridine (10^{-4}M) and maintained at the same temperature as the incubation solution. Slices were fixed in 10% buffered formalin at 0, 1.5, 3, 4.5, and 6 hours following labeling. All slices were embedded in plastic and 2um sections were cut and prepared for autoradiography. At the end of the one hour pulse at 37°C, the label was localized exclusively over the nucleus. Autoradiographs of slices maintained at 37°C show that over time, the distribution of silver grains expanded to cover the entire cell body, although the nuclear labeling remains relatively higher. At room temperature the distribution of label at the end of the pulse (0 hours) was comparable to the slices maintained at 37°. However at longer intervals, these cells exhibited no increase in cytoplasmic labeling, indicating that the lower temperature inhibited nucleocytoplasmic transport of recently synthesized RNA. Electrophysiological studies of slices maintained at room temperature reveal that the slices are viable, and fully capable of synaptic transmission. Thus, the inhibition of nucleocytoplasmic transport of RNA provides an opportunity to evaluate neuron function when no new mRNA molecules can reach the cytoplasm. Supported by NIH NS23094 to GB and OS.

MOLECULAR, CELLULAR AND GENETIC ANALYSIS OF A NOVEL RAT BRAIN-SPECIFIC PROTEIN 1B1075. H.P. Ottiger* and J.G. Sutcliffe Research Institute of Scripps Clinic, La Jolla, CA 92037

The application of molecular genetics to the study of mRNAs expressed in the brain is essential in order to understand brain function and development. In a study that was undertaken to identify recombinant cDNA clones of mRNAs that code for proteins that are unique to or preferentially expressed in the rat brain we isolated and characterized 1B1075. In northern blot experiments 1B1075 cDNA clones detect two moderately abundant (0.05% of polyA+ RNA) brain mRNAs (2.1 kb 1.9 kb), expressed at comparable levels by different regions of the brain and also by pituitary, but not detectable in any other tissue. Developmental onset occurs earlier than embryonic day 16 and peaks at postnatal days 15-20. The pattern of expression has been analyzed by in-situ hybridization and immunocytochemistry. Hybridization was observed in cellullar layers in the frontal and parietal cortex in granule cells of the dentate gyrus and in Purkinje cells in the cerebellum. Antisera directed against synthetic peptides verify the cellular distribution and reveal the protein to be partially distributed in the fibers that stem from these cells. Analysis of the primary structure deduced from the translation of the DNA sequence of a full length cDNA clone predicts a novel, acidic protein containing 533 residues, with an apparent secretion signal, several potential dibasic cleavage sites and a remarkable string of repeated elements. Chromosomal linkage analysis maps the mouse analogue of 1B1075 near the dilute-short ear (d-se) region of chromosome 9. A mouse strain deleted for the se locus is also deleted for the 1B1075 gene. The mice are viable and don't show an overt phenotype. We conclude that there may be redundancy at the molecular level in the mammalian central nervous system.

DISTRIBUTION OF mRNA FOR THE A1 ISOFORM OF NaKATPase AND ^{3}H-OUABAIN BINDING IN HUMAN HIPPOCAMPUS. M.L. BRINES*, A. GREENE*, D.D. SPENCER, E.J. BENZ*, AND R.J. ROBBINS, Yale School of Medicine, New Haven, CT 06510

Na-KATPase (NKA) is an ubiquitous enzyme which regulates cell membrane potential and volume. Three isoforms exist, the products of separate genes, which appear to have distinctive biophysical properties and anatomic distributions. We used human hippocampus to compare the distribution of mRNA for the A1 isoform of NKA, which occurs widely in brain and ion transporting epithelia, to that of the mature enzyme, as assessed by ^{3}H-ouabain autoradiography. By in situ hybridization histochemistry performed on surgical specimens of hippocampi, we found that A1 mRNA was present at highest density over the cell bodies of the dentate granule cells. Neurons in the CA fields, subiculum and deep layers of entorhinal cortex also possessed high levels of mRNA for A1. Binding was diffuse and of low intensity in the outer 2/3 and absent in the inner 1/3 of the dentate moleculare layer, as well as in layer I of entorhinal cortex. Specific ouabain binding was more widely and evenly distributed over the same regions labelled for mRNA, and extended into layer I of cortex. Regional density in ouabain binding was much less marked than for mRNA. These data suggest that neurons of the hippocampus, especially dentate granule cells, have a high turnover of NKA compared to surrounding glia, presumably related to their electrical activity.

LOCALIZATION OF NA,K-ATPASE α-SUBUNIT mRNA AND POLYPEPTIDE IN MOUSE KIDNEY, CEREBELLUM, AND RETINA. V.C. Hieber, G.J. Siegel, T.J. Desmond, J. Liu-Hwa, and S.A. Ernst. University of Michigan, School of Medicine, Ann Arbor, MI 48109

A clone encoding mouse brain Na,K-ATPase α-subunit was isolated from a mouse brain lambda gt11 cDNA library using antisera to bovine and mouse brain α (combined α1 and α2) subunit. The sequence of this clone was found to be most homologous to that of the rat brain α1, rather than the α2 or α3 isoforms. A [^{32}P]RNA antisense probe derived from the cDNA insert, but not the sense strand, hybridized strongly with brain and kidney RNA on Northern blots (single band, 4.5 kb) and with sections of kidney and retina. Specificity for α-subunit mRNA was further indicated by comparing in situ hybridization of [^{35}S]-riboprobe with immunostaining of α-subunit. In kidney, mRNA and α-subunit showed similar differential tubular distributions (distal > proximal >> thin segments). In retina, inner segments of photoreceptors, the inner nuclear layer, and ganglion cell soma were strongly reactive with both probes. α-subunit, but not mRNA, was prominently expressed in plexiform layers and optic fibers. In cerebellar cortex, α-subunit and mRNA were localized in basket and granule cell soma. Basket regions and glomeruli, which contain synaptic input from these cells, were strongly reactive for the α-subunit. Although Purkinje cell soma expressed abundant message, the somal membrane and emerging dendrite exhibited little, if any, polypeptide, suggesting transport of α-subunit to more distant sites. These results suggest that co-localization of polypeptide and mRNA will be useful in mapping expression and developmental regulation of Na,K-ATPase at the cellular level.

The role of neuron-glial interactions in the regulation of expression of glutamine synthetase (GS). K. Mearow, J. Mill* and E. Freese. LMB, NINCDS, NIH, Bethesda, MD. 20892

GS catalyzes the formation of glutamine from glutamate and NH_3^+. In the CNS, GS is predominantly localized in astrocytes in vivo. It is possible that interactions between neurons and glia might lead to the repression of neuronal GS expression in vivo; such interactions have been suggested as important in induction of glial GS expression.

We have modelled possible interactions using culture systems including primary rat astrocytes and neurons, C6 glioma, 6-3 astrocytoma and PC12 cells. GS mRNA expression under the various experimental manipulations was examined by Northern analysis using our rat brain GS cDNA as probe.

Primary astrocyte cultures expressed more GS than the neurons or the various cell lines. Coculture of primary astrocytes with cerebellar neurons resulted in a 50% induction of GS mRNA; however, coculture of these neurons with C6 or 6-3 cells showed no such induction. When C6 cells or primary astrocytes cocultured with NGF-differentiated PC12 cells were compared to cocultures with naive PC12 cells, a 2-4X decrease in GS expression was observed. A similar decrease in GS mRNA was seen when granule neurons were cocultured with astrocytoma cells. These results are consistent with glial cells playing a role in regulating neuronal GS expression.

529.12

INSULIN AND IGF-I REGULATE GLUCOSE TRANSPORTER mRNA LEVELS IN PRIMARY CULTURES OF RAT NEURONAL AND GLIAL CELLS. H. Werner*, M. Adamo*, M. Raizada, C.T. Roberts, Jr.*, I. Simpson*, and D. LeRoith. Diabetes Branch and MCNEB, NIDDK, NIH, Bethesda, MD 20892, and Dept. of Physiology, University of Florida, Gainesville, FL 32610.

The study of the potential modulation of the brain glucose transporter (GT) by insulin and insulin-like growth factor I (IGF-I) has been difficult due to the presence of the blood/brain barrier. We have, therefore, investigated the regulatory role of these factors in the expression of a brain GT gene by using primary cultures of neuronal and glial cells prepared from one-day-old rat brains.

Incubation of neuronal cultures with insulin induced a dose-dependent increase in the steady-state level of GT-specific mRNA, as measured by hybridization of a ^{32}P-labeled rat brain GT cDNA probe to Northern blots. The GT mRNA hybridized as a single band of ~ 2.9 kb. Insulin (100 ng/ml) increased GT mRNA two-fold as compared to controls, with maximal expression achieved after 1 to 2 h. IGF-I was more potent than insulin in increasing GT mRNA levels; treatment with 100 ng/ml IGF-I resulted in a 4.5-fold increase in GT mRNA. In cultured glial cells, insulin similarly increased GT mRNA in a time- and dose-dependent manner. These results suggest that insulin-like peptides can modulate the expression of a brain GT gene, and that these peptides may play a physiological role in the energy metabolism of this organ.

GENE EXPRESSION IN RAT BRAIN ASTROCYTES. Douglas L. Feinstein and Robert J. Milner. Research Institute of Scripps Clinic, La Jolla, CA 92037

Astrocytes are the predominant cell type in the mammalian brain. However, their function and developmental pathways are poorly defined. We are interested in characterizing the molecules involved in the processes of normal astrocyte differentiation and function, as well as astrocytic components whose expression may change in various pathological states. RNA was isolated from primary cultures of rat brain astrocytes, either untreated or after 4 days of treatment with dibutyryl cyclic AMP (dbcAMP). Northern blot analyses of these RNA samples with oligodendrocyte specific probes (PLP, 1B236/MAG) indicate little if any contamination with oligodendrocytes, while hybridization with neuron-specific enolase showed lack of neuronal contamination. cDNA libraries were constructed in Lambda-Gem4 and in the expression vector Lambda-Zap. These libraries are being screened with DNA probes and with antibodies, for selection of both known as well as novel astrocyte-specific molecules. cDNA clones for rat GFAP mRNA have been isolated, and its DNA sequence will be determined and compared to the mouse sequence.

To begin to evaluate changes in astrocyte function due to dbcAMP treatment (which may reflect the reactive gliotic state) we have screened the astrocyte libraries with a cDNA clone of bovine transducin to isolate clones for G-proteins present in astrocytes. Screening of approx. 100,000 primary plaques yielded a single positive clone, which corresponded to an alternatively spliced from of Gs_α. This clone was used to rescreen the 2 libraries, and an additional 25 clones were isolated. Characterization of these clones will allow us to determine the diversity of G-proteins present in astrocytes, and if any forms are preferentially induced by dbcAMP treatment.

GLIAL FIBRILLARY ACIDIC PROTEIN mRNA IS DECREASED IN RAT BRAIN REGIONS IN RESPONSE TO ACUTE AND CHRONIC CORTICOSTERONE TREATMENT N. R. Nichols, J. N. Masters, D. S. Moradzadeh* and C. E. Finch. Depts. of Biological Sciences and Gerontology, Univ. of Southern California, Los Angeles, CA 90089-0191.

Glial fibrillary acidic protein (GFAP) is a marker of reactive gliosis and is increased several-fold in brain injury, aging, and neurodegenerative disease. In contrast, glucocorticoids, which potentiate hippocampal neuronal damage (Sapolsky et al., Endo. Rev. 7:284, 1986), also decrease GFAP in rat brain (O'Callaghan et al., Neurosci. Abs. 13:1366, 1987). In this study, corticosterone (CORT; 10 mg/day sc in oil) was administered to adrenalectomized (ADX) or intact Fischer 344 male rats for 8 h or up to 3 mo and levels of GFAP RNA in rat brain regions were measured by RNA blot hybridization using a [32]P-cRNA probe to the coding sequence of mouse GFAP. GFAP mRNA was decreased 2- to 5-fold in hippocampus, cortex, hypothalamus and cerebellum in response to in vivo CORT, but did not change in primary cultures of astrocytes in response to hydrocortisone (1 ug/ml). The magnitude of change was similar in hippocampus and cortex for acute and chronic CORT treatment. In separate experiments, we have cloned cDNAs from a rat hippocampal library by differential hybridization to poly A-containing RNA isolated from ADX or ADX + CORT treated rats. Two of these show decreased RNA abundance in response to CORT and cross-hybridize with a mouse GFAP probe; sequence analysis will determine if these are clones for rat GFAP. The finding of a CORT-mediated decrease in GFAP gene activity is intriguing in light of the plethora of inhibitory CORT actions which prevent overshooting of natural defense mechanisms (Munck et al., Endo. Rev. 5:25, 1984) and the possible role of CORT in altered astroglial function which may lead to a potentiation of CNS damage. Supported by John D. and Catherine T. MacArthur Foundation Research Program on Successful Aging, ONR Grant N00014-85-K-0070 and Brookdale Foundation (NRN).

INDUCTION OF TIS GENES IN RAT ASTROCYTES BY HORMONES AND GROWTH FACTORS. A. T. Arenander, H. R. Herschman* and J. de Vellis. LBES, Brain Research Institute and Departments of Anatomy and Biological Chemistry, UCLA, LA 90024.

The proliferation and differentiation of astrocytes are regulated by a wide spectrum of hormones and growth factors. In order to study the early nuclear events which accompany the induction of glial biochemical and morphological phenotypic change, the expression of a number of TIS genes (transiently-induced sequences) were examined in secondary cultures of rat neocortical astrocytes treated with mitogens or stellation agents. The TIS family of genes, which include c-fos, are characterized by their rapid and transient expression by various agents in murine Swiss 3T3 cells (Lim etal., Oncogene 1:263, 1987) and in rat PC12 cells (Kujubu etal., Oncogene 1:257, 1987). These experiments examined seven distinct TIS clones, including c-fos (TIS 28), from a cDNA library constructed using mRNA induced in murine Swiss 3T3 cells exposed three hrs to the mitogen/promoter agent tetradecanoyl phorbol acetate (TPA) in the presence of cycloheximide. Expression of TIS gene mRNA in astrocytes was studied by Northern blot analysis of total cell RNA. All the members of the TIS gene family are rapidly and transiently induced by TPA and a variety of other mitogens such as EGF, FGF and the ganglioside GM1. Marked interaction between these mitogens was observed. Interaction was also seen in TIS gene induction by insulin, triiodothyronine and hydrocortisone. TIS genes are also induced by the stellation agents dbcAMP and forskolin. It is interesting to note that one of the TIS genes, c-fos, which is observed to be induced only in neuronal cells in vivo, is markedly induced in astrocytes in vitro.

These results indicate that TIS genes are responsive in astrocytes to a wide variety of agents thought to play important roles in brain growth, differentiation and function. TIS genes may be involved in the early events of intracellular signal transduction.

REGULATION OF SCHWANN CELL GENE EXPRESSION BY CYCLIC AMP. T. Behrman*, K. Mokuno*, D. Pleasure and J. Kamholz*. Dept. of Neurology, Univ. of Pa. Sch. of Med., Phila., PA 19104

Schwann cell expression of the major peripheral nervous system myelin proteins PO and myelin basic protein (MBP) has been shown to be dependent upon axonal contact, while expression of the Nerve Growth Factor Receptor (NGFR) is activated by withdrawal of axons. These effects are thought to be mediated by cAMP both in vivo and in vitro. We have investigated the steady state messenger RNA (mRNA) levels of NGFR, PO, MBP and proteolipid protein (PLP) in Schwann cells cultured in the absence of axons and after induction in 1 mM dibutyryl cAMP. Northern blots of total Schwann cell RNA demonstrate a decrease in NGFR mRNA and a marked increase in both PO and MBP mRNAs after cAMP treatment. No change in the steady state level of PLP message was found, although cAMP induced a dramatic increase in the number of Schwann cells expressing PLP as determined by immunofluorescence microscopy. These results demonstrate the cAMP treatment of Schwann cells mimics axonal contact, and that this effect is reflected in changes in the steady state levels of mRNA for PO, MBP and NGFR. The cAMP mediated increase in PLP expression, however, must occur by some other mechanism. Cyclic AMP thus produces at least three separate effects on Schwann gene expression: an increase in PO and MBP expression and a decrease in NGFR expression at the level of transcription, and an increase in PLP expression at a posttranscriptional level.

529.17

9A6 mRNA, A BRAIN mRNA REGULATED BY THYROID HORMONE ACROSS SPECIES AND TISSUES, [2]S.A. Stein and [2]C. Craft, Depts. of [1]Neurol. and [2]Psychiat., Univ. of Tx. Southwestern Med. Cent., Dallas, Tx. 75235

The gene expression of the adult rat and mouse brain is sensitive to alteration in thyroid hormone levels. 3-5% of the total mRNAs of adult rat brain may be altered by change in thyroid hormone from the euthyroid(ET) to hyperthyroid(HT) state(Stein, 1988, In Press). One of these mRNAs, 9A6(Stein, Soc. Neurosci. Abst., 12:367,1986), was abundant in adult and neonatal rat and mouse liver and brain. In comparing the abundance of this mRNA in ET(vehicle injected) and HT(vehicle + T4 injected) adult rats and mice, 9A6 mRNA is, in the transition from the ET to HT states: 1)Increased in rat liver and total brain (TB); 2) Decreased in mouse TB; 3)Increased in mouse cerebral cortex(CC); and 4)Unchanged in mouse liver on northern gel hybridization(NGH). This demonstrated that thyroid hormone(TH) responsiveness may be related to similar tissue or gene elements across species and across different tissues within a specie. However, the direction of the abundance change in the ET to HT transition in TB and CC may be controlled by other undefined factors. To start to define the tissue and specific gene factors that might be involved, we utilized DNA sequence analysis of the 9A6 cDNA and other TH regulated cDNAs as well as in situ hybridization(ISH) to adult rat and mouse brain. The 9A6 cDNA was sequenced in double stranded form by modified dideoxy sequencing using Sequenase(U.S. Biochemical). Because of secondary structure, the purified 9A6 insert was subcloned into M13 and resequenced by standard dideoxy sequencing.The 350 bp insert was a unique mRNA based on the sequence analysis. The initial search of the Gene Bank revealed no similarities with any known protein. On NGH, 9A6 mRNA was more more abundant in CC and cerebellum than in thalamus or brainstem. ISH of this mRNA to adult ET and HT rodent brain will be reported (Supported by NIMH #43017 and UCP #377-87).

529.18

CHARACTERIZATION OF mRNA COMMON TO NEURONS DESTROYED BY THE SELECTIVE NEUROTOXICANT TRIMETHYLTIN. J.K. Krady,*G.A. Oyler,*and M.L. Billingsley. (SPON: J.S. Long) Hershey Medical Center, Penn State Univ. Herhsey, PA, 17033

Trimethyltin (TMT) destroys selected populations of neurons which have no apparent neurochemical or anatomic linkage. Sensitive neurons may share common gene products which cause TMT toxicity. We have used avidin/biotin subtractive hybridization to generate a library of cDNAs enriched for TMT-sensitive mRNAs. cDNAs were isolated, labelled, and used to probe slot and Northern blots of brain poly(A+) mRNA from TMT and saline-treated rats. Two clones hybridized only to brain mRNA from saline-treated rats suggesting that these mRNAs were selectively lost from TMT-sensitive neurons. Hybridization studies suggest that TMT-sensitive mRNAs are rare (>0.01%). We have used sequences from the cDNAs to make oligonucleotides for probing human and rat cDNA libraries and are pursuing in situ hybridization studies in order to co-localize TMT-sensitive mRNAs in neurons destroyed by TMT. These experiments represent a useful approach for the isolation of toxicant-specific gene products. Supported By EPA-CR-813637.

S100βExpression is Regulated by Multiple Signal Transduction Pathways. Dana C. Hilt* and Douglas Kligman#. Lab of Biochemical Genetics*, NHLBI and Lab of Molecular Biology#, NINCDS, NIH, Bethesda, Md. 20892.

S100β is a small, Ca^{2+} modulated protein abundant in nervous system glial cells. Recently, neurite extension activity has been ascribed to the disulfide bonded dimeric form of S100β. In order to study the regulation of S100β expression we have obtained and characterized a near full-length cDNA clone from a rat brain cDNA library. This probe was used to examine the regulation of S100β mRNA levels in C6 glioma cells by a variety of pharmacological agents. Forskolin (10uM) significantly elevated the steady state S100β mRNA levels at 48 hours. There is a less marked increase in the mRNA levels with 1uM dexamethasone. However, when both agents are present, the S100β mRNA level is significantly decreased from that seen with forskolin alone. These findings suggest a negative cooperativity, with glucocorticoids inhibiting the cAMP-dependent increase in S100β mRNA. These results are corroborateded at the protein level by immunological methods. In particular, these results suggest that the S100β gene contains both the glucocorticoid regulatory element (GRE) and the cAMP-dependent regulatory element (CRE). Treatment of C6 cells for 48 hours with 10nM PdBu causes a marked suppression in S100β mRNA levels. This type of phorbol ester-dependent response is similar to that seen in other cell types for c-myc and c-fos expression. This result suggests that S100β may have activities related to cell cycle, growth or regulation of differentiation. These results indicate that the S100β gene is under complex regulation and implies that S100β expression is tightly regulated by a variety of extracellular signals.

LIGHT/DARK CYCLING OF S-ANTIGEN (48-KDa PROTEIN) mRNAs IN RAT RETINAS AND PINEAL GLANDS. C.M. CRAFT. Lab. of Molecular Neuroendocrinology, Dept. of Psychiatry, University of Texas Southwestern Medical Center, and VA-Medical Center, Dallas, TX 75216

During the 24 hour (circadian) period, normal physiological fluctuations occur in visual and signal transduction. These rhythmic circadian changes of neurotransmitters, receptors and second messengers regulate numerous pineal/retinal specific proteins. To extend these studies to the molecular level, complementary DNAs (cDNAs) encoding pineal/retinal tissue specific proteins are being isolated and characterized. Retinal S-antigen (S-Ag) is involved in the down regulation of photolyzed, phosphorylated rhodopsin; however, pineal S-Ag's function is not known. The cDNA for bovine retinal S-Ag (Shinohara et al., 1987, PNAS, 84:6975) was used to examine the 24 hour regulation of its mRNA. Male rats were kept in a light:dark cycle (L:D) (12:12) and killed throughout the cycle. Pineal/ retinal catecholamines and indoleamines were determined by HPLC to verify L:D levels obtained in previous experiments (Craft et al., 1984, Neuroendocrinology, 38:193). Tissue (pineal, pituitary, retina, brain and liver) from each animal (10/group) was used for protein and mRNA analysis. The labelled cDNA probe encoding S-Ag was hybridized with 10 ug of total RNA transferred to Zetaprobe from each time point. The 1.7 kilobase mRNA for S-Ag exhibited L:D fluctuations with peak levels exhibited after 5, 7, and 11 hours of lights off in retina and pineal. No message was detected in any other tissue. The same blots were reprobed with an antisense 18S ribosomal probe to standardize the amount of RNA per lane.

Total RNA was extracted from 150 pineals which had the highest S-Ag mRNA detected. PolyA^+ RNA from pineals (5 ug) was used to synthesize cDNAs and to construct a Lambda ZAP library (Stratagene); $5x10^6$ recombinants were obtained. The cDNAs encoding rat pineal S-Ag and other specific proteins are presently being isolated. (Grant support from Scottish Rite Schizophrenia Foundation).

INDUCTION OF ASTROCYTE-SPECIFIC mRNAs GFAP AND B-S100 DURING SEIZURE ACTIVITY. C.F. Landry, G.O. Ivy, N.W. Milgram and I.R. Brown. Departments of Zoology and Psychology, University of Toronto, Scarborough Campus, West Hill, Ontario, Canada M1C 1A4

Using immunohistochemical techniques, we have shown that patterns of astrocyte hypertrophy (AH) can be used to trace neural systems which undergo abnormally heightened levels of electrical activity (Ivy and Milgram, Soc. Neurosci. Abstr. 1987, 13: 1265 and this meeting). Using in situ hybridization histochemistry, we now delineate the brain distribution and time course of production of mRNAs for the astrocyte-specific markers GFAP and B-S100 following kainic acid (KA)-induced seizure activity. To this end, rats were injected systemically with KA. Both seizure time and survival time were varied. High GFAP and B-S100 mRNA levels were observed within three hours of seizure onset in specific regions of hippocampus, thalamus, neo- and pyriform cortex, endopyriform nucleus and amygdala. Signals persisted in these regions for at least four months, but at decreased intensity. The distribution of GFAP and B-S100 mRNA mimicked both GFAP immunohistochemistry and the pattern of neuronal damage however the mRNA patterns appear prior to evidence of neuronal damage. Thus, induction of astrocyte-specific mRNA species is an early and sensitive indicator of selective neuronal vulnerability caused by seizure activity. (Supported by grants from NSERC.)

LAMININ SYNTHESIS IN CULTURED MAMMALIAN ASTROCYTES. Jerome R. Wujek, Robert H. Lipsky*and Ernst Freese. Laboratory of Molecular Biology, NINCDS, NIH, Bethesda, MD 20892.

The control of laminin mRNA and protein synthesis was studied in cultured neonatal rat cerebral cortical astrocytes. Total RNA was extracted from astrocytes grown for 1-10 weeks in DMEM plus 10% fetal calf serum (FCS), then electrophoresed, blotted and hybridized with cDNA probes to the B1 or B2 laminin genes. Results indicated that mRNA for the B2 laminin chain increased in the first 2 weeks in culture and decreased in the next two weeks. In contrast, the B1 chain mRNA was found only after 10 weeks in culture. Thus, synthesis of laminin mRNA for the different laminin protein chains appears to be regulated independently. Immunocytochemistry and ELISA indicated a 10-fold greater laminin expression by astrocytes cultured in serum-free (SF) medium than by astrocytes in serum-supplemented (10% FCS) medium. Addition of transforming growth factor beta increased laminin deposition by astrocytes only in SF medium. Conversely, retinoic acid plus cyclic AMP, when added to astrocytes in 10% FCS medium, produced a 3-fold increase in laminin. Such conditions can be used as a model system for the study of laminin synthesis by astrocytes.

VARIOUS EFFECTS OF α-BUNGAROTOXIN AND PERHYDROHISTRIONICOTOXIN ON POST-TETANIC POTENTIATION OF MOUSE DIAPHRAGM TWITCH TENSION. M.C.TSAI and M.L.CHEN*. Pharmacol. Inst. College of Med., National Taiwan Univ., Taipei, Taiwan, R.O.C.

Effects of α-bungarotoxin (α-BuTX) and perhydrohistrionicotoxin (H_{12}-HTX) on the post-tetanic potentiation (PTP) of twitch tension were studied on the isolated mouse diaphragm preparation. In normal physiological solution, maximal PTP was obtained after 100 Hz tetanic stimulation for 5 sec. In preparations partially blocked by α-BuTX, PTP was less than in control preparations if tetanically stimulated at 100-200 Hz for 5-10 sec. The relationship between frequency,length of tetanic stimulation and PTP revealed that PTP was independent of the duration and frequency of tetanic stimulation. H_{12}-HTX induced post-tetanic depression of twitch tension. The relationship between frequency,length of tetanic stimulation and PTP revealed that maximal depression effect was observed after 100 Hz of tetanic stimulation for 20 sec. It is suggested that the voltage and time dependent effect of H_{12}-HTX on the endplate channel may contribute to the differences in modes of action of both toxins on the PTP of the twitch tension.

STRUCTURE-ACTIVITY RELATIONSHIPS OF ANATOXIN ANALOGS AT THE NICOTINIC ACETYLCHOLINE RECEPTOR (AChR). KL Swanson[1], RS Aronstam[2], H Rapoport[3]*, FJ Sardina[3]*, EX Albuquerque[1]. [1]Dept Pharm Exp Ther, Univ MD Sch Med, Baltimore, MD 21201, [2]Dept Pharm Toxicol, Med Coll GA, Augusta, GA 30912, [3]Dept Chem, Univ CA, Berkeley, CA 94720.

(+)Anatoxin-a (ANTX) is a stereospecific, secondary amine which has selective actions on peripheral and central AChR's (*Mol Pharmacol* 29: 250, 1986; *FEBS Lett* 222: 63, 1988). Synthetic analogs of ANTX were used to reveal the structural characteristics of agonists, competitive antagonists and noncompetitive antagonists. AChR-ligand binding was performed on *Torpedo* electroplaque membranes. Muscles from *Rana pipiens* were used for *in vitro* twitch and contracture assays. Data for agonist binding (IC_{50} for α-bungarotoxin (αBGT)) and agonist efficacy (perhydrohistrionicotoxin (HTX) binding or rectus abdominis contracture) were in general agreement. The order of agonist potency was ANTX > dihydroANTX > ANTX methylester > ANTX dimethylamide, with these compounds encompassing a 1000-fold range. N,N-dimethyl ANTX also stimulated HTX binding and weakly inhibited αBGT binding, but did not elicit muscle contractures. Several of the analogs exhibited antagonist effects. The most potent inhibitor of HTX binding was N-methyl-R-anatoxinol, although it is a weak blocker of indirect muscle twitch (sartorius muscle-sciatic nerve preparation). N-methyl and N,N-dimethyl acetoxy ANTX analogs, and N,N-dimethylANTX were antagonists at high μM concentrations. Supported by NIH Grant NS 25296.

N,N-DIMETHYLANATOXIN: AN ELECTROPHYSIOLOGICAL ANALYSIS. A.C.S. Costa*[1], Y. Aracava*[1,2], H. Rapoport*[3] and E.X. Albuquerque[1,2]. (Spon: D. Weinreich) [1]Lab. Mol. Pharmacol. II, Fed. Univ. Rio de Janeiro, Brazil; [2]Dept. Pharmacol. Exp. Ther., Univ. Maryland Sch. Med. Baltimore, MD 21201; [3]Dept. Chem., Univ. California, Berkeley, CA 94720.

(+)-Anatoxin-a, an exotoxin produced by the blue-green algae Anabaena flos-aquae, is a selective nicotinic agonist with high stereospecificity and potency superior to the neurotransmitter on both central and peripheral nAChRs. We analyzed the actions of the synthetic dimethyl analog of (+)-anatoxin-a on single channel currents recorded from isolated fibers of interosseal muscles of the adult Rana pipiens. The two additional methyl groups attached to the nitrogen atom produced a major reduction (1000-fold) of the agonist potency and gain of channel blocking properties. N,N-dimethylanatoxin (20-100 μM) induced a low-frequency, burst activity and a concentration-dependent shortening of the open times and of the burst length as well, suggesting activation and blockade of open ion channels. The blocking action was further analyzed on the currents activated by ACh (0.4 μM) in the presence of the (+)-anatoxin-a analog (1-100 μM). Bursts with increased flickering and a concentration- and voltage-dependent shortening of the open times were observed in accordance with the predictions of the sequential model of open channel blockade. At high concentrations (>50 μM), however, burst length was shortened, indicating an additional blocking pathway. Support: NIH Grant NS25296, CNPq and CAPES-Brazil.

A QUANTITATIVE AUTORADIOGRAPHIC ANALYSIS OF NICOTINIC RECEPTOR BINDING FOLLOWING CHRONIC NICOTINE INFUSION. J.R. Pauly, J.A. Stitzel*, M.J. Marks* and A.C. Collins. Univ. of Colorado, Boulder, CO 80309.

Quantitative autoradiographic procedures were used to examine the effects of chronic nicotine infusion on the number of CNS cholinergic receptors. Female DBA mice were implanted with jugular cannulae and infused with nicotine (2.0 mg/kg/hr) or saline for ten days. Nicotinic receptors were labeled with L-[^{3}H]-nicotine and alpha-[^{125}I]-bungarotoxin (BTX); [^{3}H]-quinuclidinyl benzilate (QNB) was used to measure muscarinic cholinergic receptors. Chronic nicotine infusions resulted in site-specific increases in the number of nicotinic cholinergic receptors. For [^{3}H]-nicotine, 14 of 49 brain regions quantified demonstrated significant changes in receptor binding. These regions included the cerebral cortex, caudate putamen, dentate gyrus and dorsal tegmental nucleus. [^{125}I]-BTX receptors were significantly elevated in 23 of 50 regions analyzed. These included the cerebral cortex, globus pallidus, hippocampus, cerebellum and several thalamic and hypothalamic nuclei. Chronic nicotine infusion did not significantly alter muscarinic binding. These data may help elucidate the central mechanisms that regulate nicotine response and the development of tolerance. Supported by DA-03194, MH-16880 and R.J. Reynolds Tobacco Co.

THE ACTIONS OF ACETYLCHOLINE AND NICOTINE ON NEURONS OF THE VENTRAL TEGMENTAL AREA STUDIED *in vitro*. M.S. Brodie and A.L. Mueller, Neuroscience Research Division, Pharmaceutical Discovery, Depts. 47W and 47H, Abbott Laboratories, Abbott Park, IL 60064.

The ventral tegmental area (VTA) is a brain region which has been demonstrated to mediate at least a portion of the rewarding properties of a wide variety of drugs of abuse. Nicotine is one of the most prevalent agents of abuse in American society. While the effects of nicotine on the neurons of the VTA have been studied *in vivo*, these studies have been restricted by the limitations of *in vivo* recording techniques. We have developed a brain slice preparation of the VTA in order to study the effects of known concentrations of agents on neurons in this area. Brain slices containing the VTA were prepared from Sprague-Dawley rats, and were superfused at 2 ml/min. The cells that were studied with intracellular and extracellular recording exhibited electrophysiological properties similar those of dopamine-containing cells recorded *in vivo* and *in vitro*. Acetylcholine (ACh, 1-10 mM) and carbachol (1-10 μM) produced large increases in the spontaneous firing rate of neurons of the VTA. Addition of physostigmine decreased the effective concentration range of ACh to 30-300 μM. Nicotine (1-10 μM) produced depolarization and an increase in firing rate. Nicotine-induced excitation was completely blocked by the addition of hexamethonium (HEX, 500 μM) to the bathing medium. In the presence of 500 μM HEX, ACh still evoked an increase in spontaneous firing rate. This ACh-induced excitation was blocked by the addition of atropine sulfate (100-250 nM) to the superfusate. These data indicate that both nicotinic and muscarinic receptor activation produce excitation of VTA neurons.

EFFECTS OF ACUTE AND CHRONIC ADMINISTRATION OF NICOTINE ON BRAIN METABOLISM IN THE RAT. J.Y. Chang, S.A. Azizi, C.D. Myre, and D.J. Woodward *U. of Texas Southwestern Med. Ctr., Dallas, Tx. 75235*

This experiment was performed to investigate the effect of nicotine on uptake of ^{14}C-2-deoxyglucose in rat brain. Groups of rats studied included conditions of halothane anesthesia (.75% in oxygen); quiet-awake but freely moving; and treadmill locomotion (30 sec rest and 30 sec running). The animals treated acutely were injected with nicotine (0.4 mg/kg free base) or saline ten minutes before the infusion of ^{14}C-2-deoxyglucose (150 μCi per kg). Animals were treated chronically by receiving nicotine (0.4 mg/kg free base per day) or saline injections for ten days. Anesthetized rats showed generalized decreases in metabolism but uptake appeared elevated in habenula, fasciculus retroflexus, and interpeduncular nucleus. This pattern was not observed in awake nicotine or saline injected animals. Nicotine caused little effect in anesthetized animals but caused in both awake groups elevated uptake in regions including substantia nigra (pars compacta), superficial gray layer of the superior colliculus and lateral geniculate body, a pattern related to the visual system as described by others. This pattern remained after 10 days of chronic nicotine administration indicating that tolerance did not appear. The influences of nicotine on glucose uptake required awake brain conditions but were not sensitive to the marked differences in behavior between rest and periodic locomotion. *Supported by R.J.Reynolds Tobacco Co. and Biol. Hum. Found.*

NICOTINIC BINDING IN CHICKEN MIDBRAIN: AUTORADIOGRAPHIC COMPARISON OF ^{125}I-KAPPA-BUNGAROTOXIN, ^{125}I-ALPHA-BUNGAROTOXIN AND ^{3}H-NICOTINE. E.M. Sorenson and V.A. Chiappinelli. Department of Pharmacology, St. Louis University School of Medicine, St. Louis, MO 63104.

We are characterizing the chicken midbrain as a model system for neuronal nicotinic transmission. As a prelude to intracellular electrophysiological studies, we have described the localization of choline acetyltransferase in the chicken midbrain (Sorenson, E.M., et al., Soc. Neurosci. Abstr., 13:1657, 1987). In binding studies, we have observed at least three categories of putative nicotinic receptors using ^{3}H-nicotine, ^{125}I-kappa-bungarotoxin, and ^{125}I-alpha-bungarotoxin (Wolf, K.M., et al., Brain Res., 439:249, 1988). We now compare the autoradiographic localization of these three nicotinic ligands in adjacent transverse sections of the chicken midbrain.

^{125}I-Kappa-bungarotoxin sites appear to be co-localized with the ^{125}I-alpha-bungarotoxin sites. For example, both ligands bind heavily to the nu. semilunaris, the nu. geniculatus lateralis, pars ventralis, and layer f of the stratum griseum et fibrosum superficiale (SGFS) in the optic tectum. Although ^{3}H-nicotine binds to fewer regions than the snake toxins, preliminary results indicate that nuclei which are labelled with ^{3}H-nicotine are also identified by both toxins. In particular, the nu. geniculatus lateralis, pars ventralis, and the layer f of the SGFS contain binding sites for all three ligands.

KAPPA-NEUROTOXINS: ESTABLISHMENT OF A NEW FAMILY OF SNAKE VENOM NEUROTOXINS THAT BLOCK NEURONAL NICOTINIC RECEPTORS. V.A. Chiappinelli, K.M. Wolf*, G.A. Grant*[1] and S.-J. Chen*[2]. Dept. of Pharmacology, St. Louis Univ. Sch. Med., St. Louis, MO 63104; [1]Dept. of Biol. Chem., Washington Univ. Sch. Med., St. Louis, MO 63110; [2]Dept. of Biology, Jinan Univ., Guangzhou, China.

We have reported the complete amino acid sequences of two snake venom proteins, kappa-bungarotoxin (Grant, G.A. and Chiappinelli, V.A., Biochem. 24:1532, 1985) and kappa-flavitoxin (Grant, G.A., Frazier, M.W., and Chiappinelli, V.A., Biochem. May, 1988). These neurotoxins demonstrate 82% sequence homology and exhibit similar pharmacological effects, in particular a selective blockade of nicotinic responses in a variety of neuronal preparations (Chiappinelli, V.A., Pharmacol. Therap. 31:1, 1985).

We now report the isolation of two new kappa-neurotoxins from the venom of Bungarus multicinctus. Kappa$_2$-bungarotoxin and kappa$_3$-bungarotoxin exhibit strong sequence homology with kappa-bungarotoxin. Their pharmacological effects confirm their membership in this new class of snake venom neurotoxins. All four kappa-neurotoxins lack a tryptophanyl residue which is invariant in the structurally similar α-neurotoxins. This and several other features distinguish kappa-neurotoxins from α-neurotoxins, and provide clues to the structural differences between the ligand binding site regions of neuronal and muscle nicotinic receptors. (Supported by NSF-INT-8518395 and NIH-NS17574 to V.A.C.)

ACETYCHOLINE MODULATES RESTING K-CURRENT THROUGH A PERTUSSIS TOXIN-RESISTANT G-PROTEIN IN HIPPOCAMPAL NEURONS. L.D. Brown, S. Nakajima and Y. Nakajima. Dept. of Biol. Sci., Purdue Univ., West Lafayette, IN 47907; Dept. of Pharmacology and Dept. of Anatomy and Cell Biology, Univ. of Illinois at Chicago, Chicago, IL 60612.

The purpose of the present experiments was to determine if cholinergic excitation produced by a decrease in the resting K-conductance through muscarinic receptors is mediated by a G-protein. We used primary cultures of hippocampal neurons (CA_1 or CA_3) from postnatal (2 to 8-day-old) rats. Application of acetycholine (10 μM) or muscarine (20 μM) by pressure ejection produced an inward current (peak 50-100 pA) at -74 mV under whole cell voltage clamp. This inward current was inhibited by atropine (1-2 μM). When the internal solution contained GTP (100 μM), this inward current slowly subsided, the recovery being 71% at 3 minutes. However when the internal solution contained GTPγS (200 μM), a hydrolysis-resistant GTP analogue, the inward current tended to persist, the recovery being only 41%. This insufficient recovery with GTPγS was more pronounced for the cells that showed a slow start of the inward current. Pretreatment of cultures with pertussis toxin (500 ng/ml) overnight did not affect the responsiveness of the neurons toward muscarine. The inward current was not affected by addition of 100 μM cAMP and 1 mM IBMX (an inhibitor of phosphodiesterase) to the internal solution. Thus, the cAMP system is not directly involved in the activation of the inward current. The data suggest that a pertussis toxin-resistant unidentified G-protein is involved in the cholinergic activation of the inward current at resting potential. Supported by a NIH Grant NS 24711.

530.10

REPEATED ADMINISTRATION OF NICOTINE RESULTS IN LONG-TERM DECREASE IN PROLACTIN RELEASE BY ACUTE NICOTINE IN RATS. B.A. Giblin[1]*, M.D. Lumpkin[2], and K.J. Kellar[1]. Depts. of Pharmacology[1] and Physiology and Biophysics[2], Georgetown University Medical Center, Washington DC, 20007.

Nicotine increases plasma prolactin concentrations, which peak 6 to 8 min after injection and return to control levels within 30 min. The nicotine-induced increase in plasma prolactin is dose-dependent, completely blocked by mecamylamine, and appears to be mediated by receptors in the brain. As previously reported by Sharp and Beyer (J. Pharmacol. Exp. Ther. 238:1486, 1986), when nicotine is injected a second time, 60 min after the first injection, the prolactin response is very much diminished or absent. This is consistent with rapid and protracted desensitization of the nicotinic receptors mediating prolactin release following the first injection. When nicotine is injected twice daily (0.8 mg/kg) for 10 days, the prolactin response to an acute injection of nicotine is absent 2, 4, 6, and 8 days after the last of the chronic injections. This apparent inactivation of the plasma prolactin response to nicotine is present when nicotinic receptor recognition sites are increased in the hypothalamus. These results are consistent with the hypothesis that chronic administration of nicotine results in long-term inactivation of nicotinic receptors and that this long-term inactivation, in turn, results in up-regulation of the nicotinic receptor recognition sites.

530.11

AUTORADIOGRAPHIC LOCALIZATION OF NICOTINIC RECEPTORS IN RAT BRAIN USING ^{125}I-NEURONAL BUNGAROTOXIN. D.W. Schulz, E. Aizenman, W.F. White and R.E. Zigmond. Dept. Biol. Chem. and Molec. Pharmacol., Harvard Med. School, Boston, MA 02115.

Neuronal bungarotoxin (NBT) is a peptide that is found in the venom of Bungarus multicinctus along with α-bungarotoxin (BGT). NBT has been shown to block nicotinic synaptic transmission in a variety of neuronal preparations where BGT is without effect. While BGT competes for some ^{125}I-NBT binding, it is thought that functional blockade of nicotinic activity occurs at an NBT-selective site. We recently demonstrated that NBT blocks nicotine-stimulated dopamine release in rat striatum, suggesting that NBT is a nicotinic antagonist in CNS tissue. Therefore, we sought to determine the distribution of ^{125}I-NBT binding sites in the rat brain.

Cryostat sections (20μm) from adult male rat brains were incubated in 2.0 nM ^{125}I-NBT for 1 h at 37°C. Nonspecific binding was determined by adding 1 μM NBT, while some adjacent sections were exposed to either 1 μM BGT or 100 μM nicotine. Areas densely labeled by ^{125}I-NBT include: medial vestibular nuc., nuc. of spinal tract of V, dorsal tegmental nuc., superior colliculus, medial habenula, nuc. of the optic tract, and lateral geniculate nuc. Nicotine competed for binding in these areas, but did not completely block all NBT-selective sites. The distribution of ^{125}I-NBT binding was less widespread than that previously reported for either ^{3}H-nicotine or ^{125}I-BGT (Clarke et al., J. Neurosci. 5:1307). Similarly, ^{125}I-NBT binding was present in many but not all areas where nicotinic receptors have been detected using immunohistochemical methods (Swanson et al., J. Neurosci. 7:3334) and in situ hybridization procedures (Deneris et al., Neuron 1:45). In conclusion, ^{125}I-NBT binds specifically and heterogeneously in rat brain, and a portion of these sites are recognized by nicotine. The regional distribution of ^{125}I-NBT binding differs somewhat from that reported using other methodologies, supporting the hypothesis that there are multiple nicotinic receptor subtypes in rat brain.

530.12

NICOTINE ALTERS DOPAMINE, ACETYLCHOLINE, AND OPIOID PEPTIDE CONTENT IN THE STRIATUM OF THE MOUSE. J.P. Hubble*, K.P. Gudehithlu*, G.A. Tejwani and M. Hadjiconstantinou. Dept. of Pharmacology, The Ohio State Univ. Col. of Med., Columbus, OH 43210.

Nicotine receptors are present in the peripheral and central nervous system. The function of these receptors in the brain is unclear. In vitro studies have shown that nicotine stimulates dopamine (DA) release from striatal slices. We have studied the in vivo effects following nicotine administration on dopaminergic, cholinergic and opioid neurons in the mouse striatum. Dose- and time-response studies were performed to establish the regimen producing the optimal dopaminergic response in the striatum. Based on these results nicotine, 1 mg/kg, s.c., was injected and animals were sacrificed after 60 min in acute experiments. For the chronic studies the same dose of nicotine was injected once daily for 7-14 days. Acute nicotine treatment elevated striatal DA content modestly, and significantly increased homovanillic and 3,4-dihydroxy-phenylacetic acids. The turnover of DA, estimated using alpha-methyl-p-tyrosine, was not altered by acute nicotine treatment. Chronic nicotine administration did not change the striatal DA parameters. Acute administration of nicotine decreased striatal acetylcholine (ACh), beta-endorphin and met-enkephalin content. Chronic nicotine exposure had no effect on striatal ACh, decreased beta-endorphin and increased met-enkephalin content in the striatum. In conclusion, our results provide evidence that nicotinic receptors modulate DA, ACh and opioid neurons in mouse striatum and suggest that, as in the periphery, central nicotinic receptors may participate in complex neuronal interactions.

530.13

DISSOCIATION BETWEEN ADENYLATE CYCLASE INHIBITION AND MUSCARINIC AUTORECEPTOR REGULATION OF [^{3}H]ACETYLCHOLINE RELEASE FROM RAT HIPPOCAMPUS. E.D. Cadman* and T.W. Vickroy. Abbott Laboratories, Neuroscience Research Division, Pharmaceutical Discovery, Abbott Park, IL 60064.

Several lines of evidence indicate that muscarinic receptors (mAChR) are heterogenous. In CNS tissues, activation of M_2 receptors inhibits adenylate cyclase and reduces impulse-dependent acetylcholine (ACh) release from nerve terminals. In the studies described here, we have attempted to ascertain whether inhibition of adenylate cyclase underlies M_2-mediated inhibition of electrically-evoked [^{3}H]ACh release from rat hippocampal slices. The muscarinic agonist carbachol caused a concentration-dependent (EC_{50}=80μM), atropine-sensitive decrease in evoked [^{3}H]ACh release up to a maximum of 80% inhibition. The relative potencies of several muscarinic antagonists in reversing carbachol's effect (atropine, N-methyl atropine > scopolamine >> pirenzepine) were consistent with an M_2-mediated response. In the presence of forskolin (10μM) or 8-bromo-adenosine 3':5'-cyclic monophosphate (300μM), electrically-evoked [^{3}H]ACh release was enhanced by 40-50% but the inhibitory effect of carbachol was unchanged. In addition, pretreatment of slices with N-ethylmaleimide markedly reduced carbachol inhibition of adenylate cyclase in hippocampal membranes but did not significantly alter carbachol inhibition of [^{3}H]ACh release. Taken together, these results indicate that inhibition of adenylate cyclase does not underlie mAChR-mediated inhibition of ACh release.

530.14

M-1 AND M-2 MUSCARINIC MECHANISMS IN THE REGULATION OF STRIATAL ACETYLCHOLINE RELEASE. J.M. Gorell, S. Mostafapour*, J.A. Bueri*. Division of Movement Disorders, Department of Neurology, Henry Ford Hospital, Detroit, MI 48202.

Striatal slices from adult male Sprague-Dawley rats were prelabelled with {^{3}H} choline and superfused in separate experiments with the muscarinic antagonists pirenzepine (PZ;M-1) or gallamine (GAL;M-2) or the agonist oxotremorine (OXO). OXO, 10^{-5} -10^{-8}M, produced a dose-dependent decrease in {^{3}H}acetylcholine (ACh) release, maximally at 10^{-5}M to 44% of simultaneous controls. GAL, 10^{-7}-10^{-5}M, or PZ, 10^{-8} and 10^{-6}M, alone did not significantly affect {^{3}H}ACh release. GAL at 10^{-5}M, cosuperfused with OXO 10^{-6}M, partially reversed OXO's effect to 81% of controls. PZ at 10^{-5}M fully reversed cosuperfused OXO's (10^{-6}M) ACh release-depressant effect.

These results suggest that both M-2 and M-1 muscarinic receptor mechanisms play roles in the presynaptic regulation of striatal ACh release.

Research was supported by the Fund for Henry Ford Hospital and the Gossett Fund.

PARTIAL MUSCARINIC AGONISTS AND SELECTIVE TISSUE RESPONSE. M. Dickerson*, R. Schwarz, L. Coughenour*, H. Tecle* and R.E. Davis. (SPON: W.H. Moos) Parke-Davis Pharmaceutical Research Division, Warner-Lambert Co., Ann Arbor, Mi. 48105.

BM-5, an oxotremorine analogue, has been suggested to be a partial muscarinic agonist with tissue specific agonist or antagonist activity. It is thought to show agonist-like activity in tissues with large receptor reserve and antagonist-like activity in tissues with little receptor reserve. Because of this BM-5 may be useful as a tool in defining tissues with more or less receptor reserve. We have used this approach in studying the agonist- and antagonist-like activity in the peripheral and central nervous system.

BM-5 exhibits partial agonist-like properties in vitro. It possesses high affinity for both muscarinic agonists and antagonist binding sites in the rat cerebral cortex, does not alter K^+-stimulated release of acetylcholine (ACH) but does block agonist-induced decreases in the ACH release from brain slices. These effects are similar to those seen with muscarinic antagonists.

BM-5 has agonist- and antagonist-like properties in vivo. It increases intestinal transit and motility and reverses scopolamine-induced swimming activity much like a muscarinic agonist. However, BM-5 impairs the ability of C57BL/10j mice to perform a water-maze task in a manner similar to muscarinic antagonists.

Thus, the relative agonist/antagonist properties of BM-5 are governed by the response being measured and may be determined by intrinsic receptor reserves of the target tissue. The therapeutic utility of this compound, however, is questionable since it acts as a muscarinic agonist in the periphery inducing unwanted effects and acts as an antagonist in the central nervous system to impair cognitive performance.

530.16

CHANGES IN ^{3}H-QNB AND ^{3}H-GLUTAMATE BINDING IN RAT BRAIN FOLLOWING PERSISTENT SEIZURES INDUCED BY LITHIUM/PILOCARPINE TREATMENT. K. Shahid Salles, G. Friedrich*, M.T. Price and J.W. Olney. Washington University Sch. of Med., St. Louis, MO 63110.

Systemic administration of pilocarpine (30 mg/kg sc) to rats pretreated twenty four hours earlier with lithium chloride (3 meq/kg sc) results in prolonged seizures and acute cytopathological changes in various brain regions. Muscarinic cholinergic receptor activation is presumed to play a role in the initiation of seizure activity since pretreatment with atropine prevents both the seizures and related brain damage. The brain damage resembles that associated with persistent seizures induced by various other methods and is indistinguishable from the excitotoxic type of neuronal degeneration that glutamate (Glu) is known to cause. To further evaluate the relative involvement of glutamergic and cholinergic mechanisms in this seizure-brain damage syndrome, we have studied ^{3}H-QNB and ^{3}H-Glu binding by receptor autoradiography in rat brain at various intervals from 4 hrs to 8 wks after a 3 hr episode of persistent seizures induced by Li/Pilo and terminated by diazepam. Our findings are as follows: both ^{3}H-Glu and ^{3}H-QNB binding were uniformly reduced in early time intervals (up to 2 wks) in nearly every brain region evaluated, including regions that do not display brain damage. The reductions in ^{3}H-Glu and ^{3}H-QNB binding were already evident at 4 hrs and became maximal in the 4hr to 1 wk period then gradually returned toward control levels in the 2-8 wk interval. This pattern was seen in all regions except those known to sustain permanent brain damage; in such regions, binding of both ligands remained severely depressed in the 1-3 wk interval and recovered only moderately in the 4-8 wk interval. In two regions (substantia nigra and nucleus accumbens) a substantial reduction in binding of both ligands at 4-24 hr progressively converted to a significant increase in binding at 4-8 wks. Based on Scatchard analysis, the decrease in binding for both ^{3}H-Glu and ^{3}H-QNB could be accounted for by a reduction in B_{max}. This was accompanied by a decrease in K_D for both ligands. These findings are of limited assistance in clarifying the relative importance of cholinergic vs glutamergic mechanisms in the Li/Pilo seizure-brain damage syndrome since changes in both systems were in the same direction, displayed a similar time course and were of similar magnitude. EFFECTS OF REPEATED LOW-LEVEL MICROWAVE EXPOSURE ON CENTRAL CHOLINERGIC RECEPTOR. H. Lai*, M.A. Carino*, A. Horita* and A.W. Guy* (SPON: R.H. Haschka). Dept. of Pharmacology and Psychiatry & Behavioral Sciences, and the Center for Bioengineering, University of Washington School of Medicine, Seattle, WA 98195.

Our previous research (Lai et al., J. Neurochem. 48: 40, 1987; Pharmac. Biochem. Behav. 27:635, 1987) showed that acute (45 min) exposure to circularly polarized, pulsed, 2450-MHz microwaves at power density of 1.0 mW/cm^2 (whole body specific absorption rate of 0.6 W/kg) affected cholinergic activity in the brain of the rat. Sodium-dependent high-affinity choline uptake was decreased in the frontal cortex and hippocampus after the exposure. In the present experiment, rats were exposed in 10 daily 45-min sessions to low-level microwaves, and change in muscarinic receptor, as measured by ^{3}H-QNB binding assay, was studied in the brain at 24 h after the last exposure session. There was a significant increase in the concentration of ^{3}H-QNB binding sites ($p < .005$) in the hippocampus of the microwave-exposed rats as compared to that of sham-exposed controls. No significant change in receptor sites was observed in the frontal cortex, striatum, and hypothalamus.

INTRACEREBROVENTRICULAR ADMINISTRATION OF HEMICOLINIUM-3 DECREASES URINARY OUTPUT IN THE RAT. G.R. Trimarchi*, A. Germanò*, G.M. Campo* and A.P. Caputi*(SPON:J.J.Buccafusco) Dept. Pharmacology, School of Medicine, University of Messine, I-98122 Messina, Italy.

Activation of brain cholinergic receptors results in a natriuretic and kaliuretic response.This effect seems to be mediated by both nicotinic and muscarinic receptors.Purpose of this study was to determine whether a depletion of brain acetylcholine stores is able to influence diuresis,natriuresis and kaliuresis.Adult male Wistar rats with a chronically implanted intracerebroventricular (ICV)cannula were pretreated with hemicholinium-3 (HC;20ug/10 ul ICV)or saline. At different time after the icv pretreatment the animals received 40ml/Kg saline by gavage and placed in individual metabolic cages.Urine samples were than collected every 2 hours for 6 hours and urinary volume and potassium and sodium concentration were measured.The icv injection of HC produced a time dependent inhibition of the urinary output with the maximal effect occurred using 60-90 min pretreatment time.Furthermore,icv HC produced a significant decrease in potassium (0.42+0.02 vs. 0.30+0.02 mEq/100 g.b.w./6h) and sodium urinary excretion (1.34+0.08 vs. 0.87+ 0.05 mEq/100 g.b.w./6h).

POSSIBLE INVOLVEMENT OF CALCIUM AND CALMODULIN IN THE REGULATION OF [3H]HEMICHOLINIUM-3 ([3H]HCh-3) BINDING AND HIGH-AFFINITY CHOLINE UPTAKE IN RAT BRAIN. M.D. Saltarelli, C.J. Clingroth, K.Yamada and J.T. Coyle. Department of Neurosciences, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

The sodium-dependent high-affinity choline uptake (SDHACU) system has been regarded as the rate-limiting step in acetylcholine synthesis. Calcium (Ca^{2+}) has been implicated as essential for the activation of SDHACU by many, but not all, investigators. In the present study, we have assessed the involvement of Ca^{2+} and calmodulin in the regulation of SDHACU through the use of the specific binding of [3H]HCh-3, a potent and selective inhibitor of [3H]choline uptake. Potassium depolarization of striatal, cortical, or hippocampal slices resulted in a significant increase in specific [3H]HCh-3 binding when compared to control slices incubated in normal Krebs buffer containing 1.2 mM Ca^{2+}. The changes in specific [3H]HCh-3 binding induced by potassium depolarization in cortical and hippocampal, but not striatal, slices were significantly reduced when Ca^{2+} was removed from the incubation medium. Potassium depolarization-induced activation of [3H]choline uptake in striatal slices was also unaffected by removal of Ca^{2+} from the incubation medium. In addition, a dose-dependent inhibition of potassium-stimulated [3H]HCh-3 binding was observed when striatal slices were incubated in the presence of three inhibitors of calmodulin, trifluoperazine ($IC50 = 20\ \mu M$), W-7 ($IC50 = 40\ \mu M$), and W-5; their potencies for the inhibition of potassium-stimulated activation of [3H]HCh-3 binding are consistent with calmodulin inhibition. Finally, incubation of striatal slices in the presence of the Ca^{2+} ionophore A23187 (20 μM) produced a marked increase in specific [3H]HCh-3 binding, even when Ca^{2+} was removed from the incubation medium. These studies demonstrate regional differences in the regulation of [3H]HCh-3 binding by extracellular Ca^{2+}, and suggest the involvement of calmodulin and intracellular Ca^{2+} in the regulation of SDHACU *in vitro* .

SPECIFIC ACTIVATION OF [3H]HEMICHOLINIUM-3 ([3H]HCh-3) BINDING IN RAT SYNAPTIC MEMBRANES BY PHOSPHOLIPASE A2. K. Yamada, M. D. Saltarelli, C.J. Clingroth and J.T. Coyle. Dept. of Neuroscience, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

We have demonstrated previously that treatment of rat synaptic membranes with phospholipase A_2 (PLA_2) resulted in a significant increase in the specific binding of [3H]HCh-3 as reflected by a 2-fold increase in both the affinity and capacity of [3H]HCh-3 for its binding site on or closely associated with the choline carrier. In the present study, we further characterized the role of PLA_2 upon the activation of [3H]HCh-3 binding. Incubation of rat striatal membranes with phospholipase C failed to produce an increase in the capacity of [3H]HCh-3 binding, though a marked increase in the affinity was observed. Phospholipases B and D failed to produce any changes in the specific binding of [3H]HCh-3 when assayed at pH=7.8. Alternately, PLA_2 treatment resulted in the inhibition of two other neurotransmitter carriers, as indicated by a reduction in the specific binding of [3H]desipramine and [3H]mazindol. The specific binding of [3H]HCh-3 after PLA_2 treatment exhibited an uneven regional distribution which correlated with basal levels observed in untreated membranes. The effects of PLA_2 treatment and potassium depolarization of striatal slices were not additive. Finally, quinacrine, an inhibitor of PLA_2, resulted in a dose-dependent inhibition of the potassium depolarization-induced increase in the [3H]HCh-3 binding in rat striatum, cortex, and hippocampus. These results support the involvement of PLA_2 in the regulation of [3H]HCh-3 binding.

BIS THIAZOLIUM CATIONS: A NOVEL CLASS OF POTENT CHOLINERGIC AGENTS FOR STUDYING NEUROLOGICAL DISEASE. V.Balasubramanian*, M.D.Saltarelli, J.Coyle and H.Wagner* (Spon: H.Moser). Division of Nuclear Medicine, Departments of Radiology & Neurosciences, Johns Hopkins Medical School, Baltimore, MD 21205.

Although Hemicholinium-3 is a highly selective potent inhibitor of the choline uptake carrier, its inability to cross the blood-brain barrier limits its usefulness for studies in vivo. To circumvent this, we have synthesized and studied several thiazolium cations as potential cholinergic agents. Since these cations can be reduced to the neutral dihydro analogs, we envisioned that they may cross the blood-brain barrier, revert back to parent cations and interact specifically with the cholinergic components. Among these, the bis thiazolium cation derived from 4-methyl-5-(2-hydroxyethyl)-thiazole and 4,4′-bis-bromoacetyl biphenyl is a potent competitive inhibitor of choline uptake (Ki=1nM) as well as [3H]Hemicholinium-3 binding. In contrast bis alkyl or aryl thiazolium cations were less potent ($Ki=10^{-6}$-10^{-7}M). Model studies show that these thiazolium cations can be reduced to the corresponding dihydro analogs which, as expected, showed a propensity to undergo reoxidation to parent cations. These results suggest that bis thiazolium cations may be useful ligands for in vivo visualization of central cholinergic structure and function.

BINDING OF 3H-HEMICHOLINIUM-3 TO THE HIGH AFFINITY CHOLINE TRANSPORTER IN ELECTRIC ORGAN SYNAPTOSOMAL MEMBRANES. S. O'Regan+(SPON:N. Morel). Dept. Neurochimie, NBCM-CNRS, 91198 Gif-sur-Yvette, France.

Hemicholinium-3(HC-3) is a potent inhibitor of high affinity choline uptake by cholinergic nerve terminals. Indeed, sodium dependent binding of 3H-HC-3 was 10-fold higher with pre- than postsynaptic membranes, and electric organ synaptosomal membranes bound 3H-HC-3 with a $K_D=3 \pm 4$ nM and a Bmax=5.0±0.2 pmoles/mg protein. Choline, HC-3 and their analogues had similar effects on 3H-HC-3 binding and 3H-choline uptake, but there was some evidence of site heterogeneity for 3H-HC-3 binding in the presence of choline. Coexistence of inward and outward facing conformations of the transporter in the membrane preparation may explain this, and the inhibition of 3H-HC-3 binding to intact synaptosomes by choline was monophasic while the Bmax was reduced.

By comparing uptake and binding parameters, an apparent turnover number of 3 sec^{-1} was estimated for the high affinity choline transporter at 20°C under resting conditions. The high transport rates observed with electric organ synaptosomes are likely due to a high density of high affinity choline transporters, thought to be of the order of 100/um^2 synaptosomal membrane on the basis of specific 3H-HC-3 binding.

CARBAMYL-APROPHEN ANALOGS FUNCTION AS BOTH ANTIMUSCARINICS AND ANTICHOLINESTERASES. R.M. Smejkal*, H. Leader*, C.S. Payne*, A.D. Wolfe*, N.D. Brown*, R.K. Gordon*, and P.K. Chiang. Walter Reed Army Institute of Research, Washington, DC 20307-5100.

A series of aprophen analogs were synthesized with carbamyl substitutions at the para position of the phenyl rings to determine whether such compounds would display binary drug functions with therapeutic characteristics of aprophen as well as the ability to mask cholinesterases. These compounds carbamylate human butyrylcholinesterase with K_I values similar to those of pyridostigmine and physostigmine. The antimuscarinic profile of the analog containing a monomethylcarbamate moiety at the para-position of one phenyl ring of aprophen was very similar to that of aprophen in terms of its inhibitory effect on the acetylcholine-induced contraction of guinea pig ileum, the carbachol-induced release of α-amylase from pancreatic acinar cells and the binding of [3H]NMS to bovine brain membrane. The dimethylcarbamyl-substituted analog was about as active in inhibiting ileum contraction, but the inhibition of α-amylase release and [3H]NMS binding was one order of magnitude lower. Substitution on both phenyl rings was not well tolerated. These data suggest that one of the phenyl rings of aprophen must remain unsubstituted in order to preserve antimuscarinic activity, while bulky substitutions on the phenyl rings can be tolerated by butyrylcholinesterase.

THE EFFECT OF AGING ON MUSCARINIC-STIMULATED PHOSPHATIDYLINOSITOL (PI) TURNOVER IN FISHER 344 RATS. R.D. Schwarz, Parke-Davis Pharmaceutical Research Division, Warner-Lambert Co., Ann Arbor, MI 48105.

Receptor number and function of central neurotransmitters, including ACh, have been shown to be altered during aging and in neurodegenerative disorders associated with aging (e.g. Alzheimer's disease). Recently, we reported that cortical M1 muscarinic receptors were significantly decreased in aged Fisher 344 rats (J. Cell. Biochem. 11D: 198, 1987). Since it has been suggested that M1 receptors are functionally coupled to phosphoinositide hydrolysis, the present study examined whether there are age-related changes in PI turnover. Using the method of Berridge et al., 1982 the effect of various muscarinic agonists and antagonists on PI turnover was measured in cortical slices from young (3-5mo) and aged (22-24mo) male Fisher 344 rats. In young rats carbachol produced a concentration-dependent increase in total [3H]-inositol phosphates which was blocked by scopolamine with other agonists behaving as partial agonists. In aged rats, similar effects were observed. There were no significant differences between the two age groups comparing dose-response curves and maximal responses, however, the results were more variable. Thus, the previously observed decrease in cortical M1 receptors of aged Fisher 344 rats does not appear to be functionally translated into altered PI turnover.
