The hypothesis that the decrease in arterial pressure (AP) elicited by stimulation of the NTS is mediated by NTS neurons providing a monosynaptic inhibitory input to neurons in the RVLM was tested in two sets of experiments by recording activity of spontaneously firing units in the RVLM and NTS in paralyzed and artificially ventilated male Wistar rats under urethan. In the first set, RVLM vasomotor units (inhibited by activation of baroreceptors [1-2 μg phenylephrine i.v.] and displaying a rhythmicity of their spontaneous discharge in synchrony with the cardiac cycle) were inhibited by single pulse stimulation of depressor sites in the NTS (n=13, latency 26.7 ± 2.6 ms, threshold 73 ± 16 μA). In the second set of experiments, to test the possibility that this inhibitory connection was monosynaptic, pressor sites in the RVLM were stimulated electrically (range 30-500 μA) while recording from 21 spontaneously active units in the NTS. No antidromic activation was observed. These results support recent findings suggesting a multisynaptic connection between the NTS and RVLM. (Supported by MRC of Canada).

CHEMORECEPTOR INPUTS TO NON-RESPIRATORY CELLS IN THE NUCLEUS OF THE TRACTUS SOLITARIUS (NTS). S. W. Mifflin, Department of Pharmacology, University of Texas Health Science Center, San Antonio, TX. 78284-7764

Experiments were undertaken to examine the carotid body chemoreceptor input to non-respiratory cells in the NTS. In pentobarbital anesthetized, mechanically ventilated and paralyzed cats the lingual artery was cannulated for injection of CO_2 saturated .15M HCO_3. Using K-citrate filled electrodes intracellular recordings were obtained from 14 cells which were depolarized by close arterial injection of <100ul of CO_2 saturated HCO_3 and responded to carotid sinus nerve stimulation with an EPSP at latencies of <5ms. Signal averaging revealed no fluctuation of membrane potential in phase with central respiratory activity or lung inflation in any cell. At end-tidal CO_2s of 3.5-4.5% 6 cells spontaneously discharged action potentials at very irregular frequencies. Electrical stimulation of the carotid sinus nerve evoked EPSPs with latencies of 2.05-4.33ms (3.24±.79ms). None of these cells responded to stimulation of the superior laryngeal nerve. After recording, the electrode was cut in place. Reconstructed recording sites for 12 cells were concentrated from obex to 1mm caudal to obex and dorso-medial (n=9) or dorso-lateral (n=3) to the tractus. These non-respiratory cells in the NTS might be the initial links in the reflex chain whereby arterial chemoreceptors regulate the cardiovascular and respiratory systems. (Supported by NIH grant HL-41894)

CARDIOVASCULAR ACTION OF ANGIOTENSIN II AND SARALASIN MICROINJECTION INTO THE INFERIOR OLIVE NUCLEUS OF THE RAT BRAIN STEM. Frank Wang* and M. Ian Phillips, Dept. of Physiology, University of Florida, Gainesville, FL 32610.

Several brain stem sites are involved in mediating cardiovascular responses to Ang II. In rats, one of the areas with high density of Angiotensin II receptors which has been overlooked is the inferior olive nucleus. We hypothesized that endogenous Ang II may exert neural control on blood pressure through an action on the inferior olive. Microinjections of Ang II into the lateral inferior olive (n=10) results in significant, dose related elevation of mean arterial pressure (MAP). 0.5 nmole, 1.0 nmole, and 2.0 nmole Ang II microinjections were associated with increased of 8.5 ± 1.9 mmHg, 13.1 ± 1.0 mmHg, and 23.3 ± 6.0 mmHg, respectively. Microinjections of Sar^1Ala^8 Ang II (saralasin) (n=8) were associated with significant decreases of MAP in a dose-related manner. 1.0 nmole and 2.0 nmole of saralasin alone were associated with MAP decreases of 14.7 ± 2.2 mmHg and 21.0 ± 5.5 mmHg. Sequential microinjection of 1 nmole saralasin and Ang II into the inferior olive nucleus (n=4) showed Ang II increases in MAP were reversed by the receptor antagonist. In conclusion, the findings indicate that endogenous Ang II exerts neural control on blood pressure through an action on the inferior olive nucleus because saralasin microinjection lowered normal MAP. The results imply that constant stimulation on the inferior olive nucleus by angiotensin contributes to the maintenance of normal blood pressure.

Inhibitory amino acid-induced depression of postsynaptic responses to visceral sensory input in the solitary tract nucleus. P.D. Feldman, H.D. Brinegar* and R.B. Felder. Dept. Int. Med. and Cardiovascular Center, Univ. of Iowa, Iowa City, IA 52242.

Microinjection studies suggest a role for the inhibitory amino acids glycine (**GLY**) and gamma-aminobutyric acid (**GABA**) in modulating the transmission of cardiovascular sensory information within the solitary tract nucleus (**nTS**). Action potential responses of nTS neurons to fixed-intensity electrical stimulation of afferent fibers in the solitary tract were recorded extracellularly from superfused rat brain slices. Post-stimulus time histograms of spike responses were accumulated over 50 sequential stimulations both before and during infusion of GLY or GABA. A total of 29 neurons was studied. Infusion of 100 nM GLY induced a decrease of responsiveness in 15 of the 25 neurons tested, with a mean change (±SEM) of -75.9±5.6%. Infusion of 100 nM GABA similarly induced a decrease of responsiveness in 10 of the 25 neurons tested, with a mean change of -71.8±6.4%, while increased responsiveness was seen in 3 neurons (mean±SE = +45.7±11.4%). Six cells unaffected by GLY and 6 unaffected by GABA were tested further at doses up to those inducing non-selective membrane effects (0.5-10 uM). However, responsiveness remained unchanged. Twenty-one of the 29 neurons had been tested with both agonists. Both agonists affected the responsiveness of 7 cells, while the remaining cells were affected by only GLY (N=4), GABA (N=3), or by neither (N=7). These results indicate that both GLY and GABA may depress the transmission of visceral sensory information within the rat nTS.

VESAMICOL DECREASES BOTH QUANTAL AND SYNAPTIC VESICLE (SV) SIZE AT THE NEUROMUSCULAR JUNCTION. A. Nagel* and A.G. Engel. Muscle Research Laboratory, Mayo Clinic, Rochester, MN 55905.

Vesamicol (AH5183), an inhibitor of acetylcholine (ACh) uptake into SVs, reduces quantal size after prolonged nerve stimulation. However, at >7.5 µM the drug also acts as a postsynaptic inhibitor. To further assess the presynaptic effects of the drug, mouse phrenic nerve-diaphragms were incubated with 10 µM vesamicol at 21°C; after 22 min they were stimulated at 4 Hz for 30 min, and then allowed to recover for 45 min. Control muscles were similarly treated in the absence of vesamicol. Before incubation and after recovery, portions of vesamicol and control preparations were fixed for electron microscopy and SV diameters were determined by morphometric methods. In 3 control muscles, the mean MEPP amplitude was 100, 70 and 94% before, immediately after, and 45 min after stimulation; the mean SV volume was the same before stimulation and after recovery. In 3 vesamicol muscles the mean MEPP amplitudes before drug exposure, 22 min after drug exposure, immediately after stimulation, and 45 min after stimulation were 100, 81, 46, and 37%, respectively; the mean SV volume was reduced to 58% of that before drug exposure ($p<0.001$). The results reconfirm the known presynaptic effects of vesamicol, indicate that SV size is related to SV ACh content, imply that quantal size is related to SV size, and are in harmony with the SV hypothesis of neuromuscular transmission.

328.2

CHARACTERIZATION OF THE VESAMICOL (AH5183) RECEPTOR IN VP_1 CHOLINERGIC SYNAPTIC VESICLES. B.A. Bahr and S.M. Parsons. Dept. of Chem., Univ. of Calif., Santa Barbara, CA 93106

Purified synaptic vesicles (SVs) from Torpedo exhibit transport of acetylcholine (ACh) which is inhibited by 1-trans-2(4-phenylpiperidino)cyclohexanol (vesamicol). Detergent screening established that solubilization of active vesamicol receptor (VM-R) requires the steroidal bile acid nucleus. We synthesized the nonionic detergent N,N-bis(3-D-gluconamidopropyl)cholamide (BIGCHAP) and found it to preserve [3H]vesamicol (VML) binding better than other steroidal derivatives. In a BIGCHAP-Tween80 mixed system, the purified VM-R appears to be a diffuse glycoprotein on SDS-PAGE at 240 kDa which silver stains poorly. Identification of the VML binding protein will be achieved with a new photo-affinity analogue, (±)-trans-5(4-azidobenzoyloxy)-3-hydroxy-2-(4-phenylpiperidino)tetralin. Azido-vesamicol inhibited VML binding (K_d=20.8±8.9nM) with a K_I of 2-5µM. SVs trapped on filters and incubated with azido-vesamicol irreversibly lost 60-80% of their VML binding sites (12-16/SV) when photolyzed.

A biotinylated vesamicol analogue competitively inhibited VML binding with a K_I of 126±49nM. (±)-N5-d-Biotinyl-trans-5-amino-2-hydroxy-3(4-phenylpiperidino)tetralin (Rogers et al, J.Med.Chem. 32, 1989) inhibited ACh transport with an IC50 of 138±19nM in the absence and ≫100µM in the presence of avidin. Avidin occlusion recovered 87% of VML binding (k_1=0.21 /min) from biotinyl-vesamicol saturated SVs, whereas only 4% of the ACh transport was recovered after 1HR with avidin. Transport inhibition was reversible when using centrifugative pelleting to remove neat or biotinylated vesamicol from SVs, with transport recoveries of 55-95%. This demonstrates a significant lag time the ACh transporter requires to reactivate following removal of a vesamicol-based inhibitor.

INTRASYNAPTOSOMAL SEQUESTRATION OF ^{3}H-METHYLENEDIOXYAMPHETAMINE (MDA) AND ^{3}H-AMPHETAMINE (AMPH). R. Zaczek, S. Culp* and E.B. De Souza. Neurobiology Laboratory NIDA/ARC, Baltimore, MD 21224.

We exmined the incorporation of ^{3}H-MDA and ^{3}H-AMPH into rat brain synaptosomes. Saturation studies revealed that ^{3}H-MDA interacted with two saturable sites in synaptosomes which were sensitive to tissue boiling: K_D high=295nM, B_{max}=32pmoles/mg protein.; K_D low=45µM, B_{max}=5.2nmole/mg protein. The high capacities of these sites argue against a bimolecular interaction of ^{3}H-MDA with monovalent protein binding sites. Disrupting the integrity of the synaptosomal membranes by sonication, incubation in hypotonic media and in the presence of the detergent digitonin reduced ^{3}H-MDA and ^{3}H-AMPH incorporation. These data indicate that the incorporation represents a sequestration phenomenon. Incorporation of both compounds was reduced by preincubation of the tissue at 37°C or in hypotonic buffer at 4°C, suggesting that the sequestration is maintained by an intrasynaptosomal factor which is lost under these preincubation conditions. ^{3}H-MDA incorporation was pH dependent and temperature sensitive. The synaptosomal sequestration of both ^{3}H-MDA and ^{3}H-AMPH were inhibited by permeant cations suggesting that the factor which maintains sequestration is anionic. Pharmacological profiles of ^{3}H-MDA and ^{3}H-AMPH sequestration were identical. The rank order of inhibition (desipramine>amphetamine>MDA>methylphenidate) did not correspond to the lipophilicity of the test drugs. The intrasynaptosomal internalization of ^{3}H-MDA and ^{3}H-AMPH described in the present report may be important in the molecular mechanism of monoamine release induced by the amphetamines.

RELEASE OF ENDOGENOUS DOPAMINE FROM RAT RETINA. C.J.Gibson. Dept. of Pathology, University of Western Ontario, London, CANADA N6A 5C1

A simple superfusion apparatus has been developed for the measurement of endogenous release of the rat retinal transmitter dopamine (DA). Perfusion chambers consisted of inverted Swinnex filters (Millipore Corp, Bedford, MA; SX00 013 00) through which a modified Kreb's buffer is pumped at a flow rate of 0.5 ml/min. Fractions are collected every 15 minutes and analyzed for DA by HPLC with coulometric detection. DA release was stimulated by increasing levels of potassium (from 15 to 55 mM). Basal release averaged 12 + 5 pg/retina and rose 7-fold to 95.5 + 23 pg/retina when exposed to 40 mM potassium (K) Kreb's buffer. This represented 8.9 + 2.3% of total retinal DA. In the absence of calcium, no release was evoked by the addition of 40 mM K (11 + 4 pg/retina). In contrast release caused by the introduction of 50 uM tyramine was calcium independent. Exposure of dark-adapted retina to light also increased endogenous DA release, from 9 + 4 pg/retina to 14 + 6 pg/retina. This simple system should prove useful in determining what factors may normally control retinal DA release.

PREFERENTIAL PRODUCTION OF 3-HYDROXYANTHRANILIC ACID FROM ANTHRANILIC ACID IN RAT BRAIN SLICES. H. Baran and R. Schwarcz. Maryland Psych. Res. Ctr., Baltimore, MD 21228.

As assessed by HPLC with electrochemical detection (Baran & Schwarcz, submitted), 3-hydroxyanthranilic acid (3HANA), the bioprecursor of the excitotoxin quinolinic acid, is present in the rat brain in very low concentrations (approx. 12 fmol/mg tissue).

In mammalian tissues, 3-hydroxykynurenine (3HKYN) is believed to serve as the bioprecursor of 3HANA. However, we were unable to produce substantial quantities of 3HANA from 3HKYN in rat brain tissue. In our search for alternative bioprecursors of 3HANA, we observed that anthranilic acid (AA) can be 3-hydroxylated by cerebral slices in vitro. Incubation of cortical slices was performed at 37°C in Ringer solution containing 10 μM 4-chloro-3HANA, a potent 3-hydroxyanthranilate oxygenase inhibitor (cf. Walsh et al., this meeting). Incubation with 1 mM AA or 3HKYN produced 89.0 ± 9.3 and 9.0 ± 0.3 (5 min) or 187.5 ± 11.2 and 51.6 ± 7.9 (120 min) fmol newly synthesized 3HANA/mg tissue, respectively (N = 3 each). Preferential 3HANA synthesis from AA was also noted at lower precursor concentrations. 3HANA production from AA was linear up to 5 min.

Work in whole cell preparations will aid in the assessment of the enzymatic conversion of AA to 3HANA in the brain under physiological and pathological conditions.

328.6

ANTHRANILATE HYDROXYLASE IN RAT BRAIN. R. Schwarcz, H. Baran and E. Okuno, Maryland Psychiatric Research Center, Baltimore, MD 21228.

Experiments with slices of rat cerebral cortex suggest the existence of anthranilate hydroxylase (AAOH), the enzyme responsible for the synthesis of 3-hydroxyanthranilic acid (3HANA) from anthranilic acid (AA) (cf. Baran and Schwarcz, this meeting). We therefore decided to examine its presence in cell-free rat brain homogenate. Standard assays were carried out at 37°C in 30 mM MES buffer, pH 6.0, containing 0.5 mM NADPH. 3HANA was determined by HPLC with electrochemical detection (Baran & Schwarcz, submitted). Enzyme activity could be unequivocally identified in several fractions obtained from homogenate after differential centrifugation in 0.32 M sucrose. The 3500 x g, 10 min precipitate contained the highest specific activity and was used in subsequent experiments. Heat treatment for 1 minute increased AAOH activity (maximum at 80°C). In the presence of 1 mM AA and 10 μM 4-Cl-3HANA (cf. Walsh et al., this meeting), 63 pmol 3HANA/mg protein were produced. The synthesis of 3HANA was linear until 1 h. In the presence of 0.1 mM tetrahydrofolic acid, under otherwise standard conditions, enzymatic activity was increased and greatly accelerated. Kinetic analysis showed a V_{max} of 120 pmol/h/mg protein and a K_m of 111 μM.

Supported by USPHS grants NS 16102 and NS 20509 and a fellowship from the Max Kade Foundation (to H.B.).

328.7

BRAIN BUT NOT LIVER TISSUE SLICES RETAIN QUINOLINIC ACID UPON PRECURSOR LOADING. C. Speciale, D. Clary* and R. Schwarcz. Maryland Psych. Res. Ctr., Baltimore, MD 21228.

The endogenous excitotoxin quinolinic acid (QUIN) may play a role in a variety of N-methyl-D-aspartate (NMDA) receptor-mediated events in the brain. Rat brain slices synthesize QUIN following exposure to its immediate bioprecursor 3-hydroxyanthranilic acid (3HANA; Soc. Neurosci. Abstr., 14: 479.9, 1988). We have now studied the comparative ability of brain and liver slices to retain QUIN following a preloading regimen (64 μM 3HANA, 60 min at 37°C). Slices loaded with newly synthesized QUIN (=100%), were further incubated with fresh media containing 10 μM 4-chloro-3HANA to prevent additional QUIN synthesis (cf. Walsh et al., this meeting). Efflux was estimated by measuring QUIN in tissue and medium after incubations for 30, 60 or 90 min at 37°C.

In contrast to liver slices, which rapidly lost QUIN within the first efflux period (tissue content after 30 min: 3 ± 1% of controls), brain slices retained QUIN throughout the 90 min procedure (tissue content as % of controls: 52 ± 3 (30 min), 45 ± 4 (60 min), 32 ± 4 (90 min); n=4). In all experiments, QUIN concentrations in the incubation media adequately reflected QUIN loss from the tissue. Brain-specific mechanisms regulating QUIN expulsion into the extracellular compartment may be of relevance for NMDA receptor-mediated processes. Supported by USPHS grant NS 16102 and a Fogarty Fellowship to C.S.

MULTICOMPONENT ANALYSIS OF TRYPTOPHAN AND TYROSINE METABOLISM IN HUNTINGTON'S DISEASE: EVIDENCE FOR REDUCED FORMATION OF KYNURENIC ACID

M.F. Beal, W.R. Matson, K.J. Swartz, P.G. Gamache and E.D. Bird

Department of Neurology, Mass.General Hosp. & Harvard Medical School, Boston MA. 02114 and ESA Corp., Bedford, MA. 01730.

Metabolism of tryptophan occurs by a branched pathway. One branch produces the excitatory amino acid (EAA) antagonist kynurenic acid and the EAA agonist quinolinic acid while a second branch produces the neurotransmitter serotonin. In the present study multiple components of the tryptophan and tyrosine metabolic pathways were measured in postmortem putamen of 35 controls and 30 Huntington's Disease (HD) brains using reverse phase high performance liquid chromatography (HPLC) with 16 sensor electrochemical detection. Measurements of kynurenic acid were also verified using reverse phase HPLC with fluorescence detection. Both concentrations of individual components of the tryptophan and tyrosine pathways as well as ratios of precursors to their respective metabolites were measured to assess the rate of turnover through various parts of the pathways. These ratios have the advantage that they are not affected by tissue shrinkage and gliosis. In addition, these ratios cancel out the effects of premortem nutritional status; a significant variable due to the fact that metabolism of tryptophan and tyrosine are exquisitely precursor responsive. In HD putamen there were significant increases in dopamine, 5-hydroxyindoleacetic acid, 5-hydroxytryptophan and serotonin concentrations. The ratios of precursors to products within the tyrosine metabolic pathway and the serotonin branch of the tryptophan pathway were unchanged in HD putamen as compared to controls. The absolute concentrations of kynurenine metabolites were not significantly changed in HD putamen, however there was a significant 2-fold ($p < 0.01$) increase in the ratio of kynurenine to kynurenic acid. This suggests that there may be reduced formation of kynurenic acid in HD. Since kynurenic acid is an endogenous inhibitor of EAA mediated neurotransmission and can block against EAA mediated neurotoxicity *in vivo*, a relative deficiency of this compound could directly contribute to the neuronal degeneration in HD.

328.9

α-KETOGLUTARATE AND PYRUVATE AS CO-FACTORS OF KYNURENINE TRANSAMINASE IN RAT BRAIN. E. Okuno, D.A. Parks*, M. Nakamura and R. Schwarcz. Maryland Psychiatric Research Center, Baltimore, MD 21228.

The endogenous excitatory amino acid antagonist kynurenic acid is biosynthesized from kynurenine (KYN) via a single aminotransaminase reaction using 2-oxo acids as amino-acceptors. We have described pyruvate (Pyr)-preferring KYN-transaminases (KPT) in rat kidney and brain (Ishikawa et al., submitted) and proved their identity biochemically and using anti-KPT-antibodies. We now examined the properties of brain KPT at physiological KYN concentrations. Assay of eluates from a DEAE-Sepharose column using ^{3}H-KYN (2 μM) as a substrate revealed only one enzyme which could use both α-ketoglutarate (αKG) or Pyr as a co-factor. With either oxo acid, the enzyme reacted with anti-KPT antibodies, indicating that transamination was catalyzed by a single enzyme protein. In crude brain homogenate, the enzyme showed a pH optimum of 8.5 with αKG and 8.2 with Pyr. Kinetic analysis revealed a low K_m-value (17 μM) for KYN with 1 mM αKG and a much higher K_m (910 μM) with 1 mM Pyr. Using 2 μM KYN, K_m-values for αKG and Pyr were 150 and 160 μM, respectively. Enzyme activity was also detected with other oxo-acids, namely 2-oxoadipate, phenylpyruvate, 2-oxo-isocaproate, glyoxylate and the most effective compound, 2-oxo-4-methylthiobutyrate.

Supported by USPHS grants NS 16102 and NS 20509.

SODIUM-DEPENDENT INHIBITION OF KYNURENATE SYNTHESIS BY QUISQUALATE IN RAT BRAIN. J.B.P. Gramsbergen, W.A. Turski and R. Schwarcz. Maryland Psychiatric Research Center, Baltimore, MD 21228.

The excitatory amino acid (EAA) receptor antagonist kynurenic acid (KYNA) can be produced by rat brain slices upon exposure to L-kynurenine (J. Neurochem., 52:1629, 1989). KYNA synthesis takes place predominantly in astrocytes and may be regulated by neuron-glia interactions (Soc. Neurosci. Abstr., 14:479.12, 1988).

We have now investigated the effects of EAAs on KYNA production. In cortical slices of adult rats, at 1 mM, several EAAs (including glutamate and aspartate) blocked KYNA synthesis by ≥45%. At a lower dose (200 μM), however, only quisqualate (QUIS; -80%), L-α-amino-adipate (αAA; -67%), L-cysteate (-35%) and L-cysteine sulfinate (-32%) blocked KYNA synthesis significantly. Other EAAs such as AMPA, kainate, NMDA, ibotenate and quinolinate were inactive. The QUIS effect could not be blocked by EAA antagonists (including CNQX), tetrodotoxin or in high Mg^{2+}/Ca^{2+}-free medium. In contrast, the inhibitory effect of QUIS, as well as that of αAA, were blocked in Na^+-free medium, and QUIS was not effective in the brain of 1 day old rats or in liver slices. In ibotenate-lesioned striatal slices, QUIS was as effective as in control tissue.

These results suggest that the effects of QUIS and αAA may be mediated by sodium-dependent receptors or carriers on astrocytes. Supported by USPHS grant NS 16102.

328.11

4-CHLORO-, 4-FLUORO- AND 4-BROMO-3-HYDROXYANTHRANILIC ACIDS ARE POTENT COMPETITIVE INHIBITORS OF 3-HYDROXY-ANTHRANILIC ACID OXYGENASE. J.L. Walsh*, [1]William P. Todd*, [1]B.K. Carpenter* and R. Schwarcz (SPON: M. Nakamura). Md. Psych. Res. Ctr., Baltimore, MD 21228 and [1]Dept. Chemistry, Cornell University, Ithaca, NY 14853.

4-Chloro-3-hydroxyanthranilic acid (4-Cl-3HANA) is known to inhibit liver 3-hydroxyanthranilic acid oxygenase (3HAO). Since 3HAO is responsible for the neosynthesis of the endogenous excitotoxin quinolinic acid (QUIN), 3HAO inhibitors and their molecular mechanisms of inhibition are of interest in the study of QUIN neurobiology.

4-Cl-3HANA and its fluoro- and bromo-analogs have now been prepared and tested for their ability to block 3HAO activity in human and rat brain homogenates, and to inhibit QUIN production from 3HANA in rat brain slices. All three drugs inhibited 3HAO activity or QUIN production with identical relative potencies, i.e. 4-Br-3HANA > 4-Cl-3HANA > 4-F-3HANA. In homogenates, IC_{50} values ranged from 2-4 nM (4-Br-3HANA) to 17-24 nM (4-F-3HANA).

Enzyme inhibition was assessed by following the very rapid (6 sec) 3HAO-catalyzed production of ß-carboxy-muconic-ω-semialdehyde from 3HANA. Although the drugs bind very tightly to the enzyme, kinetic analysis demonstrated the inhibition to be competitive in nature.

4-Halo-3-hydroxyanthranilates represent model 3HAO inhibitors which may be of therapeutic value in cases of enhanced QUIN production in neuro-psychiatric diseases.

328.12

POTASSIUM DEPENDENT SODIUM FACILITATION OF DOPAMINE (DA) TRANSPORTER BINDING IN FRONTAL CORTEX. A. Hitri, D. Venable* and R.J. Wyatt. Neuropsychiatry Branch, NIMH Neurosciences Center at St. Elizabeths, Washington, D.C. 20032.

The sodium dependency of the DA transporter binding is a relevant biochemical characteristic to uptake. In the brain, 3H-GBR 12935 labeled DA uptake sites have been found to be both Na dependent and independent (Andersen, P.H., J. Neurochem. 48: 1887, 1987); Na dependent sites are either enhanced or inhibited by increasing concentrations of this ion. We attempted to characterize the Na inhibited 3H-GBR 12935 labeled DA uptake sites in the frontal pole (FP). The FP of three postmortem human brains were individually homogenized in 50mM Tris buffer pH 7.9. The binding reaction was carried out in the presence of 30, 60 and 120 mM NaCl, with or without the addition of 5mM KCl. Consistent with a previous report (Janowsky, A. et al., J. Neurochem. 46: 1272, 1986), our data indicate a Na concentration dependent decrease in Bmax, in a potassium free medium (Bmax=202+56; 139+50; 111+36 for 30, 60 and 60mM NaCl). With the addition of potassium ions, the effect of Na was reversed (Bmax=93+29; 261+78; 239+76, for 30, 60 and 120mM NaCl). The affinity constants were not changed in either case. The FP and striatum are different, striatal DA uptake sites do not require potassium for Na enhancement, while in the FP there is a permissive effect of potassium ions on the Na dependent increase in Bmax.

SOMATIC AND VISCERAL AFFERENTS III

329.1

INDUCTION OF JUN AND FOS PROTO-ONCOGENE PROTEINS J. Leah *, T. Herdegen * and M. Zimmermann.
II. Physiologisches Inst., Uni. Heidelberg, D-6900 FRG

The production of jun and fos proteins was examined, immunocytochemically, after neuronal stimulation and axonal transport block in pentobarbital anaesthetised rats.

Both jun and fos appeared in nuclei of numerous, somatotopically corresponding spinal dorsal, but not ventral horn or DRG neurones 1 hr after cutaneous, muscle or visceral noxious stimuli; and in the trigeminal, solitary tract and lateral reticular nuclei following noxious stimulation of the nasal mucosa. Both appeared here, and in brain sensory nuclei after electrical stimulation of sciatic nerve C-fibers. Non-noxious, A-fiber activation was much less effective. Both appeared in many neurones in similar regions after general CNS activation by i.p. metrazol.

Jun, but not fos, appeared after 4 d and persisted for 20 d following transection or crush of the axons of DRG or motoneurones. Jun also appeared in spinal projection and cortical neurones after axotomy; and in many CNS neurones after local block of axonal transport by microinjection of colchicine, and in motoneurones and DRG neurones after sciatic nerve axonal transport block by local vinblastine.

Thus, jun and fos can both be induced transynaptically and by direct stimulation. Jun is differentially induced by axonal transport block, probably by absence of a trophic factor, and it may code for those proteins required for axonal regeneration.

EARLY ECTOPIC DISCHARGES ARE GENERATED AT THE DORSAL ROOT GANGLION IN RATS WITH A PAINFUL PERIPHERAL NEUROPATHY. K.C. Kajander, S. Wakisaka* and G.J. Bennett*. NAB, NIDR, NIH, Bethesda, MD 20892

We have reported pathophysiological changes in primary afferent fibers (Soc. Neurosci. Abstr. 14:912, 1988) in an animal model of painful peripheral neuropathy (Pain 33:87-107, 1988). One of these abnormalities is the appearance of ectopic discharges in myelinated fibers as early as 1 day after the injury. The present experiments were designed to determine the origin of these discharges.

Microfilament recording techniques were used to record sciatic nerve afferents from the L4-5 dorsal rootlets of rats 1-3 days after nerve injury. Microfilaments were severed proximally to eliminate the possibility of activity originating in the spinal cord. Three kinds of experiments were conducted to determine the site of origin of the ectopic spikes. First, the sciatic nerve was transected about 5 mm proximal to the injured region while recording from afferents with ongoing ectopic discharge. Nerve transection never eliminated the activity (16 fibers tested to date). Second, we determined the critical interval for collision between antidromic ectopic spikes and othrodromic shock-evoked spikes. Computations using each fiber's conduction velocity, critical interval and refractrory period indicated that the ectopic spikes originated near the dorsal root ganglion (DRG). Third, potassium channel blockers, gallamine triethiodide or 4-aminopyridine, applied directly to the DRG increased the activity of all fibers exhibiting ongoing ectopic discharge. Application of the blockers to the region of injured nerve had no effect. We conclude that the ectopic discharge originates in the DRG at or near the afferent's cell body.

REPRESENTATION OF SHAPE IN THE RESPONSES OF CUTANEOUS MECHANORECEPTIVE AFFERENT FIBERS. M.A. Srinivasan* and R.H. LaMotte (SPON: S. E. Kapadia). Research Lab. of Electronics, MIT, Cambridge, MA 02139 and Dept. Anesthesiology, Yale Univ. Sch. Med., New Haven, CT 06510.

The distribution of surface curvature of an object defines its shape. In order to investigate the peripheral neural representation of shape, we recorded responses of slowly and rapidly adapting mechanoreceptive afferent fibers (SAs and RAs) to cylinders differing in curvature, and to a pattern of curvatures forming a smooth wavy surface applied to the monkey fingerpad. The discharge rates of both SAs and RAs to indentations by the cylinders increased with curvature. SA responses discriminated the curvatures very well both during the ramp and steady phases, in comparison to the ramp responses of RAs. RA responses were well modulated by the curvatures when the cylinders were sinusoidally vibrated: Their response thresholds decreased with increases in curvature. When the wavy surface was stroked at constant force over the fingerpad, both SAs and RAs responded with bursts to the convex portions and pauses to the concave. The width and frequency of SA responses were correlated with the wavelength and radius of the skin curvature, respectively. The RAs responded only to the leading half of the convex portions with poorer modulation. These findings are consistent with our earlier hypotheses [J. Neurosci. 7(6) 1655-1695]: SA discharge rates increase with increases in the depth of indentation and curvature change at the receptive field, and SAs do not respond to the unloading of curvature; RA discharge rates increase with increases in the velocity of indentation and rate of curvature change at the receptive field. (PHS grant NS 15888 and ONR contract N00014-88-K-0604)

329.4

A 3-D CONTINUUM-MECHANICS MODEL OF SKIN PREDICTING MECHANORECEPTOR RESPONSES TO SCANNED, EMBOSSED STIMULI. J.R. Phillips. University Laboratory of Physiology, Parks Road, Oxford. OX1 3PT. U.K.

Neural images reconstructed from primary mechanoreceptive afferent responses to embossed letters scanned across the skin, have distorted features (Phillips et al., Proc. Natl. Acad. Sci. USA, 85:1317-1321, 1988). The objective of this study was to extend the static, 2-D model of skin described previously (Phillips & Johnson, J.Neurophysiol. 46:1204-1225, 1981) to three dimensions, and to account for the response features observed using scanned stimuli. Skin is modelled as an ideal medium in which the principle of superposition of forces applies. Moving stimuli are modelled as assemblies of point loads applied normal to the skin surface summed with frictional forces applied tangential to the surface. Time dependent effects are modelled as receptor properties. The 3-D model accounts qualitatively for many of the effects observed in slow adaptor responses to scanned stimuli, assuming that compressive strain is the effective stimulus at the receptor terminal. In particular, the model accounts for the asymmetry in responses observed between the leading and trailing edges of letters and also between horizontal and vertical elements of horizontally scanned letters. Asymmetry results from superimposing stresses derived from the action of skin frictional forces.

MECHANISMS OF TWO-POINT DISCRIMINATION USED BY RAPIDLY-ADAPTING (RA) MECHANORECEPTORS IN GLABROUS SKIN. E.P. Gardner and C.I. Palmer. Dept. of Physiology, NYU Sch. of Med., NY, NY 10016.

In order to measure spatial acuity of phasic cutaneous mechanoreceptors in macaque monkeys, we displayed horizontal bar patterns spaced 1-13 mm apart on a computer-controlled OPTACON stimulator. Two-point resolution was measured by simultaneously pulsing pairs of rows at rates of 100, 50 and 25 Hz; each pair was shifted in tandem across the hand in order to simulate tangential motion. Receptive field diameter appears to be the critical determinant of spatial resolution of gaps between two bars. RAs fire continuously if bar spacing is less than the field diameter, but do not summate inputs when both active rows are contained within the field. 75% discharge one spike/pulse as bar patterns cross the field, yielding a uniform spike train whose frequency reflects OPTACON pulse rates, but fails to indicate gaps between bars. When bar spacing exceeds the field diameter, the spike train splits into two sets of impulses as first one and then the second bar traverses the field. Burst onset latencies reflect both bar spacing and apparent speed of motion across the hand. 20% of RAs show a pause in firing at 3 row bar spacing (3.6 mm), while nearly all resolve 4 row (5 mm) gaps. Another 20% differentiate gaps narrower than the field diameter. These RAs respond to both probe indentation and retraction at the field center, firing two spikes/pulse; they show double peaked response profiles to bar patterns spaced at least 2.5 mm apart, whose timing corresponds to bar spacing. None resolve bars spaced 1.2 mm apart, as double spike responses occur only to the leading edge.

Although no gap occurs in RA response profiles when closely spaced bar patterns cross their fields, their duration of firing distinguishes bars spaced less than the field diameter. Spike train duration is directly related to bar spacing; at subthreshold separations, RAs show linear increases in total spikes/sweep as spacing between active rows widens. Furthermore, less overlap of receptive fields contacted by each stripe occurs as bar spacing widens, leading to enlargement of the pool of RAs activated. These population mechanisms may explain psychophysical observations that humans can discriminate probes spaced 1 mm apart, and can differentiate single row gaps on the OPTACON. Most RAs do not differentiate 2 narrow bars spaced less than the field diameter from a single filled bar spanning a similar length of skin. Thus, RA afferents appear to use similar temporal coding mechanisms for subthreshold spatial resolution and for distinguishing bars of varying width. *(Supported by USPHS Research Grant NS11862.)*

TWO-POINT DISCRIMINATION AND TEXTURE CODING BY PACINIAN CORPUSCLES (PCs) IN PRIMATE GLABROUS SKIN. C.I. Palmer and E.P. Gardner. Dept. of Physiology, NYU School of Medicine, NY, NY 10016.

In order to measure spatial acuity of Pacinian corpuscle afferents in the median and ulnar nerves of anesthetized macaque monkeys, we displayed horizontal bar patterns spaced 1-13 mm apart on a computer-controlled OPTACON stimulator placed on the hand. Two-point resolution was measured by simultaneously pulsing pairs of rows at rates of 100, 50 and 25 Hz; each pair was shifted in tandem across the skin in a row by row sequence in order to simulate tangential motion at speeds of 120-30 mm/s. Like RA afferents, receptive field diameters of PCs also appear to be the critical determinant of spatial resolution of gaps between two bars. However, RAs display finer spatial resolution than PCs, due to their smaller fields, and more regular firing patterns. PCs fire continuously to bar patterns spaced less than the field diameter, displaying multiple-spike bursts throughout much of the field. None of the PCs studied resolve bar patterns spaced 1 or 2 rows apart (1.2-2.5 mm). Only half the PC population shows pauses in activity signalling gaps between bars spaced 5 mm apart, whereas nearly all RAs tested resolve this spacing. Resolution of OPTACON bar patterns by the entire PC population is observed only at bar spacings of 1 cm (8 rows) or more. Spatial resolution is also impeded by the tendency of PC afferents to summate closely-spaced inputs near the field center; this results in response profiles with a single, large-amplitude broad peak. Moreover, irregularities in PC firing patterns usually preclude the use of multiple-spike bursts at subthreshold spacings for distinguishing individual stripes.

Like RAs, PC afferents can use their duration of firing to distinguish bars spaced less than the field diameter, even if there is no gap in the response profile. However, total spike output from PCs is a less reliable metric than from RAs due to greater variability in trial to trial responses, and the tendency of PCs to summate adjacent stimuli. High frequency (100 Hz) sweeps evoke weaker responses than low frequencies (25 Hz), due to response attenuation at the far end of receptive fields, and decreased probability of burst responses to individual OPTACON pulses. These characteristics of PC receptive fields, together with receptor adaptation mechanisms to high pulse rates, endow PC afferents with poor spatial sensitivity, and may explain their inability to encode spatial frequencies of periodic gratings scanned across the hand. *(Supported by USPHS Research Grant NS11862.)*

STUDIES OF THE INTRAFASCICULAR ORGANIZATION OF HUMAN NERVES: R.G. Hallin* and R. Ekedahl* (SPON: K. Tornqvist). Dept. of Clin. Neurophysiol., Huddinge University Hospital, 141 86 Huddinge, Sweden.

Microneurography in man was carried out in median nerve sensory fascicles with 200-250μm diameter concentric needle electrodes with a recording lead diameter of 20-30μm. Such electrodes permit detailed studies of activity within even a part of a fasicle.

Multiunit fields of myelinated fibres innervating palmar skin did not correspond to the innervation zone of one or two adjacent digital nerves but instead often comprised spatially separate parts of such skin territories. Upon repeated intrafascicular electrode adjustments there were successive somatotopically organized transitions from fields composed by separate parts to fields which were coherent or vice versa. The receptive fields of single A and C fibres were all localized within the previously screened multiunit areas.

These findings suggest the presence of a somatotopy in human limb nerves comparable to that previously established in the spinal cord and somatosensory cortex.

329.8

POSTOCCLUSIVE HYPEREMIA IN FELINE CORTICAL GREY MATTER IS MEDIATED BY TRIGEMINAL AXONS. M.A. Moskowitz, D.E. Sakas, E.P. Wei, M.G. Buzzi, C. Ogilvy, H.A.Kontos. Mass. Gen. Hosp, Boston, MA 02114. Med. Coll. VA, Richmond, VA 23298.

Marked hyperemia may develop in brain following temporary cessation of blood flow, and is associated with morbidity following cardiac arrest, stroke and head injury. Blood flow was compared in 10 symmetrical brain regions using radiolabeled microspheres under resting conditions, during ischemia, and with reperfusion in cats 2-3 weeks after chronic trigeminal ganglionectomy, trigeminal rhizotomy or sham operation. Pentobarbital anesthetized animals (n = 16) were subjected to 10 minutes of combined brachiocephalic-left subclavian occlusion and hypotension (BP < 50 mm). Blood flow values were within normal range and symmetrical at rest. During ischemia, blood flow was not detected in brain. Within 30 minutes after reestablishing flow, values increased to nearly 5 fold above resting and were symmetrical in rhizotomy and sham cats. However, values were attenuated by as much as 65% ipsilateral to the ganglionectomy within cortical grey matter corresponding to the territories supplied by anterior, middle and posterior cerebral arteries. These data demonstrate that axon reflex-like mechanisms mediate cortical hyperemia following recirculation and are likely to contribute to the tissue damage (e.g., edema formation) associated with recirculation injury.

LOW AND HIGH THRESHOLD MECHANOSENSITIVE UNITS IN THE LUMBAR FACET JOINT. JM Cavanaugh[1,*], T Yamashita[1,*], TV Getchell[2], AA El-Bohy[2,*], AI King[1,*] (SPON: ML Getchell[2]). Bioengineering Center[1] and Dept. of Anatomy and Cell Biology[2], Wayne State University, Detroit, MI 48202.

Our aim was to characterize somatosensory units in the lumbar facet joint, proposed to play a key role in low back pain. **METHODS:** Rabbits (3-4 kg) were anesthetized with Nembutal iv, and an L4-L5 laminectomy was performed. L5 dorsal rootlets were cut at their proximal ends, split, and draped over bipolar recording electrodes. The left L5/L6 facet joint was searched with 1-2 mm diameter rods for mechanosensitive units. Identified units were stimulated electrically to obtain conduction velocities (cv's) and with von Frey hairs to determine threshold. **RESULTS:** Seventeen units have been identified at this joint: 6 in joint capsule, 2 in ligamentum flavum and 9 in regions common to capsule and tendon. Of these, 5 had thresholds > 6g and 8 < 6g. Two had cv's < 2.5 m/s (Group IV), 9 had cv's of 2.5-20 m/s (Group III), and 6 > 20 m/s. Eight of these responded to joint movement that caused tissue stretch. Ten other mechanosensitive units were found in muscle tendon inserting into the facet; 6 had cv's of 2.5-20 m/s and 4 > 20 m/s. **CONCLUSIONS:** The facet joint contains low to high threshold mechanoreceptors, some of which respond to stretch. The results indicate that both proprioceptors and nociceptors are present in this joint. SYNTHESIS-MODULATING DOPAMINE AUTORECEPTORS ON PC12 CELLS. D.L. Rosin, D. Bagaglio* and R.H. Roth. Department of Pharmacology, Yale School of Medicine, New Haven, CT 06510.

The presence of release-modulating dopamine (DA) autoreceptors in PC12 cells has previously been demonstrated (N.D. Courtney et al., Soc. Neurosci Abstr. 14:926, 1988). We therefore reasoned that these cells may also possess synthesis-modulating DA autoreceptors. PC12 cells were grown in DMEM with 5% heat-inactivated horse serum and 10% fetal bovine serum. At the time of the experiment, cells were preincubated in a HEPES-modified Krebs-Ringer buffer (pH 7.4) at 37° for 30 min prior to incubation with K^+ or drugs. Catecholamine synthesis was determined by measuring the accumulation of DOPA in a 10 min period following inhibition of DOPA decarboxylase by NSD 1015; DOPA was measured by HPLC-EC. The addition of 30 or 60 mM K^+ for 10 min prior to NSD increased DOPA accumulation in a concentration-dependent manner. The selective DA D_2 antagonist, sulpiride (10 μM), added 15 min before NSD, also increased basal synthesis but did not significantly increase K^+-stimulated DOPA accumulation. The increase in DOPA accumulation produced by K^+ or sulpiride could be attenuated by the DA autoreceptor-selective agonist, EMD 23 448 (10 μM, added 10 min before NSD). Basal synthesis was also inhibited by the addition of EMD alone. These results suggest that, in addition to DA release, catecholamine synthesis is also regulated by DA autoreceptors in PC12 cells. EPINEPHRINE IS SYNTHESIZED BUT NOT STORED IN RAT SPINAL CORD. A.F. Sved and J.N. Salter*. *Department of Behavioral Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.*

Epinephrine (EPI) levels in the intermediolateral cell column of the rat spinal cord (SC) are undetectable, although there is a dense projection to this region from neurons in the medulla containing all the enzymes required for EPI synthesis. One explanation for this finding is that EPI in the nerve terminals is degraded as soon as it is synthesized, so that no EPI is actually stored in synaptic vesicles. To test this hypothesis, EPI, norepinephrine (NE), and dopamine (DA) levels were measured in SC of rats pretreated with an inhibitor of monoamine oxidase (MAO), the major enzyme involved in EPI degradation. Pargyline treatment (75 mg/kg ip, 4 hrs prior to sacrifice; n=6) significantly increased EPI, NE, and DA levels. However, the increase in the level of EPI in thoracic SC (<0.2 to 1.3±0.1 pg/mg tissue; >600%) was much larger than that for DA (134%; 20.5±1.1 to 27.5±1.1 pg/mg tissue) and NE (158%; 209±7 to 332±16 pg/mg tissue) in the SC or other regions of the central nervous system (130-170% increase from control). These results suggest that the interaction of MAO with EPI synthesis is such that high MAO activity can prevent the storage of EPI in certain nerve terminals containing the enzymes required to synthesize EPI. Thus, PNMT-containing catecholamine neurons are not necessarily adrenergic.

330.3

REGULATION OF RAT ADRENAL MEDULLARY PHENYLETHANOLAMINE N-METHYLTRANSFERASE. D.L. Wong, Y.S. Yoo and C.L. Bildstein*. Stanford Univ. Sch. Med., Stanford, CA 94305

Rat adrenal medullary phenylethanolamine N-methyltransferase (PNMT) is regulated hormonally and neurally. Neural stimulation induces PNMT synthesis and requires an intact splanchnic nerve. Hormones, in contrast, act permissively. Steroids restore PNMT to basal levels but not beyond. They regulate PNMT degradation via its cosubstrate, S-adenosylmethionine. PNMT transcriptional activity should reflect the above. PNMT mRNA should concommitantly increase with protein synthesis unless mRNA pools are not fully utilized. Hormonal changes should not alter PNMT mRNA. To examine neural effects, male Sprague Dawley rats were administered reserpine (10mg/kg, alternate days, 1 week), and changes in adrenal PNMT activity, protein (immunotitration) and mRNA (Northern analysis) were assessed in individual animals. Respective changes were 1.8, 1.4 and 2.0-fold. These results suggest that PNMT mRNA pools may not be fully utilized for protein synthesis and that neural induction may elicit a more active form of the enzyme. A time course shows that mRNA increases rapidly (≤24 hr) while responses in enzyme activity and protein are protracted. Hormonal studies were similarly consistent with translational events. Hypophysectomy depleted PNMT activity and protein by ~90 percent while mRNA showed only a 13 percent reduction. ACTH administration (4 I.U. daily, 1 week) restored enzyme activity and protein to ~62 percent of normal values with a slight, albeit insignificant further reduction in mRNA.

330.4

EXPRESSION OF TYROSINE HYDROXYLASE AND ITS mRNA IN CULTURED HYPOTHALAMIC-MIDBRAIN NEURONS. W. Kedzierski*, N. Aquila-Mansilla* and J.C. Porter (SPON: R.M. Stewart). Dept. OB/Gyn and Physiology, U.T. Southwestern Med. Ctr., Dallas, TX 75235

Trypsin dissociated neurons from the hypothalamus-midbrain of 20-day old fetal rats were cultured in serum-free, chemically defined medium. Tyrosine hydroxylase (TH) and its mRNA were quantified using an immunoblot assay and an S1 nuclease protection assay, respectively. During culture, DOPA and a lesser amount of dopamine were secreted into the medium. DOPA and dopamine secretion could be blocked in a dose-dependent manner by 3-iodo-L-tyrosine and α-methyl-L-tyrosine, specific inhibitors of TH. In one experiment, neurons from 140 rat fetuses were combined and distributed among 140 24-mm wells, using 1.5 million cells per well. The rate of secretion of DOPA, the quantity of TH mRNA, and the mass of TH were determined weekly for 11 weeks. The results of this study are shown in Table 1.

Table 1. TH and TH mRNA in cultured neurons and DOPA secretion.

Age of culture (weeks)	TH mRNA (amoles/well)	TH mass (fmoles/well)	DOPA secretion (pmoles/18 h/well)
1	1.6	3.2	0.4
2	2.0	5.8	1.3
3	2.3	6.4	1.5
4	2.8	11.5	4.9
5	2.7	15.3	8.6
6	2.8	21.1	9.2
7	2.8	25.2	7.2
8	2.6	17.5	8.8
9	2.9	15.0	7.9
10	2.1	15.9	8.1
11	2.0	10.5	7.5

After 1 week of culture, there was 1.6 amoles TH mRNA per well, increasing to 2.8 amoles at the end of the 4th week. By the end of the 11th week, there was 2 amoles TH mRNA/well. The mass of TH was lowest (3.2 fmoles/well) after the first week, increasing to 25.2 fmoles by the end of the 7th week. The quantity of TH fell to 10.5 fmoles/well by the 11th week. DOPA secretion increased from 0.4 pmoles/18 h/well after the first week to 9.2 pmoles by the 6th week, then fell slowly until the 11th week. These studies demonstrate that TH gene expression occurs in neurons in culture as indicated by TH mRNA, TH synthesis occurs, and these neurons secrete DOPA for several weeks in serum-free medium. (Supported by NIH grant DK-01237.)

CHARACTERIZATION OF cDNA FOR AROMATIC L-AMINO ACID DECARBOXYLASE (AADC) FROM BOVINE ADRENAL MEDULLA U.J. Kang and T.H. Joh. Lab. Mol. Neurobiol., Cornell Univ. Med. Coll. Burke Rehab. Center, White Plains, NY 10605

AADC (EC 4.1.1.28) catalyzes the syntheses of dopamine and serotonin, two major neurotransmitters in the nervous system. We previously reported isolation of the lambda gt-11 recombinant clone containing the cDNA for AADC from bovine adrenal medulla (Albert et al, J Biol Chem 1262:9404,1987). Nucleotide sequence analysis of this cDNA shows an open reading frame starting from base 18, extending to base 1478 followed by a 554 bp untranslated region and the poly (A) tail. The deduced amino acid sequence shows a 60% homology to the complete coding region of the epidermal form of drosophila AADC mRNA (Morgan et al, EMBO J 5:3335,1986). Primer extension reactions using two different primers from base 2 to 19 and 112 to 130 consistently produce a distinct band extending 68 bases from the 5' end of our cDNA. This fragment probably represents the 5' untranslated region corresponding to the first exon of drosophila AADC gene. The hepta-peptide stretch representing the pyridoxal phosphate binding site is completely conserved between the two species and is also the same as the peptide sequence from pig AADC. Four of the seven amino acids are shared with feline glutamic acid decarboxylase and 417 bases surrounding this site are well conserved between the two enzymes (54%) (Kobayashi et al, J Neurosci 7:2768,1987). The 3' untranslated region has no significant homology to that of drosophila AADC. It contains, however, about a 200 bp stretch of novel Alu-type repeat sequence (Duncan, Nuc Acids Res 15:1340,1987).(supported by AG00406 and MH 24285)

SEQUENCE ANALYSIS OF BOVINE DOPAMINE B-HYDROXYLASE cDNA. O. Hwang, K.S. Kim*, and T.H. Joh. Cornell Univ. Med. Coll., Burke Rehab. Center, White Plains, N.Y. 10605.

The enzyme dopamine B-hydroxylase (DBH) catalyzes the conversion of L-DOPA to norepinephrine. Bovine adrenal medullary DBH has been extensively studied for elucidation of its apparent structural complexity. Towards an understanding of the mechanism underlying synthesis of multiple forms of DBH, we isolated and characterized a bovine DBH cDNA. We previously reported the isolation of a 2.3 kb DBH cDNA which was missing it's 5' end (Hwang et al, Neurosci. Abs.14:26, 1988). Here we report the complete sequence of the full length cDNA.

For the isolation of the 5' end fragment, we constructed a random primed lambda gt11 cDNA library and obtained several clones by screening with the 240 bp EcoRI-AvaI fragment as a probe. Analysis of the translated region reveals 87% homology with that of human DBH (Lamouroux et al, EMBO J.6:3931, 1987) and indeed hybridizes to a 3.1 kb human adrenal medullary message. The untranslated region, on the other hand, exhibits a lower homology of 51% compared to the human (Kobayashi et al,Nuc. Acid Res.17:1089, 1989). In addition, 304 bases upstream of the poly A tail lies the stretch of AGTAAA, which was identified as a second polyadenylation site in human. If alternative splicing does occur in bovine DBH as demonstrated for human, however, the second site must be utilized at a much lower rate since our cDNA probe could not detect a smaller message by Northern blot analysis.(supported by MH24285-14)

MODULATION OF THE LOW THRESHOLD CALCIUM CONDUCTANCE IN GUINEA-PIG THALAMIC NEURONS BY AGONISTS AND ANTAGONISTS OF DOPAMINE RECEPTORS *IN VITRO*. E. Geijo-Barrientos and R. Llinás. (SPON: V. DeCrescito). Dept. Physiol. & Biophys. NYU Med. Ctr. NY 10016.

Thalamic neurons are innervated by fibers originating in the periventricular dopaminergic system (Moore and Bloom, Ann. Rev. Neurosci. 1:29:1978). We have shown (Geijo-Barrientos and Llinás, Soc. Neurosci. Abstr. 1988) that dopamine (DA) increases the magnitude of the thalamic low threshold calcium current (LTC), while haloperidol and forskolin decrease it. In order to further elucidate the role of DA receptors in the modulation of this current, we have investigated the effects of quinpirole, a selective D2 receptor agonist and the two isomeric forms of the antipsychotic drug flupentixol. The experiments were performed *in vitro*, in the guinea-pig thalamic slice preparation using current clamp and single electrode voltage-clamp techniques. 5μM quinpirole induced either a decrease of the LTC or no marked change. Those neurons that demonstrated a change showed a decrease of the LTC in the range of 50% of the control value, with no change in the voltage dependence of the steady state inactivation of the current. The two isomeric forms of flupentixol were used to discard the possibility of a non-specific effect of haloperidol on the low threshold calcium conductance. The cis- and trans- forms of flupentixol were tested at concentrations of 1-10 μM, and the cis-flupentixol induced a decrease in the LTC in 90% of the cells tested, while the trans-flupentixol had a very reduced effect. In the latter case only a small decrease of the LTC in 20% of the cells was observed. This result, which agree with the different affinity of this two isomers for the DA receptors (Cros and Owen, Eur. J. Pharmacol. 65:341:1980), suggest that the effect of these DA blockers on the Ca current is not due to the inespecific high membrane solubility of these drugs. The above results suggest that DA could generate the increase of the LTC by acting simultaneously on D1 and D2 receptors, not unlike what has been proposed in other neurons (Walters et al., Science, 236:719:1987). The issue of interest here is that DA, which has been related to the genesis of several psychiatric disorders, may contribute to the modulation of the thalamo-cortical activity through its actions on the thalamic LTC.

DOPAMINERGIC CELLS AND FIBRES IN THE MEDULLA OBLONGATA OF CAT REVEALED BY ANTI-DOPAMINE IMMUNOHISTOCHEMISTRY. T.F.C.Batten*, P.N.McWilliam* and A.Maqbool* (SPON: European Neuroscience Association). Dept. of Cardiovascular Studies, Leeds University, Leeds LS2 9JT, U.K.

Formaldehyde fluorescence histochemical localization of catecholamines in the brain failed to provide evidence for dopamine neurons in the medulla oblongata (Dahlstrom, A. & Fuxe, K., *Acta Physiol. Scand.* 62(suppl.232):1, 1964), but recent studies utilizing antisera to catecholamine synthetic enzymes, including our own work on the cat (Batten, T.F.C. & McWilliam, P.N., *J.Physiol.* 399:76, 1988) have shown cells in the caudal dorsal motor vagal nucleus (DMVN) which appear to be immunoreactive for tyrosine hydroxylase (TH) alone, suggesting they may be dopaminergic. We have now used antibodies to dopamine-glutaraldehyde conjugates (prepared by Drs. H.W.M. Steinbusch and R.M. Buijs) to re-examine this region on Vibratome sections of cat brainstem after rapid perfusion with phosphate-buffered 5% glutaraldehyde. Dopamine-immunoreactive (DA-IR) cell bodies were indeed found in the DMVN at the level of, and at levels caudal to the obex. More surprisingly significant numbers of "A1 catecholamine" cells of the ventrolateral medulla also exhibited DA-IR at levels between the obex and spinal cord. DA-IR fibres were scattered in the reticular formation, but were particularly numerous in the DMVN, spinal trigeminal nucleus and dorsal column (gracile and cuneate) nuclei. Thus, dopamine immunohistochemistry has allowed us to demonstrate previously unrecognized systems of dopaminergic cells and fibres in the lower brainstem of the cat.

DOPAMINERGIC NEURON CULTURES FROM THE SUBSTANTIA NIGRA AND THE VENTRAL TEGMENTAL AREA. S. Masuko, S. Nakajima and Y. Nakajima. Dept. of Anat. and Cell Biol. and Dept. of Pharmacol., Univ. of Illinois, College of Med. at Chicago, Chicago, IL, 60612 and Dept. of Biol. Sci. Purdue Univ., W. Lafayette, IN 47907.

We have developed dopaminergic neuron cultures separately obtained from the substantia nigra (SN) and the ventral tegmental area (VTA) of new born rats by using our previously reported method in which brain nuclei dissected out from brain slices are dissociated and cultured (Masuko et al., J. Neurosci., 1987, 6: 3229). Double immunocytochemical treatments to tyrosine-hydroxylase and GABA in 2-3 week-old cultures showed the presence of 41% dopaminergic (DA) and 38% GABAergic neurons in SN cultures, whereas in VTA cultures there were 65% DA and 21% GABAergic neurons. DA neurons were characterized by 2 to 5 thick primary processes originating from the cell body. These processes had sparse arborization. Varicosities were mainly found on the distal segments of processes. In contrast, GABAergic neurons had highly branched thick and thin primary processes with intensive arborization, their processes having numerous varicosities. The coexistence of DA and cholecystokinin was found in 70% of DA neurons in the SN and in 30% of DA neurons in the VTA. Electrophysiological studies on cultured DA neurons revealed that the action potentials elicited by constant current depolarization adapted and stopped firing. This is in contrast to the non-adapting action potentials recorded from the cultured locus coeruleus neurons. Supported by NIDA grant (DA05701) and NIH grants (AG06093 and NS24711).

330.10

PURIFIED CULTURES OF VENTRAL TEGMENTAL AREA (VTA) DOPAMINE NEURONS. Stephen Rayport, David Sulzer* & Deirdre Batson*. Dept. Psychiatry and Ctr. Neurobiol. & Behav., Columbia Univ. and New York State Psychiatric Inst., New York, NY 10032.

Highly purified preparations of midbrain dopamine (DA) neurons would advance both cellular physiological studies *in vitro* as well as offer an improved source of such cells for brain transplantation. Typically, DA neurons constitute only a few per cent of the cells dissociated from embryonic midbrain. A 10-fold enrichment for DA neurons has been achieved using fluorescence activated cell-sorting to NSP-4, a selectively expressed surface antigen (DiPorzio *et al.*, 1987); but, because the initial numbers of DA cells were extremely low in the E13 mice used, the fraction of DA cells in the final cultures did not exceed 1% (~100 out of 20,000 cells plated in 1 cm^2 wells).

To develop VTA cultures composed principally of DA neurons, we took advantage of the high concentration of DA cells in postnatal VTA and of their comparatively large size (*e.g.*, Loughlin & Fallon, 1985). In our routine midbrain cultures, where about 5% of the cells were tyrosine hydroxylase-positive (TH+), the average diameter of TH+ cells was 14 ± 0.5 μm (mean ± s.e.m.), while TH- cells measured 10 ± 0.2 μm. When we dissected VTA (encompassed in 2 mm^3) from postnatal rats and dissociated it utilizing methods that favor survival of large cells (*e.g.*, Kay & Wong, 1986; Huettner & Baughman, 1986 & 88), 25 to 30% of the cells were TH+. To enrich cultures for large DA cells further, we fractionated the cell suspension on a 0-10-25% Percoll step gradient (*e.g.*, Hatten, 1985). Minimally 35% of the cells in the large cell fraction (top of the 25% layer) were TH+.

When purified cultures were incubated with 5-hydroxy-dopamine, which makes catecholaminergic vesicles electron dense, accumulations of synaptic vesicles in the soma perimeter and in numerous *en passant* varicosities were seen. The majority of large cells in purified cultures also showed the broad action potentials characteristic of midbrain DA cells.

A COMPARISON OF THE RELATIVE POTENCIES OF DOPAMINE UPTAKE INHIBITORS IN INHIBITING DOPAMINE UPTAKE AND [^{3}H]GBR 12935 BINDING. S. Izenwasser, L.L. Werling, and B.M. Cox. Dept. of Pharmacology, Uniformed Services University, Bethesda, MD 20814-4799.

It is thought that inhibition of dopamine uptake may be the mechanism by which cocaine produces its reinforcing effects. There are, however, a number of compounds which also inhibit dopamine uptake but which are not widely abused. It is therefore possible that cocaine may act preferentially in those brain regions which are specifically involved in drug reinforcement. In the present study, the effects of various dopamine uptake inhibitors were examined on both competition against [^{3}H]GBR 12935 binding and on dopamine uptake in the striatum, medial prefrontal cortex, nucleus accumbens and olfactory tubercle of rat. There were no significant differences in either binding affinity or ability of these drugs to inhibit dopamine uptake among the different brain regions. Furthermore, the order of potencies for the compounds tested was similar for both inhibition of dopamine uptake and displacement of [^{3}H]GBR 12935 binding. GBR 12909 and amfonelic acid were each approximately 40-100 times more potent than either cocaine or methylphenidate in both assays. Thus, for these compounds, there do not appear to be significant differences in drug sensitivity in the brain regions tested and there seems to be a correlation between potency for inhibition of dopamine uptake and competition against [^{3}H]GBR 12935 binding. Carbamazepine, however, potently inhibited dopamine uptake but did not inhibit binding of [^{3}H]GBR 12935 at concentrations up to 100 μM. This suggests the possibility that dopamine uptake may be regulated by more than one mechanism.

DARP, A NOVEL POTENT DOPAMINE-RELEASING PROTEIN: IN VITRO AND IN VIVO STUDIES. G.D.Chang, A.D.Ramirez*, C.Gross*, F.Marcus*, V.D.Ramirez. Department of Physiology and Biophysics, University of Illinois, Urbana, IL 61801; Chiron Corporation, Emeryville, CA 94608.

DARP, a putative protein discovered in the rat adrenal gland (Chang and Ramirez, Brain Res. 463:385, 1988), has been purified from bovine adrenals to a high degree of purity. This protein was used 1) to study its DA-releasing activity from corpus striatum (CS) fragments superfused in vitro and 2) to examine its capacity to evoke behavioral responses in rats bearing a push-pull cannula in the caudate nucleus (CN). The in vitro data indicate that the DA-releasing activity of DARP is a Ca^{2+} dependent phenomenon. In preparations infused with DARP for 1 h, a rapid decline in activity occurs by 40 min. Infusion of DARP for 20 min at 20 μg/ml induced a marked DA release (> 8-fold) that peaks by 20 min whereas an identical pulse 60 min later barely increased DA release. Contrariwise, infusion of DARP into the CN of freely behaving male rats at 10 μg/ml for 15 min but not at 1 μg/ml evoked strong amphetamine-like stereotyped motor behaviors within 10 min which ceased completely 5 min after termination of the infusion when the rat was again calm. An identical infusion of DARP 25 min later re-initiated similar short-lived stereotyped behaviors. Robust increases in DOPAC and DA were observed with higher levels during the second infusion. Lastly, DARP partially purified from bovine brain also stimulated the in vitro DA release.

330.13

DOPAMINE RELEASE AND METABOLISM IN THE FRONTAL CORTEX AND STRIATUM BY TYPICAL AND ATYPICAL NEUROLEPTICS. F. Karoum, M. Egan* and R.J. Wyatt. Neuropsychiatry Branch, NIMH Neurosciences Center at St. Elizabeths, Washington, D.C. 20032.

The effects of haloperidol and clozapine on frontal cortex (Fx) and striatal (ST) dopamine (DA) metabolism, and release were evaluated in rats. DA metabolism was assessed from changes in 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA). DA release was estimated by the accumulation of 3-methoxytyramine (3MT) following microwaving, 10 min after pargyline (65 mg/kg). The neuroleptics were administered i.p. one hour before sacrifice. Biochemical analyses were by mass fragmentography. Up to 0.1 mg/kg haloperidol did not change ST DOPAC or HVA. They were, however, significantly elevated in the Fx (0.05 and 0.1 mg/kg ip). In contrast, clozapine significantly elevated DA metabolism in both the ST and Fx (5, 10, 20 mg/kg). Haloperidol increased 3MT accumulation in both the Fx (min. dose 0.2 mg/kg) and the ST (min. dose 0.05 mg/kg). Thus, in the ST DA release appears more sensitive to haloperidol than in the Fx. 3MT accumulation was increased by clozapine in the Fx, but reduced in the ST (min. dose 5 mg/kg). The data suggest a dissociation between DA release and metabolism. Differential stimulation of DA release and metabolism in different brain regions may underlie certain clinical differences between haloperidol and clozapine. Additional data on other neuroleptics will be presented.

EXPRESSION OF THE GLUCOSE TRANSPORTER mRNA IN RAT AND HUMAN CEREBRAL CORTEX DEMONSTRATED BY IN SITU HYBRIDIZATION. R. N. Kalaria, M. Usiak*, T. Golde*, L. Younkin, S. I. Harik and S. Younkin.
Departments of Neurology, Pathology and Pharmacology, Case Western Reserve University, Cleveland, Ohio 44106

We have previously described the enrichment of the glucose transporter protein in brain intraparenchymal vessels by D-glucose displaceable Cytochalasin B binding and immunocytochemistry. Here, we used in situ hybridization to study the expression of the glucose transporter (GT) mRNA in rat and human brain. The plasmid prGT-Sac containing a 1.65 kilobase fragment of the rat brain glucose transporter cDNA cloned into a pBluescribe M13+ (Strategene) was used to produce a ^{35}S-labeled 346 nt cRNA probe for GT mRNA. To control for non-specific binding, sections adjacent to those hybridized with the antisense GT probe were hybridized with a non-complementary probe of quivalent length, concentration and specific activity. Hybridized sections were stained with cresyl violet and hematoxylin to visualize parenchymal structures. As expected from studies on the distribution of the protein, the probe for GT RNA labeled pial and intracortical vessels and some neurons in both human and rat brain. In rat brain, this probe also produced many grains over ependymal cells lining the lateral ventricle.

Supported by a grant from the ADRDA and NIA ADCRC.

331.2

DISTRIBUTION OF THE HEXOSE TRANSPORTER IN THE EYE. S.I. Harik, R.N. Kalaria and G. Perry. Depts. of Neurology and Pathology, Case Western Reserve Univ. Sch. of Med., Cleveland, OH 44106.

It is accepted that "tight" intercellular junctions (zonulae occludens) underlie the blood-ocular barriers that protect the eye from injurious substances in the systemic circulation. These barriers also prevent the diffusion of water-soluble nutrients like glucose which are essential for metabolism. We hypothesized that cells that have barrier characteristics must also have a high density of the hexose transporter protein (HTP) to assure steady glucose supply. We tested this by immuno-cytochemical studies using specific antibodies to HTP.

Adult Wistar rats were anesthetized and perfused-fixed in situ. The eyes were embedded in paraffin and sections were stained by the peroxidase-antiperoxidase method, using a monoclonal antibody to the C-terminus of HTP of human erythrocytes. The following cells stained intensely: (1) endothelium of blood vessels in retina and optic nerve, (2) retinal pigmented epithelium, (3) ciliary body nonpigmented epithelium, (4) posterior epithelium of the iris, and (5) vessels of the iris. All other cell types in the eye and retro-orbital tissues, including striated muscles and lacrimal glands, did not stain intensly for HTP. Thus, we find high density of HTP in all locations of the eye where "tight" junctions were discribed by ultrastructural studies.

331.3

DEXAMETHASONE DECREASES HEXOSE UPTAKE BY ISOLATED CEREBRAL MICROVESSELS. S.R.Chipkin* and A.L.McCall.(Spon: D.Rosene) Depts. of Med. & Physiol., B.U. Sch. Med. Boston, MA 02118

Dexamethasone (DEX) decreases protein entry into the brain and depresses hexose transport into adipocytes and aortic endothelial cells. To determine whether DEX affects hexose transport by the brain microvasculature, we studied ^{3}H-2-deoxy-D-glucose (2DG) transport into isolated cerebral microvessels (ICMV) after DEX preincubation. Calf ICMV were prepared by homogenization and filtration as previously described (Microvasc. Res. 35:167, 1988). After isolation, ICMV were preincubated with DEX or phosphate buffered saline for 1-2 h and then assayed for hexose transport. ICMV were exposed to ^{3}H-2DG (100 nM; 6-8 uCi/ml) and ^{14}C-sucrose (to correct for nonspecific uptake) for up to 10 min. Uptake was stopped with cold 1mM phloretin (in 0.5% ethanol). ICMV retention of 2DG was linear and anion exchange chromatography demonstrated that almost all 2DG was phosphorylated, implying that 2DG uptake reflects transport. Inhibition of 2DG uptake (pmol/mg protein/hr) into ICMV after preincubation for 2h in DEX (10^{-9} to 10^{-3}M) at 23 degrees C is shown below.

{DEX}	0	10^{-9}	10^{-8}	10^{-7}	10^{-6}	10^{-5}	10^{-4}	10^{-3}
2DG uptake	9.68	7.83	5.99	6.40	6.60	5.04	4.21	1.96
(x +SE)	1.3	0.95	0.96	1.7	1.7	1.1	0.4	0.4

Rates of 2DG uptake varied with individual ICMV preparations. DEX inhibition of 2DG uptake was greater at 37 than 23 degrees, and was more marked after 2 h than 1 h. Conclusions: 1) Brief DEX exposure in vitro inhibits hexose transport into ICMV. 2) Inhibition is concentration and temperature dependent. 3) Longer preincubations may inhibit uptake to a greater degree.

331.4

L-PHENYLALANINE TRANSPORT ACROSS THE BLOOD-NERVE BARRIER IS STEREOSPECIFIC, SATURABLE AND SODIUM INDEPENDENT. K.C. Wadhwani, Q. R. Smith and S. I. Rapoport. Lab. Neurosciences, NIA, NIH, Bethesda, MD 20879.

L-Phenylalanine (L-phe) transport across the blood-nerve barrier was studied using an in-situ perfusion technique. Hepes-buffered Ringer's solution containing tracer amounts of [14C]-L-phe and [3H]-dextran was perfused at 5 ml/min into the hindlimb of an anesthetized rat. After 2 min of perfusion, a segment of sciatic nerve was removed, frozen in liquid isopentane, desheathed in dry ice and processed for radioactivity counting. A portion of biceps femoris muscle was also removed and processed. The permeability-surface area products at the blood-nerve barrier [PA(bnb)] to [14C]-L phe decreased, from 58+9 to 1.6+0.3 x10(-5) ml/s.g, as the concentration of unlabeled L-phe in the perfusate increased, from 0mM to 10mM. D-Phe had less of an inhibitory effect in [14C]-L-phe uptake than L-Phe. There was no significant difference in PA of the biceps femoris muscle in the above perfusion media. Replacing NaCl by TrisCl in the perfusion medium did not alter PA(BNB). PA(per) of [14C]-L-phe at the epi-perineurial barrier, measured at 2 min of incubation was 1.4+0.2 x10(-5) ml/s.g (n=6), and was uneffected by 10 mM L-phe in the incubation medium. The results demonstrate concentration depend unidirectional transport of Phenylalanine at the BNB, most likely at the endoneurial capillaries.

331.5

BLOOD-NERVE TRANSFER OF ^{22}NA IN RAT SCIATIC NERVE. A. Weerasuriya* (SPON: C.H. Hockman). Peripheral Nerve Center, Dept. Neurology, Mayo Clinic & Fdn., Rochester, MN 55905.

Peripheral nerve fibers and associated glial cell function within a specialized extracellular compartment--the endoneurial microenvironment. Access to this milieu interieur from other extracellular spaces is limited and controlled by the blood-nerve interface (BNI) consisting of the endoneurial vascular endothelium and perineurium. To investigate the effects of changes in plasma ion concentration on axonal excitability, blood-nerve transfer rates of ions need to be quantified. This was done for ^{22}Na with the i.v. bolus injection technique and estimation of radiotracer in desheathed rat sciatic nerves. Employing a multiple time point analysis and tracer circulation periods of 3 to 12 minutes, graphically determined permeability coefficient-surface area product (PS) to ^{22}Na of BNI is 1.02±0.09 (SEM)x10^{-4} ml.s^{-1}.g endoneurium^{-1} and residual endoneurial plasma volume (V_p) is 1.56±0.66 (SEM) µl.g endoneurium^{-1} (n=17 and r^2=0.884). PS to ^{22}Na of the perineurium alone measured in situ is 1.01±0.15 (SEM)x10^{-5} ml.s^{-1}.g endoneurium^{-1} (n=5). Therefore, it is concluded that blood-nerve exchange of Na (and probably other ions as well) occurs across both components of the BNI and the relative contributions of the endoneurial microvasculature and perineurium are approximately 9:1 in rat sciatic nerve. (Borchard Fund and NS14304-P4 to J. F. Poduslo).

RETROGRADE TRANS-SYNAPTIC TRANSFER OF A BLOOD-BORNE PROTEIN. J. Villegas* and R. Broadwell. Divs. Neurosurg. & Neuropath., Univ. MD Sch. of Med., Balto., MD 21201

A 0.5% solution of the lectin wheatgerm agglutinin (WGA) conjugated to HRP was administered intravenously to adult rats and mice. Post-injection survival times were 6-48hr. The animals were fixed by perfusion and vibratome sections of their brains and posterior pituitary glands were incubated in a TMB or DAB medium. Cerebral vessels, perivascular phagocytes, the supraoptic (SON) and paraventricular (PVN) nuclei, median eminence, and posterior pituitary gland were conspicuously HRP-positive at 6-24hr and noticeably less so at 48hr. Cranial motor nuclei and other neuronal groups remained unlabeled. At 24hr, reaction product was evident in the Golgi saccules of cerebral endothelia and pericytes and in the perivascular clefts but not beyond the basal lamina. Endocytic vesicles and endosomes were HRP-positive in posterior pituitary terminals and underwent axonal retrograde transport to SON and PVN perikarya which harbored labeled dense bodies, inner Golgi saccules, and secretory granules. Reaction product occupied the extracellular and synaptic clefts, and endocytic vesicles in glial cells and presynaptic terminals within the SON and PVN nuclei. The results suggest that the absorptive endocytosis of a blood-borne lectin-HRP conjugate promotes transcytosis of the protein through the blood-brain barrier and neurosecretory neurons. Supported by NINDS grant #NS18030.

331.7

TRANSCYTOSIS OF A ß-ENDORPHIN -CATIONIZED ALBUMIN CHIMERIC PEPTIDE THROUGH THE BLOOD-BRAIN BARRIER (BBB) IN VIVO. W. M. Pardridge, D. Triguero*, and J. Buciak*. (SPON: J. Walsh). Department of Medicine and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024-1682.

One strategy for drug delivery through the BBB is the production of chimeric peptides, i.e., the covalent coupling of a nontransportable peptide (e.g., ß-endorphin) to a transport vector compound that is normally transcytosed through the BBB (e.g., insulin, transferrin, cationized albumin, or cationized immunoglobulin G). [D-Ala^2]ß-endorphin (DABE) was covalently coupled to cationized albumin with the disulfide-based coupling reagent N-succinimidyl 3-(2-pyridyldithio)-proprionate (SPDP), following iodination of the DABE. Transcytosis into rat brain was studied with an internal carotid artery perfusion technique coupled with a capillary depletion step to differentiate true transcytosis into the postcapillary compartment of brain parenchyma versus simple binding and/or endocytosis at the brain microvasculature. The unconjugated [^{125}I]DABE was not measurably transcytosed into brain parenchyma during a 10 minute perfusion. However, the [^{125}I]DABE-cationized albumin chimeric peptide was rapidly transcytosed into brain and achieved a postcapillary volume of distribution of 32 ± 10 µL/g brain at 10 minutes. This volume of distribution was comparable to that achieved when [^{125}I]cationized albumin was perfused alone. Conclusions: The use of cationized albumin as a transport vector allows for the transcytosis through the BBB and delivery into brain parenchyma of ß-endorphin in vivo.

331.8

TRANSCYTOSIS OF BLOOD-BORNE FERROTRANSFERRIN AND INSULIN THROUGH THE BLOOD-BRAIN BARRIER. R. Broadwell, A. Wolf, and M. Tangoren*. Div. Neurosurg., Univ. MD. Sch.Med., Balto.,MD 21201

Ferrotransferrin, apotransferrin, and insulin conjugated to HRP (1:1; 10-20mg in 0.5-1cc) were confirmed (excluding apotransferrin) by receptor binding essay to sustain their biological activity and were infused into the internal carotid artery of adult rats; post-injection survival times were 10-60mins. Cerebral endothelia incorporated the ligands readily by receptor-mediated endocytosis. At 10mins., HRP reaction product was in endothelial endocytic vesicles, endosomes, and secondary lysosomes; reaction product was not evident in the perivascular clefts or in perivascular phagocytic cells. At 1hr, perivascular phagocytes and clefts in discrete areas of the CNS, such as the striatum, were HRP-positive in animals injected with insulin and ferrotransferrin conjugates. Presumptive exocytic vesicles occasionally were seen in continuity with the abluminal plasmalemma and exhibited "puffs" of HRP-reaction product extruding into the perivascular clefts. The apotransferrin (iron-free) conjugate was not in perivascular clefts and phagocytes. The results suggest that blood-borne ferrotransferrin and insulin undergo transcytosis through the blood-brain barrier. The transendothelial route most likely utilizes the endosomal apparatus and transfer vesicles arising from endosomes as opposed to a direct vesicular transfer of the peptides. Supported by NINDS grant #NS18030.

331.9

ANTISERUM TO BOVINE BRAIN CAPILLARY MEMBRANES BINDS A 45K, 53K, AND 200K TRIPLET OF BRAIN CAPILLARY-SPECIFIC PROTEINS (BSPs). R.J. Boado*, J. Yang*, and W.M. Pardridge (SPON: H. Weiner). Department of Medicine and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024-1682.

The brain capillary endothelium which makes up the blood-brain barrier (BBB) in vivo, is endowed with a number of proteins that are either highly enriched or specific to that cell. To begin characterization of BSPs, an antibody specific to the brain microvasculature was prepared by immunizing rabbits with bovine brain capillary plasma membrane proteins. Following absorption of the antiserum with the acetone powders of rat kidney and rat liver, the antiserum specifically illuminated the cerebral microvasculature in brain. There was no immunostaining of any structures in bovine myocardium, liver, kidney, or urinary bladder epithelium. The only other structure found to be immunostained by the antiserum was the basolateral membrane of the bovine choroid plexus epithelium. Western blotting on nylon filters showed that the antiserum bound specifically to a 45K, 53K, and 200K triplet of proteins in the bovine brain capillary fraction, whereas there was no staining of proteins in a bovine brain synaptosomal preparation that was 98% depleted of microvasculature. Conclusions: These proteins are specific to the brain capillary and are not found in neurons or glia, or in endothelium of other organs. Their co-localization to the basolateral membrane of the choroid plexus epithelia suggests that these proteins may be integral components of BBB transport mechanisms.

331.10

BRAIN CAPILLARY ENDOTHELIAL 46K PROTEIN IS CYTOPLASMIC ACTIN BASED ON AMINO ACID SEQUENCING AND LIMITED PROTEOLYSIS STUDIES. T.B. Choi*, D.M. Nowlin*, J. Yang*, J. Calaycay*, J.E. Shively*, and W.M. Pardridge (SPON: W. Oldendorf). Department of Medicine and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024 and Beckman Research Institute of City of Hope, Duarte, CA 91010.

The most abundant protein in the brain capillary which makes up the blood-brain barrier (BBB) in vivo is a protein that migrates at a molecular weight of ~46K on SDS-PAGE. To determine the identity of this protein, it was extracted from gels and desalted over Sephadex G25. The protein was digested with trypsin and two peptides of 11 and 18 amino acids in length, respectively, gave a 100% match with cytoplasmic actin. The SDS-PAGE gel-purified 46K protein was also subjected to limited proteolysis using S. aureus V8 protease, and the peptide fragments were separated by subsequent SDS-PAGE. This resulted in the formation of a prominent 31K doublet and these fragments were of identical molecular weight to those generated from limited proteolysis of bovine actin. Electron microscopic immunoperoxidase studies of primary cultures of bovine brain capillary endothelium showed immunoreactive actin was intimately associated with the plasma membrane. Conclusions: The brain capillary 46K protein, which comprises ~10-15% of total brain capillary protein, is cytoplasmic actin. This protein is believed to, in part, anchor the brain capillary cytoskeleton, and abnormalities in actin function in the brain capillary endothelium may lead to changes in BBB permeability.

331.11

EFFECTS OF INTERNAL CAROTID ADMINISTRATION OF MPTP ON RAT BRAIN AND BLOOD-BRAIN BARRIER. N.J. Riachi and S.I. Harik. Dept. of Neurology, Case Western Reserve Univ. Sch. of Med., Cleveland, OH 44106

Unlike primates, rats are resistant to systemic MPTP, but their substantia nigra dopamine (DA) neurons are destroyed by direct MPTP infusion. This may be due to their unique "biochemical" blood-brain barrier (BBB), which prevents MPTP and MPP+ from reaching DA neurons. To study this further, we gave MPTP to rats via the internal carotid artery, which delivers 16% of MPTP dose to the ipsilateral cerebrum, with less than 0.5% to the contralateral cerebrum or cerebellum. This method yields 40-fold higher MPTP in the ipsilateral cerebrum than in a similar injection into the right atrium of the heart. Carotid injections of 1 to 3.5 mg of MPTP resulted in 10 to 30% depletion in ipsilateral striatal DA, but without detectable behavioral abnormalities. When 5 mg of MPTP were given, all rats died from acute cardiorespiratory failure. Pargyline did not alter the lethality of MPTP but prevented DA reduction. We also studied the possibility that sequestration of MPTP and MPP+ in endothelial cells could cause BBB abnormalities. However, we found that BBB diffusion of [^{14}C]amino-isobutryic acid was not altered. Thus, we conclude that the rat is resistant to MPTP toxicity even when large doses are given into the brain circulation, and that the BBB integrity is not affected.

331.12

NEOVASCULARISATION OF THE CNS IN EAE. B.Watkins*, P.Glynn*, A.Gautam* and R.Small . (SPON: M.Dubois-Dalcq). Institute of Neurology, Queen Square, London WC1N 3BG, UK.

Inflammatory diseases of the CNS such as multiple sclerosis and experimental allergic encephalomyelitis (EAE) involve focal breakdown of the blood-brain barrier (BBB), which can be visualised by magnetic resonance imaging and horseradish peroxidase (HRP) tracing techniques. The factors involved in BBB dysfunction are not understood, but may include changes in the endothelial cell population during the disease process. We have examined the population dynamics of CNS endothelial cells in a Lewis rat adoptive transfer EAE model by injecting 5'-bromo-2-deoxyuridine (BUdR), a thymidine analog, to label dividing cells. At the height of the disease, EAE rat spinal cord contained many BUdR$^+$ endothelial cells in both large and small blood vessels. In addition, a marked increase was seen in the number of blood vessels in EAE spinal cords. In contrast, no BUdR$^+$ endothelial cells were seen in the spinal cord blood vessels of control rats. These results suggest that inflammatory disease of the CNS involves mitotic activation of normally quiescent CNS endothelial cells which may function in (a) hypervascularisation of the CNS and/or (b) the repair of endothelial cells damaged by infiltrating cells. We are currently combining BUdR prelabelling with HRP perfusion to correlate focal leakage with endothelial cell division, and to study the relationship between neovascularisation and induction of BBB function.

CALCIUM CHANNELS IV

332.1

INACTIVATION OF CALCIUM CURRENT IN CULTURED ADULT MOUSE PANCREATIC B-CELLS IS MEDIATED BY CALCIUM AND VOLTAGE. W.F. Hopkins, L.S. Satin, and D.L. Cook*, Depts. of Physiology/Biophysics and Medicine, Univ. of Washington and VA Medical Center, Seattle, WA 98108.

We have previously shown two components to calcium (Ca) current inactivation in clonal insulin-secreting HIT cells (Satin and Cook, Pflügers Arch, in press, 1989). The fast (<200 msec) Ca-dependent and slow, voltage-dependent components are revealed when long depolarizing pulses are used. To determine if similar Ca currents exist in adult mouse B-cells, we voltage-clamped whole B-cells while blocking K and Na currents as done in HIT cells. The inactivation during short (100 msec) depolarizing pulses was proportional to peak Ca current elicited by the pulse (Plant 1988). On the other hand, the slow inactivation during long (10 sec) pulses was prominent for conditioning pulses below the Ca current threshold (-40 mV) and at very positive (>+50 mV) potentials. Using either Ca or barium (Ba) as charge carrier, this component of inactivation was half-maximal at -30 mV and maximal (>90%) at 0 mV. Peak Ca or Ba current significantly decreased as holding potential was made more positive in the range of -100 to -40 mV. These results suggest that, like HIT cells, mouse B-cells possess fast and slow components of Ca current inactivation mediated by calcium influx and voltage, respectively.

332.2

A DOMAIN MODEL FOR CA^{2+} INACTIVATION OF CA^{2+} CHANNELS. A. Sherman*, J. Keizer*, and J. Rinzel* (SPON: W. Rall). Mathematical Research Branch, NIDDK, NIH, Bethesda, MD 20892, and Institute of Theoretical Dynamics, UC-Davis, Davis, CA 95616.

Most models of Ca^{2+} inactivation assume that Ca^{2+} concentration is elevated in a "shell" near the membrane and acts on both closed and open channels, with a time scale determined by the rate of filling of the shell. In cells with low channel densities (a few μm^{-2}), such as pancreatic β-cells, rat clonal pituitary cells, and bovine chromaffin cells it is likely that high Ca^{2+} exists only at the mouths of open channels. Further, in β-cells it is believed that macroscopic Ca^{2+} oscillates in parallel with bursts of action potentials on a time scale of seconds, suggesting that it cannot also be responsible for inactivation on the 10-100 ms time scale. Following a suggestion of Chad and Eckert [*Biophys. J.*, 45:993, 1984], we propose that domains (~500 μM) form and disappear instantaneously as channels open and close, and that Ca^{2+} inactivates open channels on a time scale determined by the kinetics of binding to the channel. If activation is much faster than inactivation, our mathematical model predicts 1) U-shaped inactivation curves, 2) U-shaped dependence of the inactivation time constant on membrane potential, 3) that inactivation is greatest where the magnitude of Ca^{2+} current is greatest, and 4) that inactivation is an apparent function of total calcium entry during the pre-pulse of a two-pulse experiment, even though whole cell Ca^{2+} current plays no direct role. We fit data of Plant [*J. Physiol.*, 404:731, 1988] on β-cells and show that this model is consistent with previous models for bursting based on slow feedback of cytosolic Ca^{2+} on calcium-activated K^+ channels. In contrast to some investigators we conclude that Ca^{2+} inactivation plays no role in generating bursts in these cells.

332.3

DIVALENT CATION PERMEABILITY THROUGH CHROMAFFIN CELL CALCIUM CHANNELS. K.S. Wilcox and R.J. Bookman*. Dept. of Physiology and Howard Hughes Medical Institute, University of Pennsylvania, Philadelphia, PA 19104-6085.

We examined the permeability of various divalent cations through voltage-dependent calcium channels in bovine adrenal chromaffin cells using the whole cell patch clamp technique. Chromaffin cells were isolated and maintained in primary tissue culture at 37°. Internal and external solutions were designed to minimize all ionic conductances except for calcium. A range of concentrations (2.5, 5.0, or 10.0 mM) of either $BaCl_2$, $SrCl_2$, or $CaCl_2$ were added to the bath. According to the relative reversal potentials, the permeability sequence through calcium channels was $Ba^{++}>Ca^{++}>Sr^{++}$. Both Ba^{++} and Sr^{++} shifted the voltage-dependent activation of the Ca^{++} channel current to a more hyperpolarized potential, whereas deactivation kinetics at -80 mV were unaffected. Whole cell current measurements revealed that Ba^{++} and Sr^{++} produced more charge entry than equimolar Ca^{++} for a given level of depolarization. These results enable us to select external divalent conditions to yield equal charge entry at different pulse potentials, thus setting the stage for the determination, through measurement of membrane capacitance changes, of the relative ability of these divalent cations to support exocytotic secretion from chromaffin cells.

The generous support of R.G. Johnson, Jr. is gratefully acknowledged.

THE EFFECTS OF Pb^{2+} AND Zn^{2+} ON THE VOLTAGE ACTIVATED CALCIUM CHANNEL DEPENDS ON THE Ca^{2+} CONCENTRATION. **D. Büsselberg[1,2], M.L. Evans[1], H. Rahmann[*2] and D.O. Carpenter[1] (SPON: C. Allen). [1]NYS Dept. of Hlth. & Sch. of Pub. Hlth., Albany, NY 12201, USA. [2]Univ. of Stuttgart-Hohenheim, D-7000 Stuttgart 70, FRG.**

We have shown that Pb^{2+} and Zn^{2+} block dose and voltage dependent calcium currents in Aplysia neurons. The blockade by Pb^{2+} but not Zn^{2+} appears to be specific for the calcium current. Using conventional two electrode voltage clamp techniques we have analyzed the effects of varying calcium on these blocking actions. The concentration of Pb^{2+} which reduced the current by 50% was 24.0 μM in 10 mM Ca-ASW and 69.2 μM in 40 mM Ca-ASW. The Hill coefficient was close to 1.0 in both solutions. For the same reduction 2.7 mM Zn^{2+} was needed in 10 mM CA-ASW and 4.0 mM Zn^{2+} with 40 mM calcium. We calculate a Hill number between 1.3 and 1.6 for the dose-response curve of Zn^{2+}. With increasing calcium in the external bathing solution there was a reduction in the degree of blockade for a given concentration of Pb^{2+} or Zn^{2+}. The blockade by Pb^{2+} was highly voltage dependent, increasing with depolarization. In contrast, the blockade by Zn^{2+} showed almost no voltage dependence. The addition of Pb^{2+} shifted the peak of the current voltage-relation to hyperpolarized voltages whereas Zn^{2+} moved it to depolarized voltages. Our results suggest that Pb^{2+} and Ca^{2+} compete for the same binding site in or near the channel. While Zn^{2+} can also cause a near total blockade of Ca^{2+} current it appears to act primarily if not exclusively through a charge screening effect as indicated by the lack of voltage dependence of blockade and the shift of activation, inactivation and the current voltage relation.

"LVA" Ca^{++} CURRENTS EVIDENT IN CORTICAL NEURONS ONLY AT ELEVATED (≥30°C) TEMPERATURE. K. Giffin & J.M. Nerbonne, Dept. of Pharmacology, Washington Univ., St. Louis, MO. 63110.

Previously, we reported that Ca^{++} currents in rat visual cortical neurons comprise two kinetically-distinct components (Giffin et al., **Neurosci. Absts. 13**: 1010, 1987). Both components displayed voltage- and time-dependent properties consistent with High Voltage-Activated ("HVA") Ca^{++} channels and no Low Voltage-Activated ("LVA") Ca^{++} currents were seen. Here, we present evidence that "LVA" channels are present in these cells.

Callosal-projecting cells were identified in vitro following in vivo retrograde labeling with rhodamine "beads". Whole-cell voltage-clamp recordings were obtained in bath solution containing (in mM): 140 TEACl, 4 KCL, 2 $MgCl_2$, 5 $CaCl_2$, 10 Hepes 5 glucose. Pipets contained (in mM): 140 CsCl, 10 EGTA, 10 Hepes, 5 glucose, 3 Mg*ATP, 0.1 Tris*GTP. During (125 ms) depolarizations from -80 mV at 20-22°C, the "HVA" current activates to a transient peak and subsequently decays to a plateau; the currents begin to activate at -20 mV, peak at +10-+20 mV and reverse positive to +50 mV (n=13). At 32°C, the rates of "HVA" current activation and inactivation are increased and current amplitudes are reduced. In addition, a third current was observed in 3/5 cells examined at 32°C; this current begins to activate at ≈-40 mV, peaks at ≈-30 mV and is only evident during depolarizations from HPs ≤-80 mV, consistent with the presence of "LVA" Ca^{++} channels. The temperature sensitivity of the "LVA" current may explain differences in physiological properties of cortical neurons in slices and dissociated culture. (Support: NSF #BNS8809823 and NIH #T32-HL07275).

CALCIUM CHANNELS IN RAT NEURONS: HIGH-THRESHOLD CHANNELS THAT ARE RESISTANT TO BOTH w-CONOTOXIN AND DIHYDROPYRIDINE BLOCKERS. D.W.Y. Sah, L.J. Regan, and B.P. Bean. Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

We studied w-conotoxin and dihydropyridine block of Ca channel currents in freshly dissociated neurons from young (< 2 wks.) rats. Only cells with no evident T-type current were studied, using 5 mM Ba as charge carrier. The table shows block of peak current by w-conotoxin (10 uM) and nitrendipine (3 uM); similar results were obtained with 3-10 uM nimodipine.

	% block (mean ± s.e.m), h.p. -70 to -90 mV		
Cell type	Nitr.	w-CTX	w-CTX + Nitr.
DRG	18 ± 3	64 ± 2	67 ± 2 (n=8)
SCG	20 ± 3	61 ± 7	78 ± 7 (n=4)
spinal	33 ± 7	36 ± 4	56 ± 4 (n=5)
cortical	24 ± 3	40 ± 5	70 ± 4 (n=5)
CA1	66 ± 7	9 ± 9	99 ± 1 (n=4)
Purkinje			8 ± 4 (n=4)

In contrast to the current picture of N and L channel pharmacology, these results show that most neurons contain a substantial fraction of high-threshold current that is resistant to block by both w-conotoxin and dihydropyridines. (CA1 cells are an exception and Purkinje cells are an extreme case.) Such channels might underlie the many instances of synaptic transmission not blocked by these agents.

332.7

MULTIPLE CALCIUM CHANNEL TYPES EXIST IN ACUTELY ISOLATED GUINEA PIG HIPPOCAMPAL NEURONS FROM THE CA3 REGION. D.J. Mogul and A.P. Fox* (SPON: B. Arnason) Dept. of Pharmacology/Physiology, Univ. of Chicago, Chicago, IL 60637

Previous electrophysiological studies of calcium channels in the CA1 region of mammalian hippocampus have found no evidence of a small conductance, rapidly-inactivating, low-depolarization (T-type) Ca channel (Kay & Wong, 1987; Kay, 1988). The existence of such a channel may provide an important component in spontaneous epileptiform events since it has been suggested that this channel is responsible for pacemaker potentials in various tissues (Llinas & Yarom, 1981). Spontaneous bursting in the hippocampus, which occurs upon application of convulsive agents, always begins in the CA2-CA3 pyramidal region and propagates into the CA1 region. Furthermore, application of the anti-convulsants phenytoin or ethosuximide results in reduction of a low-depolarization rapidly-inactivating Ca channel in neuroblastoma cells (Twombly & Narahashi, 1986) or thalamic neurons (Coulter et. al., 1988). Therefore, we sought to determine what Ca channels exist in the hippocampal CA3 region and, in particular, whether the T-type channel is present in this region. Acutely dissociated adult guinea pig CA3 pyramidal cells (Kay & Wong, 1986) were voltage-clamped using both the whole-cell and single-channel configurations. Fig. 1 shows whole-cell current recordings elicited upon depolarization to -30 mV from a holding potential (HP) of -110, -90, or -50 mV. Barium (5 mM) was the external charge carrier with TEA and TTX outside; Cs, EGTA, Mg-ATP & GTP inside. With HP=-50 mV, a single component inward current showing little to no inactivation was observed during a 230 ms test pulse. With HP=-110 mV, a large rapidly inactivating inward current was observed. This early current was abolished upon application of 100 uM Ni^{2+} (see fig. 2) consistent with T-type channels observed in DRG neurons (Fox et al., 1987). Single-channel recordings suggest the presence of three different types of unitary Ca channel activity, each with a different slope conductance. Our results indicate that differences in the types of Ca channels between CA1 and CA3 may play an important role in hippocampal physiology.

332.8

MULTIPLE CALCIUM CHANNELS IN ADRENAL CHROMAFFIN CELLS. C-R. Jan*, M. Titeler, and A.S. Schneider. Dept. Pharm. & Tox., Albany Med. Coll., Albany, N.Y. 12208.

Radioligand binding of ^{125}I-ω-conotoxin (CTX) and ^{3}H-nitrendipine to membranes from bovine adrenal medulla was investigated in order to test for the presence of multiple Ca^{2+} channels in adrenal chromaffin cells. CTX is a blocker of both N and L-type Ca^{2+} channels in neurons. Nitrendipine is a specific blocker of L-type Ca^{2+} channels. Specific binding sites for both ^{125}I-CTX and ^{3}H-nitrendipine were detected in this study. The K_D was found to be 215 ± 56 pM for ^{125}I CTX binding, and 500 ± 170 pM for ^{3}H-nitrendipine binding; while the B_{max} was 99 ± 18 pmol/g protein for ^{125}I-CTX binding. Dihydropyridines and diltiazem failed to affect ^{125}I-CTX binding, while the binding was blocked by unlabeled CTX and Ca^{2+}. ^{3}H-nitrendipine binding was not affected by CTX, while it was inhibited by dihydropyridines. In fura-2 measurements, BAYK8644 (L-type Ca^{2+} channel agonist) potentiated the K^{+}-evoked rise in cytosolic $[Ca^{2+}]$, and this effect could be blocked by nitrendipine, nifedipine and nimodipine. CTX did not affect the BAYK8644-potentiated Ca^{2+} transients. the results suggest that the binding sites for CTX and nitrendipine are different and indicate the possible presence of both N and L-type Ca^{2+} channels in bovine adrenal chromaffin cells. Supported by NIH grant DK39220 to A.S. Schneider.

DISSOCIATION OF RECEPTOR OPERATED AND VOLTAGE SENSITIVE CALCIUM CHANNELS IN SYNAPTOSOMES AND CULTURED PRIMARY NEURON PREPARATIONS. M.G. Hamilton*, and T.W. Sawyer* (SPON: James W. Maas). Defence Research Establishment Suffield, Ralston, Alberta, Canada, T0J 2N0.

We have examined the effects of activation of both receptor operated channels (ROC's) and voltage sensitive Ca^{++} channels (VSCC's) on intracellular free Ca^{++} levels ($[Ca^{++}]i$) in chicken synaptosomes and primary neuronal cultures using FURA-2. In chicken synaptosomes, K^{+} caused an immediate elevation in $[Ca^{++}]i$ that was unaltered in Mg^{++} free Krebs'. ω-Conotoxin GVIA (CgTx; 0.1-5μM) caused a significant and dose-dependant reduction of the rise in $[Ca^{++}]i$ in both normal and Mg^{++} free Krebs', but the dihydropyridine antagonist (-)202-791 (up to 5μM) was without effect. In cultured chicken cortical neurones, where CgTx reduced the rise in $[Ca^{++}]i$ after K^{+} depolarization, (-)202-791 also reduced the K^{+} induced rise in $[Ca^{2+}]i$, and when combined with CgTx, the $[Ca^{2+}]i$ increase was abolished. Activation of ROC's using NMDA caused a rise in $[Ca^{++}]i$ only in the chicken neuronal preparation and only in the absence of Mg^{++} ions. CgTx or (-)202-791 had no effect on the NMDA-induced rise in $[Ca^{++}]i$. AP-7 and (±)CPP both inhibited the effect of NMDA. Conversely, neither AP-7 nor (±)CPP affected K^{+} stimulated increases in $[Ca^{++}]i$. The data suggests the presence of ROC and L type VSCC's on nervous elements other than synaptosomes with principally N type channels on nerve endings.

MEMBRANE POTENTIAL, ION GRADIENTS AND INTRACELLULAR CALCIUM IN SYNAPTONEUROSOMES. M. Benuck, M.E.A. Reith and A. Lajtha. Center for Neurochemistry, NS Kline Inst., Ward's Island, New York NY, 10035.

Previous investigations on the increased turnover of phosphatidylinositol (PI) in neural tissue upon depolarization (KCl) or sodium channel activation (veratridine) have implicated membrane potential and ion gradients as important factors in determining the release of inositol trisphosphate. Indirect evidence from our laboratory suggests participation of the Na+/Ca2+ exchanger in PI turnover. In the present study, Ca2+ levels were measured in mouse cerebrocortical synaptoneurosomes with Fura 2 AM. Addition of KCl or veratridine led to an increase in [Ca2+]i. TTX blocked the effect of veratridine, in contrast to KCl depolarization. Omission of Na+ from the external medium reduced the effect of KCl and veratridine. Verapamil (100 uM), an inhibitor of the Na+/Ca2+ exchanger and a calcium channel blocker, reduced [Ca2+]i in the presence of KCl or veratridine. In contrast, the calcium channel activator, BAY K 8644, or blocker, nimodipine, did not alter the effect of KCl. Other blockers of the Na+/Ca2+ exchanger, Mg2+ (5 mM) and La3+ (10 uM), did not significantly reduce the increase in [Ca2+]i by KCl or veratridine. The results suggest that, in addition to the Na+/Ca2+ exchanger, other factors are involved in regulating [Ca2+]i in synaptoneurosomes.

CALCIUM-DEPENDENT EXOCYTOSIS AND THE TYPE OF CALCIUM CHANNELS IN A SMALL-CELL LUNG CANCER CELL LINE. Yong I. Kim, J.J. Pancrazio and M.P. Viglione. Depts. of Biomedical Engineering, Neurology and Neuroscience, University of Virginia Health Sciences Center, Charlottesville, VA 22908.

Small-cell carcinoma (SCC) of the lung is associated with a wide variety of paraneoplastic syndromes, including the Ca^{2+} channel disorder Lambert-Eaton syndrome (LES). Using whole-cell patch-clamp techniques, we studied voltage-gated Ca^{2+} currents (I_{Ca}) and the Ca^{2+}-induced changes in cell membrane capacitance (C_m) in human SCC cell line NCI-H146. I_{Ca} was recorded with 10 mM $[Ca^{2+}]_o$ after I_{Na} and I_K were blocked. Depolarization from a holding potential (V_h) of -80 mV to test potentials at -60 to +90 mV evoked I_{Ca} with no or minimal inactivation during 40 or 400 msec excitation. Maximum I_{Ca}, which occurred at about +20 mV, ranged from 20 to 200 pA among different cells tested (n=23 cells). When V_h was changed to -40 mV, both the time course and maximum amplitude of I_{Ca} remained relatively unchanged. The cell's ability for exocytotic secretion and its Ca^{2+} dependency were tested by injecting Ca^{2+} buffer through the recording patch pipette. With 5.8 mM Ca^{2+}/6 mM EGTA buffer, C_m rose from its initial value of 8.85 pF (n=10) (immediately after the establishment of whole-cell configuration) to 16.36 pF within about 4½ min. In contrast, cytoplasmic application of 1.2 mM Ca^{2+}/6 mM EGTA buffer resulted in no change in C_m within 5 min.

These data suggest that i) these SCC cells express L-type Ca^{2+} channels and ii) secretory events in these cells are mediated via Ca^{2+}-dependent exocytosis. Although the presence of T- or N-type channels cannot be excluded from this and other SCC cell lines, L-type channels appear to constitute the majority of the Ca^{2+} channel population in NCI-H146 cells (supported by NIH NS18607 and Muscular Dystrophy Association).

A VOLTAGE-INDEPENDENT, DIVALENT-SELECTIVE ION CHANNEL IS LOCALIZED ON THE NEURITES OF LYMNAEA NEURONS IN PRIMARY CULTURE. S. A. Scott* and J. A. Strong, Dept. of Biol. Sci., Purdue Univ., W. Lafayette, IN 47907.

Previous reports[1-3] have described an unusual voltage-independent, divalent-selective ion channel in neurons of the molluscs Lymnaea and Aplysia. Although the channel is present in high density, it virtually never opens during cell-attached recording. Channel activity is unmasked by formation of a cell-free patch, as if a cytoplasmic inhibitor keeps the channel closed. Previous studies of this channel in Lymnaea used cell-free patches taken from the soma of acutely isolated neurons[2]. In tissue culture dishes, these cells attach and grow extensive neurites. We now report that following such attachment and growth the channel disappears from the cell soma. We made inside-out cell-free single channel recordings in $BaCl_2$//K-aspartate-10 mM EGTA. Channel activity was observed in 40% of patches taken from unattached neurons, but no channels were seen in any of the patches (N=15) taken from the soma of attached cells maintained in primary culture for 1 or more days. This suggests that the channel is localized to the neurites of attached, growing cells. In support of this idea, we observed channel activity in 75% of patches taken from the neurites, as opposed to the soma, of attached cells.

CALCIUM CURRENTS IN DEVELOPING MOUSE SPINAL NEURONS. M. Mynlieff, D.P. McCobb and K.G. Beam. Dept. of Physiology, Colorado State Univ., Fort Collins, CO 80523.

Voltage clamp "whole-cell" patch recording was used to measure calcium currents in dissociated spinal neurons from 14 day embryonic (E14) and 7 day postnatal (P7) mice. At E14 the period of motoneuron (MN) cell death is just beginning; at P7 MN cell death is complete and polyneuronal innervation of individual muscle fibers is being eliminated. All recordings were made 24 hr after dissociation; data were taken from the largest neurons, i.e., those cells most likely to be MNs. In the case of the P7 mice, a number of recordings were made from MNs identified by retrograde labeling with the carbocyanine dye dil prior to dissociation. Three calcium currents were distinguished in the cells on the basis of kinetics and voltage dependence. There was a low voltage activated current (Vtest>-50 mV) with characteristics similar to the T current described in sensory neurons. The current reached maximal size at Vtest=-20 to -10 mV with a relatively slow time to peak (20 ms). Half-maximal inactivation of the current was achieved with a 1 s prepulse to -50 or -40 mV. Strong depolarizations (Vtest>-20 mV) activated an inactivating current and a current which was sustained for at least 200 ms. Both currents reached a maximal size with Vtest=+20 to +30 mV. Half-maximal inactivation of the inactivating current was achieved with a 1 s prepulse to -20 or -10 mV. The inactivating and sustained currents resembled the N and L currents described in sensory neurons, respectively. The voltage dependence of the activation and inactivation of all three currents was similar in E14 and P7 neurons. There was a large amount of variability between cells in the magnitude of each current (normalized by linear cell capacitance), some of which may be attributed to a heterogenous cell population. Despite this variability, the average N and L currents were 2.5 fold larger in P7 neurons than in E14 neurons. A developmental increase in N and L currents has been found previously in chick MNs (McCobb et al., Neuron, in press). Study was supported by NIH grant NS-26416 to KGB.

CALCIUM CURRENTS IN ADULT RAT SENSORY NEURONS. A.Formenti*, A.Pollo*, M.Taglialatela* and E.Carbone* (SPON:European Neuroscience Association). Dept. Anat. Physiol., 10125 Torino, Italy.

Ca currents in freshly dissociated adult rat sensory neurons (DRG) were studied by the whole-cell patch-clamp. Low-threshold (LVA, T) Ca currents turned-on transiently at about -50mV and inactivated fully within 100ms in a voltage dependent manner. This current persisted during bath application of 3.2 μM ω-CgTX or 30 μM Cd and was strongly depressed by 500 μM Amiloride. High-threshold (HVA, L and N) Ca currents turned-on between -10 and 0 mV, inactivated slowlyand incompletely even after prolonged depolarizations. Bath application of 3.2μM ω-CgTX blocked 80 to 90% of this currents. Residual ω-CgTX-resistant currents (10 to 20%) proved to be sensitive to DHP-derivatives. At -60mV holding potential (Vh), 1μM Nitrendipine reduced by 60% the size of this component while BAY K 8644 (1μM) had an agonistic action independent of Vh. BAY K 8644 enhanced the size and speeded-up the inactivation kinetics of CgTX-resistant currents. Inactivation was maximal at potentials positive to -20mV and persisted in the presence of 500μM Amiloride. Our data suggest a multiple action of BAY K on HVA Ca currents and the possible existence of multiple types of Ca channels in adult rat DRG.

PATCH CLAMP STUDIES OF CALCIUM CHANNELS IN CA1 HIPPOCAMPAL NEURONS. T.J. O'Dell* and B.E. Alger. Dept. Physiol., Univ. Maryland School of Medicine, Baltimore, MD 21201.

Previous whole-cell voltage clamp data suggested that dihydropyridine-sensitive, high-voltage-activated (L-type) calcium channels like those found on other neurons were present on hippocampal CA1 neurons. However, no single channel recordings have tested this hypothesis.

We used the cell-attached patch configuration of the patch-clamp technique to study single calcium channels on pyramidal cells enzymatically dissociated from the CA1 region of guinea pig hippocampus. The cells were bathed in 140 mM KCH_3SO_3 saline to zero the membrane potential and barium ions were used to carry the charge (110 mM $BaCl_2$ in the pipette solution). Single channels with a slope conductance of 23.6 + 3.4 pS (mean ± S.D., 12 patches) were detected during step depolarizations to potentials more positive than -30 mV in about 50% of the patches. Channel openings were also plentiful during maintained (≥1 min) depolarizations to or beyond -20 mV. Channel percent open time was enhanced by bath application of 5.0 μM BAYK 8644 and reduced by application of 1.0 - 5.0 μM nifedipine. These findings are consistent with previous reports and indicate the presence of L-type calcium channels on hippocampal CA1 pyramidal cells. We are investigating the actions of protein kinase C activators on L-channel activity. Supported by NIH NS22010 (B.E.A.) and NS08669 (T.J.O.).

LOW- AND HIGH-THRESHOLD CA^{2+} CURRENTS IN RAT SPINAL DORSAL HORN NEURONS P. D. Ryu, and M. Randic, Dept. of Vet. Physiol. and Pharmacol., Iowa State University, Ames, IA 50011, USA.

We have used single-electrode voltage-clamp technique and transverse spinal cord slice in an attempt to characterize voltage-dependent Ca^{2+} conductances underlying the low- and high-threshold Ca^{2+} spikes in 2-4 week old rat dorsal horn neurons. Cs^+-filled microelectrodes and solutions containing TTX/TEA/Ba^{2+}/zero-Ca^{2+}/Cs^+ were used to minimize fast voltage-dependent Na^+ and K^+ channel currents. The low-threshold transient inward current and the high-threshold transient and sustained components of the inward current were reversibly depressed by removing external Ca^{2+} ions and enhanced when Ca^{2+} was replaced by Ba^{2+}. The low- and the high-threshold Ca^{2+} conductances were characterized on the basis of their voltage- and time-dependence and sensitivity to the Ca^{2+} channel agonist and antagonist drugs. The low-threshold transient current was selectively blocked by Ni^{2+} and amiloride whereas the high-threshold sustained current was preferentially enhanced by Bay K 8644 and reduced by nifedipine. Cd^{2+} ions blocked both transient and sustained components of the high-threshold current but only slightly reduced the low-threshold transient current. SP reversibly increased the high-threshold transient current in 15 out of 24 neurons tested and in about half of examined cells the low-threshold Ca^{2+} current. The results indicate the existence of multiple types of Ca^{2+} conductances in immature rat spinal dorsal horn neurons that are modulated by SP. Supported by grants from NIH, NSF and USDA.

EFFECTS OF THYROID HORMONES ON CALCIUM CHANNEL EXPRESSION IN CULTURED RAT SKELETAL MUSCLE. S.R. Sampson and Chaya Brodie*. Dept. of Life Sciences, Bar-Ilan University, Ramat-Gan 52900, Israel.

Thyroid hormones (TH) influence Na-channels in cultured myotubes by 2 opposing mechanisms: (i) up-regulation by stimulation of synthesis, and (ii) down-regulation by what appears to be to an increase in cytosolic Ca^{2+} (Brodie, C. and Sampson, S.R., The Physiologist, 31, 133, 1988). In this study, we examined effects of TH on the number of Ca-channels as measured by specific binding of [^{3}H]PN200-110 to cultured skeletal myotubes derived from 1-day-old neonatal rats. Cells (6-7 DIV) were treated with T_3 (10 nM) for 12-48 hr. TH-treatment caused an increase in Ca-channel density beginning 12 hr after addition of the hormone to the growth medium. Peak effects were obtained after 24 hr. Scatchard analysis of the properties of PN200-110 binding showed that B_{max} increased from control levels of 45.8 to 70.7 fmoles/dish, and Kd increased from 0.22 nM to 0.85 nM (total protein values were unchanged by TH-treatment). Thus, TH causes an increase in number of Ca-channels with decreased affinity for the ligand, similar to TH effects on Na-K pumps and Na-channels in cultured skeletal muscle. We conclude that the effect of TH to up-regulate Ca-channels may be an important component of the mechanism by which these hormones increase cytosolic Ca^{2+} and regulate Na-channel expression in skeletal muscle.

332.18

DIHYDROPYRIDINE (DHP) -SENSITIVE Ca^{++} CHANNELS AND ANKYRIN ARE LOCALIZED IN THE TRIADS OF SKELETAL MUSCLE. B.E. Flucher*, M.E. Morton, S.C. Froehner and M.P. Daniels. Lab. of Neurobiology, NINDS, Lab. of Biochem. Genetics NHLBI, NIH, Bethesda, MD and Dept. of Biochem., Dartmouth Medical School, Hanover, NH.

The DHP receptor of skeletal muscle is thought to function both as a voltage-sensitive Ca^{++} channel and as a voltage sensor in excitation-contraction (E-C) coupling. Cell fractionation studies suggest that the receptor is concentrated in the transverse (T-) tubular system. In order to test this hypothesis a monoclonal antibody (1A) against the α_1 subunit of the Ca^{++} channel was used for immunofluorescence staining, and for immunogold labeling of low temperature resin embedded rat diaphragm muscle. The α_1 polypeptide was localized in the junctional T-tubule membrane but not detected in unspecialized regions of the T-tubules. In contrast, no concentration of the voltage-gated Na^+ channel was observed in the triads (using the monoclonal antibody[1] A/B2; Haimovich et al., 1987). The concentration of the DHP receptor α_1 subunit in the triads is consistent with a role of this protein in E-C coupling. Ankyrin-like molecules are thought to immobilize various integral membrane proteins (erythrocyte anion transporter, nerve Na^+ channel and kidney Na^+/K^+ ATPase) in specialized domains of the plasma membrane. In muscle we have previously demonstrated ankyrin-immunoreactivity in the synaptic folds of the neuromuscular junction, colocalized with Na^+ channels. Here we show the localization of an ankyrin-immunoreactive molecule at the junction between sarcoplasmic reticulum and T-tubules (using an affinity purified antibody[2] against erythrocyte ankyrin; Bennett and Stenbuck, 1979). Thus, ankyrin may be involved in the specialization of two different membranous structures in muscle cells.

THE EFFECT OF LYOTROPIC ANIONS ON Ca^{2+} CURRENTS, CHARGE MOVEMENT AND Ca^{2+} TRANSIENTS OF FROG SKELETAL MUSCLE. D.E. García-Díaz*, M.J. Delay** and J.A. Sánchez***. *Depto. de Fisiología, Fac. de Medicina, UNAM. **Dept. of Medical Physiology, University of Calgary, Alta., Canada and *** Depto. de Farmacología, CINVESTAV-IPN, México.

Thiocyanate (SCN^-) and other lyotropic anions facilitate the activation of charge movement in skeletal muscle (García-Díaz & Sánchez, Biophys. J. 33, 334a, 1988) the present experiments examine further its action on charge movement, slow Ca^{2+} currents (ICa) and Ca^{2+} transients. Methods: the triple vaseline gap technique (Hille & Campbell, J. Gen. Physiol. 67, 265, 1976). Internal solution (mM) for voltage clamp experiments: TEA_2EGTEA=20, Cs-glutamate=89, Na_2ATP=2, MOPS=4. Ca^{2+} transients were measured under current clamp conditions in Cl^- Ringer's and internal solution: EGTA=1, K-aspartate=121.5, $MgCl_2$=2, MOPS=5, Na_2ATP=2, T=22-24°C. Arsenazo III (1 mM) or Anti-pyrylazo III (2 mM). Results: time to peak of ICa during large depolarization (ms) was 512±80(14) and 330±36(14) after SCN^-. I-V curve shifted -21±2.7 mV(14) after SCN^-. On-charge shifted (mV) from -39.9±9.1(6) to -50±2.0(6). Internal SCN^- produced similar results on ICa and charge movement. Tail currents were fitted with 2 exponentials (ms): τ_1=15.1±2.8(11) and 67.0±20.4(11) after SCN^-. Off-charge step to -10 mV was slowed down ca 2.4 times. Peak amplitude of Ca^{2+} transients increased by 70-100% by SCN^- in both Arsenazo and Antipyrylazo experiments.CONACYT/H.F.

332.20

Ca channel activity in fetal skeletal muscle cells from normal and "Muscular Dysgenesis" mutant mice. R Bournaud*[2], T Shimahara*[1] and I Inoue*[1]. (SPON: Y Bruner) [1]Lab. de Neurobiol. Cell. et Moléc. CNRS Gif-sur-Yvette France, [2]Lab. de Physiol. Gén. Univ. Paris XII 94000 Créteil. France.

Experiments were performed in enzymatically dissociated intercostal muscle cells from 13-19 days old fetuses using the whole cell patch clamp technique. During this period of the myogenesis, all muscle cells studied from normal and Muscular Dysgenesis (*mdg/mdg*) mutant fetuses showed low threshold T type Ca currents; this current was reversibly blocked by amiloride. In normal fetuses the high threshold L type Ca current (sensitive to PN 200-110 and Bay K8644) began to be expressed on the 14th or 15th day of gestation and the number of cells having this current increased until the 19th day. At birth, all normal muscle cells showed the L-type current. Even though the L type current is totally absent in *mdg/mdg* muscle cells from 14 days old fetuses, an "L type like current" appeared in such cells at 16 days and older. This current was also sensitive to dihydropyridines. The number of cells showing the "L-type like" current increased to the end of gestation. The maximum amplitude of this current never exceeded the maximum amplitude of the T type current. These results agree with our previous observations in primary culture of dysgenic muscles. (Supported by a grant from A.F.M)

DISTRIBUTION OF L-TYPE CALCIUM CHANNELS IN THE ADULT RAT NERVOUS SYSTEM. R.E. Westenbrock*, M.A. Ahlijanian, and W.A. Catterall (SPON: J. DeVito). Department of Pharmacology, School of Medicine, University of Washington, Seattle, WA 98195.

Voltage-sensitive calcium channels are involved in the control of calcium-dependent cellular processes such as action potential generation, muscle contraction, and secretion of hormones and neurotransmitters. L-type channels mediate slowly activated, long-lasting calcium currents that are blocked by dihydropyridine calcium channel antagonists and enhanced by dihydropyridine calcium channel agonists. A monoclonal antibody that recognizes neuronal L-type calcium channels (MANC-1) has been recently developed (Ahlijanian and Catterall, *Neurosci. Abst.*, 1989). In this study, MANC-1 has been used in combination with the indirect peroxidase-anti-peroxidase technique to investigate the distribution of L-type calcium channels in the brain and spinal cord of adult rats. Light microscopic studies revealed that L-type calcium channels are localized in neuronal somata along the entire rostral-caudal extent of the brain and spinal cord. The MANC-1 staining is confined to a narrow zone around the periphery of the soma. Both interneurons and projection neurons exhibited this pattern of staining. For example, in the hippocampus L-type calcium channels in interneurons in the stratum radiatum, stratum oriens, and hilus are labeled with MANC-1 as are pyramidal neurons in Ca1-Ca3 and granule cells in the dentate gyrus. In addition, dense MANC-1 staining is present in proximal regions of major dendrites of projection neurons such as hippocampal pyramidal cells and spinal motor neurons. These results indicate that L-type calcium channels have a discrete distribution on neurons in cellular regions which generate calcium-dependent action potentials.

332.22

IDENTIFICATION OF α_1- AND α_2-LIKE SUBUNITS OF THE NEURONAL L-TYPE CA^{2+} CHANNEL WITH A MONOCLONAL ANTIBODY. M.K. Ahlijanian and W.A. Catterall. Department of Pharmacology, School of Medicine, University of Washington, Seattle, WA 98195.

Voltage-dependent, dihydropyridine-sensitive, L-type Ca^{2+} channels (CaCh) play an important role in controlling the dynamics of intracellular Ca^{2+} concentration in brain cells, but their biochemical properties are unknown. Purified L-type CaCh from rabbit skeletal muscle (SkM) consist of 5 specifically associated subunits: α_1 (175 kDa), α_2 (145 kDa) which is disulfide-linked to δ (24 kDa), β (54 kDa), and γ(30 kDa). Using SkM microsomes as immunogen, a mouse monoclonal antibody (MANC-3) was developed which immunoprecipitates purified CaCh from rabbit SkM radiolabeled by binding of [^{3}H]PN-200-110, by iodination, or by phosphorylation with the catalytic subunit of cAMP-dependent protein kinase. Immunoprecipitation of radiolabeled SkM CaCh is half maximal at 25 nM and is blocked by incubation of the antibody with unlabeled SkM CaCh. Immunoblotting suggests that MANC-3 recognizes the α_1 subunit of the SkM CaCh. Partially purified brain CaCh radiolabeled by binding of [^{3}H]PN-200-110 or by iodination is also immunoprecipitated by MANC-3. This immunoprecipitation is half maximal at 54 nM and is also blocked by unlabeled SkM CaCh. Immunoprecipitation, SDS-PAGE, and autoradiography of the iodinated neuronal CaCh preparation yields a main protein band of 165 kDa. Reduction of disulfide bonds prior to electrophoresis reveals two distinct bands of 170 and 145 kDa. These data suggest that, similar to the SkM CaCh, rabbit brain L-type CaCh contains of at least two noncovalently associated, high molecular weight polypeptides: an α_1-like subunit of 165 kDa and an α_2-like subunit of 145 kDa that is disulfide-linked to a smaller polypeptide of approximately 25 kDa. MANC-3 may be an important tool for purification and characterization of neuronal L-CaCh.

332.23

MONOCLONAL ANTIBODIES TO THE CALCIUM CHANNEL BLOCKER ω-CONOTOXIN. L.P. Fortier, J. Rafrafi, J. Tremblay and R. Hawkes. Lab. Neurobiology, Hôpital Enfant-Jésus, Quebec, Canada, G1J 1Z4.

Murine hybridoma cell lines were constructed that secrete antibodies to the Ca-channel blocker ω-conotoxin (Ctx). Anti-Ctx recognizes Ctx on Western blots, and can be used to localize Ctx binding sites in tissue sections. Fresh rat cerebellar slices were incubated for 1h in 10^{-6}M Ctx, then aldehyde fixed and the Ctx binding sites identified by using peroxidase immunocytochemistry. When Ctx was omitted from the first incubation no staining resulted. Neuronal somata and dendrites of all cerebellar main neuronal types are immunoreactive. On the Purkinje cells the reaction product is not distributed uniformly. Strong staining is seen on the somata and at the branch points of the large dendrites, while the secondary dendrites, spines, and primary dendritic shafts are all more lightly stained. The labelling on cells in deep cerebellar nuclei appear as small discrete dots. These data suggest that the distribution of Ctx binding sites is subtly regulated, and that anti-Ctx may prove a valuable tool to study Ca-channel distributions within neurons.

LIGAND-GATED ION CHANNELS: CHOLINERGIC

331.1

KINETIC CHANGES OF THE NICOTINIC IONIC CHANNEL INDUCED BY (-)METHYLSCOPOLAMINE. J.F.P. Melo[*1] and Y. Aracava[*1,2] (SPON: J.G. Krikorian) [1]Lab. Mol. Pharmacol. II, UFRJ, Brazil; [2]Dept. Pharmacol. Exp. Ther., Univ. Maryland Sch. Med., Baltimore, MD 21201.

The effects of (-)scopolamine on the kinetics of endplate currents of the nicotinic ionic channels activated by acetylcholine were previously studied (Adler *et al., Mol. Pharmacol.* 14:514, 1978). The aim of the present study is to evaluate the action of (-)methylscopolamine on single channel currents recorded from the perijunctional region of isolated interosseal muscle fibers of the frog Lepdodactylus ocellatus by using patch clamp technique. In the presence of (-)methylscopolamine two populations of currents were noticeable: one dominated by single openings and another by long bursting events. Most of the kinetic alterations produced by (-)methylscopolamine could be interpreted on the basis of sequential blockade of the open state of the channels: i) the mean channel open time was shortened with hyperpolarization and blocker concentration; ii) the burst duration and number of openings per burst were increased with drug concentration; iii) the blocked state was prolonged with hyperpolarization but its duration, although longer than that under control conditions, was independent of the concentration of scopolamine analog. The rate of channel blockade was increased with hyperpolarization of the membrane, and with the blocker concentration while the rate of unblocking reaction decreased by negative transmembrane voltage. Thus, (-)methylscopolamine produced an open channel blockade of the nicotinic receptor. (Support: CNPq, FINEP & CAPES, Brazil; US Army Med. Res. & Devel. Comm. Contract DAMD17-88-C-8119 to Dr. E.X. Albuquerque[2])

331.2

ACTIONS OF ENANTIOMERS OF ESEROLINE, A PHYSOSTIGMINE METABOLITE, ON THE NICOTINIC ACETYLCHOLINE RECEPTOR-ION CHANNEL COMPLEX. W.M.Cintra[1,2*], K.-P.Shaw[1*], G.T.Scoble[1*], Q.S.Yu[3], A.Brossi[3] and E.X.Albuquerque[1,2]. (SPON: G.J. Markelonis) [1]Dept. Pharm. Exp. Ther., U. MD Sch. Med., Baltimore, MD 21210; [2]Lab. Mol. Pharm. II, Fed. Univ. RJ, Brazil & [3]Lab.Chemistry, NIDDKD, NIH, Bethesda, MD 20892.

Eseroline is a major metabolite of the reversible anticholinesterase agent physostigmine. End plate currents (EPCs) from frog sartorius muscle reveal that the time constant of the EPC decays (τ) increased at concentrations ranging from 10^{-7}M to 10^{-5}M of (+) eseroline but no change in (τ) was observed in the presence of (-) eseroline at this range of concentration. At 10^{-4}M, an increase in (τ) was observed with both enantiomers and biphasic decays of EPC were observed at hyperpolarized potentials. No increase in the EPC amplitude was observed with either enantiomer in accordance with their weak anticholinesterase activity as compared with (-) physostigmine. Using the frog interosseal muscle fibers for patch clamp recordings in the cell attached configuration, a concentration-dependent reduction in the mean open time of ACh-activated channels (400 nM) was observed with both enantiomers of eseroline. In the presence of eserolines the channels appeared as square-wave current pulses interrupted by many flickers forming long bursts of openings and closings. The mean channel open time decreased with membrane hyperpolarization while both intraburst closed intervals and burst duration increased. Histograms of open times of ACh-activated channels in the presence of eserolines was fitted by a single exponential function, burst times were fitted by double exponential functions. Correlation was made between the biphasic decays in the EPCs and the kinetics of single channel currents. Both enantiomers of eseroline are open channel blockers of ACh-activated channels; they did not unveil stereoselectivity on the ion channel site(s). (Support: U.S. Army Med. Res. & Devel. Comm. Contract DAMD17-88-C-8119).

331.3

NONCOMPETITIVE BLOCKADE OF THE PERIPHERAL AND CENTRAL NICOTINIC ACETYLCHOLINE RECEPTORS (AChR) BY MK-801 AND PCP. A.S. Ramoa[1,2], M. Alkondon[2*], Y. Aracava[1,2*], J. Irons[3*], G.G. Lunt[3], S.S. Deshpande[2*], S. Wonnacott[3] and E.X. Albuquerque[1,2]. [1]Lab. Molec. Pharmacol. II, Fed. Univ. Rio de Janeiro, Brazil, [2]Dept. Pharmacol. & Exp. Ther., Univ. of Maryland Sch. of Med., Baltimore, MD 21201 & [3]Dept. Biochem., Univ. of Bath, BA2 7AY, England.

MK-801and PCP, drugs known to block the NMDA-activated channels, were tested on the nicotinic AChR located in the peripheral and central nervous systems to disclose functional homologies existing between these receptors. Endplate currents (EPC) from frog sartorius muscle, ACh-activated single channel currents from frog interosseal muscle fibers, and anatoxin (AnTX)- or ACh-activated single channel currents from identified retinal ganglion neurons were used in this study. Also, biochemical assays of receptor function were carried out to assess the effect of MK-801. MK-801 (5-80 μM) produced a voltage- and concentration-dependent acceleration of the EPC decay and a decrease in the peak amplitude of the EPCs. The drug (1-10 μM) decreased the frequency of ACh-induced openings in muscle fibers, as well as their mean open time and burst duration. Currents recorded from outside-out patches of retinal ganglion neurons in presence of either AnTX or ACh looked very similar to NMDA-activated currents in terms of conductance. Interestingly, these currents were blocked by MK-801 and PCP, as evidenced by a reduction in the frequency of openings as well as a shortening of open time at concentrations of MK-801 (0.2-2.0 μM) and PCP (1 μM) which block the NMDA receptors. MK-801 (10-25 μM) also inhibited the (-)nicotine-evoked release of [^{3}H]GABA from hippocampal synaptosomes without affecting the binding of (-)nicotine. MK-801 inhibited the binding of [^{3}H]perhydrohistrionicotoxin to the Torpedo membranes, indicating noncompetitive blocking activity. These results disclose a functional homology between the AChR and the NMDA-related ion channels. (Support: CNPq and FINEP, Brazil; NIMH P-50MH44211; US Army Med. Res. & Devel. Comm. Contract DAMD17-88-C-8119; NIH Grant NS25296).

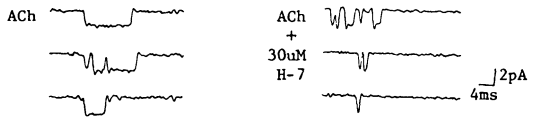
INTERACTIONS OF ACRIDINE ANALOGS WITH NICOTINIC ION CHANNELS: EVIDENCE FOR HOMOLOGY AMONG FUNCTIONALLY DISTINCT PROTEINS. R.A.M. Reis[1*], Y. Aracava[1,2*], C.M. Himel[2*] and E.X. Albuquerque[1,2]. (Spon: R. Sjodin) [1]Lab. Mol. Pharmacol. II, UFRJ, Rio de Janeiro, Brazil and [2]Dept. Pharmacol. and Exp. Ther., Univ. Maryland Sch. of Med., Baltimore, MD 21201.

1,2,3,4-Tetrahydro-9-amino acridine (THA), a cholinesterase (ChE) inhibitor, has been used in the treatment of Alzheimer's disease (Summers et al., New Engl. J. Med., 315:1241, 1986). More recently, THA has been reported to reduce NMDA-mediated neurotoxicity (Choi et al., Eur. J. Pharmacol. 154:73, 1988) in a manner similar to that described for noncompetitive blockers such as phencyclidine (PCP). In light of the findings that PCP acts on both NMDA and nicotinic macromolecules, thus supporting the notion of conserved ion channels, we studied the actions of THA and 1,2-propane-9-amino acridine araphane (1,2-pAA), a weaker ChE inhibitor than THA, on the muscle nicotinic acetylcholine receptor ion channel (AChR). Single channel currents activated by acetylcholine (ACh) were recorded from the perijunctional region of the frog interosseal muscle fiber. Both THA and 1,2-pAA (0.5-10 μM) blocked the open channels activated by ACh and induced a marked reduction of the opening frequency such that at 10 μM almost no channel activity could be recorded. Both effects were enhanced by membrane hyperpolarization. Also, the analyses of the open-channel currents showed that THA induced bursting-like activity whereas with 1,2-pAA only randomly separated brief events were observed. These results strengthen the notion of homology between nicotinic and NMDA channels (see Costa et al., this meeting). Therefore, although it is clear that these compounds alter the nicotinic AChR, great caution must be taken in relating effects on the AChR to their effectiveness in Alzheimer's disease. (Support: FINEP & CNPq, Brazil; US Army Res. & Devel. Comm. Contract DAMD17-88-C-8119)

333.5



EFFECTS OF FORSKOLIN AND ANALOGS ON NICOTINIC RECEPTOR-MEDIATED $^{22}Na^+$ FLUX AND ON VOLTAGE-DEPENDENT $^{45}Ca^{++}$ FLUX AND VOLTAGE-DEPENDENT $^{86}Rb^+$ EFFLUX IN PHEOCHROMOCYTOMA PC12 CELLS. Y. NISHIZAWA, K.B. SEAMON and J.W. DALY. National Institutes of Health and Food Drug Administration, Bethesda, MD 20892.

Forskolin (FSK), a polar 6-8-piperidinoacetoxy analog (HL706) and an analog, 1,9-dideoxy-FSK that is inactive at adenylate cyclase, were examined for effects on nicotinic receptor-mediated $^{22}Na^+$ flux, high potassium-induced $^{45}Ca^{2+}$ flux through L-type calcium channels and high potassium-induced $^{86}Rb^+$ efflux through calcium-dependent potassium channels in PC12 cells. FSK and analogs completely blocked carbamylcholine-elicited flux at 30 uM. 1,9-Dideoxy-FSK was most potent (IC_{50} 1.6 uM) with FSK and HL706 2 to 3-fold less potent. HL706 and 1,9-dideoxy-FSK had little effect on desensitization of the nicotinic response, while FSK slightly antagonized the desensitization evoked by high concentrations of carbamylcholine. Neither an adenosine analog, NECA, that elevates cyclic AMP, nor 8-bromo-cyclic AMP had any effect on desensitization. The results suggest that FSK and analogs either directly block or are noncompetitive blockers of nicotinic receptor-mediated ion flux in PC12 cells, but that unlike many noncompetitive blockers, they do not markedly enhance desensitization. 1,9-Dideoxy FSK at 30 uM, but not FSK or HL706, markedly inhibited $^{45}Ca^+$ flux and $^{86}Rb^+$ efflux in PC12 cells suggesting generalized effects of this analog on ion channels.

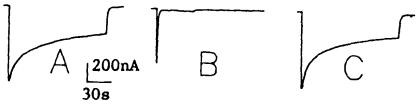
COMPOUNDS COMMONLY USED TO ALTER PHOSPHORYLATION ACT DIRECTLY ON THE CHANNELS TO DECREASE CURRENTS THROUGH NICOTINIC ACETYLCHOLINE RECEPTORS. T. Reuhl*, J. Pinkham**, J.R. Moorman* and J.A. Dani. Dept. of Molecular Physiology & Biophysics, Baylor College of Medicine, Houston, TX 77030, and *Section of Molecular Neurobiology, Yale Univ., New Haven, CT 06510.



Nicotinic acetylcholine receptor (nAChR) channels were expressed in Xenopus oocytes, and macroscopic currents induced by 50 μM ACh were measured with a two electrode voltage clamp. Consistent with the work of Wagoner and Pallotta (Science, 1988, 240:1655-7), we found that external application of 20 μM forskolin rapidly decreases ACh-induced currents. Bath application of 3-isobutyl-1-methyl xanthine (IBMX, a phosphodiesterase inhibitor) or of 1-(5-isoquinolinylsulfonyl)-2-methylpiperazine (H-7, a protein kinase inhibitor) also decreases ACh-induced currents. The decrease of ACh-induced currents was concentration dependent and was reversed by washing the drug out of the bath. Single-channel measurements were made with excised outside/out patches containing nAChR channels. When o/o patches were rapidly exposed to 0.5 μM ACh in the presence of H-7, the mean open time and the open probability decreased but the conductance was unchanged (Fig.). The rapid effect of IBMX and H-7 on ACh-induced currents and the action of H-7 on excised patches indicate that these compounds directly alter nAChR channels independent of their action on enzymes that participate in protein phosphorylation. Supported by NIH grant NS21229.

SOLUTIONS EXPOSED TO CERTAIN POLYPROPYLENE TISSUE CULTURE TUBES DECREASE CURRENTS THROUGH NICOTINIC ACETYLCHOLINE RECEPTOR CHANNELS EXPRESSED IN XENOPUS OOCYTES. J.A. Dani and T. Reuhl* (SPON: E. Stefani). Department of Molecular Physiology and Biophysics, Baylor College of Medicine, Houston, TX 77030.

Acetylcholine-induced macroscopic currents through nicotinic acetylcholine (ACh) receptor channels expressed in Xenopus oocytes were studied using a two electrode voltage clamp. Exposing our electrolyte solution to Falcon polypropylene tubes decreased the current induced by application of ACh. Our experiments were with the Falcon 2098 50 ml polypropylene tubes from lot numbers 72180188 and 80290188 and with a Falcon 2097 15 ml polypropylene tube from lot number 83560283. Rapid infusion of 50 μM ACh in frog Ringer's solution produced robust currents that decayed in minutes (Fig. A). Simultaneous application of 50 μM ACh in Ringer's solution that had been shaken in the Falcon tubes produced currents with smaller peak currents that decayed in seconds (Fig. B). The currents progressively recovered as the Falcon-exposed solution was washed out of the 0.4 ml chamber for 19 minutes at a flow rate of 2 ml/min (Fig. C). Other tests indicated that a water soluble substance was coming off the Falcon tubes. Spectrophotometry revealed a significant absorbance near 200 nm after distilled water was shaken in a Falcon tube. When distilled water was shaken in 5 Falcon tubes and lyophilized, a white precipitate was formed. We thank Dr. J. Pinkham for providing the mRNA used in this study. Supported by NIH grant NS21229.

333.8

MULTIPLE PHASES OF DESENSITIZATION OF ACETYLCHOLINE RECEPTOR FROM ELECTROPHORUS ELECTRICUS. D. J. Cash, A. M. Rao* & G. G. Mayes*, Biochemistry Dept., Univ. of Missouri-Columbia and Neurochemistry Unit, Missouri Inst. of Psychiatry, School of Med. Columbia, MO 65211

Acetylcholine mediated cation flux and receptor desensitization were measured with quench flow techniques with native membrane vesicles. Three phases of desensitization were observed with half times of approximately 30ms, 250ms and 7s. The fast phase is due to a new receptor (or form of the receptor) distinguishable from the previously studied receptor. This is demonstrated by the constant initial activity of the second phase of desensitization over a wide range of acetylcholine concentration. The second phase is due to the previously studied receptor. The third phase is desensitization of activity remaining in a preequilibrium after the prior desensitization of the same receptor in the second phase. This is demonstrated by the large dependence of the initial activity of the third phase on acetylcholine concentration. The distinguishable receptors are on the same membrane. The different phases of desensitization are characterized by different dependencies on pH. The distinguishable receptors differ in their inhibition by high concentrations of bromoacetylcholine and their inactivation on reduction with dithiothreitol. This characterization of these responses is necessary in order to interpret correctly the effect of pH or bromoacetylcholine on this system. Supported by a grant from NINCDS (DHS 5ROI NS 20377-03).

333.9

FUNCTIONAL PROPERTIES OF SYNAPTIC ACETYLCHOLINE RECEPTORS IN FAST TWITCH FIBERS OF DYSTROPHIC MICE. L. P. Henderson. Department of Physiology, Dartmouth Medical School, Hanover, NH 03756.

Focal extracellular measurements of miniature endplate currents (mepcs) were made from flexor digitorum brevis (fdb) muscle of 2 month old, male C57BL/6J-dy^{2J} and control mice. Mepcs from control mice decayed with an average time constant of 1.2 ms, whereas the time constant of synaptic current decay from dystrophic fibers was significantly faster (0.8 ms). In order to ascertain whether this difference reflected a true difference in the functional properties of acetylcholine receptors (AChR), single channel recordings were made from the synapses of dissociated dystrophic fdb fibers. Two amplitude classes of events (65 and 45 pS) were present in recordings from dystrophic endplates, as has previously been reported for control fdb fibers (Brehm and Kullberg, P.N.A.S. Vol 84: 2550, 1987). However, the open duration of the 65 pS channel was briefer in many fibers (τ<1 ms, Vp=+80mV, cell-attached) than in control fibers (τ~2ms, Vp=+60 mV, cell-attached). In addition, openings of the 45 pS channel, which constituted ~3% of the total events in control fibers, were more prevalent in recordings from dystrophic fiber endplates (~20%). The mean channel open time of the 45 pS channel was also brief (τ<1 ms, Vp=+80 mV, cell-attached). These data suggest that the dystrophic phenotype affects the expression of AChR in innervated fast twitch fibers.

333.10

CHOLINERGIC CHANNELS IN *XENOPUS* MYOCYTES ACTIVATED BY COMBINATIONS OF AGONISTS. Anthony Auerbach, Dept.of Biophysical Sciences, SUNY, Buffalo, NY. 14214

Cholinergic channels usually open only after binding two agonist molecules. The rates of channel opening and closing depend on the nature of the bound agonist. In order to understand how channels behave when two different agonist molecules are bound, embryonic *Xenopus* myocytes were patch-clamped (cell-attached configuration) with pipette solutions of ACh (5 or 10 uM) plus either choline (Ch; 50-500 uM) or carbamylcholine (CCh; 10-200 uM). The applied potential was +40 mV and the temperature was 18 °C. Both large (g_{60}) and small (g_{40}) conductance channels were examined.

Preliminary results are given below (t_c = predominant closed interval time constant, t_o = predominant open interval time constant; times are in ms, concentrations are in uM; 2-4 patches for each experimental condition):

	t_c			g_{40}	
ACh/Ch	g_{40}	g_{60}	ACh/CCh	t_c	t_o
5/0	18	36	10/0	4.7	5.4
5/100	10	20	10/100	0.9	4.7
0/100	-	-	0/100	5.0	1.8

With 100 uM Ch alone the channel opening rate is very low and t_c is too long to be measured.

These results indicate that doubly-liganded channels occupied by ACh and either Ch or CCh open and close at rates similar to channels occupied by two ACh molecules. In this regard, the action of Ch is particularly interesting since endplates are exposed to choline produced by the hydrolysis of ACh during synaptic transmission. Supported by NS235130.

333.11

EARLY DEVELOPMENTAL CHANGES IN ACETYLCHOLINE RECEPTOR CHANNEL KINETICS IN CULTURED XENOPUS MYOCYTES

J. Rohrbough* and Y. Kidokoro. Dept. of Physiology, U.C.L.A. School of Medicine, Los Angeles, 90024.

Developmental changes in single acetylcholine receptor (AChR) channel properties were studied in aneural *Xenopus* myocyte cultures using single-channel recording techniques. Cultures were prepared from stage 15-18 embryos, and recordings taken at developmental stages ranging from several hours to five days after AChR first appear in the membrane.

The burst durations of both low and high conductance channels decreased during development. At 50 mV applied hyperpolarization, the low conductance burst duration decreased from 24 ms at stage 24 to 6 ms at stage 47, a 4-fold decrease; high conductance burst duration also decreased 2.5-fold in the same period, from 10.6 ms to 4 ms. Much of the decrease for both channel types occurred during the first day in culture. Most low conductance burst duration histograms were not well-fit with a single exponential, having an excess of brief openings. The excess could be largely accounted for by singly-liganded openings. The burst durations were determined by the best single exponential fit to the main, slow component. High conductance burst durations were well-fit by single exponentials. The percentage of high conductance channel events, which was initially a few percent, increased gradually beginning around stage 34 to 60% at stage 47. Neither the single channel conductances nor the voltage dependency of burst duration changed with development. To identify the kinetic parameter(s) associated with the burst duration changes, closed time analysis was done at high temporal resolution. The developmental decrease in burst duration could be due to changes in true channel mean open time ($1/\alpha$), or to changes in β or k_{-2}, which would be reflected in the mean closed time of gaps within bursts and the number of gaps per burst. For the low conductance channel, the brief component of the closed time was 25 μs, and mean number of gaps per burst was 1.95. Neither value changed with development. Therefore, we conclude that the channel closing rate constant, α, is the kinetic parameter changing.

333.12

THE POSSIBLE IMPORTANCE OF THE NEURONAL NICOTINIC SUBUNIT β_4 TO THE KINETIC PROPERTIES OF THE ADRENAL CHROMAFFIN CELL AChR.

R. L. Papke, R. Duvoisin*, J. Boulter, and S. Heinemann. Molecular Neurobiology Laboratory, Salk Institute, La Jolla, CA 92037

At least four genes coding for neuronal nicotinic acetylcholine receptor subunits (α_3, α_5, β_2, & β_4) are expressed the PC-12 cell line, which was derived from an adrenal tumor. The α_3 subunit can form functional receptors when expressed with either of the beta subunits. Cell-attached patch clamp recordings were made from *Xenopus* oocytes injected with mRNA coding for the agonist binding subunit, α_3, in combination with message for either the β_2 or β_4 subunits. Multiple conductances are observed with both combinations and may relate to the presence of receptors with different ratios of alpha and beta subunits (Papke *et al.* in preparation). The primary open state of receptors formed with the β_4 subunit was of higher conductance and had open times 4 to 6 fold longer than those formed with β_2. Openings of the $\alpha_3\beta_4$ receptors were grouped in bursts with an average of 8 openings per burst. Bursts of the $\alpha_3\beta_2$ receptors had an average of only 1.5 openings. The open time and burst durations of the $\alpha_3\beta_4$ receptors are similar to what has been described for adrenal chromaffin cell AChR.

In situ hybridization studies have shown that the genes for the α_3 and β_2 subunits are expressed in many parts of the brain (Wada *et al.* J of Comp. Neur., May 1989), while the expression of β_4 in the brain is largely restricted to a portion of the medial habenula (Duvoisin *et al.* in preparation). However, significant amounts of β_4 are expressed in the adrenal gland.

333.13

MAPPING BY SITE-DIRECTED MUTAGENESIS OF NICOTINIC ACETYLCHOLINE RECEPTOR RESIDUES INVOLVED IN LIGAND BINDING.

W. H. M. L. Luyten and S.F. Heinemann. Molecular Neurobiology Lab, Salk Institute, San Diego CA92138.

We have previously demonstrated (Soc. Neurosc. Abstr. 40:3 1986) that a nicotinic acetylcholine receptor fragment, comprising residues 87-208 of its α-subunit, contains a large part of the binding site for α-bungarotoxin (α-btx), as well as for smaller cholinergic ligands. To define more precisely the residues contributing to this binding site, we changed single amino acids in α87-208 by site-directed mutagenesis. Because a positively charged moiety of cholinergic compounds has been postulated to interact with a negative charge in the binding site, all conserved negatively charged residues were mutagenized to His one by one: Asp89, Asp97, Asp99, Asp111, Glu129, Asp138 Asp152, Glu161, Asp163, Asp166, Glu175, Asp180 and Asp200. The mutant proteins were expressed in an *E. coli* lon$^-$ strain; all had to be solubilized from inclusion bodies by denaturation/ renaturation. All mutant proteins accumulated to comparable levels, and all bound α-btx on blots. In solution, α-btx binding to all mutants showed biphasic association as well as dissociation kinetics, consistent with prior evidence (*loc. cit.*) for two non-interconvertible sites with different affinities. Only one mutant (Asp166->His) showed essentially unaltered kinetics compared to wild-type. For the high affinity site, all other mutants had lower association rate constants (k_+) than the wild-type, and fell into three classes based on their dissociation rate constants (k_-). One class showed comparable reductions in k_+ and k_-, suggesting that all binding site residues were intact, but that orientational or conformational impediments in the mutant slowed complex formation. In the two other classes, k_- changed by a larger or smaller factor than k_+, leading to increased or decreased K_Ds, and suggesting that interactions with binding site residues had been altered. Most of the mutants were not stable during the long incubations required to reach equilibrium in competition binding experiments with small cholinergic ligands, so that the effect of the mutations on their affinity could not be evaluated.

NEURONAL NICOTINIC ACETYLCHOLINE RECEPTORS IN DROSOPHILA MELANOGASTER.

E. Sawruk*, B. Schmitt* and H. Betz. (SPON: W. Oertel), Zentrum für Molekulare Biologie, Im Neuenheimer Feld 282, 6900 Heidelberg, FRG.

Two genes - ard and als - are known to encode subunits of the neuronal nicotinic acetylcholine receptor (nAChR) in Drosophila. Genomic Southern blot analysis using probes derived from these genes suggested the existence of additional nAChR subunits in Drosophila. Screening a Drosophila genomic library with these probes we have isolated several crosshybridizing DNA clones. An alignment of the amino acid sequence predicted from partial nucleotide sequences revealed that two of the clones isolated showed significant homology to putative transmembrane regions of ard and als. Using fragments of these genomic clones as probes additional positive clones were isolated from an embryonic cDNA library of Drosophila. Our data indicate that considerable diversity of acetylcholine proteins exists in insects.

LIGAND-GATED ION CHANNELS: GLUTAMATE

334.1

EFFECT OF BETA ADRENERGIC BLOCKERS ON N-METHYL-D-ASPARTATE (NMDA)-ACTIVATED CHANNELS OF RAT HIPPOCAMPAL NEURONS.

V. Radhakrishnan* and E.X. Albuquerque (Spon: N. Brookes). Dept. of Pharmacol. and Exp. Ther., Univ. Maryland Sch. Med., Baltimore, MD 21201.

NMDA receptors have been implicated in neuronal plasticity, and excessive activation of these receptors may result in seizures and/or injury to the cell (Cotman, C.W. et al., Ann. Rev. Neurosci. 11:61-80, 1988). Antagonists to excitatory amino acids have strong anticonvulsant actions and can protect against epileptic seizures and cell death (Meldrum, B.S. et al., Neurosci. Lett. 39:101-104, 1983). Beta adrenergic blockers have been shown to possess anticonvulsant and mood impairment properties, but it is not known if they affect the NMDA receptors. In the present study, the effects of (±)-propranolol and its stereoisomers were tested on the NMDA-activated single channel currents of cultured hippocampal neurons of fetal rats, using the patch clamp (outside-out configuration) technique. (±)-Propranolol (5-50 μM) reduced the mean open time of NMDA-activated channels in a concentration-dependent manner. A greater reduction in channel lifetime was evident at -80 mV (50-55% reduction with 50 μM propranolol) than at -120 mV (30-35%). At positive potentials, the block was less pronounced. The frequency of activation of NMDA channel currents was also reduced by propranolol in a concentration-dependent manner. A reduction was also observed in the frequency of bursts, though the mean burst time remained unaltered. The long clusters seen after NMDA were not evident after propranolol. The enantiomers of propranolol and the racemic mixture acted in similar manner without showing stereospecificity of responses. It is quite likely that the blockade of NMDA-activated channels may also contribute to the depressive symptoms and alterations in emotional states induced by propranolol. (Support: US Army Med. Res. & Devel. Comm. Contract DAMD17-88-C-8119)

334.2

ZINC REDUCES THE NUMBER OF LARGE-CONDUCTANCE NMDA CHANNEL EVENTS.

G.L. Westbrook & P. Legendre*†. †INSERM, Bordeaux, France and Vollum Institute, Oregon Health Sciences Univ., Portland, OR 97201.

The transition metal cations, Zn and Cd inhibit the NMDA receptor/channel in a non-competitive manner. Whole-cell voltage clamp studies indicate that this inhibition is voltage-independent unlike a number of channel-blocking divalent cations and drugs. However, Zn does cause small reductions in both mean opentime (MOT) and single channel conductance ($\sqrt{}$) of the large conductance level, calculated from spectral analysis of NMDA current noise (Mayer, Westbrook & Vyklicky, J. Neurophysiol., **60**, 645, 1988). To further examine this action of Zn , we have used outside-out patches from cultured neurons of the olfactory bulb and hippocampus of newborn rats.

Extracellular solution contained (mM): Na 165, K 2.5, Ca 1, Mg 0, HEPES 10, glucose 10; glycine .005; picrotoxin, strychnine, and tetrodotoxin were also added. Pipette solution contained (mM): Cs 140, Ca 0.5, EGTA 5, Mg 1, HEPES 10, Cl 126, Fl 14. Cation salts were ultrapure; NMDA (1-10 μM) and Zn (1-30 μM) were applied by flowpipes. Patches from both cell types nearly always contained more than one NMDA-activated channel. As expected, several conductance levels were apparent, consisting primarily of large conductance levels of 45 pS (MOT 5-10 ms) and 35 pS (MOT 1-3 ms); and a much lower frequency of 10 pS events. At -60 mV or +40 mV, the most prominent effect of Zn was a dose-dependent reduction in the frequency of the large conductance events such that at 30 μM Zn, the number of events was 25-30% of control. Amplitude histograms demonstrated a relative increase in the proportion of 10 pS events in the presence of Zn. The MOT of the 45 and 35 pS states were reduced as well. Zn also caused a small, dose-independent reduction in the single channel conductance which was accompanied by an increase in the current variance of the open channel; this appeared to be due to an increase in small (appx. 5 pS) transitions around the 35 and 45 pS levels. This contrasts with the smooth reduction in $\sqrt{}$ in the presence of elevated Ca. Supported by INSERM, NATO Fdn., NIH and the McKnight Fdn.

334.3

INORGANIC LEAD (Pb^{++}) SELECTIVELY BLOCKS N-METHYL-D-ASPARTATE (NMDA)-ACTIVATED CHANNELS. M. Alkondon*[1], V. Radhakrishnan*[1], A.C.S. Costa*[1,2], M. Nakatani[2] and E.X. Albuquerque[1,2]. (Spon: D. Weinreich) [1]Dept. Pharmacol. & Exp. Ther., Univ. of Maryland Sch. of Med., Baltimore, MD 21201 & [2]Lab. Molec. Pharmacol. II, Fed. Univ. Rio de Janeiro, Brazil.

The heavy metal lead has been recogonized as an environmental toxicant which causes a deficit in cognition in children and learning impairment in experimental animals. In view of the recent evidence that implicates NMDA receptors in the processes of learning and memory, we studied the effect of Pb^{++} on glutamate receptors. Using cultured hippocampal neurons (7-21 days old) of fetal rats, we studied the single channel currents (outside-out patch configuration) activated by NMDA and quisqualic acid (Quis). $PbCl_2$ reduced the frequency of openings (1-40 μM), the mean channel open time (5-40 μM) and the mean burst time (10-40 μM) of the single channel currents activated by NMDA in a concentration-dependent manner. These effects were observed at both negative and positive membrane potentials (-100 mV to +80 mV), unlike that observed with another cation, Mg^{++}, which elicited its blocking effect only at hyperpolarized potentials. On the Quis-evoked currents, however, >70 μM $PbCl_2$ was required to produce any significant kinetic alteration. The single channel conductance of channels activated by either NMDA or Quis was unaltered by Pb^{++} at the concentrations used in this study. Selective impairment of NMDA-type of glutamate receptors thus leading to a reduced influx of Ca^{++} and interference with the Ca^{++}-dependent processes may underlie some of the behavioral alterations observed in Pb^{++} neurotoxicity. (Support: US Army Med. Res. & Devel. Comm. Contract DAMD17-88-C-8119 & CAPES Proc. 4987/88-2).

REDUCTION OF NMDA RECEPTOR CURRENT BY MK-801: SINGLE CHANNEL KINETICS. R.L. Macdonald, N.M. Porter, and R.E. Twyman. Dept. of Neurology, Univ. of Michigan, Ann Arbor, MI. 48104

It has been suggested that the reduction of NMDA receptor current by MK-801 occurs via *fast* open channel block (*Huettner and Bean, PNAS 85:1307, 1988*). In the present study, we further characterized the actions of MK-801 on NMDA receptor currents by studying the kinetic properties of the main conductance state (50 pS) of the NMDA receptor. Outside-out patches from cultured mouse spinal and cortical neurons were held at -75 mV in nominal Mg^{2+} solutions. Data were digitized at 20 kHz (2 kHz Bessel filter). Frequency distributions of open times, closed times, and burst durations were analyzed by curve fitting to sums of exponential functions.

MK-801 (1 and 10 μM) reduced the current evoked by NMDA (50 μM) and glycine (2 μM) primarily by decreasing the frequency of channel opening, with a small decrease in mean open time. Frequency distributions of NMDA evoked openings were best fit by two exponential functions whose time constants were not altered but whose proportion of longer openings was reduced by MK-801. NMDA openings occurred in short bursts, and MK-801 decreased mean burst duration. Burst duration frequency histograms were best fit by two exponential functions whose time constants were not altered. The proportion of longer duration bursts was reduced by MK-801. The number of openings per burst also was decreased by MK-801. Neither intraburst nor interburst closed time constants were affected by MK-801, but the proportion of long duration interburst closures was increased by MK-801.

These results suggest that MK-801 may reduce NMDA receptor current by *slow* open channel block or by binding to an allosteric site on the receptor-channel. *Supported by NIH DA04122 to RLM and NS08216 to NMP.*

KINETIC PROPERTIES OF NMDA-ACTIVATED CHANNELS IN EMBRYONIC *XENOPUS* SPINAL NEURONS. Yinong Zhang* and Anthony Auerbach, (SPON: C. Bowman). Dept. of Biophysical Sciences, SUNY, Buffalo, NY 14214

NMDA receptors in *Xenopus* play important roles in motor pattern generation and in the plasticity of retino-tectal connections. We are studying the properties of single channel currents elicited by combinations of NMDA and glycine in spinal neurons from 1-day old *Xenopus* embryos. Experiments have been carried out at 24 °C on cell-attached patches of cells grown in culture for 1-7 days.

Xenopus NMDA receptors resemble those of mammalian systems in that the predominant channel conductance is ~50 pS and channel activity is inhibited by Mg^{++} and potentiated by glycine. Open interval durations can be fitted by the sum of 2 exponentials. With channel currents of 4 pA (estimated V_m = -80 mV), >90% of openings are from the slower component which has a time constant of ~1.2 ms. Open interval durations increase with depolarization but do not vary with [NMDA] (1-1000 uM) or added [glycine] (up to 100 uM). Closed interval duration distributions are complex. Under all experimental conditions we have examined, 2 fast (t = 0.1, 1.0 ms) and one very slow (t > 200 ms) are apparent, with an intermediate component(s) in the range 2-30 ms. At very high [NMDA] and [glycine] channel activity is reduced, suggesting that these molecules may compete with each other. With prolonged application of NMDA plus 10 or 100 uM glycine, there is a gradual rundown of activity, but this effect is less marked than the profound desensitization of *Xenopus* cholinergic receptors.

NMDA-activated currents are present on about 60% of the neurons. In some cells, two distinct amplitudes of NMDA currents were apparent. Some of the complexity in channel kinetics may arise from inhomogeneity of channels with regard to both cell type and channel type in a single cell. Supported by NS235130.

334.6

RAPID ACTIVATION AND DESENSITIZATION OF QUISQUALATE-TYPE GLUTAMATE CHANNELS IN EMBRYONIC MOTONEURONS. D.O. Smith, J.L. Rosenheimer, H. Hatt*, and F. Zufall*. Dept. of Physiol., Univ. of Wisconsin, Madison, WI 53706 and Physiol. Inst., Tech. Univ. Munchen, West Germany.

Ionic currents in response to 100- to 300-ms applications of glutamate or quisqualate were measured in motoneurons isolated from embryonic chick spinal cords. A piezo-coupled device was used to produce rapid solution exchanges. In whole-cell recording mode, the inward currents rose in 2 to 8 ms and then decayed to a steady-state level of about 10% of the peak amplitude with a time constant of about 30 ms. In outside-out recording mode, activation could be achieved within <1 ms after glutamate application. The average current desensitized to the lower conductance states with a time constant of about 5 ms. Channel activity was grouped in 6-ms bursts; mean open and close times were 2.8 and 1.5 ms, respectively. Depolarization increased burst length and open time, and increasing agonist concentration prolonged burst length. This rapidly desensitizing quisqualate-type receptor may mediate fast excitatory synaptic transmission in spinal motoneurons. Supported by NIH grant NS13600 and SFB 220.

NMDA-STIMULATED CALCIUM INFLUX IN RAT CORTICAL SYNAPTOSOMES. M.A. Oleshansky, M.L. Koenig, D.E. Mark*, and M.A. Jackson*. Walter Reed Army Institute of Research, Washington DC 20307-5100.

N-methyl-D-aspartate (NMDA) has been reported to open a non-specific cation channel in a variety of neuronal cell types. As Ca^{2+} influx is a critical component in neurotransmitter release, we have examined the effect of NMDA on Ca^{2+} influx and intracellular Ca^{2+} levels in rat brain synaptosomes.

$^{45}Ca^{2+}$ influx was measured in crude (P2) and purified (P3) synaptosomes prepared from rat cortex. NMDA stimulated $^{45}Ca^{2+}$ influx in P2 which was maximal at 30 sec. In the presence of 5 or 50 mM K^+, NMDA stimulated ^{45}Ca influx in a concentration-dependent manner over a range of 1 to 50 uM with maximal stimulation (150% of control) seen at 50 uM NMDA. The dose-response curve for NMDA was shifted to the left in the presence of 50 mM K^+. NMDA-stimulated ^{45}Ca influx was also apparent but less pronounced in P3. These findings demonstrate that NMDA stimulates Ca^{2+} influx into synaptosomes and suggest that depolarization may be releasing endogenous factors including glycine or glutamate which are supplementing NMDA-stimulated Ca^{2+} influx.

Preliminary experiments with Indo-1 in purified cortical synaptosomes failed to show any significant effects of NMDA on intracellular Ca^{2+} levels. Depolarizing concentrations of K^+ produced only small changes in intracellular Ca^{2+} levels. The effect of an interaction of NMDA and glycine on intracellular Ca^{2+} levels in this system is currently under investigation.

Excitatory Amino Acid (eaa) Antagonists Decrease the Medium and Slow Afterhyperpolarization (m-ahp/s-ahp) and Hyperpolarize Neurons of the Basolateral Amygdala (bla). P. Shinnick-Gallagher and A.C. Anderson. Dept. of Pharmacology, Univ. of Texas Med. Br., Galveston Tx 77550 (spon: K.D. Phelan)

The effects of endogenous eaa's on intrinsic membrane properties were studied using eaa antagonists, dl-2-amino-5-phosphonovaleric acid (dl-apv, 50uM), 7cl-kynurenic acid (7clkyn, 10uM), and 6-cyano-7-nitroquinoxaline-2,3-dione (cnqx, 5uM). The eaa antagonists induced a voltage independent decrease (10 to 50%) in the m-ahp following 100 msec depolarizing pulses in 77% and a decrease in the s-ahp (20 to 60%) in 66% of the experiments in kindled cells; in control cells the m-ahp/s-ahp decreased 33 to 83% in 60% of the experiments. At peak drug effect the membrane was hyperpolarized 1 to 7 mV in kindled and 2 to 3 mV in control neurons followed by a rebound depolarization from 1 to 14 mV (median: 5mV) above baseline upon washout. Input resistence decreased 5 to 20% in dl-apv, <5% in 7clkyn, and 10 to 15% in cnqx in kindled and control neurons. Previous studies have shown that n-methyl-d-aspartate increases the ahp in CNS neurons and this appears to be true in bla neurons. The current data supports the hypothesis that an tonic release of eaa's modulate voltage gated conductances and resting excitatory tone in both control and kindled bla neurons. (Supported by NS24643)

335.1

PROTEIN KINASE C AND cAMP-DEPENDENT PROTEIN KINASE PHOSPHORYLATE THE PURIFIED $GABA_A$ RECEPTOR. M.D. Browning[1], M. Bureau[2], E. Barnes[1], and R. Olsen[2]. (Spon: J. Sikella) [1]Department of Pharmacology, University of Colorado HSC, Denver, CO 80262; [2]Department of Pharmacology, UCLA Sch Med, Los Angeles, 90024.

A number of recent studies have suggested that phosphorylation of the $GABA_A$ receptor could modulate receptor function. Activators of protein kinase C (PKC) and cAMP-dependent protein kinase (A kinase) have been shown to influence $GABA_A$ receptor function. In addition, Sweetman et al. (J. Neurochem. 51,1274,1988) have reported that a kinase associated with the partially purified preparation of the receptor could phosphorylate the α-subunit of the receptor. This kinase activity was not influenced by cAMP, cGMP, Ca^{2+}, calmodulin, or phosphatidylserine. To explore the issue directly, we have examined the ability of specific kinases to catalyze significant phosphorylation of the $GABA_A$ receptor which has been purified to near homogeneity.

The $GABA_A$ receptor was purified as previously described using benzodiazepine affinity chromatography. The purified receptor possessed no detectable kinase activity. PKC and the A kinase catalyzed the phosphorylation of both the β- and α-subunits of the receptor. However, most of the PO_4 incorporation was associated with the β-subunit. Two muscimol binding polypeptides designated β_h (higher molecular weight; M_r 59,000) and β_l (lower molecular weight; M_r 57,000) were present in the preparation. The higher molecular weight polypeptide, β_h, was phosphorylated specifically by the A kinase. β_l was phosphorylated specifically by PKC. β_h and β_l gave distinct patterns in a one-dimensional phosphopeptide analysis. Taken together these data suggest that there are two forms of the β-subunit of the $GABA_A$ receptor and that these two forms of the β-subunit are phosphorylated by distinct kinases. (supported by PHS grants NS22071 to R.O. and NS26377 and DK 40483 to M.D.B.)

335.2

MONOCLONAL ANTIBODIES RECOGNIZING THE BENZODIAZEPINE RECEPTOR OF CHICK EMBRYO BRAIN. H.S. Yin and S.S. Fan*, Dept. of Anatomy, College of Medicine, National Taiwan University, Taipei, Taiwan, R.O.C.

Monoclonal antibodies(mAbs) have been produced by immunizing BALB/c mice with the benzodiazepine(BZD) receptor proteins from 20 day chick embryo brain. The fluorogram and gel slice extraction of SDS-PAGE gels of the brain membranes photolabelled by ^{3}H-flunitrazepam(FNZ) showed that the binding sites were located at 51KD and 48KD proteins. The proteins from 48KD to 51KD were eluted from gels and then injected into the mice. Screening was performed by ELISA, immunoblotting, and radioligand binding after the splenocytes were fused with NS-1 myeloma cells. Six positive clones were obtained. Western blot of ^{3}H-FNZ-labelled membranes showed that the mAbs recognized a major radioactive 51KD and a minor 50KD bands. Immunoblotting of two-dimensional slab gels revealed same bands with pIs ranging from 5.6 to 6.0. Cultured brain neurons stained with the mAbs showed that the immunoreactivity was localized on the membranes of cell soma and neurites of certain neurons. Immunostaining of paraffin sections of brain tissue labelled neurons located at various areas including hippocampus, optic tectum and cerebellum. These results indicate that the mAbs recognize the BZD receptor of chick embryo brain. Futher characterization of the receptor using these mAbs is in progress.

335.3

THE PRODUCTION AND CHARACTERIZATION OF MONOCLONAL ANTIBODIES DIRECTED AGAINST THE γ-AMINOBUTYRIC ACID ($GABA_a$) RECEPTOR. P. A. Gallombardo and J. F. Tallman. Abraham Ribicoff Research Facilities, Yale University School of Medicine, 34 Park St., New Haven, CT 06508

The molecular complex which mediates the effects of the neurotransmitter GABA and the anxiolytic benzodiazepines has been purified; and the genes encoding the receptor subunits have been sequenced. Molecular genetic techniques, including *in situ* hybridization histochemistry, have revealed that multiple combinations of subunits can form an array of receptor subtypes. Monoclonal antibodies directed against the rat brain $GABA_a$ receptor were produced to be used as biochemical and immunocytochemical probes for assessing the function and localization of specific receptor subunits. The monoclonal antibodies were produced by the immunization of Balb/c mice with purified rat brain $GABA_a$ receptor followed by the formation of antibody secreting hybridomas. The resulting antibodies were characterized by solid phase radioimmunoassay, immunoblot, and epitope protection assay. All of the antibodies reacted with a 50kD protein in preparations of purified receptor and brain membranes. This protein was identified as the benzodiazepine binding subunit by photolabeling the protein with ^{3}H-flunitrazepam and performing two dimensional immunoblots. The specificity of two of the antibodies was further demonstrated by immunoprecipitating the solubilized benzodiazepine binding site. The antibodies could be divided into five epitope groups. Immunoreactive proteins were identified in rat astrocytes and in three species of Nemathelminthes. These cross reactive proteins may be homologues of the $GABA_a$ receptor γ subunit.

335.4

DIFFERENTIAL DISTRIBUTION OF $GABA_A$ α1,α2 AND α4 RECEPTOR mRNAs IN THE RAT NERVOUS SYSTEM. N. Brecha, C. Sternini, K. Anderson*, K. Bhakta*, M. Khrestchatisky*, A.J. MacLennan*, M.Y. Chiang*, R.W. Olsen and A.J. Tobin. Depts. of Med., Anat. & Cell Biol., Pharm. and Biol. and CURE, UCLA Sch. Med. and VAMC-West Los Angeles, LA, CA, 90024.

The $GABA_A$ receptor consists of several structurally distinct components including α, β and γ subunits. Three distinct rat $GABA_A$ α cDNAs (1, 2 and 4) have been isolated. The cellular localization of $GABA_A$ α mRNAs in the rat brain was studied using *in situ* hybridization histochemistry with ^{35}S-labeled rat α1, α2 and α4 RNAs. Cryostat sections were incubated in antisense or sense RNAs, washed at high stringency and processed for autoradiography. The α1 transcripts have a wide distribution along the neuroaxis. Regions with heavy labeling include the olfactory bulb, hippocampal formation, cortex, inferior colliculus, cerebellum and cerebellar nuclei. Hypothalamic, thalamic and midbrain structures are also labeled. Low to undetectable α1 mRNA levels are found in the caudate and in many regions of the pons and medulla. The α2 and α4 transcripts have a more limited distribution, with heavy labeling in the olfactory bulb and hippocampal formation and moderate labeling in the cortex. The α2 mRNA is also expressed in the caudate. Areas with low to negligible levels of α2 and α4 mRNAs include the inferior colliculus, cerebellum, deep cerebellar nuclei and many regions of the pons and medulla. These studies show that the α transcripts are differentially expressed in the brain. Some areas contain all three α mRNAs, while in other areas there are marked differences in their localization patterns and levels of expression.

335.5

FUNCTIONAL EXPRESSION AND REGIONAL DISTRIBUTION OF A AND B SUBUNITS FOR THE GABA A RECEPTOR. M. Khrestchatisky*, A.J. MacLennan*, M.Y Chiang* W. Xu*, M. Jackson, K. Anderson, C. Sternini, N. Brecha, R.W Olsen and A.J. Tobin. Departments of Biology, Medicine, Anatomy, and Pharmacology, UCLA, Los Angeles, CA 90024. (SPON: M. Wexler).

Four cDNAs (α1, α2, α4 and β) from a rat hippocampal cDNA library encode isoforms of the subunits of the GABA receptor. α1, α2 and β polypeptides are very similar to the bovine α1, α2 and β polypeptides. The α4 polypeptide differs in the presumed extracellular and intracellular domains from previously reported subunits and is thus a novel isoform. The cDNA probes detect mRNAs with distinct sizes and regional distributions in the rat brain. When injected into Xenopus oocytes, combinations of in vitro transcribed RNAs for the α and β subunits produce GABA- dependent inward currents. In some cases, picrotoxin alone applied to oocytes elicits an outward current. These responses suggest that α and β polypeptides can produce GABA-gated ion channels that can also open spontaneously. Supported by NS 21908 and 22256.

335.6

ANALYSIS OF GABA-A RECEPTOR SUBUNIT COMPOSITION WITH SUBTYPE-SPECIFIC ANTISERA. S. Endo*, G.B. Smith*, L. Deng*, J.D. Young* and R.W. Olsen. Depts. of Pharmacology and Biological Chemistry, UCLA School of Medicine, Los Angeles, CA 90024.

Antisera were produced against subunit subtype-specific peptide sequences of the $GABA_A$ receptor from bovine brain. Putative extracellular and cytoplasmic domains of α_1, α_2, α_3 and β receptor subunits as published were evaluated and unique sequences identified. From these, sequences predicted to be highly immunogenic were selected. Peptides corresponding to the putative cytoplasmic domain between membrane spanning regions 3 and 4 were synthesized and purified by reverse phase HPLC. The purified peptides were characterized by amino acid analysis. A C-terminal cysteine was added to each to facilitate coupling to carrier protein; the peptides were conjugated to KLH and injected into rabbits. Antisera to peptides from α_1, α_2, and β_1 have been screened by indirect ELISA using synthetic peptides and shown to give half maximal reaction at dilutions of 100,000. Affinity purified receptor shows bands on SDS gels at 52-54 kD which are recognized by α antisera. In addition, the β subunit at 58 kD, and additional bands at 35, 45, and 70 kD, are being investigated for specific labeling on Western blots and immunoprecipitation with antisera.

Supported by NIH grants NS22071 and HD06576.

335.7

ONTOGENY OF THE $GABA_A$/BENZODIAZEPINE RECEPTOR COMPLEX IN THE RAT BRAIN: LOCALIZATION OF α_1-SUBUNIT mRNA AND LIGAND BINDING SITES. C. Gambarana, R. Pittman*, G.A.Ordway*, and R.E. Siegel. Dept. of Pharmacology, Case Western Reserve University, Cleveland, OH 44106.

The $GABA_A$/benzodiazepine receptor complex mediates the actions of the major inhibitory transmitter in the brain, γ-aminobutyric acid (GABA). The action of GABA at the receptor is modulated by two classes of clinically important compounds, the benzodiazepines (BZD) and barbiturates. It appears that the receptor complex is composed of multiple subunits and that its composition may differ in different brain regions.

Much remains to be learned concerning the importance of the different subunits in the formation of a functional $GABA_A$/benzodiazepine receptor complex. To approach this issue, expression of the receptor in the developing rat brain was examined with in situ hybridization and receptor autoradiography. Using a probe complementary to the mRNA encoding the α_1 subunit, only low levels of message were detectable during the first postnatal week. At this time, the mRNA was most prominent in the cortex, hippocampus, and in the inferior colliculus. A dramatic rise in mRNA levels occurred in the second week, particularly in the cerebellum where increased levels of message were paralleled by increases in the binding of [^{3}H]RO 15-1788 and [^{3}H]GABA, ligands for BZD and GABA sites, respectively. In the cerebellum, the α_1 mRNA and binding sites continued to increase until day 28, and then decreased to adult levels. These findings will allow us to assess the relation between receptor expression and GABAergic synapse formation, as much is known about the ontogeny of the cerebellum.

335.8

MODULATION OF $GABA_A$ RECEPTOR CHANNEL EXPRESSED IN XENOPUS OOCYTES, BY FULL AND PARTIAL AGONISTS OF THE BENZODIAZEPINE RECEPTOR. L. Prado de Carvalho*, P. Curutchet*, J. Stinnakre[1]* and J. Rossier. Laboratoire de Physiologie Nerveuse and Laboratoire de Neurobiologie Cellulaire et Moléculaire[1], C.N.R.S., 91198-Gif sur Yvette, CEDEX, France.

Voltage-clamped oocytes injected 2-4 days before recording with chick brain poly(A^+)RNA were used to compare the ability of benzodiazepine (BZ) receptor full and partial agonists to enhance Gaba induced current. Diazepam (DZ) and flunitrazepam enhanced current induced by 10 μM Gaba in a dose dependent manner. Maximal effect (190% of controls) was attained with micromolar concentrations. Long application (30 min) of agonists did not change the initial potentiating effect: thus equilibrium is rapidly attained and BZ receptors do not desensitize. Ro 16-6028 and Ro 17-1812 had only small enhancing effects up to 1 μM, but at 100 μM were as potent as DZ. Clonazepam enhanced Gaba current at sub-micromolar concentrations but the Gaba response did not surpass 150% of controls.

Ro 16-6028 and Ro 17-1812 have a higher affinity than DZ (*Eur. J. Pharmacol.*, 156: 169, 1988), thus their lower effect at 1 μM on the oocyte is in agreement with their partial agonist profile in other systems. Effects observed above 1 μM may deserve further studies.

335.9

EXPRESSION OF mRNA IN XENOPUS OOCYTES DEMONSTRATES GENETIC DIFFERENCES IN ETHANOL SENSITIVITY OF THE $GABA_A$ RECEPTOR COMPLEX K.A. Wafford, R.A. Harris and T.V. Dunwiddie. Dept. of Pharmacology, Univ. of Colo. Hlth. Sci. Cntr., and V.A. Medical Center, Denver, CO 80262

Ethanol has a number of effects on the brain, producing sedation and anesthesia. Genetically selected lines of mice and rats have been generated which display differing degrees of sensitivity to these effects of ethanol. Biochemical studies suggest differences in the $GABA_A$ receptor of these lines, for example in long sleep and short sleep mice. Increasing evidence suggests that ethanol enhances the opening of $GABA_A$ chloride channels and increases GABA-mediated $^{36}Cl^-$ influx into mouse brain microsacs. Messenger RNA was extracted from LS and SS mouse brain using a Fast-Track isolation kit and 50ng injected into defolliculated oocytes. Cells were incubated for 2-3 days before recording. Currents were recorded under voltage-clamp conditions and drugs were applied by perfusion. $GABA_A$ receptors were expressed in oocytes and application of GABA elicited a similar inward current in both lines of mouse, the GABA current was enhanced by pentobarbital (100μM) and diazepam (0.1μM). Ethanol (10-50mM) in the presence of GABA had a large potentiating effect on LS GABA receptors (20mM enhanced the initial current by ~57%) but had no significant effect on SS GABA receptors. Ethanol also had a "long-term" potentiating effect which peaked at ~20 min. GABA responses were enhanced by concentrations of ethanol which had no effect alone. Hence the diffences in ethanol sensitivity of LS and SS mice can be at least partially explained by some difference in one or several of the GABA receptor subunit genes. Supported by the V.A. and grants AA06399.

CHRONIC ETHANOL EXPOSURE ALTERS BENZODIAZEPINE (BZ) RECEPTOR LIGAND MODULATION OF GABA-ACTIVATED CHLORIDE FLUX. K.J. Buck* and R.A. Harris. Dept.of Pharmacology, UCHSC, Denver, CO 80262; and VA Med. Res. Serv., Denver, CO 80222.

We found that chronic ethanol exposure attenuated the ability of flunitrazepam (FNZ) to modulate muscimol-activated $^{36}Cl^-$ uptake, and enhanced the actions of BZ inverse agonists, Ro15-4513 and DMCM. Cortical membrane vesicles were prepared from ICR mice given a liquid diet containing 6% (v/v) ethanol, or an equicaloric diet with sucrose substituted for ethanol, for 10 days. Muscimol-activated $^{36}Cl^-$ uptake was measured as previously described (Life Sci. 39: 2005, 1986). Attenuatation of FNZ's effect was the result of reduced efficacy in microsacs prepared from nonwithdrawn mice, but not those withdrawn for 6 or 24 hr. Sensitization to the actions of BZ inverse agonists was reflected by increased efficacy. Ro15-4513 efficacy was increased in microsacs prepared from nonwithdrawn mice and those withdrawn for 6 hr, 24 hr or 8 days, and was greatest in those withdrawn for 6 hr.

Our results indicate a role for the chloride channel in the development of cross-tolerance to FNZ following chronic ethanol exposure. Furthermore, they demonstrate that chronic ethanol exposure sensitizes the channel to the actions of BZ inverse agonists. This may be responsible for sensitization to BZ inverse agonists observed behaviorally in ethanol-dependent animals. Moreover, these changes in chloride channel function may play a role in the development of tolerance or physical dependence to, or withdrawal from, ethanol or other intoxicant/sedative drugs. Supported by the VA and AA06399.

EFFECTS OF CONTINUOUS DIAZEPAM ADMINISTRATION ON GABA-A SUBUNIT mRNA IN RAT BRAIN. C. Heninger, N. Saito*, J.F. Tallman, R.S. Duman, K.M. Garrett*, M.P. Vitek and D.W. Gallager. Dept. of Psychiatry, Yale Univ. School of Med, New Haven, CT 06508.

Chronic treatment with the benzodiazepine agonist diazepam (DZ) results in the development of tolerance and physical dependence. Our laboratory has documented regionally specific differences in GABA sensitivity both electrophysiologically and biochemically after chronic exposure to DZ. In order to investigate a possible molecular basis for these changes, we have measured levels of GABA-A receptor α and β subunit mRNAs after chronic treatment with vehicle or DZ implants. Levels of mRNA were examined by Northern blot using cDNA clones for GABA-A α and β receptor subunits, and resulting autoradiograms were analysed by densitometry. Levels of α subunit mRNA in cerebral cortex were decreased compared to levels resulting from vehicle treatment. Levels of GABA-A β subunit mRNA were similar after chronic vehicle or DZ treatment. Acute DZ (2 hr) did not alter levels of either α or β specific mRNA. These results suggest that changes in GABA receptor subunit mRNAs may be related to the GABA sensitivity changes seen with chronic DZ treatment. Asssociation of such changes with chronic treatment will be assessed by comparing regional differences in GABA-A subunit mRNA with regional changes in binding to ligands specific for the benzodiazepine recognition site and the GABA recognition site.

MAPPING THE BENZODIAZEPINE PHOTOAFFINITY LABELLING SITE WITH $GABA_A$ RECEPTOR ANTIBODIES. F.A. Stephenson* and M.J. Duggan* (SPON: P.A. Kirkwood) School of Pharmacy, Brunswick Square. London WC1N 1AX, England.

Analysis of the amino acid sequence of the $GABA_A$ receptor polypeptides has predicted a model for the protein with a large extracellular N-terminal hydrophilic domain and four hydrophobic transmembrane regions M1-M4. The location of the drug binding sites within the protein sequence are not known. We have focused on the identification of the agonist benzodiazepine binding site. The $GABA_A$ receptor was purified from adult bovine cerebral cortex, photoaffinity labelled with [^{3}H] flunitrazepam and subjected to complete and limited cyanogen bromide chemical cleavage. The products of these reactions were analysed for radioactivity, for immunoreactivity in Western Blots with anti-α1 1-15, anti-α1 324-341 and anti-α1 413-429 $GABA_A$ receptor antibodies and for reactivity with biotinylated Concanavalin A. Using the deduced amino acid sequence of the 1 subunit and these results, it was shown that the site of benzodiazepine agonist photoaffinity labelling does not lie within the sequence α1 1-58 and α1 149-429.

A STUDY OF NEUROTRANSMITTER RECEPTORS AND VOLTAGE-ACTIVATED CHANNELS OF THE RAT CEREBELLUM USING mRNA-INJECTED XENOPUS OOCYTES. D. Ragsdale* and R. Miledi. Laboratory of Cellular and Molecular Neurobiology, Department of Psychobiology, University of California, Irvine 92717.

We have investigated the neurotransmitter receptors and voltage-activated channels of cerebellar cells by isolating mRNA from rat cerebellum, injecting it into Xenopus oocytes and then examining the functional receptors and channels expressed in the oocyte membrane using a conventional two-electrode voltage-clamp to record membrane currents. We found that "cerebellum oocytes" had a distinct pattern of expression of receptors and channels. They gave large responses to GABA and glutamate but small responses to acetylcholine, kainate, glycine and serotonin. They also exhibited large voltage-activated Na^+, K^+ and transient outward currents. This pattern of responses was clearly different than that seen in oocytes injected with mRNA from rat cerebral cortex. We presume that the relative sizes of the various drug-and voltage-activated currents in cerebellum and cortex oocytes reflect the levels of mRNA encoding receptors and channels in these two brain regions, and this is supported by northern blot analysis which indicated that the degree of hybridization of a Na^+ channel probe to different cerebellum and cortex mRNA preparations correlated well with the relative sizes of the voltage-activated Na^+ currents in cerebellum and cortex oocytes.

EFFECT OF LONG-TERM TREATMENT WITH ANTIDEPRESSANT DRUGS ON PHORBOL ESTER-BINDING SITES IN RAT BRAIN. K. Osada*, M. Asakura*, M. Shibata*, H.Kubota*, A.Sato*, J. Adachi*, and K. Hasegawa* (SPON: M.OKAMOTO) Dept. of Neuropsychiat. St. Marianna Univ. Sch. Med., 2-16-1, Sugao, Miyamae-ku, Kawasaki, Kanagawa, 213, Japan

We examined the effects of long-term treatment with antidepressants on the binding characteristics of [^{3}H]-phorbol 12,13-dibutyrate (PDBu) which binds to a regulatory domain of Ca^{2+}-phospholipid dependent protein kinase (PKC) in rat hippocampal membranes. Treatment with antidepressants (desipramine, imipramine, clomipramine, mianserin, fluoxetine) for 14 days caused a significant inhibition of the Ca^{2+}-chelator (EGTA)-induced dissociation of [^{3}H]PDBU binding from membranes following incubation with Ca^{2+} and [^{3}H]PDBu. However there was no significant change in the [^{3}H]PDBu binding of membranes washed with 5 mM EGTA. Therefore, the difference between the binding to membranes by preincubation with [^{3}H] PDBu which does not completely dissociate by EGTA and the remaining binding even after washing with EGTA was significantly increased following treatment with antidepressants. This subtructive binding might represent a newly synthesized membrane-inserted PKC. These data suggest that long-term treatment with antidepressants made PKC stabilized to EGTA following incubation with Ca^{2+} and phorbol esters, suggesting the facility of formation of membrane-inserted PKC.

336.2

CHARACTERIZATION OF PHORBOL ESTER-BINDING SITES IN MEMBRANE FRACTIONS OF RAT BRAIN M.Asakura*, K.Osada*, T.Tsukamoto*, J. Imafuku*, J. Nakanishi* and K. Hasegawa* (SPON:T. HAMA) Dept. of Neuropsychiat. St.Marianna Univ. Sch. Med. 2-16-1 Sugao, Miyamae-ku, Kawasaki, Kanagawa, 213 Japan

Characteristics of [^{3}H]phorbol 12,13-dibutyrate (PDBu) binding to Ca^{2+}-phospholipid-dependent protein kinase C (PKC) were examined in rat brain membrane fractions. The equilibrium binding of [^{3}H]PDBu displayed upward curvilinear Scatchard plots, showing an apparent existence of multiple affinity states of binding sites or negative cooperativity. The high-affinity state of [^{3}H]PDBu binding sites was markedly reduced at 50 μM of Ca^{2+}-chelator (EGTA) without change in maximum binding sites. However, there was a 60 % reduction in total binding sites with a linear plots after washing with 100 μM EGTA. The PKC bound to membranes is controlled by not only Ca^{2+} but also phorbol esters. Therefore, the membrane-bound PKC induced by [^{3}H]PDBu in a dose-dependent manner may contribute to an apparent low-affinity state of curvilinear Scatchard plots. Prior incubation with higher concentrations of [^{3}H]PDBu diminished the PKC release by low concentration of EGTA. Furthermore, incubation of membranes with phosphatidylserine (PS) also inhibited the PKC release by EGTA. Accordingly the chelator-stable PKC induced by Ca^{2+}, phorbol esters or PS might be the membrane-inserted PKC.

336.3

PROTEIN KINASE C ISOZYMES IN PRIMARY CULTURES OF CEREBELLAR GRANULE CELLS: GLUTAMATE-STIMULATED MEMBRANOUS ASSOCIATION OF TYPE II PKC. F.L.Huang[1], D.-M. Chuang[2] and K.-P.Huang[1]*. [1]NICHD, NIH, Bethesda, MD and [2]NIMH, Washington, D.C.

Our previous studies have shown that both type II and III, but not type I, protein kinase C (PKC) isozymes were present in the granule cells of adult rat cerebellum (BBRC 87, J. Neurosci. 88). During postnatal cerebellum development, expression of these isozymes were under separate controls. In the present study, type II and III PKCs, but not type I, were also found in the primary cultures of granule cells prepared from 8-day old rats. Expression patterns of these isozymes were different. Except for a slightly elevated level at 4-5 days, type II PKC was expressed at a relatively stable level throughout 13 days in culture. On the contrary, type III PKC was expressed at a low level initially and the content increased as the culture continued up to 13 days. Treatment of the 8-day cultures, when type II PKC was the predominant species, with PMA resulted in the down-regulation of PKC, whereas PKC in the 13-day culture, when type III PKC was predominant, was less susceptible to down-regulation by PMA. Treatment of the culture with glutamate, the excitatory amino acid, caused a reduction of both type II and III PKCs from the cytosol and an increase of these isozymes in the membrane fraction. Though the time course and extent of translocation varied from culture to culture, an accumulation of type II, but not type III, PKC in an unique membranous fraction which was not extractable by 0.5% NP40 containing buffer, was consistently observed. These results suggested that type II and III PKCs, with their dissimilar expression patterns and responses to glutamate, may also be endowed with dissimilar and specific functions in granule cells of cerebellum.

PROTEIN KINASE C ISOFORMS IN RAT HYPOTHALAMUS AND MIDBRAIN CENTRAL GRAY. U.E. Olazabal, R.H. Lustig, D.W. Pfaff, and C.V. Mobbs Rockefeller Univ., New York, NY 10021.

We have shown previously that phorbol esters infused into the midbrain central gray (MCG) facilitate the estrogen-dependent behavior, lordosis. Therefore, we examined the distribution of protein kinase C (PKC) isoforms in the MCG and ventromedial hypothalamus (VMH), brain regions which control lordosis. PKC isoforms were detected by 1- and 2-dimensional gel electrophoresis followed by immunoblot analysis using a monoclonal antibody directed against PKC (Amersham). Further immunoblot analysis used three different polyclonal antibodies against synthetic peptides which were reported to recognize respectively alpha, beta, or gamma isoforms (the kind gift of Makowske et al., JBC 263:3402-3410). All three isoforms were present in VMH, MCG, and hippocampus, although the relative amounts of each isoform varied between regions. The gamma PKC isoform migrated slightly more slowly, suggesting a higher molecular weight, than the other isoforms, and was absent in pituitary. At least six different PKC isoforms were detected on 2-D gels using the monoclonal PKC antibody. Further, we have used this antibody to demonstrate PKC by immunocytochemistry in paraformaldehyde-fixed tissue. We conclude that at least 6 PKC isoforms exist in the VMH and at least three PKC isoforms exist in the MCG.

DIFFERENTIAL ASSOCIATION OF FOUR PKC SUBSPECIES WITH SUBCELLULAR COMPONENTS OF NEURONS. N. Saito, A. Kose*, A. Ito*, T. Tsujino*, M. Hirata*, C. Yoshihara*, and C. Tanaka* Dept. of Pharmacology, Kobe University School of Medicine, Kobe 650, Japan.

Protein kinase C (PKC) is known as a Ca^{2+}/ phospholipid dependent protein kinase involved in various signal transduction in tissues. This enzyme has been shown to be a large family consisting of more than four PKC-subspecies (α,βI, βII and γ) by molecular cloning studies. But the physiological difference between the function of each subspecies is unclear. We demonstrate here the regional and intracellular localization of each subspecies of PKC in the rat to elucidate the specific functional role of each PKC subspecies. Immunochemical and immunocytochemical studies revealed the different localization of these four subspecies; γ-PKC is rich in hippocampus and cerebellum, βI-PKC is seen in pontine nucleus and triangular septal nucleus, βII-PKC is abundant in CA1 region of the hippocampus, caudate-putamen and amygdaloid complex. α-PKC is diffusely present through the brain. Under electronmicroscopy, γ-PKC is seen in perikaryon, dendrite, nucleus, and axon. βI-PKC is mainly present in the periphery of the neuronal perikarya. βII-PKC is seen to be associated with Golgi complex of the neuron and α-PKC is abundant in the nucleus. The different localization of each subspecies of PKC in the neuronal components suggests that each subspecies is involved in the specialized function in the different neurons.

336.6

THE PROTEIN KINASE C INHIBITOR STAUROSPORINE REDUCES EXCITABILITY OF HIPPOCAMPAL CA1 NEURONS. **J. B. Denny*, J. Polan-Curtain*, C. Salvador*, D. L. Armstrong and M. J. Wayner. Division of Life Sciences, University of Texas at San Antonio, San Antonio, TX 78285.**

We have investigated the role of the signal-transducing enzyme protein kinase C in hippocampal neurons using staurosporine. This microbial alkaloid specifically inhibits protein kinase C at nanomolar concentrations. In the present study intracellular recordings were made from CA1 neurons before, during and after a 30 min bath application of 50 nanomolar staurosporine.

Hippocampal slices (400 um thick) were isolated from Sprague-Dawley rats aged 37-41 days and placed in a constant perfusion recording chamber mounted on a microscope stage. Resting membrane potential, input resistance, EPSP and action potential amplitude were measured. Passive membrane properties were not affected; however, EPSP amplitude was reduced by 30% and action potential amplitude was reduced by 19% (n=6). None of these effects were observed when only the staurosporine solvent, dimethylsulfoxide, was applied (n=5). The effects of staurosporine were reversed during a 40 min saline wash. These results indicate that protein kinase C is necessary for normal excitatory responses to synaptic activation within the CA1 region of the hippocampus.

Supported in part by NIH Grant RR08194.

336.7

ESTRADIOL MODULATION OF PROTEIN KINASE C (PKC) ACTIVITY IN THE RAT PITUITARY IN VIVO AND IN VITRO. S.V. Drouva, I. Gorenne*, E. Laplante*, E. Rérat*, A. Enjalbert, C. Kordon U. 159 INSERM, 2ter rue d'Alésia, 75014 Paris (France).

Ovarian steroids are known to affect numerous levels of pituitary regulation. The present study was designed in order to investigate PKC activity in pituitary tissue of ovariectomized rats (OVX) or OVX treated with 17 β-estradiol (E2) ; to evaluate the distribution pattern of the enzyme and possible E2-induced variations among the different cell types of pituitary cells in primary cultures separated by unit gravity gradient sedimentation ; finally to analyze E2/PKC interactions on hormone secretion in pituitary cell cultures treated or not with E2. Partially purified soluble (S) and particular (P) PKC was assayed by 1,2 diolein or TPA induced phosphorylation in the presence of Ca^{2+}, PS, histone III S and γ32P(ATP). E2 treatment significantly increased pituitary PKC levels of both S and P fractions on in vivo or in vitro models in a time dependent manner (30 min 96 h). The steroid effect was specific since stereoisomers were inactive. PKC activity was found in all pituitary cell types. E2 treatment (10^{-9} M for 72 h) significantly increased the enzyme activity in all cell types with a preferential effect on a subpopulation of lactotrophs. In addition, administration of E2 to cell cultures strongly increased the TPA induced LH and PRL release ; it had no effect on TPA evoked GH secretion.

DECREASE IN CALCIUM CALMODULIN-DEPENDENT PROTEIN KINASE II ACTIVITY IN RAT HIPPOCAMPAL SLICES IN MAGNESIUM-FREE MEDIUM. W.W. Anderson, S.B. Churn*, and R.J. DeLorenzo. Dept. of Neurology and Dept. of Pharm., Med. Col. of Virginia, Richmond, VA 23298.

Induction of seizures by kindling leads to a long-lasting decrease in calcium-calmodulin dependent protein kinase II (CKII) activity (Wasterlain and Farber, PNAS 81:1253, 1984; Goldenring et al., Brain Res. 377:47, 1986). Removal of extracellular Mg induces electrographic seizures and epileptiform bursting in rat hippocampal slices (Anderson et al., Brain Res. 319:215, 1986). We therefore investigated whether exposure of hippocampal slices to Mg-free medium would also decrease CKII activity.

Experiments were performed on hippocampal slices from female Sprague-Dawley rats (115-260 gm). Extracellular recording and stimulation were performed in CA3. Experimental slices (3 to 8 slices pooled from one animal per experiment) were incubated in 2 mM Mg, then exposed to Mg-free medium for 1 hr, and frozen. The same number of control slices were run concurrently in 2 mM Mg. Calcium-calmodulin stimulated CKII autophosphorylation in homogenates was measured by standard techniques. Biochemistry was performed on those experiments where control slices showed no bursting.

Phosphorylation of the CKII 50 kDa subunit in homogenates isolated from slices exposed to Mg-free medium was decreased by 37.5 $\pm$ 5.5 % (mean $\pm$ sem) compared to controls. The decrease was observed in all experiments (n=7) and was significant ($p<.005$, paired Students t-test).

The results indicate that exposure of slices to Mg-free medium causes a decrease in CKII activity, as does kindling. They are also consistent with the hypothesis that the induction and/or generation of seizure activity involves a decrease in the ability of calcium and calmodulin to stimulate CKII activity.

336.9

DEVELOPMENTAL EXPRESSION OF THE GRANULE CELL-ENRICHED CALMODULIN-DEPENDENT PROTEIN KINASE (CaM KINASE-GR). C-A. Ohmstede,* K.F. Jensen and N. Sahyoun. (SPON: B. Cooper), Wellcome Research Laboratories and NTD, HERL, USEPA, Research Triangle Park, NC 27709.

In the adult rat cerebellum, CaM kinase-Gr is found primarily in granule cells. Antibodies to CaM kinase-Gr stain a heterogeneous population of these neurons. In fixed tissue, this staining is primarily localized to the nucleus; however, staining of unfixed tissue and ultrastructural localization have demonstrated a more extensive distribution within the granule cell including cytoplasm, dendrites and axons. No staining was observed in the Purkinje cells of adult animals. To further characterize this enzyme, we investigated its distribution with the developing cerebellum. Western blots from postnatal cerebellum had suggested a specific developmental profile which may reflect important events in the maturation of neuronal circuitry. On postnatal day 7, CaM kinase-Gr was present in Purkinje cells but was not detected in the proliferating cells of the external germinal layer. By postnatal day 14, the enzyme distribution reflected that of the adult cerebellum. These data suggest that CaM kinase-Gr may play an important role in the maturation of Purkinje cells as well as in the mature function of granule cells.

336.10

DNA-PROTEIN INTERACTIONS WITHIN THE 5'-FLANKING REGION OF THE CaM KINASE II α-SUBUNIT GENE. T. Sunyer* and N. Sahyoun. (SPON: J. Reinhard), Wellcome Research Laboratories, Research Triangle Park, NC 27709

Ca^{2+}/calmodulin-dependent protein kinase II (CaM Kinase II) is an abundant neuronal enzyme whose level and polypeptide composition are dependent on the neuronal subtype and stage of development. CaM Kinase II isoenzymes are also present in non-neuronal tissues. These observations led to the study of DNA-protein interactions which may regulate the expression of the α-subunit of the enzyme. Three restriction fragments were isolated from the 5'-noncoding region of the α-subunit gene. Fragment A (170 bp) contained the transcription initiation site; fragment B (120 bp) included GGGCG and TATATAA sequences 76 and 160 bp upstream from the mRNA start site; and fragment C extended 106 bp further upstream. Only "B" appeared to bind specifically to nuclear protein when assayed by the gel mobility shift method. Protein extracts from purified nuclei obtained from rat brains at different ages (E16, newborn, 2-week old and adult) resulted in similar DNA-protein complexes. Likewise, nuclear extracts from the cerebellum and forebrain yielded similar mobility shifts. Nuclear extracts from rat liver, kidney and spleen produced tissue-specific electrophoretic mobility shifts of fragment B. These results indicate that fragment B may bind to different nuclear proteins from different tissues.

336.11

EXPRESSION OF THE CALCIUM CALMODULIN PROTEIN KINASE II GENE AND THE YEAST ADENYLATE CYCLASE GENE IN NEURONS FROM HSV-1 VECTORS. A. I. Geller and R. L. Neve. Dana Farber Cancer Institute and Childrens Hospital, Boston, MA. 02115.

To study second messenger physiology, in vivo, we are using defective HSV-1 vectors (Science 241, 1667, 1988) to express, in neurons, altered second messenger enzymes which should not be regulated, instead they should always be active. The increased activity resulting from a second messenger enzyme which is always active may allow us to determine its role in such processes as neurotransmitter release, regulation of voltage gated ion channel activity, and long term potentiation. Specifically, expression of a segment of the calcium calmodulin protein kinase II gene or the yeast adenylate cyclase gene encoding the catalytic domain of each enzyme should result in enzymes which are always active. Previous work supports our approach: Calcium calmodulin protein kinase II protein is composed of a domain structure in which the calcium-calmodulin binding domain and the catalytic domain are located on distinct segments of the polypepetide; following limited proteolysis the catalytic domain of calcium calmodulin protein kinase II is equally active in the absence or presence of calcium. Similarly, the yeast adenylate cyclase protein is composed of a domain structure in which the regulatory and catalytic domains are located on distinct segments of the polypeptide; expression of the catalytic domain in yeast results in a ten fold increase in the concentration of cAMP. We are now studying virus stocks of HSV-1 vectors which may express the catalytic domain of the calcium calmodulin protein kinase II gene or the yeast adenylate cyclase gene. Expression of a calcium calmodulin protein kinase II which is always active may permit us to determine its role in neurotransmitter release. Elevation of cAMP levels might activate the cAMP dependent protein kinase, perhaps revealing its role in regulating the activity of the voltage gated sodium channel. HSV-1 vectors expressing catalytic fragments of second messenger enzymes may prove to be a useful tool to modify neuronal physiology in the adult brain.

CYCLIC AMP AND CA/CALMODULIN STIMULATED PROTEIN PHOSPHORYLATION IN RAT CEREBELLUM, STRIATUM AND HIPPOCAMPUS. J.W. Kasckow, S.T. Cain and C.B. Nemeroff. Dept. of Psychiatry, Duke Univ. Med. Ctr., Durham, NC 27710.

We analyzed cAMP and Ca/calmodulin-dependent protein phosphorylation in various brain regions. Male, Sprague-Dawley rats were decapitated and the caudate, hippocampus and cerebellum rapidly dissected and homogenized. S_2 and P_2 fractions were obtained by centrifugation. Samples were phosphorylated for 60 seconds with 10 μM ATP in the presence of $CaCl_2$/calmodulin, cAMP or vehicle. Phosphorylated proteins were separated on 11% polyacrylamide gels. Autoradiograms of the dried gels were scanned and phosphate incorporation quantified using microdensitometry. In cerebellum, only the S_2 fraction showed marked stimulation of cAMP-stimulated protein phosphorylation. Furthermore, in the cerebellar P_2, but not S_2, we observed the cAMP-independent phosphorylation of 45 kDa, 43 kDa and 30 kDa proteins. In cerebellum, in contrast to hippocampus and caudate, the phosphorylated form of the β subunit (64 kDa) was enriched relative to the α subunit (53 kDa). In caudate, but not in hippocampus or cerebellum, two proteins of molecular weights 38 kDa and 25 kDa showed cAMP enhanced phosphorylation. Supported by NARSAD and MH-39415.

G_s ACTIVATION OF SYNAPSIN PHOSPHORYLATION IN NEOSTRIATAL AXON TERMINALS. N. Aronin and K. Chase* Dept. of Medicine, Univ. of Mass. Med. Sch., Worcester, MA 01655

Previous studies in this laboratory showed in neostriatal axon terminals that adenylate cyclase activity was coupled to the signal transducing protein, G_s. Here we examined whether G_s is located in axon terminals of intrinsic neurons in the neostriatum and whether G_s activation of adenylate cyclase is sufficient for synapsin phosphorylation. First, quinolinic acid (40 μg in 1 μl), which destroys intrinsic neurons but not afferent fibers, or vehicle (1 μl) was injected into neostriatum (n=24 rats) and G_s was measured in neostriatal synaptosomes by cholera toxin-induced ^{32}P-NAD ribosylation after protein separation on SDS-PAGE. Quinolinic acid produced a 50% decrease in G_s in neostriatal synaptosomes compared to vehicle treated tissues. Substance P, a peptide found only in intrinsic neurons of the neostriatum, was markedly reduced in the synaptosomes of quinolinic acid treated animals. Second, synaptosomes were treated with an activator of G_s, 10mM NaF. After back-phosphorylation of acid-extracted synapsin, the 10k cAMP-dependent fragment of synapsin was identified by limited proteolysis on SDS-PAGE. A two-fold increase in cAMP-dependent synapsin phosphorylation was found.

Adenylate cyclase in the neostriatum and cortex can be regulated by several signaling mechanisms (i.e., voltage-dependent activation, Ca^{++}/calmodulin) in addition to G_s. These studies suggest that in axon terminals of neostriatal neurons, G_s activation is sufficient to produce phosphorylation of synapsin. Since there is no evidence for synaptic inputs onto axon terminals of neostriatal neurons, these findings provide additional support for non-synaptic, receptor mediated, presynaptic regulation of neostriatal neurons. Supported by the NSF and the Joseph Healy Foundation.

OPIOID-INHIBITED PROTEIN PHOSPHORYLATION IN BRAIN MEMBRANES FROM NORMAL AND MORPHINE-DEPENDENT RATS. L. M. Fleming and S. R. Childers. Dept. Pharmacology, Univ. Florida Coll. Med., Gainesville, FL 32610.

Previous studies have shown that opioid-inhibited adenylate cyclase (AC) decreased membrane protein phosphorylation by cAMP-dependent protein kinase when membranes were incubated with opioid agonists in the presence of the AC substrate App(NH)p before addition of 32P-ATP. In rat striatal membranes, we detected two such phosphoproteins (MW 63 kDa and 85 kDa) whose forskolin-stimulated phosphorylation (in the presence of App(NH)p) was inhibited by 20-25% by opioid agonists. This inhibition was naloxone-reversible, and required both sodium and GTP. Inhibition by D-ala enk was maximal in striatum; inhibition was also seen in frontal cortex but not in cerebellum. In thalamus, where mu receptors are highest, inhibition of forskolin-stimulated protein phosphorylation by DAGO was observed. Two dimensional electrophoresis (NEPHGE & SDS-PAGE) confirmed that opioid agonists inhibited forskolin-stimulated phosphorylation of at least two bands; the 63 kDa band had a relative pI of 6.0 while the 85 kDa doublet had a highly basic pI at approx. 9.0. While the identity of the 63 kDa band remains unknown, the 85 kDa doublet is thought to be synapsin, since its molecular weight and pI correspond to reported values of synapsin. To determine the effect of chronic morphine treatment on opioid-inhibited protein phosphorylation, rats were implanted s.c. with morphine pellets (75 mg; 1/day) for 1-7 days. In membranes from thalamus, phosphorylation of both 63 kDa and 85 kDa bands was increased by chronic morphine treatment. Chronic morphine treatment increased App(NH)p-stimulated phosphorylation by 160%, while increasing forskolin+App(NH)p-stimulated phosphorylation by 180%. Morphine treatment did not change phosphorylation of bands not stimulated by forskolin. The increase in App(NH)p and forskolin stimulation was observed relatively early in the chronic morphine treatment (after 2-3 days), but was not observed in membranes from rats injected acutely with morphine (10 mg/kg). These results suggest that a molecular mechanism of tolerance may involve two principal proteins (63 kDa and 85 kDa) of opioid-inhibited AC in brain membranes.

336.15

PHOSPHORYLATION OF DARPP-32 AND PROTEIN PHOSPHATASE INHIBITOR-1 IN RAT CHOROID PLEXUS. G.L. Snyder, J.-A. Girault*+, J. Chen*, J. Kebabian, and P. Greengard+. Abbott Labs, Abbott Park, IL 60064 and +The Rockefeller University, New York, NY 10021.

DARPP-32 and inhibitor-1 are two related proteins which become potent inhibitors of protein phosphatase-1 upon phosphorylation by cAMP-dependent protein kinase. DARPP-32, but not inhibitor-1, is enriched in dopamine-innervated cells possessing the D1 dopamine receptor. We have examined the regulation of the phosphorylation of DARPP-32 and inhibitor-1 by agents which raise cAMP levels in choroid plexus, a tissue containing high levels of both proteins. Rat choroid plexus were incubated in warm, oxygenated RPMI medium with or without drugs for 15 min. Proteins were acid-extracted, separated by SDS-PAGE and transferred to nitrocellulose. The levels of the phosphorylated forms of DARPP-32 and inhibitor-1 were determined by immunoblotting with a monoclonal antibody specific for the phosphorylated forms of DARPP-32 and inhibitor-1. This antibody was prepared against a phospho-peptide encompassing a sequence surrounding the cAMP-dependent phosphorylation site shared by DARPP-32 and inhibitor-1. Forskolin (10uM) and isoproterenol (10uM) increased the levels of two immunoreactive bands of Mr 29,000 and 36,000, which were identified as inhibitor-1 and DARPP-32, respectively, using antibodies specific for each of these proteins. The phosphorylation state-specific monoclonal antibody should provide a useful tool for the study of the regulation of the phosphorylation of DARPP-32 and Inhibitor-1.

336.16

PHOSPHORYLATION OF DARPP-32 BY CASEIN KINASE II Jean-Antoine Girault, Hugh C. Hemmings Jr., Kenneth R. Williams*+, Angus C. Nairn, and Paul Greengard. Lab. of Molecular & Cellular Neuroscience, The Rockefeller University, New York NY and *Dept. of Mol. Biophysics & Biochemistry, Yale University, New Haven CT.

DARPP-32 is a dopamine- and cAMP-regulated phosphoprotein (Mr=32,000) enriched in dopaminoceptive neurons that possess the D1 dopamine receptor. DARPP-32, when it is phosphorylated by cAMP-dependent protein kinase on a threonine residue, is a potent inhibitor of protein phosphatase-1. In rat striatal slices labeled with [^{32}P]-phosphate, DARPP-32 was also phosphorylated on serine under basal conditions. The protein kinase responsible for this phosphorylation has been identified as casein kinase II. Purified DARPP-32 was a good substrate for purified casein kinase II (stoichiometry>2mol phosphate/mol protein, apparent K_m=3.4 μM, k_{cat}=0.32 sec^{-1}). The main residues phosphorylated in vitro were Ser_{45} and Ser_{102}. The k_{cat} of phosphorylation of Ser_{102} was 5-fold higher than that of Ser_{45}. The residue phosphorylated in striatal slices was identified as Ser_{102}. Phosphorylation of DARPP-32 by casein kinase II did not affect its ability to inhibit protein phosphatase-1 which depended only on phosphorylation by cAMP-dependent protein kinase. Phosphorylation of DARPP-32 by casein kinase II facilitated its phosphorylation by cAMP-dependent protein kinase with a 2.2-fold increase in the V_{max}. DARPP-32 phosphorylated by casein kinase II was dephosphorylated by protein phosphatase-1 and -2A. This dephosphorylation was inhibited by the concomitant phosphorylation of the cAMP site. In conclusion phosphorylation of DARPP-32 by casein kinase II and cAMP-dependent protein kinase exhibit positive interactions in vitro. Phosphorylation of DARPP-32 by casein kinase II in intact cells may regulate the responsiveness of DARPP-32 to cAMP-dependent protein kinase and therefore to dopamine. Supported by USPHS MH40899.

REGULATION OF THE PHOSPHORYLATION OF DARPP-32 BY CASEIN KINASE II. Stevin H. Zorn, Jean-Antoine Girault, and Paul Greengard, Lab. of Molecular and Cellular Neuroscience, The Rockefeller University, 1230 York Ave., New York, NY 10021.

DARPP-32 is a dopamine- and cAMP- regulated phosphoprotein (Mr 32,000) enriched in dopaminoceptive neurons possessing D_1 receptors. It is phosphorylated on threonine by cAMP-dependent protein kinase and on serine by casein kinase II (CKII) (Girault et al., accompanying abstract). We assessed the activity of CKII in brain during development and found it to be high as early as embryonic day 16. This activity persisted throughout development. We also studied the regulation of CKII by hormones and neurotransmitter agents in rat brain striatal slices. Kinase activity was measured directly in extracts from slices by employing a specific peptide substrate. The state of serine phosphorylation of DARPP-32 immunoprecipitated from striatal slices prelabelled with [^{32}P]-orthophosphate was also evaluated. A small but significant increase in the activity of CKII was observed in extracts of striatal slices exposed to insulin (100nM) compared to vehicle-treated slices. Insulin also enhanced the phosphorylation of DARPP-32 on seryl residues in prelabelled striatal slices. These data suggest that the phosphorylation of DARPP-32 by CKII in intact striatal cells may be regulated by insulin. (Supported by USPHS MH40899)

REGULATION OF PROTEIN TYROSINE PHOSPHORYLATION IN RAT LOCUS COERULEUS BY CHRONIC ANTIDEPRESSANTS. J. Mattessich* and E.J. Nestler (SPON: J.F. Tallman). Lab. of Mol. Psych., Depts. of Psych. and Pharmacol., Yale Univ. Sch. of Med., New Haven, CT 06508.

We have shown previously that chronic glucocorticoids increase protein tyrosine kinase activity and levels of immunoreactivity of c-src, a well-characterized protein tyrosine kinase, in specific regions of rat brain, including locus coeruleus (LC) (Mol. Pharmacol. 35: 265). In an attempt to gain further understanding of the regulation and functional role of protein tyrosine phosphorylation in LC, other psychotropic drugs with known physiological effects on LC neurons were studied.

Immunoblot analysis revealed that chronic administration of imipramine (IMI) or electroconvulsant treatments (ECT) to rats increased c-src levels in LC by 30-50% compared to controls. In contrast, chronic valium and haldol treatments produced no effect on c-src in this brain region. IMI regulation of c-src displayed regional specificity: no change was detected in hippocampus or dorsal raphe. Consistent with the rise in c-src in LC with chronic IMI, levels of some tyrosine-phosphorylated proteins were also increased in this area as studied by immunoblot experiments with an anti-phosphotyrosine antibody.

Future experiments will determine whether regulation of protein tyrosine phosphorylation is shared by other classes of antidepressant drugs or by other types of psychotherapeutic agents known to alter LC function. These investigations will help elucidate the role that protein tyrosine phosphorylation plays in mediating chronic psychotropic drug action in brain.

336.19

TYROSINE PHOSPHORYLATION OF A 40-KD PROTEIN IN HIPPOCAMPUS: RAPID AND TRANSIENT INCREASE INDUCED BY SEIZURES. K.R. Stratton, P.F. Worley, R.L. Huganir, J.M. Baraban. Dept. of Neuroscience, Johns Hopkins University School of Medicine, Baltimore, MD 21205.

Although tyrosine kinase activity is particularly abundant in brain, little is known about regulation of this intracellular signalling pathway. In recent studies using the hippocampal slice preparation, we have identified a soluble 40-kD protein that exhibits increased tyrosine phosphorylation after exposure of intact slices to muscarinic agonists or phorbol esters that activate protein kinase C (Proc. Natl. Acad. Sci. USA 86:2498, 1989).

To determine whether increased tyrosine phosphorylation of this protein also occurs in vivo, we have used anti-phosphotyrosine antibodies to assay levels of tyrosine phosphorylation in brain homogenates after seizure activity. After maximal electroconvulsive shock (MES) treatment, there is a selective increase in tyrosine phosphorylation of the 40-kD protein. The increase is maximal by 1 min after MES and returns to basal levels by 8 min. This phosphotyrosine containing protein is present in higher levels in hippocampus than cortex and not detected in cerebellum or brain stem. These studies demonstrate that tyrosine phosphorylation of this 40-kD protein is also rapidly regulated in vivo.

PEPTIDES: ANATOMICAL LOCALIZATION IV

337.1

DISTRIBUTION OF INHIBIN SUBUNIT mRNA and IMMUNOREACTIVITY IN THE RAT BRAIN. V.J. Roberts, H. Meunier,* W. Vale and P.E. Sawchenko, The Salk Institute, La Jolla, CA 92037.

Inhibin (α/β_A or α/β_B subunit heterodimers) and activin (β/β dimers) are best known as gonadal glycoprotein hormones, but are also expressed in brain. Regional S1-nuclease analysis and immunohistochemical methods were used to further clarify the central distribution of inhibin/activin subunits. The results may be summarized as follows: 1. mRNA encoding each of the α-, β_A- and β_B-subunits is expressed in all major brain regions examined. The relative abundance of the three mRNA species varies markedly from region to region, with α generally predominating. 2. Antisera that preferentially read the β_A- or β_B-subunit stain cytoplasmically a small population of cells centered in the caudal part of the nucleus of the solitary tract and their axonal projections to the neurosecretory hypothalamus. 3. β_A antisera also stain the nuclei of neurons in several discrete brain regions; β_B antisera stain perikarya in many of the same regions. Cerebellar Purkinje cells, for example display β_A-immunoreactivity (ir) in their nuclei and β_B-ir in their cytoplasm. 4. We have as yet failed to succeed in localizing α-subunit-ir in the CNS. These results suggest that inhibin/activin-related molecules may in some CNS systems play a conventional role in intercellular communication, and in others function intracellularly, the latter consistent with their structural similarity to a larger family of growth and differentiation factors.

337.2

LOCALIZATION OF GTP BINDING PROTEINS $G_{o\alpha}$ AND G_β IN RAT CEREBELLUM. C.T.Lin, W.H.Tsai, L.S.Kao*, K.J.Chang. Institute of Biomedical Sciences, Academia Sinica, Taipei 11529, Taiwan, R.O.C.

The physiological roles of GTP binding regulatory proteins (G_o) are not well established in neurons yet. The purpose of this study was to prepare and characterize polyclonal antibodies against α and β subunits of G_o for the localization study of these G proteins in rat cerebellum in order to provide further information regarding G protein function. For preparation of $G_{o\alpha}$ and G_β antiserum , we used two synthesized peptides Goα (Thr^{262} - Gln - Phe - Glu - Ser - Lys - Asn - Arg - Ser - Pro - Asn - Lys - Glu^{274}) and G_β (Met^1 - Ser - Glu - Leu - Glu - Gln - Leu - Arg - Gln - Glu - Ala - Glu - Gln- Leu^{14}) as antigens. These peptides were attached to a core heptalysine oligomer, each carrying eight copies of these peptide fragments (octopus immunogen) as previously described (K.J.Chang et al. Proc, Nat'l. acad. Sci. USA, 85:4929,1988). Each octopus immunogen was then used to immunize rabbits by conventional method. The antisera were checked at first by dot blot method. After purification of monospecific antibodies by peptide-gel affinity chromatography, the antibodies were used to stain the crude brain membranes by Western blot analysis which showed a single band of 35 kD for G_β and 39 kD for $G_{o\alpha}$. Finally, the antibodies were used to localize the rat cerebellum which had been fixed by perfusion fixation method using 3% formaldehyde. In the cerebellar cortex, anti-G_β reaction product was seen mainly on the cell membrances of some Purkinje neurons and granule cells, with occasionally in the cytoplasm of a few Purkinje neurons. On the other hand, the anti-$G_{o\alpha}$ reaction product was mainly found in the cytoplasm of some Purkinje cells and their dendritic processes. These findings suggest that only certain Purkinje cells and granule cells contain G protein, and some of them may present on the cell membrane while others in the cytoplasm. 337.3

INTERLEUKIN-2 (IL-2) IN THE RAT BRAIN: RECEPTORS AND IMMUNOREACTIVITY (IR). P.A. Lapchak, D.M. Araujo, J.-G. Chabot, A. Beaudet and R. Quirion. Neuroanat. Lab., Mtl. Neurol. Inst. and McGill Univ., Montreal, Quebec, Canada.

Recent evidence suggests that IL-2 plays a physiological role in the mammalian CNS. In the present studies, the distribution of both IL-2 and specific IL-2 binding sites was examined in rat brain using biochemical, immunohistochemical and autoradiographic techniques. The presence of IL-2 was first demonstrated in homogenates from hippocampus, neostriatum and cerebral cortex by RIA (0.7, 0.65, 0.15 ng/mg tissue, respectively). Immunoautoradiography using a primary polyclonal antibody against IL-2 confirmed the presence of IL-2 like material in the hippocampus and dentate gyrus. ^{125}I-IL-2 was then shown to bind specifically with limited capacity and with high affinity to hippocampal (Bmax=0.48 ± 0.08 fmol/mg protein, Kd=25 ± 6 pM), but not neostriatal or cortical homogenates. Quantitative autoradiographic analysis of ^{125}I-IL-2 binding revealed specific labeling in hippocampus, external plexiform layer of the olfactory bulb, cerebellum, corpus callosum, stria terminalis, commissura anterior pars posterior; very low, but diffuse binding was also detected in cerebral cortex and neostriatum. In summary, our results demonstrate that IL-2 and IL-2 receptors are present in specific regions of the rat brain, where they may be involved in the regulation of neuronal function. 337.4

IMMUNOHISTOCHEMICAL LOCALIZATION OF DIABETES-ASSOCIATED PEPTIDE IN PORCINE PANCREATIC ISLETS. Y.N. Wang, D. Chang* and J. K. Chang*. Peninsula Laboratories, Inc., Belmont, CA 94002.

Amyloid deposits in the islets of Langerhans of the pancreas are a common finding in noninsulin-dependent diabetes. Recently, a novel 37 amino acid peptide, diabetes-associated peptide (DAP), has been identified in amyloid-containing pancreatic extracts from diabetic patients (A. Clark et al., *The Lancet ii*:231, 1987). It may be possible that DAP is a factor leading to the pathologic abnormalities in noninsulin-dependent diabetes. In this study, we demonstrate that DAP is abundantly located in B-cells of the porcine pancreatic islets by immunohistochemistry. The porcine pancreases were fixed in 4% paraformaldehyde solution and sectioned at 15 μm on a cryostat. Tissue sections were processed for immunohistochemistry by the indirect immunofluorescence method. The DAP antiserum was used at a dilution of 1:200. The secondary antiserum was goat anti-rabbit-FITC at a dilution of 1:60. Specificity was assessed by incubating tissue sections with the antiserum preabsorbed with 10 μM synthetic DAP. Immunoreactive DAP-containing cells were found only in the islets, not in other areas of the porcine pancreas. In the islets, immunoreactive DAP-containing cells were large, polyglonal and heavily stained. Absorption control showed that no crossreaction of DAP antiserum with human CGRP or rat CGRP was observed. The results suggest that DAP is located in islet B-cells of the porcine pancreas and may co-exist with insulin and CGRP in the B-cells. DAP may play an important role in pancreatic endocrine functions.

337.5

INTRACEREBROVENTRICULAR BOMBESIN ADMINISTRATION LEADS TO INCREASED GLUCOSE UTILIZATION IN THE RAT ANTEROVENTRAL THALAMIC NUCLEUS. B.W. Bates*, Z. Merali and P. Ramm. Dept. of Psychology, Brock University, St. Catherines, Ont. L2S 3A1.

The tetradecapeptide bombesin elicits stereotyped grooming behavior in the rat. Mechanisms which have been proposed for this effect include activation of cholinergic and/or dopaminergic receptor systems, particularly those originating in the lower brainstem (Johnston & Merali, *Peptides* 9:245, 1988). We have used ^{14}C2-deoxyglucose (^{14}C2-DG) autoradiography to map local cerebral glucose utilization (LCGU) in an attempt to localize sites at which bombesin exerts its effects.

Rats were prepared with chronic cannulae in the femoral artery and vein. Three days later, the freely moving animals received 0.4 ug bombesin in 5 μl saline into the third ventricle, or vehicle alone. The brains were then processed in the normal fashion for the fully quantitative ^{14}C2-DG method. Rates of glucose utilization were read by computerized densitometry.

The most striking effect was an obvious, consistent, and localized elevation of metabolic activity in the anteroventral thalamic nucleus, ventrolateral aspect. This region stains heavily for AChE and may contain bombesin receptors (Wolf & Moody, *Peptides*, 6:111, 1985). It receives input from the pallidum and projects to frontal premotor cortex. It is included in thalamic regions involved in the integration of motor initiation and control, and may be a component of a functional circuit mediating the behavioral effects of bombesin.

337.6

BRAINSTEM PROJECTIONS TO MEDIAL THALAMIC NUCLEI SUBSERVING ANALGESIA. L.J. Sim and S.A. Joseph. Neuroendocrine Unit, University of Rochester, Rochester, N.Y. 14642

The involvement of medial thalamic nuclei in nociceptive modulation has been demonstrated in numerous lesion and stimulation studies. Medial thalamic stimulation relieves a variety of pain syndromes in the human. The integration of the medial thalamus and brainstem nociceptive regions were investigated in this study. We neuroanatomically identified the origin and neurochemical nature of brainstem inputs to parafasicular (PF) and centromedial (CM) nuclei in the rat. Wheat germ agglutinin-horseradish peroxidase (WGA/HRP) was stereotaxically injected into either CM or PF. After 48 hours, rats were perfused or administered intraventricular colchicine. Colchicine treated rats were sacrificed 24 hours later. WGA was visualized immunocytochemically with nickel enhancement. Appropriate sections were then routinely stained for appropriate neuropeptides or transmitters. Both CM and PF injections resulted in labeled cells throughout the raphe complex, with the densest labeling in dorsal raphe nucleus (DRN), median (MnR) and paramedian raphe nuclei and nucleus raphe magnus (NRM). Retrogradely labeled neurons were also identified in locus coeruleus (LC), ventrolateral periaqueductal gray (PAG) and lateral and posterior dorsal tegmental nuclei after both injections. CM injections also produced labeled neurons in ventral tegmental area and interpeduncular nucleus and PF injections in pontine reticular nuclei, nucleus reticularis paragigantocellularis and spinal nucleus V. Our double label studies demonstrated that the majority of cells projecting to CM and PF from DRN, MnR, PAG and LC are peptidergic and a small percentage contain either serotonin or norepinephrine. These results demonstrate anatomical connectivity between medial thalamic nuclei and brainstem nuclei of the descending pain pathway and are consistent with a role for CM and PF in pain and analgesia. 337.7

LOCALIZATION OF NEUROPEPTIDES TO TARGET-SPECIFIC SUPERIOR CERVICAL GANGLION NEURONS. J.I. Luebke and L.L. Wright. Dept. Anatomy, Boston Univ. Sch. Med., Boston, MA 02118.

There is evidence for an organizational system in the peripheral sympathetic nervous system in which populations of neurons projecting to different targets differ in their neuropeptide content. The present studies were initiated to determine whether such a system of chemical coding exists in superior cervical ganglion (SCG) neurons which project to three functionally diverse targets: the pineal gland, the submandibular gland (SMG) and the anterior chamber of the eye (eye). Adult male rats (220-300g) were anesthetized and injected with a 2% solution of fluorogold (FG) in: 1) the pineal gland (0.5 ul), 2) bilaterally in the SMG (5ul), or 3) bilaterally in the eye (5ul). Following the appropriate survival periods, the animals were perfused with paraformaldehyde and SCGs were removed. Frozen sections were serially mounted onto slides and subsequently processed for immunoreactivity (IR) to either neuropeptide Y (NPY), somatostatin (SS), or vasoactive intestinal peptide (VIP) using Vector's ABC-G.O. system. Sections incubated in the absence of either primary or secondary antisera showed no IR. Sections were examined for cells labelled with FG and displaying IR to one of the three peptides. Preliminary data show differences in the expression of NPY and VIP but not SS in populations of neurons projecting to the pineal, the SMG and the eye. The percentages of target-specific neurons IR for each peptide are given below:

	NPY (s.e.)	VIP (s.e.)	SS (s.e.)
Pineal gland (n=4):	23 (2.5)	7 (1.5)	23 (2.8)
SMG (n=2):	23 (4.1)	24 (1.3)	20 (2.3)
Anterior Eye (n=2):	36 (3.1)	14 (3.7)	26 (5.3)

MESSENGER RNAs FOR NEUROPEPTIDES IN PETROSAL GANGLION. *M.F. Czyzyk-Krzeska*, K.B. Seroogy, D.A. Bayliss, N. Mohopatra* and D.E. Millhorn. Department of Physiology, University of North Carolina, Chapel Hill, N.C. 27599.*

We examined petrosal ganglia of the rat using *in situ* hybridization histochemistry to determine the existence of messenger RNAs for neuropeptides [preprotachykinin A (PPT-A), calcitonin gene-related peptide (CGRP), somatostatin, neuropeptide Y (NPY) and cholecystokinin (CCK)] in individual cells. A population of neurons which innervate the carotid body and carotid sinus was retrogradely labeled by perfusing the carotid bifurcation with Fast Blue dye. In another series of experiments the carotid sinus nerve was cut 7 days prior to study. Hybridization was performed with [^{35}P] labeled synthetic oligonucleotides applied to 10 μm thick tissue sections. After hybridization the tissue was processed for film and emulsion autoradiography. We determined that neurons in petrosal ganglia contain mRNAs for PPT-A, CGRP, somatostatin and NPY. There is no evidence for CCK mRNA. The mRNAs for all neuropeptides except somatostatin were present in somata retrogradely labeled with dye from carotid sinus. Somatostatin was found only in the non-labeled cells, which presumably do not project to carotid sinus structures. The number of cells expressing PPT-A and CGRP was decreased following transection of the carotid sinus nerve.

337.9

PEPTIDERGIC INNERVATION OF THE KIDNEY IN THE MONKEYS, *MACACA FASCICULARIS*, *MACACA MULATTA*, AND IN MAN. J. E. Norvell, Department of Anatomy, Cell Biology and Neuroscience, Oral Roberts University, Tulsa, OK 74171.

Nerve fibers immunoreactive for neuropeptide Y (NPY), vasoactive intestinal polypeptide (VIP), and substance P (SP) are demonstrated for the first time by the indirect immunofluorescence technique in monkey and human kidneys. NPY-like immunoactivity (NPY-LI) was seen in nerve fibers in the connective tissue of arteries and to a lesser extent, veins. Varicose fibers were seen leaving blood vessels and passing between tubules in the inner cortex, or between blood vessels and tubules. These fibers are also seen surrounding afferent and occasionally efferent arterioles associated with glomeruli. VIP-LI nerve fibers, although fewer in numbers, have a similar distribution to NPY-LI fibers. SP-LI was observed as varicose nerve terminals in the adventitia of blood vessels as well as running between tubules of the cortex. This study shows that NPY-LI, VIP-LI and SP-LI nerve fibers have similar distributions in the primate kidney as those reported in other species.

337.10

LAMINAR DISTRIBUTION OF NEUROTRANSMITTERS IN CONVEXITY NEOCORTEX OF DOLPHINS. I.I. Glezer, P.J. Morgane and C. Leranth. Dept. of Cell Biol. and Anatomy of CUNY Med. SCH., New York, NY 10031, Worcester Found. for Exp. Biol., Shrewsbury, MA 01545, Yale Univ. Sch. of Medicine, New Haven, CT 06510.

Immunocytochemical methods were used for light and electron microscopic analysis of transmitter localization in neuronal perikarya and synapses in different layers of visual neocortex of several species of toothed whales. Neuropeptide Y (NPY) is localized in non-pyramidal neurons of variable shapes which are concentrated mostly in layers II, IIIa and VI. Almost all NPY synapses are of en passage type and diffusely dispersed in all cortical layers with a significant concentration occuring in varicose axons running tangentially in the upper third of layer I. Neurons with cholecystokinin (CCK) are localized mainly in layers I,II and VI and belong to the bipolar/fusiform types. Tyrosine-hydroxylase (TH) is found only in tangential axons running for long distances in lower part of layer I. These findings support our views and concepts on the importance of layers I and II as the major input laminae of the whale convexity cortex. 337.11

SPECIFIC LOCATION OF NEURONS EXHIBITING MOLLUSCAN, SMALL CARDIOACTIVE PEPTIDE (SCP)-LIKE IMMUNOREACTIVITY IN LARVAE OF TRITONIA DIOMEDEA. S.C.KEMPF. Dept. of Zoology and Wildlife Science, Auburn University, AL 36849

Previous investigation (Kempf, Masinovsky, Willows. 1987. J. Neurobiol. 18:217-236) established the presence of neurons in larval T. diomedea labeled by a monoclonal antibody binding molluscan SCPs. Labeling occurred in a single axon in the cerebral commissure and small cells (presumably neurons) in each cerebral ganglion (CG) in the late embryo. During the larval stage 2 pairs of neurons with axons extending to their respective CG became antigenic. Examination of labeled wholemounts, suggested that the pair of neurons with axons extending to the left CG were located in or near the visceral ganglion and the other pair, on the right, outside the central nervous system, near the mantle edge and adjacent to the anus. This investigation establishes these as the actual locations of the neurons using serial sections of whole larvae labeled with a peroxidase marker prior to embedding. In addition, fluorescent markers elicited a third neuron, not observed in the previous study, that is present on both the left and right sides of the larva and has an axon extending to its respective CG.

337.12

IMMUNOCYTOCHEMICAL STUDY OF THE RAT SUPRATENTORIAL DURA MATER. J.T. Keller, C.F. Marfurt, and M.J. Fritts*. Dept. of Neurosurgery and Anatomy/Cell Biology, Univ. of Cincinnati, James N. Gamble Inst. of Med. Res., and The Christ Hospital, Cincinnati, OH 45219; Dept. of Anatomy, Indiana Univ. Sch. of Med., Northwest Ctr. for Med. Ed., Gary, IN 46408.

Because of the recent association of trigeminal dural fibers, neurogenic inflammation, and vascular headache we chose to immunocytochemically examine the neural elements of the rat supratentorial dura mater for the presence and distribution of substance P (SP), calcitonin gene related peptide (CGRP), dopamine-B-hydroxylase (DBH), neuropeptide Y (NPY) and vasoactive intestinal polypeptide (VIP). The supratentorial dura of 30 male Sprague Dawley rats was examined for SP (1:500), VIP (1:700), DBH (1:600), NPY (1:400), CGRP (1:2000). Trigeminovascular (SP, CGRP), sympathetic (DBH, NPY) and parasympathetic (VIP) fiber patterns were identified in association with the middle meningeal artery (MMA) and its branches, and on the superior sagittal sinus (SSS). In addition, a third pattern of fibers coursed obliquely over the dural convexity from the transverse sinus, caudal and inferior, to the SSS, rostral and superior. CGRP, SP, and VIP were found to be more loosely associated with the vasculature than the DBH and NPY positive fibers. In all cases, the SSS was more densely innervated than the convexities. The density of VIP fibers was less than that of other fibers examined. The functional interaction of these elements and the prominent mast cell population previously identified (Keller et al., Neuroscience Abst. 14:972, 1988) warrants further consideration regarding their role in the pathogenesis of headache. (Supported by NIH grant NS 22969)

337.13

GABAERGIC INNERVATION IN CEREBRAL ARTERIES. T. OKUNO and T. J-F. LEE. Dept. of Pharmacology Southern IL Univ. School of Medicine, Springfield, IL 62794-9230. (SPON: K. Sherman)

Our recent studies have demonstrated that cerebral blood vessels receive dense GABAergic innervation (Lee et al., 1989). It has been suggested that neuronal GABA may act as a modulator altering the release of transmitters from the neighboring nerve terminals. The origin and distribution of GABAergic innervation, and its morphological relationship with other autonomic innervations in cerebral arteries therefore were examined using sequential double-labelling immunocytochemical techniques. Results indicate that the distribution pattern of glutamic acid decarboxylase-immunoreactive (GAD-I) fibers is similar to that of GABA-transaminase immunoreactive (GABA-T-I) fibers but is different from those of tyrosine hydroxylase (TH)-I and choline acetyltransferase (ChAT)-I nerve fibers. Some GAD-I fibers, however, were found to overlap with ChAT-I and TH-I fibers. These results demonstrate that GAD-I fibers are distinctive fibers. The close relationships among GAD-I, ChAT-I and TH-I fibers, however, suggest that a functional interaction may occur between GABAergic and other autonomic innervations. Furthermore, GAD- and GABA-T-immunoreactivities were found in the ciliary ganglion cells suggesting that some GABAergic fibers to cerebral blood vessels may originate from the ciliary ganglion. (Supported by NIH HL27763, AHA/IHA and Southern IL Univ. School of Medicine)

337.14

VIP- AND ChAT-IMMUNOREACTIVE FIBERS ARE DISTINCTIVE FIBERS IN CEREBRAL ARTERIES OF THE CAT. F. J-P. Miao*and T. J-F.Lee. Dept. of Pharmacology, Southern Illinois University School of Medicine, P.O. Box 19230, Springfield, Il 62794.

The question as to whether or not vasoactive intestinal polypeptide (VIP) is localized in cholinergic nerves in cerebral arteries has not been clarified. A sequential double-labelling immunohistochemical technique using avidin-biotin complex (ABC) method was therefore employed to examine the possible co-localization of choline acetyltransferase (ChAT) and VIP in nerve fibers innervating the cat cerebral arteries. Isolated arteries were fixed by immersion in buffered periodate-paraformaldehyde-picric acid-lysine-formaldehyde (PPPLF) solution. Diaminobenzidine (DAB) and tetramethylbenzidine (TMB) were used as chromogens to distinguish ChAT and VIP immunoreactivities. Both ChAT-I and VIP-I fibers in cerebral arteries appeared as bundle and fine fibers. Most CHAT-I and VIP-I fibers were independent fibers. ChAT-I and VIP-I fibers, however, were often found to overlap. Overlaying of VIP-I fibers on ChAT-I fibers and relay connections between them were also observed. Only in less than 5% of the fibers examined, did ChAT- and VIP-immunoreactivities appear to be co-localized. These results suggest that acetylcholine and VIP are not co-localized in most neurons innervating cerebral arteries. The intimate relationships between VIP-I and ChAT-I fibers, however, suggests a functional interaction between these two distinctive innervations. (Supported by NIH HL 27763, 24683, and SIU School of Medicine)

338.1

COMPENSATORY ACTIVATION OF SUBSTANCE P BIOSYNTHESIS BY L-DOPA IN STRIATONIGRAL NEURONS OF DOPAMINERGIC DENERVATED RATS. S. P. Sivam and J. E. Krause. Dept. Pharmacol. & Toxicol., Northwest Ctr. Med. Ed., Indiana Univ. Sch. Med., Gary, IN 46408 and Dept. Anat. & Neurobiol., Washington Univ. Sch. Med., St. Louis, MO 63110.

Previous studies showed that L-DOPA treatment to neonatal 6-hydroxydopamine (6-OHDA) lesioned rats led to a marked decrease in the levels of striatonigral substance P (SP), which was linked to a D1 dopamine receptor mediated mechanism. The present study examined the hypothesis that there is a compensatory activation of SP biosynthesis in order to replenish the L-DOPA induced SP depletion. Three-day old Sprague-Dawley rat pups were lesioned with 6-OHDA and were challenged with L-DOPA at about 60 days of age. Animals were killed 80 min, 6 h or 24 h following L-DOPA treatment. L-DOPA treatment (80 min group) produced a greater decrease in SP levels in the striatum and substantia nigra than that observed with lesion alone. The SP levels recovered to lesioned-control values by 6 h. This recovery was accompanied by a marked increase in striatal preprotachykinin-mRNA at 6 h, and mRNA levels were below lesioned-control levels by 24 h. The results indicate that the L-DOPA induced depletion of SP levels in lesioned rats is replenished by an enhanced biosynthesis of SP. Thus, the integrity of dopamine system is essential for the development and maintenance of striatonigral SP neurons.

CORRELATION OF SUBSTANCE P (SP) AMINO TERMINAL (SP-N) METABOLITES IN VIVO WITH SP-INDUCED DESENSITIZATION IN THE MOUSE SPINAL CORD. O.J. Igwe*, X. Sun*, C. Schamber* and A.A. Larson. Dept. of Vet. Biology, U of Minnesota, St. Paul, MN 55108.

We have previously reported that intrathecal (i.t.) injection of mice with SP or C-terminal fragments of SP results in a behavioral syndrome characterized by reciprocal caudally-directed biting and scratching (CBS). Repeated injection of SP, but not SP C-terminal fragments, results in desensitization (DES) to SP-induced CBS. The major products of SP catabolism are SP N-terminal fragments, which we has shown to be capable of inhibiting SP-induced CBS. We hypothesize that the generation of SP N-terminal metabolites play a role in the development of DES. In this study, peptidase inhibitors- phosphoramidon (PH), bacitracin (BAC) and angiotensin converting enzyme inhibitor (ACEI or SQ20881) - each having distinct effects on the production of SP-N fragments, were used to investigate the accumulation of tritiated SP-N metabolites in vivo during the development of DES to SP using ^{3}H-SP. SP-N metabolites in the spinal cord were quantified by reversed-phase HPLC. The magnitude of SP-induced DES correlates well (r=0.99) with the total SP-N metabolites recovered from the spinal cord in each group. The magnitude of SP-induced DES was also found to be negatively correlated (r=1.00) with total recovered intact ^{3}H-SP. These results, together with our previous studies, indicate that SP-induced DES depends, at least in part, on the concentration of SP N-terminal metabolites in the spinal cord. To determine which enzymes participate in the metaboilism of *endogenous* SP, we examined the effect of these peptidase inhibitors on SP degradation using a synaptic membrane preparation. The order of efficacy for in vivo inhibition of ^{3}H-SP metabolism was PH=BAC>ACEI while that for in vitro synaptic membrane-derived peptidases was BAC>PH>>ACEI. These results suggest that BAC-sensitive endopeptidases may be primarily responsible for SP metabolism in SP synapses of the spinal cord while PH- and ACEI-sensitive enzymes play supporting roles. The rank order of the peptidase inhibitors in attenuating the magnitude of SP-induced DES was BAC~PH<<ACEI. Supported by USPHS grants DA04090, DA04190 and DA00124.

SEGREGATION OF NEURONS EXPRESSING DIFFERENT SPECIES OF PREPROTACHYKININ mRNAs IN THE RAT TRIGEMINAL GANGLION. **Jian-Hua Zhang*, Yasuhiro Morita, Takashi Hironaka*, Shiro Nakagawa*, and Masaya Tohyama*. Dept. of Anatomy, Osaka Univ. Med. Sch., and Kagoshima Univ. Med. Sch., Japan**

The preprotachykinin-A (PPTA) gene encodes substance P (SP) and substance K (SK) and generates 3 different species of mRNAs (α, β and γ) following alternative splicing. α-mRNA contains a sequence coding for SP, while β- and γ-mRNAs contain sequences for SP and SK. Accordingly, the expression of PPTA-gene was studied by in situ hybridization using several synthetic oligonucleotide probes specific to the PPTA-mRNAs.

A concurrence on the basis of the number, distribution, and hybridization density of labeled neurons indicates one population of trigeminal ganglion cells expresses a large number of γ-mRNA and another population expresses a small number of α-mRNA. Density of hybridization signals in the former was ten times higher than that of the latter. Neurons labeled with different probes showed a similar distribution, but the number of γ-mRNA expressing neurons was over 1.5 times more than that of α-mRNA expressing neurons.(SPON: T. Nagai)

Reserpine increases neuropeptide Y precursor gene expression in rat adrenal via transsynaptic control. Hiroshi Higuchi, Atsushi Iwasa* and Hiroshi Yoshida*. Department of Pharmacology I, Osaka University School of Medicine, 4-3-57 Nakanoshima, Kita-ku, Osaka 530, Japan.

Neuropeptide Y (NPY) is an important cotransmitter of catecholaminergic neuron, which regulates blood pressure; central administration of NPY causes hypotension, whereas peripheral administration produces a long-acting pressor response. In order to study whether some antihypertensive drugs may modify the biosynthesis and/or turnover of NPY, the effect of reserpine on NPY and NPY mRNA contents in rat adrenal and brain was studied by NPY radioimmunoassay and quantitative Northern blot analysis. Reserpine (0.5 mg/kg, i.p., 5 days) reduced by 50 % the NPY content in rat adrenal 24 h after the first injection, and then the NPY level recovered gradually so that NPY amount increased conversely 1 week after cessation of reserpine administration. The NPY mRNA level in rat adrenal also increased gradually (obvious in 2 days-treatment), and the increase continued until 2 weeks after cessation of reserpine treatment. In contrast, β-actin mRNA abundance did not change by reserpine treatment. The changes in NPY and NPY mRNA were not observed in rat brain areas. Reserpine-induced increase of NPY mRNA was completely abolished by Splanchnic nerve transection. These findings indicated that reserpine increases NPY precursor gene expression and NPY biosynthesis via trans synaptic control.

338.6

INCREASED LEVELS OF NEUROPEPTIDE-Y mRNA IN LOCUS COERULEUS FOLLOWING RESERPINE TREATMENT. B.J. Wilcox and J.R. Unnerstall. Dept. Neurology and Alzheimer Research Labs, Case Western Reserve Unv. Sch./Med., Cleveland, OH 44106.

Acute treatment of animals with reserpine depletes brain norepinephrine and increases the levels of tyrosine hydroxylase (TH) in locus coeruleus (LC) neurons. Recently, it has also been shown that this treatment increases the relative levels of TH mRNA in LC neurons (Berod *et al.*, *PNAS* 84:1699, 1987). In these experiments, we address the question whether reserpine treatment can also modulate the relative mRNA levels of neuropeptide-Y (NPY) in the LC. Animals were treated with a single subcutaneous injection of reserpine (10 mg/kg) or an equivalent volume of vehicle. Two days following treatment, the animals were sacrificed. A 45 mer anti-sense DNA oligonucleotide directed toward the N-terminal of the coding region of rat NPY mRNA was 3' end-labeled with [^{35}S]dATP and used for *in situ* hybridization histochemistry. In general, the distribution of positively labeled LC neurons agrees well with that seen by immunohistochemistry. A greater grain density was consistently seen over neurons in the dorsal medial portion of the LC when compared to other labeled neurons in both control and reserpine-treated animals. An approximate 50% increase in the average relative grain density per neuron were seen in treated animals when compared to controls. A broadening of the distribution of grains per cell in the treated group was also seen. Greater increases in relative grain densities were seen in sets of neurons in areas where the baseline grain densities were low (e.g. ventral vs. dorsal aspects of the medial LC). These increases in relative NPY mRNA levels in specific subsets of LC neurons may reflect a ceiling effect where neurons with tonic lower levels of NPY activity may be affected to a greater extent by the drug treatment. Conversely, the possibility of specific neural mechanisms affecting individual subsets of peptide-containing neurons cannot be excluded.

EVOLUTIONARY CONSERVATION OF CCK AND NEUROPEPTIDE Y: cDNA CLONES FOR CHICK CCK AND GOLD-FISH NPY. A. Blomqvist* and D. Larhammar. Dept of Medical Genetics, Uppsala University, Box 589, S-751 23 Uppsala, Sweden.

CCK (cholecystokinin) and NPY (neuropeptide Y) are widely distributed and abundant neuropeptides in the central nervous system of all mammals investigated. Both peptides have highly conserved sequences among mammals. CCK-8 is identical in all mammals known. However, its larger forms, CCK-33, -39, and -58, all display several amino acid differences.

We wished to investigate the evolutionary conservation of CCK-8 and its larger forms by comparing the mammalian prepro-CCK sequences with a non-mammalian sequence. If the various forms of CCK turn out to display different degrees of conservation, it will imply that they have functional roles that differ in importance in an evolutionary perspective. We have used a rat CCK cDNA probe to screen a chick brain cDNA library. Several clones were isolated and are in the process of being characterized.

NPY is a 36-amino acid peptide which is virtually identical in all mammals known. We have recently deduced the chick NPY sequence from a cDNA clone and found that it has only one difference as compared to the mammalian sequences. Also the carboxyterminal part of the NPY precursor, CPON (for C-terminal peptide of NPY), is highly conserved between chicken and mammals which suggests that this peptide too may serve as a neurotransmitter.

Our previous findings of strong sequence conservation of NPY between chicken and mammals was complemented by using a rat NPY probe in so-called zoo blots, i.e. Southern hybridizations to genomic DNA isolated from various animal species. The rat NPY probe detected cross-hybridizing bands in a reptile (crocodile), an amphibian (Xenopus laevis), and a bony fish (salmon). We have used a chick cDNA probe to screen a gold-fish retina cDNA library. Several clones were identified and will be sequenced.

THE EFFECTS OF AGING AND NUCLEUS BASALIS LESIONS ON NEUROPEPTIDE Y (NPY) LEVELS AND ITS ENCODING mRNA IN THE RAT BRAIN. J.J.Poulakos[1], W.J.Millard[2], G.W.Arendash[3], & E.M. Meyer[1]. Depts. of Pharmacology[1] & Pharmacodynamics[2], Univ. of FL, Gainesville, FL, & Dept. of Biology[3], Univ. of So. FL, Tampa, FL.

NPY is a 36 amino acid peptide found in the brain. Two conditions known to alter brain NPY levels are aging and prolonged cholinergic hypofunction to the cerebral cortex. The present study characterized brain NPY and prepro NPY mRNA levels in Sprague Dawley (SD) and Fischer 344 rats ranging from 6 to 26 months of age. Additionally, cortical cholinergic hypofunction was induced in rats with bilateral lesions to the nucleus basalis magnocellularis (nBM) with ibotenic acid. NPY levels were measured by RIA and prepro NPY mRNA levels were ascertained by dot blot analyses with a rat cDNA probe provided by Dr.J. Allen. Cortical NPY levels progressively decreased in SD rats of 4, 12, 16 and 24 months of age (250 pg/mg tissue - 4 months of age to 100 pg/mg tissue - 24 months of age). Cortical prepro NPY mRNA levels increased approximately 40% from 6 to 16 months of age in Fischer 344 rats and then progressively decreased at 20 and 24 months of age. In nBM lesioned SD rats NPY levels were unchanged while its encoding mRNA levels decreased slightly 2 months post lesioning. These results suggest that aging and cholinergic transmission may be involved in the regulation of cortical NPY levels.

NEUROPHYSIN EXPRESSION ON CELL MEMBRANE OF A HUMAN LUNG CARCINOMA CELL LINE SUGGESTS ABSENCE OF PROCESSING ENZYME. L.C. Rosenbaum*, G. Nilaver, H.H.M. Van Tol* & E.A. Neuwelt* (SPON: W.R. Woodward) Dept. Neurol., Biochem., Neurosurg., & VIABR, Oregon Hlth Sci. Univ., Portland, OR 97201.

Carcinomas of the lung are sometimes associated with neurophysin (NP) secretion and inappropriate antidiuresis (SIADH) (North et al. Cancer 62:1343, 1988). We have detected NP-reactivity on the surface of human lung carcinoma (LX-1) cells intracerebrally xenografted in nude rats by immunohistochemistry (IHC). Northern analysis and in situ hybridization with a 50 base-pair oligonucleotide probe to the C-terminal region of human pro-pressophysin (PPYsin) demonstrated the expression of PPYsin mRNA in LX-1 tumor xenografts. IHC with NP and vasopressin antibodies, however, revealed no detectable staining in the cytoplasm of LX-1 tumor cells. Similar results were obtained by Western blot analysis of LX-1 cells, suggesting lack of post-translational processing of PPYsin in the cytosol of this cell line. Inability to document SIADH in LX-1 tumor bearing-nude rats implied the tumor to be non-secretory. The accumulation of NP immunoreactivity in the cytoplasm of colchicine-treated LX-1 cultures with reduction of cell membrane staining further suggested the preferential targeting of unprocessed PPYsin to cell membranes in LX-1 tumor cells. All of these findings may be relevant to the lack of SIADH noted with this cell line (supported by PHS grants NIDDKD-37205 & NCI-31770).

338.10

COMPARISON OF BOMBESIN, NEUROMEDIN-C AND NEUROMEDIN-B ON PHOSPHATIDYLINOSITOL TURNOVER IN RAT HYPOTHALAMIC SLICES. M.S. Saporito, R.O. Warwick, Jr., T.J. Shickley and S.K. Murphy*. Philadelphia College of Pharmacy and Science, Department of Pharmacology and Toxicology, and *Department of Biology, Philadelphia, PA. 19104.

Bombesin-like (BN) peptides are biologically active in mammalian CNS. Direct injection into the hypothalamus (HYP) leads to a disruption in thermoregulation and satiety. Although the neuronal mechanisms which mediate these responses remain unclear, BN stimulates phosphatidylinositol (PI) turnover in brain slices. Further, BN, neuromedin-C (NM-C, GRP 10), but not neuromedin-B (NM-B) inhibit K$^+$ evoked release of ^{3}H-serotonin (^{3}H-5-HT) from HYP slices and alter ^{45}Ca influx into HYP synaptosomes. This study compares the effects of BN, NM-C and NM-B on PI turnover with effects of these peptides on ^{3}H-5-HT release and ^{45}Ca uptake.

^{3}H-inositol phosphate (IP_1) accumulation was used as an index of PI turnover. BN and NM-C (1 uM) significantly increased IP, accumulation by 65 and 83%, respectively ($p < 0.05$). NM-B (1 uM) was inactive. These data agree, qualitatively, with reports that BN and NM-C are more active then NM-B in evoking HYP mediated disruptions in thermoregulation and inhibiting ^{3}H-5-HT release from HYP slices. As observed in ^{3}H-5-HT release and ^{45}Ca uptake studies, BN, but not NM-C, activity was abolished by the endopeptidase 24.11 inhibitor phosphoramidon (10 uM). Further, BN and NM-C activities were enhanced (70%) by the peptidyl dipeptidase inhibitor enalaprilat (10 uM). These data indicate that in this HYP slice preparation a) endopeptidase 24.11 generates an active peptide fragment from BN that is similar to NM-C, and; b) peptidyl dipeptidase inactivates BN and NM-C.

This study suggests that IP, accumulation may represent a useful in vitro model for the study of BN-like peptides and strengthens the hypothesis that BN-like peptides function as modulators of neurotransmission in the CNS.

This study was supported by USPHS Grant NS 26007 to ROW.

SUBCELLULAR DISTRIBUTION OF CORTICOTROPIN-RELEASING FACTOR IN THE RODENT CENTRAL NERVOUS SYSTEM. S.T. Cain, M. Owens, M. Johnson* and C.B. Nemeroff. Depts. Psychiat. and Pharmacol., Duke Univ. Med. Ctr., Durham, NC 27710.

Corticotropin-releasing factor (CRF) is a 41 amino acid peptide with a heterogenous anatomical distribution within the central nervous system (CNS). When administered into the CNS, CRF exhibits a variety of electrophysiological, pharmacological and behavioral effects. A further criterion which must be satisfied for a substance to be considered a neurotransmitter is preferential enrichment in presynaptic terminals and vesicles. We have now analyzed the subcellular distribution of CRF within the CNS by combining density gradient fractionation procedures with a highly specific and sensitive radioimmunoassay for CRF.

Adult, male, Sprague-Dawley rats were decapitated and the brain regions of interest rapidly dissected. A crude synaptosomal fraction (P_2) was prepared by centrifugation. The P_2 fraction was then subfractionated into synaptosomal and mitochondrial components. The concentration of CRF-like immunoreactivity (CRF-LI) in the subcellular fractions was determined by radioimmunoassay. CRF-LI was enriched 50% in the crude synaptosome preparation relative to the homogenate. Within the P_2 fraction, synaptosomal CRF-LI was enriched almost 2-fold relative to the mitochondrial fraction. The synaptosomal enrichment of CRF-LI is consistent with a role for this peptide as a neurotransmitter in the CNS. Supported by NIMH MH-42088.

CHARACTERIZATION OF SEVERAL ENDOPROTEOLYTIC ACTIVITIES FROM RAT TISSUES WHICH CLEAVE PROSOMATOSTATIN AND MODEL SUBSTRATES AFTER SINGLE ARGININE RESIDUES. Margery C. Beinfeld, Jason C. Viereck*, Julie Bourdais*, Paul Kuks*, Alain Morel*, and Paul Cohen*. Dept. of Pharmacology, St. Louis Univ. Med. Sch., St. Louis, MO 63104 and Universite Pierre et Marie Curie, Paris, France.

During the post-translational processing of neuropeptides most cleavages occur at dibasic residues such as Arg-Lys. However, the prohormones of a number of neuropeptides (such as somatostatin, CCK, dynorphin, PHM, and ANF) are also cleaved at one or more single arginine residues. We found that rat intestinal secretory granules, brain cytosol, and brain synaptosomes all contained enzymatic activity which cleaved a model substrate containing the site which is cleaved when somatostatin 28 is generated in vivo. Both preparations contained both soluble and membrane associated activities.

These enzymes were all active at neutral or slightly basic pH, displayed different molecular weights, Km values, substrate specificity, and inhibitor sensitivity. Based on their inhibitor sensitivity they were either serine, metallo- or thiol proteases. Most of these enzymes could correctly cleave anglerfish prosomatostatin to produce somatostatin 28. One of the enzymes could also cleave some dibasic substrates. Supported by NIH NS18667 and The Fogarty International Center.

***IN VIVO* RELEASE OF N-ACETYL-ASPARTYL-GLUTAMATE FOLLOWING OPTIC NERVE STIMULATION.** G. Tsai, B.L. Stauch, J.J. Vornov*, J.K. Deshpande and J.T. Coyle. Depts. of Neuroscience, Pharmacology, and Psychiatry, The Johns Hopkins School of Med., Balto., MD 21205.

N-Acetylaspartylglutamate (NAAG), a peptide found in remarkably high concentrations in the vertebrate CNS, may serve as a neurotransmitter or modulator in several putative glutamatergic pathways. To date, the release of endogenous NAAG upon stimulation of an appropriate pathway *in vivo* has not been documented. NAAG is a candidate transmitter of the retinotectal pathway of the rat based on immunocytochemical, lesion and radiolabeling release studies. To determine whether the peptide is released *in vivo*, the optic nerve stump was stimulated for 10 minutes (10Hz, 10 microamp, 0.1 msec duration) immediately after enucleation, while the ipsilateral and contralateral superficial layers of superior colliculi were perfused with Krebs-bicarbonate buffer utilizing the technique of *in vivo* microdialysis. The evoked release of endogenous NAAG was quantified by a liquid phase radioimmunoassay (RIA), according to which the fractions were subject to an anion exchange HPLC chromatography followed by RIA of the eluant. NAAG release was increased by 270±25 % over baseline in superior colliculus contralateral to the stimulation (n=6). This evoked release was markedly inhibited (>95%) by perfusion of the colliculus with calcium-free buffer containing 1mM EGTA (n=6). Reperfusion with normal buffer in the same animal resulted in restoration of NAAG release. These results demonstrate that endogenous NAAG is subject to calcium-dependent release *in vivo* upon electrical stimulation of a defined NAAG-containing pathway and suggest that NAAG may serve as a neurotransmitter/modulator in the optic pathway.

338.14

VISUALIZATION OF NAALADase ACTIVITY WITHIN AN ACRYLAMIDE GEL FOLLOWING ITS PURIFICATION TO HOMOGENEITY. B.L. Stauch, M.B. Robinson, G. Tsai, M.L. Simmons*, and J.T. Coyle, Departments of Pharmacology and Neuroscience, The Johns Hopkins School of Medicine, Baltimore, MD. 21205.

The acidic neurodipeptide, N-acetyl-aspartyl glutamate (NAAG), is thought to function as a neurotransmitter/neuromodulator in the mammalian nervous system. Our laboratory has identified a membrane-bound metallopeptidase, N-acetylated alpha-linked acidic dipeptidase (NAALADase), capable of degrading NAAG to N-acetyl-aspartate (NAA) and glutamate *in vitro* (Robinson et al., J. Biol. Chem. 262, 14498-14506, 1987); and has recently demonstrated that NAAG is degraded by a pharmacologically similar enzyme *in vivo* (Stauch et. al., Neurosci. Let., *in press*). The salient features of this metallopeptidase include its chloride dependency, potent sensitivity to quisqualate (IC50=500nM) and phosphate, and selective stimulation by cobalt. In addition, we have found that NAALADase is an unusually basic protein with a pI of 9.0, as assessed by chromatofocusing chromatography. We have solubilized this peptidase from rat brain and purified nearly to homogeneity by sequential column chromatography including DEAE-Sepharose, CM-Sepharose, Concanavalin A Sepharose, and size exclusion chromatography. SDS gel electrophoresis of the purified protein developed with silver stain revealed one band migrating at 94 kD. To confirm that this band represents NAALADase, we have developed a specific enzymatic activity stain, enabling us to visualize NAALADase activity within the polyacrylamide matrix. This procedure couples the hydrolysis of glutamate from NAAG to the reduction of iodonitrotetrazolium to formazan. Using this methodology, we have demonstrated unequivocally that the band migrating at 94 kD on an SDS gel represents NAALADase. Furthermore, consistent with its exclusive localization to kidney and neural tissue, we have demonstrated NAALADase activity in an acrylamide gel loaded with crude brain and kidney homogenates, but not with liver homogenate.

EXCITATORY AMINO ACIDS IN AMYOTROPHIC LATERAL SCLEROSIS. JD Rothstein, G Tsai, RW Kuncl, L Clawson*, DR Cornblath*, DB Drachman, A Pestronk, BL Stauch, JT Coyle. Departments of Neurology and Psychiatry, Johns Hopkins Univ School of Medicine, Baltimore, MD 21205.

Excitatory amino acid neurotransmitters have been proposed as potential toxic agents in a number of chronic neurological disorders including ALS. N-Acetyl-aspartyl-glutamate (NAAG) is an endogenous excitatory neuropeptide present in the CNS, with high concentrations in the motor cortex and motor neurons of the spinal cord. To define the changes in excitatory amino acids and NAAG in ALS, we measured cervical spinal cord and CSF glutamate, aspartate, NAAG, and its metabolite N-acetyl-aspartate (NAA) concentrations in patients with well characterized classic ALS. All assays were blinded for diagnosis. Mean age and age ranges were similar for all groups. Cervical spinal cord was studied in 2 groups of patients: ALS (n=8) and non-motor neuron disease controls (n=9). Spinal cord NAAG and NAA levels were similar in ALS and control tissue specimens. Tissue choline acetyl transferase and glutamate amino decarboxylase levels were also unchanged between groups. CSF studies utilized three study groups: ALS (n=18), other neurological diseases (OND; n=13), and hepatic encephalopathy (HE; n=10). Patients with HE have high CSF glutamine and thus served to control for artifactual hydrolysis to glutamate. CSF excitatory amino acids and NAAG were significantly altered in patients with ALS. CSF NAAG and NAA levels were increased 2-3 fold compared to OND specimens. There was a significant 3-fold elevation of CSF glutamate concentration and a doubling of CSF aspartate concentration. There were no significant changes in CSF branched chain, aromatic, or basic amino acids. CSF glutamate concentration was not artifactually elevated by hydrolysis to glutamine, as evidenced by the normal glutamate levels in HE patients. Our data suggest altered excitatory amino acid metabolism in patients with ALS. Increased release of NAAG with its concomitant metabolism to aspartate and glutamate may account for our results. The role of NAAG in the pathogenesis of ALS remains to be explored.

BIOCHEMICAL AND BIOLOGICAL CHARACTERIZATION OF LONG CHAIN-BIOTINYLATED GNRH ANALOGUES. B.T. Miller, T.J. Collins*, G.T. Nagle and A. Kurosky*. Depts. of Anatomy & Neurosciences and Human Biological Chemistry & Genetics, Univ. Texas Medical Branch, Galveston, TX 77550.

The incorporation of biotin moieties into bioactive peptides and proteins often yields derivatives which retain biological activity. Such biotinylated probes, which form stable complexes with either free or immobilized avidin, can be used for both the localization and the isolation of specific peptide and protein receptors. Proteins and peptides are often biotinylated with commercially available N-hydroxysuccinimide (NHS) esters of biotin. These reagents are chemically reactive toward the epsilon amino groups of lysine residues. Using such a biotinylating reagent which contains an extended spacer arm, we linked biotin moieties to [D-lys^6]-GnRH. We examined the structure of the resultant peptides by HPLC, amino acid compositional analysis and automated peptide sequencing. Biological activity was tested by assessing the ability of the derivatized analogues to stimulate LH release from cultures of dispersed anterior pituitary cells. Our results indicate that different bioactive, biotinylated GnRH derivatives can be synthesized by varying the reaction conditions during biotinylation. Preliminary structural analysis of biotinylated [D-lys^6]-GnRH molecules and other GnRH analogues suggests that residues other than lysine are capable of being biotinylated with NHS esters.

338.17

THE EFFECTS OF PRENATAL METHADONE EXPOSURE ON POSTNATAL mRNA EXPRESSION OF NEUROPEPTIDES IN THE RAT HYPOTHALAMUS. J.W. Nemitz, A.H. Hassen, and J.A. Schriefer. Depts. of Anat., Physiol. and Pharm., WV School of Osteopathic Med., Lewisburg, WV 24901

Adult, female Sprague-Dawley rats made methadone dependent using a subcut. pump (9 mg/kg/day), were mated to produce offspring. The prenatally methadone exposed rat pups were sacrificed at different postnatal days by decapitation. Frozen serial coronal sections (20um) at the level of the hypothalamus were cut and processed for *in situ* hybridization using ^{35}S-oligonucleotide probes (DuPont). Results indicate that significant differences exist between the amount of oxytocin probe observed in the Day 1 controls (animals that have not been prenatally exposed to methadone) as compared to Day 1 methadone animals for the paraventricular, supraoptic and retrochiasmatic supraoptic nuclei of the hypothalamus. The levels of mRNA oxytocin labelling was decreased in the methadone animals. A comparison of the Day 10 control and methadone animals showed no significant differences in the level of oxytocin mRNA for the same hypothalamic nuclei. These data suggest that chronic prenatal exposure to methadone alters the mRNA expression of a pituitary peptide and that this change is rapidly reversed postnatally. Supported by WVSOM funds.

338.18

A POSTERIOR LOBE PROLACTIN RELEASING FACTOR (PRF) DISTINCT FROM OXYTOCIN. W.K.Samson*, R.Mogg*, L.Martin* and R.J.Fulton* (SPON: M.J.Duncan) Anatomy, Univ. MO Sch. of Med., Columbia MO 65212 and Inland Laboratories, Dallas TX 75207.

In addition to oxytocin (OT), bovine and rat neurointermediate lobes (NILs) contain a novel peptidergic PRF. This factor is not OT because removal of endogenous OT by immunoaffinity reduces, but does not abolish, the PRL response to NIL extracts seen *in vitro*. The PRF activity can be resolved from OT on sizing gels and by HPLC. Unlike OT, the bioactivity of this PRF remains after oxidative extraction procedures and is expressed *in vivo* and *in vitro* even in the presence of dopamine. This PRF does not act via OT receptors on the lactotroph, since cell preparations in which the OT responsive subpopulations of lactotrophs have been selected out by preincubation with OT-ricin A chain conjugates still respond to the NIL PRF. These cytotoxin studies have also revealed that the VIP responsive lactotrophs are the same subpopulation as those responsive to OT, but not TRH. In agreement with Ben-Jonathan's pioneering work (ENDO 122:2533), our data provide further evidence for the existence of a nonoxytocinergic PRF in the NIL.

338.19

EXOGENOUS AND ENDOGENOUS ANGIOTENSIN III ARE NOT EQUIVALENT. R.H. Abhold. VCAPP, Wash. St. Univ., Pullman, WA 99164-6520.

This study examined the difference between the ANG III endogenously generated from ANG II (ANG(2-8)g) and exogenously applied ANG III (ANG(2-8)a) In the metabolism of ANG(2-8)g, only ANG(2-7) and ANG(2-4) were directly produced from the parent peptide, ANG(2-7) being the principal product. This contrasts with the metabolism of ANG(2-8)a in which ANG(3-8) is also generated and is the primary product. In vitro, ANG(2-7) and ANG(2-5) inhibited the formation of ANG(3-8), ANG(1-7) and ANG(2-7) inhibited the formation of ANG(2-4), and ANG(1-5) had no discernable effects on fragment formation. In vivo, ANG(1-7) and ANG(2-7) increased the dipsogenic effect of ANG(1-8) whereas ANG(1-7), ANG(2-7), and ANG(2-5) increased that of ANG(2-8)a. None of the ANG fragments themselves possessed intrinsic dipsogenic activity. These data indicate that ANG(2-8)g and ANG(2-8)a are metabolized differently and suggest this difference may be important when pharmacologic and physiological comparisons are made between ANG(1-8) and ANG(2-8).

mRNA REGULATION III

339.1

N-METHYL-D-ASPARTATE CHANNEL BLOCKERS INHIBIT SEIZURE INDUCED RISE IN C-FOS mRNA IN HIPPOCAMPUS OF KINDLED RATS. D.M. Labiner, D.A. Hosford, C. Shin, J.O. McNamara. VA and Duke University Medical Centers, Durham, NC 27705.

c-fos is an early gene which encodes a transcription factor. An afterdischarge (AD) triggers a dramatic rise in c-fos mRNA in the hippocampus of both naive and kindled animals. Understanding the mechanism by which AD effects this may provide a clue to the functional significance of the c-fos induction. We hypothesized that NMDA receptors participate in AD-induced c-fos expression since anatomic distribution of c-fos induction parallels that of NMDA receptors. We therefore examined the effects of NMDA channel blockers on c-fos expression activated by AD.

Hippocampal kindled rats were treated with vehicle, MK-801 (1.5 mg/kg), or phencyclidine (PCP, 5 mg/kg) 60 min prior to a seizure and sacrificed 30 min later. Frozen sections were used for in situ hybridization with a ^{32}P-oligonucleotide probe. Control animals exhibited a dramatic rise in c-fos mRNA bilaterally in the dentate granule cell layer. MK-801 attenuated the rise by 50% ($p<.01$). A similar suppression was observed with PCP. There was no change in AD duration in either group compared to vehicle.

These data indicate that NMDA channel activation is one mechanism by which AD induces c-fos. Interestingly, NMDA channel activation appears to play a critical role in kindling development. Linking c-fos expression to NMDA channel activation thus strengthens the likelihood that c-fos expression serves a causal role in kindling development.

339.2

EARLY GENE EXPRESSION IN THE HIPPOCAMPUS IN THE KINDLING MODEL. M.G.Simonato*, D.A.Hosford, D.M.Labiner, C.Shin, J. Morgan*, T.Curran* & J.O.McNamara (SPON: M.Bowman). Epilepsy Res. Lab, Duke & V.A. Med. Ctrs., Durham, NC, 27705.

Changes in gene expression may explain the longlasting hyperexcitability of the kindling model. Early genes encode transcriptional regulators that may mediate longlasting changes in target gene expression. We therefore examined the effects of a single kindling afterdischarge (AD) on the level of mRNA of 3 early genes that are expressed in other seizure models: c-fos, c-jun, and NGF1a (homologous to zif/268; Saffen et al., PNAS, 1988). Hippocampal AD was produced by stimulating the angular bundle of rats that were sacrificed at multiple timepoints up to 3 hrs later. Sham-stimulated animals served as controls. In situ hybridization of hippocampal sections was performed with radiolabelled oligonucleotide probes (50-mers). Autoradiograms were analyzed by computer-assistance (Loats) to determine the relative levels of mRNA.

In dentate granule cell layer, c-fos and c-jun mRNA were markedly increased ($p < .01$) at 30 min and returned to near-control levels by 60 min; by contrast, NGF1a mRNA exhibited a similar abrupt rise but remained significantly elevated at 60 min before returning to control levels at 120 min. In CA1 pyramidal cell layer, NGF1a mRNA was elevated (40%) by 30 min whereas little (10%) or no increase was detected in c-fos and c-jun, respectively. The apparent differential expression of early genes following the same stimulus may imply that target genes are also differentially controlled in distinct neuronal populations.

PHORBOL MYRISTATE ACETATE (TPA) AND SERUM ENHANCE NERVE GROWTH FACTOR SYNTHESIS IN FIBROBLASTS.
D. Wion*, R. Houlgatte*, P. Clochon*, D. Mac Grogan*, E. Dicou* and P. Brachet. INSERM U 298, CHR, 49033 Angers, France.

Previous studies performed with mouse L fibroblasts have shown that serum causes in this system a specific elevation of the cellular content of NGF mRNA and increases coincidently the amounts of NGF protein secreted in the medium (Houlgatte et al, Biochem. Biophys. Res. Comm. (1988)150:723-730). Further experiments provided evidences that serum, or a macromolecular fraction of serum, stimulates also the synthesis of NGF in rat primary fibroblasts or in iris transplants. This suggests that serum elements may be involved in the control of NGF synthesis in vivo, for instance in wound mechanisms. The effect of serum in L cells may be mimicked by the protein-kinase C activator, TPA. Conversely, the promoting effect of serum and TPA was abolished by the protein-kinase C inhibitor, polymyxin as well as by the protein synthesis inhibitor, cycloheximid. These results suggest that induction of NGF-gene expression in L cells requires both protein-kinase C activation and protein synthesis.

FOS PROTEIN EXPRESSION IN CULTURED CENTRAL NEURONS AND ASTROCYTES. Kinya Hisanaga*, Stephen M. Sagar, and Frank R. Sharp (SPON: M. Floeter) Depts. of Neurology and Physiology, UCSF, and VA Medical Center, SF, CA 94121 USA.

Expression of the proto-oncogene c-fos in rat neocortical neurons and astrocytes was examined using in vitro immunocytochemistry for the gene product, Fos. Nearly pure neurons and nearly pure astrocytes were cultured in serum-free medium for 3-5 days, and then stimulated as follows. Remarkable Fos expression in astrocytes was observed 2 hours after mechanical stimulation by changing media (even returning the same medium in which the cells had been cultured), and after treatments with serum (10%), epidermal growth factor (EGF, 100ng/ml), and dibutyryl-cyclic AMP (db-cAMP, 1mM), but not potassium chloride (KCl, 46mM) and nerve growth factor (NGF,100ng/ml). Fos was induced in neurons after treatments with serum, KCl and db-cAMP, but not carbachol (acetylcholine agonist, 1mM), EGF and NGF. Fos immunocytochemistry in cultured cells might be useful for determining the specific factors (e.g. neurotransmitters and trophic factors) responsible for "third messenger" c-fos expression in the nervous system.

339.5

A RAPID AND TRANSIENT INCREASE IN c-fos AND zif/268 mRNA INDUCED BY ELECTROCONVULSIVE SHOCK. S.R. Abu-Shakra*, A.J. Cole, D.W. Saffen*, J.M. Baraban and P.F. Worley (SPON: D. Drachman). Depts. of Neuroscience, Johns Hopkins University, Baltimore, MD 21205.

Recent studies have identified a set of genes referred to as immediate early genes (IEG) that respond rapidly to growth factor stimulation. Several of these IEGs, thought to encode transcription factors, are also activated by neuronal stimulation in vivo. For example, metrazole induced seizures lead to a rapid increase in c-fos and zif/268 mRNAs. To analyze the seizure induced activation of IEGs in brain, we used the maximal electroshock model (MES). mRNA levels were assayed in rat brain sections by in situ hybridization with ^{35}S-labelled anti-sense riboprobes. MES increased both mRNAs in the dentate gyrus and cortex. mRNA levels are maximal by 30 min, return to basal levels by 2 hr, appear below basal levels at 4 hrs and normalize at 24 hrs. Diazepam, carbamazepine, phenobarbital and phenytoin blocked hindlimb extension due to MES, but not the rise of c-fos and zif/268 mRNAs. Additionally, NMDA antagonists MK-801 (1 or 10mg/kg) and CGS-19755 (15mg/kg) blocked hindlimb extension but failed to block zif/268 mRNA increases and only partially reduced the c-fos mRNA response to MES. Our findings suggest that MES elicits a rapid genomic response that is not blocked by anticonvulsants.

339.6

ADENOSINE RECEPTOR ACTIVATION INDUCES A RAPID INCREASE IN C-FOS, BUT NOT C-JUN, EXPRESSION IN NEURON-GLIA HYBRIDS AND FIBROBLASTS R.M.Gubits, J.B.Wollack, H.Yu*,and W.K.Liu*, Dept. of Neurology, Columbia College of Physicians & Surgeons,New York, N.Y.10032

The neuromodulator adenosine, is thought to act through its cell surface receptors as an endogenous anti-convulsant. One step in the signal transduction pathways of several cell surface receptors is the rapid, transient induction of c-fos and c-jun gene expression. Both of these events,i.e.1.)enhanced adenosine release and 2.)the induction of c-fos and c-jun mRNAs, occur with similar kinetics in the brains of animals following metrazol-induced seizures. In order to determine whether these 2 phenomena are related, i.e. whether enhanced expression of c-fos and c-jun mRNAs could occur, in part,as a result of the interaction of adenosine with its receptor, we treated 3T3 fibroblasts and NG108-15 neuroblastoma/ glioma hybrid cells with adenosine agonists and analyzed them for c-fos and c-jun mRNAs and Fos protein.

Both lines responded to treatment with the adenosine agonists, CHA (A1-selective) and NECA (non-selective adenosine agonist) with a concentration-dependent transient increase in c-fos mRNA of 3.5- to 8-fold. c-jun mRNA was present in both treated and untreated cells at approximately the same concentration. The kinetics of the c-fos response were much more rapid for 3T3 cells (peak at 15 min) than for NG cells (peak at 60-90 min). This slower, more prolonged response in the NG cells was quite similar to that of c-fos induction in brains of animals following seizures. Specificity of the response was further investigated by the addition of the non-selective adenosine receptor antagonist, theophylline, just before the agonist drugs. Fos protein induction was demonstrated by immunocytochemical staining of Fos in NECA-treated 3T3 cells. These results suggest that Fos induction is a component of the adenosine receptor signal transduction pathway. Fos and Jun are nuclear proteins, which may interact to regulate the transcription of other genes. Our results are therefore consistent with the hypothesis that part of adenosine's anticonvulsant activity could involve changes in gene expression mediated by Fos and Jun. DIFFERENTIAL INCREASE IN LEVELS OF C-FOS AND CALCYCLIN, BUT NOT HEAT-SHOCK PROTEIN, mRNAs IN RESPONSE TO PLATELET-ACTIVATING FACTOR IN A HUMAN NEUROBLASTOMA CELL LINE. **G. Allan* and N.G. Bazan. (SPON: H.E.P. Bazan) LSU Eye Center and Neuroscience Center, New Orleans, LA 70112.**

Platelet-activating factor (PAF) is a potent lipid mediator implicated in a wide range of pathophysiological conditions including cerebral ischemia (BBRC 149:580, 1987) and epilepsy (J. Neurochem. 51:1900, 1988). Post-ischemic recovery of neuronal function may include activation of gene expression by such mediators in either those cells that survive after damage, those that take over functions of lost cells, or both. To investigate PAF effects on neuronal gene expression the neuroblastoma cell line SH-SY-5Y was treated with 1 μM PAF, RNA was isolated after various times of PAF exposure and steady-state levels of the mRNAs coding for c-Fos, calcyclin, heat-shock proteins 24 and 70 (HSP 24 and 70), and ß-actin analyzed by slot- and Northern blotting. Levels of c-Fos mRNA were elevated at between 30 and 90 min PAF exposure. Levels of calcyclin mRNA, preferentially expressed in cycling cells, increased after 6-7 h. Levels of HSP 24, HSP 70, and ß-actin mRNA did not alter during this time. These results suggest that PAF can initiate cascades of neuronal gene expression. (Supported by NIH NS 23003).

ONCOGENES IN CAT CORTICAL STRUCTURES. G.D. Mower, K.M. Rosen*, M. McCormack* and L. Villa-Komaroff. (SPON:F.H. Duffy). Neurology Research, The Children's Hospital, Boston, MA 02115.

Proto-oncogenes could be genetic elements involved in short and long term changes in neural function. The present study compared expression of a series of oncogenes, by Northern blots, in visual, frontal, and cerebellar cortices of cats. Analyses were done on kittens (1 week), mature (5 month) cats, and in mature cats deprived of all visual experience by dark rearing from birth, to test whether there were environmental effects on gene expression.

Expression of oncogenes showed regional and age related differences. Fos was nearly absent in all cortical regions of kittens and expressed about equally in all regions of mature cats. Myc was highly expressed in all regions of kittens, but persisted only in the cerebellum of mature cats. PDGF-B (sis) was very low in all regions of kittens but expressed in all regions of mature cats, being lowest in cerebellum. H-ras was expressed in all cortical regions and was higher in kittens. Other oncogenes (eg. int, neu) are currently under study.

No marked differences were found between normal and dark reared animals in visual cortex for any oncogene tested to date. This result is surprising since expression of many oncogenes is activity dependent. Moreover, since dark rearing extends the "critical period" of visual cortex, these negative results put into question a simple role of oncogenes in visual cortical plasticity.

RAPID REGULATION OF GENE EXPRESSION BY NERVE GROWTH FACTOR IN PC12 CELLS. Stephen R.J. Salton* (SPON: Harvey Reisine). Fishberg Research Center in Neurobiology, Mt. Sinai Sch. of Med., NYC, NY 10029.

PC12 cells undergo a transition from an adrenal chromaffin-like cell to a sympathetic neuron-like cell in the presence of nerve growth factor (NGF) but not epidermal growth factor (EGF). NGF and EGF have been shown by a number of investigators to rapidly turn on the transcription of several mRNA's in PC12 cells; the proteins encoded by some of these mRNA's are structurally related to and/or appear to interact with several known transcription factors. I and others (Twiss, J.L. and Landreth G.E., Soc. Neurosci. Abst. Vol. 14, Part 2, p1324, 1988) have used subtractive hybridization to increase the possibility of detecting low abundance mRNA's that are regulated uniquely by NGF. RNA from PC12 cells treated with NGF and cyclohexamide (Milbrandt, J., Science 238, 797) was used to construct a lambda GT-10 library of 2 million recombinants. 100,000 pfu's of the primary library were screened with subtracted cDNA and 75 NGF-induced clones identified. The positives were rescreened with cDNA's from NGF-treated and EGF-treated PC12 cells, v-fos, v-myc, v-fgr, c-fos and actin ß cDNA's, and with oligonucleotide probes to NGF-1A, NGF-1B, and to consensus sequences in Zn^{++}-finger containing transcription factors and steroid hormone receptors. Approximately 55 of the 75 clones were found to hybridize with NGF-1A and 15 with actin ß. Four clones encode mRNA's that are rapidly induced to relatively high levels by NGF; two additional clones encode mRNA's of lower abundance, one of which hybridizes at high stringency with the transcription factor consensus oligonucleotide. Anti-sense oligonucleotides are being used to rapidly assess the functional importance of the encoded proteins during NGF-induced neural differentiation of PC12 cells.

INDUCTION OF NEUROFILAMENT (NF-H) FOLLOWING DIFFERENTIATION OF NEUROBLASTOMA CELLS IS DUE TO AN INCREASE IN mRNA K.C. Breen* & B.H. Anderton, Department of Immunology, Cranmer Terrace, London SW17 ORE, England. (SPON: BRA)

Dibutyryl-cyclic AMP (dbcAMP) treatment of neuro-2A neuroblastoma cells induces cell differentiation and neurite outgrowth. Undifferentiated cells express heavy neurofilament polypeptide (NF-H) at a low level. Following differentiation, there is a significant increase in NF-H immunoreactivity, the induced filaments being in the phosphorylated form as determined using a specific monoclonal antibody RT97. Immunocytochemical studies showed that the phosphorylated form of hte polypeptide is specifically localised in the neurites and is not present in the cell bodies which only contain the dephosphorylated form. Furthermore, the induction of the NF-H polypeptide was shown to be controlled at a genetic level, as differentiation of the cells results in an increase in mRNA corresponding to NF-H. This is in contrast to NGF-induction of NF-H in PC12 cells which occurs at a post-transcriptional level.

THE ANDROGEN-BINDING PROTEIN GENE IS EXPRESSED THROUGHOUT THE RAT BRAIN OF BOTH SEXES. Y-M Wang, D. A. Bayliss*, D. E. Millhorn, and D. R. Joseph*. Curriculum in Neurobiology, Departments of Pediatrics and Physiology, The Laboratories for Reproductive Biology, University of North Carolina, Chapel Hill, NC 27599.

The presence of brain identifier sequences in the rat androgen-binding protein (ABP) gene (Molec. Endocrinol. 2:3, 1988) prompted us to look for ABP expression in the brain. Northern blot analyses of poly(A)$^+$ RNA isolated from various brain regions of both sexes with cDNA as probe revealed major mRNA species of 1.7 and 2.3 kb. The highest concentrations were found in the hippocampus, olfactory bulb, striatum and cerebral cortex with no gender differences. A postnatal study emcompassing newborn to mature rats shows the 1.7-kb transcript is expressed at increasing levels with age, whereas expression of the 2.3-kb transcript was maximal between days 30-50. Sequence analysis of brain cDNA clones indicates ABP mRNAs are processed differently in the brain. Expression of ABP in the brain may provide a mechanism to fine-tune androgen effects or ABP may act as an independent neuropeptide. (supported by NIH grants HD-21744, 5-P30-HD18968 and HL 33831).

COMPLEX DISTRIBUTION OF mRNAs OF ISOFORMS OF THE NA,K-ATPASE IN RAT BRAIN. P.E. Filuk*, W.L. Stahl, D.M. Dorsa and M.A. Miller*. V.A. Medical Center and Univ. Washington Sch. Med., Seattle, WA 98108.

Although three isoforms of the catalytic subunit of the Na,K-ATPase have been identified in nervous tissue, their distribution, regulation and specific function are as yet unknown. We have examined the distribution of mRNAs encoding the α1, α2, and α3 isoforms by in situ hybridization. Brain sections were treated with [^{35}S]-oligonucleotide probes (30 mer) complementary to both coding and non-coding regions of each isoform. Specificity was assessed by competition of labelled probe with excess unlabelled probe and by Northern analysis. Even though all three isoforms were localized in cerebral cortex and hippocampus, their distributions were often distinct. α1 mRNA was associated with laminae 2, 3 and 4 of cerebral cortex. Strong labelling was present in CA1, CA2 and CA3 pyramidal cells with significantly lower labelling associated with the granule cells of hippocampus. α2 mRNA was diffusely distributed in cerebral cortex and in all layers of the hippocampus. Cortical laminae 4 and 5 and all regions of the hippocampus (e.g. CA1, CA2, CA3, dentate gyrus) exhibited high levels of α3 mRNA. In addition, selected nuclei of the thalamus and hypothalamus were labelled by probes to α2 and α3, isoforms of the Na,K-ATPase which may be sensitive to hormonal regulation.

ACTIVITY-DEPENDENT GENE EXPRESSION IN VISUAL CORTEX NEURONS OF ADULT MONKEYS D.L.Benson,P.J.Isackson,E.G.Jones Dept. of Anatomy and Neurobiology, Univ. of California,Irvine,CA 92717.

Following monocular deprivation in adult monkeys, there is an increase in RNA encoding calcium calmodulin dependent protein kinase type II(CAMK-II) in primary visual cortex. This increase is detected as early as four hours after deprivation by intraocular injection of tetrodotoxin. Parallel immunocytochemical experiments confirm previous studies indicating that the increase occurs in ocular dominance columns corresponding to the deprived eye (SHC Hendry and MB Kennedy, PNAS 83:1536(1986)).

Total RNA, isolated from normal animals and from animals that had been monocularly deprived 4 hours to 7 days, was reverse transcribed. The resultant cDNA was selectively amplified using the polymerase chain reaction (PCR, Saiki, et al,Science 230:1350(1985)) Amplified reaction products were examined on agarose gels and demonstrated an increase in CAMK-II mRNA with deprivation. The transcripts were isolated, cloned, and sequenced. These clones were used to generate antisense RNA for S1 nuclease protection experiments which confirmed the results obtained from the PCR reactions.

Using the same methodology, a monkey specific glutamic acid decarboxylase (GAD) clone has been isolated. S1 nuclease protection experiments indicate a small decrease in GAD mRNA following monocular deprivation. In situ hybridization experiments will more definitively determine the cellular response of GAD and CAMK-II to a decrease in afferent activity. Supported by NIH Grants EY 07193 and NS 24747-03.

339.14

HIGH-LEVEL EXPRESSION AND SPECIFIC REGULATION OF APOLIPOPROTEIN D mRNA IN ENDONEURIAL FIBROBLASTS OF REGENERATING RAT PERIPHERAL NERVE. P.Spreyer*, H.Schaal*,G.Kuhn* and H.W.Müller. Mol. Neurobiol. Lab., Neurology Dept., Univ. of Düsseldorf, FRG.

A cDNA clone containing the entire coding region of rat apolipoprotein D (apo D) was isolated from a cDNA library of regenerating rat sciatic nerve (SN) by a differential hybridization procedure selecting for sequences enriched in the distal stump following crush lesion. Northern blots revealed that apo D mRNA was present in small amounts in noninjured mature SN and brain, but not in neonatal rat brain. In spatio-temporal analyses moderately increased levels of apo D mRNA were detected in the proximal segment of crushed SN as well as in the proximal and distal stumps of nonregenerating transected and ligated SN at 1 and 4 weeks after injury. In contrast, in the distal stump of crushed SN the steady state level of apo D mRNA transiently increased at least 40-fold above control levels at the time when axons regenerate into this nerve segment. Cellular localization of apo D transcripts could be detected by in situ hybridization in endoneurial fibroblasts. These results suggest that stimulation of high-level expression of apo D mRNA is a specific molecular event of endoneurial fibroblasts in nerve regeneration.

THE HORMONAL REGULATION OF GLUTAMINE SYNTHETASE IN CULTURED ASTROCYTES. W.A. Schreier*, A.C. Passaquin*, K. Huff, and J. de Vellis. (SPON: Z.H. Zhang) Dept. of Anatomy & Cell Biology, U.C.L.A. School of Medicine, Los Angeles, CA 90024.

The hormonal regulation of glutamine synthetase was examined in cultures of astrocytes from neonatal rat cerebrum. The effects of three hormones: hydrocortisone (HC), insulin, and thyroid hormone (T3) were investigated. Both the enzymatic activity of glutamine synthetase (GS) and the level of the corresponding mRNA were followed during hormonal treatments. All three hormones enhanced the specific activity of GS, however the effects of insulin and T3 were quite variable. Whereas the HC-induction of GS activity was correlated with a corresponding increase in GS mRNA, no significant change in the level of GS mRNA was observed after insulin or T3 induction. This suggests that insulin and T3 regulation of GS activity in astrocytes is a post-transcriptional event in contrast to the transcriptional regulation of GS by HC. Supported by USPHS grant HD-07032, NIH grant HD-06576 and DOE contract DE-FC03-87-ER60615.

339.16

EXPRESSION OF MYOSIN LIGHT CHAIN 2 mRNAs IN THE DEVELOPING RAT BRAIN. D. L. Feinstein and R. J. Milner, Research Institute of Scripps Clinic, La Jolla, CA, 92037.

In order to gain a better understanding of the molecular basis for the diversity of astrocyte function, we have isolated cDNA clones for molecules whose expression is specifically regulated in these cells. cDNA libraries were constructed from primary cultures of neonatal rat brain astrocytes. Clone pAT11 hybridized to a mRNA species that was expressed at highest levels in the embryonic brain, absent from liver or kidney RNA samples, and which was greatly enriched in astrocyte versus whole brain RNA. The DNA sequence of clone pAT11 indicated that it encoded smooth muscle myosin light chain 2 (smMLC2), a regulator of myosin contraction. A second mRNA species, detected by cross-hybridization with the open reading frame of clone pAT11, was expressed at low levels in astrocytes and in the embryonic brain, but at high levels in the postnatal day 23 brain. This mRNA was also the predominant MLC2 species present in RNA from neuronal cultures. Screening of a rat cortex cDNA library resulted in the isolation of clone RLC3-8, which encodes a novel MLC2 and is derived from the larger mRNA species. The tissue distribution of this mRNA was that expected of a nonmuscle isotype. We conclude that at least two forms of MLC2 are expressed in rat brain and that their expression is regulated developmentally and in a cell-specific manner. Supported by a fellowship from the National Multiple Sclerosis Society and grants from NIH (NS21815, NS22347).

339.17

INSULIN-LIKE GROWTH FACTOR II GENE EXPRESSION IN CEREBELLAR GRANULE CELLS. K.M. Rosen*, R. O'Brien*, B. Yankner, and L. Villa-Komaroff.
Dept. of Neurology, The Children's Hospital, Harvard Medical School, Boston, MA 02115

We have examined the expression of the insulin-like growth factor II gene in mitotically-active murine cerebellar granule cells. The cerebellum was dissected free of meninges and choroid. Percoll gradient fractionation of dissociated tissue yielded a homogeneous population of granule cells. Immunohistochemical staining of these granule cell preparations for GFAP indicated < 1% of the cells were glial cells. RNA was isolated from granule cells immediately after purification and from glial cells maintained in culture for 7 days. IGF-II gene expression was characterized using a highly sensitive S1 nuclease protection assay. A high specific activity single stranded DNA probe was generated by subcloning a human IGF-II cDNA restriction fragment into bacteriophage M13. No expression of IGF-II was detected in RNA from glial cells. A low but reproducible level of IGF-II mRNA expression was detected in RNA from granule cells isolated at postnatal days 2, 3 and 4. These results indicate that the IGF-II gene is expressed in neuronal cells during the period of granule cell differentiation.

339.18

INTERLEUKIN 1-ß MESSAGE LEVELS INCREASE IN ALZHEIMER'S DISEASE WHILE GAP-43 MESSAGE LEVELS ARE DIMINISHED. K. E. Rogers*, A.B. Wadhams* and P.D. Coleman.
Department of Neurobiology and Anatomy, University of Rochester, Rochester, NY, 14642.

Interleukin-1(IL-1) is an immunomodulator which has been shown to be produced by microglia and astrocytes. In addition IL-1 is an astroglial mitogen which can also induce the expression of ß-amyloid precursor gene. Thus, we have compared the message levels of IL-1ß in AD to their normal aged matched controls in the superior frontal gyrus. Poly-A+ mRNA was isolated from 500 mg samples using the method of Badley, et al. Typically, 12 mg or more of mRNA was obtained with an A260/280 ratio of 2.0. A 2.0 ug sample of mRNA was electrophoresed on a denaturing agarose gel to assess the quality of the mRNA. A series of dilutions was then slot blotted and probed with a radioactive IL-1ß cDNA probe obtained from D. Cosman (Immunex Corp.). The resulting autoradiogram was densitometrically scanned. Since virtually all mRNA is contaminated by rRNA, all samples were normalized for the amount of polyA+ mRNA present in each sample. Results showed an average of 65% increase in IL-1ß mRNA in young AD SFG. Conversely, in old AD SFG an average decrease in IL-1ß mRNA of 14% was seen. These data are consistent with data of Mountjoy et al., 1983, indicating a smaller loss of neurons in very old AD as compared to younger AD cases. Identical studies were done using a probe for the growth associated protein, GAP-43. These studies indicated that GAP-43 message was decreased in AD SFG as compared to the normal controls. Currently, mRNA blots from AD and normal control SFG are being probed with IL-α

339.19

REGULATION OF THE GROWTH-ASSOCIATED ALPHA-TUBULIN GENE, T ALPHA 1, IN SYMPATHETIC NEURONS *IN VIVO* AND *IN VITRO*. F. Miller, T.C. Mathew*, H.C. Wilson*, and R.B. Campenot.
Department of Anatomy and Cell Biology, University of Alberta, Edmonton, Alberta, Canada T6G 2H7.

Previous reports have shown that expression of T alpha 1 alpha-tubulin mRNA is specifically correlated with neuronal growth in developing and mature mammalian neurons. To investigate how T alpha 1 mRNA expression is regulated by extraneuronal influences, we have experimented with sympathetic neurons of the rat superior cervical ganglion (SCG). Unilateral transection of the carotid nerve close to the SCG (short cut) leads to induction of T alpha 1 mRNA in injured neurons as well as in uninjured, contralateral neurons. In contrast, transection of sympathetic axons projecting to the iris by unilateral enucleation (long cut) results in increased T alpha 1 mRNA only in ipsilateral ganglia. The contralateral increase in T alpha 1 mRNA following a short cut may be due to increased available nerve growth factor (NGF) in bilaterally-innervated target organs, since, in cultured sympathetic neurons, NGF regulates T alpha 1 mRNA in a dose-dependent fashion. T alpha 1 mRNA may also be regulated transneuronally: unilateral decentralization of the SCG by transection of the afferent preganglionic input leads to increased T alpha 1 mRNA in both the deafferented and in contralateral sympathetic neurons.

339.20

EXPRESSION AND LOCALIZATION OF CALMODULIN DEPENDENT PROTEIN PHOSPHATASE (CALCINEURIN) mRNA AND PROTEIN IN RAT BRAIN. M.L. Billingsley, J.W. Polli* J. K. Krady* and R. L. Kincaid*.
(SPON: R. Pelligrino) Dept. Pharmacology, Penn State Univ. College of Medicine , Hershey, PA 17033 and Section on Immunology, NIAAA, Rockville, MD 20892.

Calmodulin-dependent protein phosphatase (CN) is present at high levels in rat brain. In order to identify neurons and brain regions expressing CN, we used immunocytochemistry, immunoblotting and *in situ* hybridization to explore this question. Immunocytochemistry revealed that the highest levels of CN were found in hippocampus, substantia nigra, striatum, amygdala, neocortex and cerebellar Purkinje cells; however, neurons throughout the brain had detectable amounts of CN. Immunoblotting confirmed this pattern of localization, and subcellular fractionation showed CN to be associated with both cytosolic and membrane compartments. Analysis of developing rat brain indicated that CN expression increased postnatally, with near-adult levels observed at postnatal day 20. A series of specific 200-300 bp fragments corresponding to the antisense strand of a cDNA clone for CN were radiolabelled and used for *in situ* hybridization. CN mRNA was highest in the hippocampus, followed by striatum, cerebellum, amygdala and neocortex. The patterns of CN expression using both immunochemical and hybridization methods were in concordance, suggesting that regional differences in CN may reflect differences in transcription. Supported by grants from NIH (MLB) and the PMA Foundation (JWP).

OPIATES, ENDORPHINS AND ENKEPHALINS: BEHAVIORAL EFFECTS

340.1

NALOXONE REDUCES SOCIAL LOCOMOTOR ACTIVITY IN RATS. C.P.J. Dokla and J.K. DeFilippis*. Dept. of Psychology, Fairfield University, Fairfield, CT 06430.

Social affiliation (Panksepp et al., Biological Psychiatry, 13:607, 1978), exploration, and locomotor activity (Arnsten et al., Life Sciences, 25:1035, 1979) are thought to be modulated by opioid mechanisms. File (Psychopharmacology, 71:41, 1980) reported that naloxone (NAL), an opioid antagonist, significantly reduced activity in rats tested in pairs but not individually during a 10-min session. In the present study, groups of male Long-Evans hooded rats received NAL (1 or 4 mg/kg,ip) or vehicle only (isotonic saline) 30 min prior to testing sessions. Individual locomotor activity was measured in two photobeam-type activity boxes (41-cm^3) using daily 30-min sessions for 5 days. Following a 1-week washout period, activity was measured in pairs of rats from each group using daily 15-min sessions for 4 days. Locomotor activity was not significantly affected by NAL in individually tested rats, although retention (recovery) of activity habituation was improved by NAL (1 mg/kg group compared to the 4 mg/kg group only, $p < .05$). In the social (paired) activity tests, both doses of NAL reduced activity over the 4 days of testing ($ps < .01$). The present results suggest a role for opioids in social affiliation.

340.2

BIOCHEMICAL AND BEHAVIORAL EFFECTS OF INTRA-MR INJECTIONS OF OPIATE AGONISTS. M.A. Klitenick and D. Wirtshafter,
Dept. of Psychology, Univ. of Illinois, Chicago, IL 60680.

Recent studies have reported pronounced behavioral and biochemical effects following various manipulations of the midbrain raphe nuclei. In previous studies we have shown that injections of morphine, DAGO or DPDPE into the median raphe (MR) elicit increases in locomotor activity (LA). In an attempt to further clarify the role of opiates within the MR we decided to investigate the biochemical effects of intra-MR injections of DAGO or DPDPE following activity measures within a photocell cage.

LA was increased ($p<.05$) after intra-MR DAGO (437.5ng) compared to vehicle controls, confirming previous results. Levels of DA, DOPAC and HVA in the striatum (CAU) as well as 5-HT and 5HIAA in the hippocampus (HIPP) were not altered ($p>.5$). Intra-MR DAGO injections resulted in decreased levels of DA ($p<.05$) and increased levels of DOPAC and HVA ($p<.05$). Intra-MR injections of DPDPE (10µg) elicited an increase ($p<.05$) in LA compared to vehicle controls. In HIPP, only 5HIAA/5-HT was lower ($p<.05$) in DAGO-injected animals. Within the NA, DA levels were lower then controls ($p<.01$), DOPAC and HVA levels were higher ($p<.001$), and both 5-HT and 5HIAA were lower than control values ($p<.01$). No significant effects were found within the CAU for levels of DA, 5-HT or their metabolites.

(Supported by NIH NS21350)

340.3

NALOXONE DIFFERENTIALLY DISRUPTS THE ACQUISITION AND THE EXPRESSION BY MALE RATS OF A CONDITIONED PLACE PREFERENCE FOR AN ESTROUS FEMALE. B.J. Mehrara* and M.J. Baum, Dept. of Biology, Boston University, Boston, MA 02215.

Experiments were conducted to explore the possible contribution of endogenous opioid peptides to sexual reward in adult male rats. Sexually experienced males were allowed to mate with an estrous female in an initially 'non-preferred' chamber; on alternate days they were placed alone in an initially 'preferred' compartment. Males injected s.c. with saline prior to 8 such conditioning sessions acquired a conditioned place preference (CPP) for the initially non-preferred compartment whereas control subjects which were simply placed alone in each chamber on alternate days acquired no CPP. Administration of naloxone (1 or 5 mg/kg s.c.) 5 min. prior to each conditioning session had no effect on the acquisition of a CPP for an estrous female; however, these treatments attenuated the expression of a previously established CPP in gonadally intact males. Two weeks after castration males given saline prior to each conditioning session readily acquired a CPP despite their reduced mating performance. However, in contrast to gonadally intact males, acquisition of a CPP was blocked in castrates treated with a high dose of naloxone (5 mg/kg s.c.). Naloxone (1 or 5 mg/kg s.c.) also blocked the expression of a CPP in castrates. In male rats opioid inputs to neural reward circuits may normally be activated by incentive stimuli, but not by the primary rewarding stimuli associated with an estrous female. ROLES OF OPIOID AND BENZODIAZEPINE SYSTEMS IN MEDIATING EFFECTS OF SOCIAL COMPANIONS ON ULTRASONIC DISTRESS CALLS IN INFANT RATS. **S.E. Carden & M.A. Hofer. Columbia Univ. & N.Y.S. Psychiatric Inst., New York, NY 10032.**

Low doses of morphine (0.125mg/kg) and chlordiazepoxide (2.0 mg/kg) are equally effective in lowering the rate of ultrasonic distress calls in 10-day-old rat pups. The presence of a single anesthetized littermate in the test chamber reduces vocalization to a comparable degree.

We sought to evaluate the impact of opioid and benzodiazepine antagonists on the comforting effects of littermate or dam during testing in a novel environment.

Naltrexone, but not RO 15-1788, blocked the reduction in vocalization associated with the presence of a social companion. The opioid antagonist disrupted quiet contact between test pup and companion while the benzodiazepine blocker facilitated the behavior.

The presence of a companion may provide comfort by inducing a release of endogenous opioids and, in addition, may inhibit the release of an endogenous anxiogenic ligand to the benzodiazepine receptor.

340.5

PLACENTAL OPIOID-ENHANCING FACTOR DOES NOT MODIFY MORPHINE-INDUCED HYPERTHERMIA. M.B. Kristal, E.F. Ferguson*, J.J. Bruschetti* & A.C. Thompson*. Dept. of Psychology, SUNY at Buffalo, Buffalo, NY 14260.

We have reported that Placental Opioid-Enhancing Factor, ingested in amniotic fluid (AF), enhances opioid-mediated analgesia in rats. The present study assessed the effect of AF ingestion on opiate-mediated hyperthermia. This problem was of interest for two reasons. (1) The tail-flick test, used to assess pain threshold, is dependent on tail-skin temperature. If AF enhances morphine-induced hyperthermia and decreases tail-skin temperature, the use of the tail-flick test to assess analgesia would be confounded. (2) Is the opioid-enhancing effect of AF ingestion limited to analgesia?

Body temperature was monitored before and after rats were treated with 3mg/kg ip morphine sulfate (or .9% saline) and an orogastric infusion of AF (or a control). Three doses of fluid were assessed (.125 ml, .25 ml, and .75 ml) in 3 separate groups. Each rat served as its own drug x infusate control.

No significant interaction between AF (at any dose) and morphine-induced hyperthermia was found. As expected, this dose of morphine significantly increased body temperature at all post-injection test times (30,90, & 135 min).

The results suggest that (a) the assessment of analgesia after AF/morphine treatment is not confounded by concurrent changes in body temperature, and (b) that the effect of AF on opioid-mediated analgesia is not generalizable to all other opioid-mediated processes.

OPIOID RECEPTOR REGULATION OF MATERNAL BEHAVIOR IN RATS. P.E. Mann, C.H. Kinsley, P.M. Ronsheim, and R.S. Bridges. LHRRB, Harvard Medical School, Boston, MA 02115.

Opiates inhibit maternal behavior (MB) in rats. Central or systemic administration of morphine (MOR) disrupts MB in steroid-primed, pup-induced virgin and lactating rats. MOR, a putative mu agonist, interacts with different opioid receptor subtypes. The aim of the present study was to characterize those opioid receptor subtypes mediating opiate disruption of maternal behavior. Virgin, Sprague-Dawley rats were mated and then implanted with lateral ventricle cannulae on day 13-15 of gestation. On postpartum day 5 mothers were tested for MB 30 min after vehicle (VEH) injections (5 ul) into the lateral ventricle. On day 6 the rats received one of the following opioid receptor agonists (5 ul) 30 min before testing: B-endorphin (BE; mu/epsilon; 0.29, 0.72, 1.45, or 2.9 nm), [D-Pen^2,D-Pen^5]-Enkephalin (DPDPE; delta; 2.9, 29 nm), U-50,488H (kappa; 2.9, 29, 145 nm), SKF-10047 (SKF; sigma; 2.9, 29, 145 nm), or DAGO (mu; 0.29, 0.72, 1.45, 2.9 nm). Both BE (mu/epsilon) and DAGO (mu) significantly disrupted MB at the 2.9 and 1.45 nmolar doses compared to vehicle. Retrieval was affected by the 2.9 dose of BE and the 1.45 and 2.9 doses of DAGO. DPDPE (delta), U-50,488 (kappa) and SKF (sigma) failed to affect full MB or retrieval at any of the doses tested. These results suggest that disruption of maternal behavior by opiates and opioid peptides is regulated by the mu opioid receptor.

DELTA AND KAPPA OPIATE RECEPTOR CONTROL OF SEPARATION DISTRESS: J. Panksepp, P. Lensing* and G. Bernatzky*, Dept. of Psychol., Bowling Green State Univ, OHIO and Univ. of Salzburg, AUSTRIA.

The mu-opioid receptor system exerts powerful inhibition over isolation-induced distress vocalizations (DVs). We have now evaluated delta and kappa receptor agonists and antagonists (ant.) effects on DVs of 1-8 day old domestic chicks. For delta opioid receptors, ED-50s for DADLE and DPDPE (icv into 4th ventricle) were approx. 1.0 nmoles and for DSLET 0.5 nmoles. The delta receptor ant. ICI-154129 increased DVs following ip (10 mg/kg) and icv (10 ug) injections, but ICI did not antagonize the inhibitory effects of icv DPDPE (1 nmole) or morphine (1 ug). For kappa receptors, U-50,488 reduced DVs by about 50% at doses above 5 mg/kg but also produced sedation. These effects were reversed with the kappa specific ant. Mr-2266. U-50,488 icv up to 15 ug had little effect on DVs, while Mr-2266 at similar doses (ip and icv) reliably elevated the frequency of DVs. Delta receptor control of DVs is weaker than mu receptor control. Kappa-specific involvement in the inhibition of DVs remains ambiguous, but the Mr-2266 effects suggest a reduction of kappa tone may also promote this type of emotional arousal.

CNS BETA-ENDORPHIN: ITS ROLE IN GROWTH AND DEVELOPMENT AND IN BIOLOGICAL RESPONSES TO MATERNAL SEPARATION IN RAT PUPS. J. Bartolome, M. Bartolome*, B. Lorber*, A. Chao* and S. Schanberg*. Dept. Pharmacol. Duke Univ. Med. Ctr., Durham, N.C. 27710.

Accumulated evidence indicates that endogenous opioid peptides may have an important role in the regulation of perinatal development. The question remains as to which neuropeptides are involved and through which mechanisms do they regulate growth. This study examines the effects of central administration of beta-endorphin (BE) on important growth determinants. The responses to BE were then compared to those seen after a short-term separation of pups from their dams to find out whether the growth deficits observed in the deprived pups could be explained by changes in brain BE levels.

Intracisternal injection of BE to rat pups reduced ornithine decarboxylase (a key growth-regulatory enzyme) activity, and inhibited DNA synthesis in both brain and liver. Inhibition of DNA synthesis was still evident 12 hr after BE exposure. In addition, BE treatment prolonged the apparent half-life of plasma insulin, a classical trophic factor. Essentially the same pattern of biochemical and endocrine responses was seen in maternally deprived rat pups.

The results obtained strongly suggest a regulatory role for CNS BE in growth and development. The data also suggests that BE may be a prime mediator of the biological and physiological responses seen following interruption of mother-pup interactions. EVIDENCE THAT MU AND KAPPA OPIOID RECEPTOR SITES MEDIATE SUCKLING-INDUCED PROLACTIN SECRETION IN LACTATING RATS. M. Baumann and J. Rabii. Department of Biological Sciences, Rutgers University, Piscataway, NJ 08855.

Several investigators have reported that the opioid antagonist naloxone can significantly inhibit suckling-induced prolactin (PRL) release in the rat. However, the specific opioid receptor subtype(s) involved are not known. The relatively high doses of naloxone required to completely block the suckling-induced PRL surge [Selmanoff and Gregerson, 1986] suggest the importance of a non-mu receptor mechanism. We have employed selective opioid antagonists to determine the role of mu and kappa receptors in mediating PRL release during suckling *in vivo*.

Lactating mothers were implanted with intracerebroventricular (ICV) cannulae and chronic indwelling jugular cannulae. On day 10 of lactation, litters were removed for 4 hours and mothers were treated with opioid antagonists or vehicle. Pups were returned and allowed to suckle for 30 minutes. The irreversible mu opioid antagonist ß-funaltrexamine (ß-FNA) was injected ICV at doses of 2.0 and 10.0 nmol, 4 hours before pup return. Nor-binaltorphimine (nor-BNI), a putative kappa antagonist, was injected ICV at doses of 5.0 and 20.0 nmol, 45 minutes before pup return. Serial blood samples were withdrawn prior to and at 10, 20, 30 and 60 minutes after the onset of suckling.

Suckling stimulated a rapid and dramatic rise in plasma prolactin in all vehicle treated females. ß-FNA, on the other hand, suppressed suckling-induced PRL secretion in a dose-related manner. The 10.0 nmol dose of ß-FNA caused almost total abolition of the response. Likewise, the higher dose of nor-BNI completely blocked the surge of PRL during suckling. These data imply that both mu and kappa opioid receptors are physiologically relevant mediators of PRL release during lactation in the rat. ATTENUATION OF THE MORPHINE INDUCED ANALGESIC RESPONSE DURING LACTATION IN THE RAT. J. Janik, M. Baumann, P. Callahan and J. Rabii. Dept of Biological Sciences, Rutgers University, Piscataway, NJ 08855.

We have previously reported that lactating females are not sensitive to morphine or methadone stimulation of prolactin release. However, this model does show a prolactin secretory response to both β-endorphin and d-ala-d-leu-enkephalin (DADLE). The purpose of this study was to further characterize the sensitivity of the lactating model to morphine administration by measuring the morphine induced analgesic response using a hot water tail immersion test.

Lactating female rats between days 6 and 10 postpartum received saline or morphine at 2.5, 5.0 or 10.0 mg/kg (iv). Cycling females in the diestrous stage of the estrous cycle were similarly treated and served as controls. Some of the animals in each of the groups were pretreated with the μ_1 specific antagonist naloxonazine (NAZ; 20 mg/kg, iv) 24 hours prior to the morphine. A latency of 15 seconds was considered complete analgesia and the animal's tail was removed from the hot water bath.

Although the lactating model did exhibit analgesia following morphine administration, the analgesic response was attenuated compared to the non-lactating rats. In addition, NAZ pretreatment did not alter the analgesic response in the lactating model suggesting that the analgesia was produced by a receptor subtype other than the μ_1 site. However, NAZ pretreatment did attenuate the analgesia observed in the diestrous control rats. These results are consistent with the results obtained regarding the sensitivity of the prolactin secretory response to morphine during lactation. It seems likely that the μ_1 opiate receptor subtype is not active during lactation. (Supported by the Busch Memorial Fund and the Anne B. and James H. Leathem Scholarship Fund).

THE EFFECT OF ACUTE STRESS ON LEVELS OF IMMUNOREACTIVE BETA-ENDORPHIN IN DISCRETE BRAIN REGIONS IN RATS PRENATALLY EXPOSED TO ETHANOL. R.A. Baker and W.J. Shoemaker. Neuroscience Program and Dept. of Psychiatry, Univ. of Connecticut Health Center, Farmington, CT 06032.

Among many functions proposed for beta-endorphin is a role in modulation of stress. Several studies have reported depletion of immunoreactive beta-endorphin from certain brain regions after footshock (Izquierdo et al.1984, Netto et al.1985, Netto et al.1988). We have attempted to localize more specifically the regions affected by footshock stress in both normal rats and rats prenatally exposed to ethanol. Two baseline control groups were used, a) rats handled daily for 14 days prior to sacrifice and b) rats not handled prior to sacrifice. Rats were sacrificed by decapitation at 3, 10 and 30 minutes after a five second continuous 0.8 milliamp shock. Levels of beta-endorphin were measured by radioimmunoassay in the mediobasal hypothalmus, remainining hypothalamus, amygdala, mediodorsal thalamus, midbrain, medulla/pons and septal area including the nucleus accumbens. Levels in all brain regions, except the amygdala showed decreased beta-endorphin levels at 3 minutes post-shock, with the most dramatic effect seen in the septal region, in agreement with prior reports. Beta-endorphin levels after foot-shock in rats prenatally exposed to ethanol is particularly relevant since these rats have abnormal peptide levels (Shoemaker et al. 1983) and respond abnormally to behavioral measures of stress (Kehoe et al. 1988). Supported by NIAAA #06279.

UNILATERAL MICROINJECTIONS OF |D-ALA^2,N-ME-PHE^4,GLY^5-OL|-ENKEPHALIN (DAGO) INTO THE VENTRAL PALLIDUM (VP) PRODUCES CONTRALATERAL TURNING IN RATS. D.C. Hoffman, T.E.G. West* and R.A. Wise. Dept. Psych., Concordia Univ., Montreal, Canada, H3G 1M8.

Turning behavior following unilateral microinjection of the selective mu agonist, DAGO, into the VP of rats was investigated. Male Long-Evan rats were chronically implanted with bilateral cannulae aimed at the VP. Testing involved placing each rat in a cylindrical container and measuring the number and direction of 360° turns over a 120-min test period. Following tests with no injection and vehicle (Ringers solution), the effects of three doses of DAGO (0.02, 0.2 and 2.0 nmoles; administered in a counterbalanced order) were determined in each rat. Pretreatment with the opiate antagonist, naltrexone (1.0 mg/kg IP), on DAGO-induced circling was subsequently tested, followed again by control tests with vehicle and no injection. DAGO resulted in dose-dependent contralateral circling with both the frequency and duration increasing with larger doses. Circling produced by 2.0 nmoles was blocked in rats pretreated with naltrexone. These results suggest that mu receptors in the VP are involved in motor behavior and because this enkephalinergic projection likely originates in the nucleus accumbens, these neurons may represent an important output pathway in mediating locomotor activity associated with dopaminergic release in the accumbens.

LETHALITY OF MORPHINE IN MICE INFECTED WITH TOXOPLASMA GONDII. C. Chao*, B.M. Sharp*, C.Pomeroy*, G. Filice* and P.K. Peterson* (SPON: S.E. Nicol). Hennepin County Medical Center, VA Medical Center, and University of Minnesota Medical School, Minneapolis, MN 55404.

Opiates modulate a variety of immune functions. The present study was designed to investigate the effect of morphine on the pathogenesis of T. gondii infection. Repeated sc injections with morphine sulfate (6 mg/mouse) every 36 h addicted mice and markedly increased the mortality of mice infected with an avirulent strain of T. gondii (86% vs 0% mortality in addicted vs control mice, P<.001). However, addiction to morphine did not seem to be necessary for the lethal effect, since a single challenge with morphine also markedly (P<.001) increased mortality of infected mice when the morphine was administered at day 13 post-infection. Lethality after a single injection of morphine (6 mg) was not observed until day 9 post-infection, a time when significant immune reactivity was evident (i.e., 3-4 fold splenic hypertrophy). Death occurred rapidly - within 2 h of morphine administration. This lethal effect was dose-dependent (LD_{50}=1.75 mg) and was reduced (P < .05) by treatment with naltrexone. Sulfadiazine treatment for 5 days abrogated the lethality of morphine indicating an absolute prerequisite of an active infectious state for this phenomenon. These findings suggest that immune activation by T. gondii infection plays a critical role in morphine-induced mortality in this murine model. (Supported by grants DA-04381 and DA-04196).

ATTENUATION OF RESPONSE OF POMC PEPTIDES IN AUTISTIC AND SIB CHILDREN TO CHRONIC VERSUS ACUTE NALTREXONE. P.H. Herman, A. Arthur-Smith, K. Verebey* and J. Alrazi*. Brain Res Cen & Dept Psychiatry of Children's Hosp Natl Med Cen & George Washington Univ Sch Med, Washington, DC and PDLA, South Plainfield, NJ.

Naltrexone (NTRX) may be a useful tool in evaluating the proopiomelanocortin (POMC) HPA axis in autistic and self-injurious (SIB) children (Herman et al., Soc Neurosci 14:465, 1988), and this may relate to the therapeutic usefulness of this drug in these children. Here we compared NTRX(0.5,1.0,1.5 and 2.0mg/kg)and placebo administered acutely (once) versus chronically (three times) a week in 8 autistics without SIB (4-12 yrs) and in 5 severe SIBs(10-17 yrs). Blood was drawn 1 hr after oral drug. Plasma irß-endorphin (ß-E), cortisol (COR) and irACTH were measured by RIA, and plasma NTRX and 6ßnaltrexol (6ßNLT) by GC/MS. Acute NTRX resulted in two groups - one showing at least a 50% increase in irß-E, COR and irACTH in response to NTRX (POMC Stim) and a second showing no change (POMC NonStim). There was a highly significant difference in the irß-E, COR and irACTH response of these two groups to every acute NTRX dose (all p's < .0005), and these differences were not due to differences in plasma NTRX and 6ßNLT. These effects were greatly attenuated when the same doses of drug were chronically administered. Plasma NTRX and 6ßNLT concentrations were about twofold higher when drug was chronically versus acutely administered.

340.15

NALTREXONE BLOCKS THE EFFECTS OF PRENATAL EXERCISE ON REFLEX DEVELOPMENT IN THE MALE RAT. S.K. Elliott* and J.L. Voogt (SPON: M.K. Shellenberger). Dept. of Physical Therapy Ed. and Dept. of Physiology, Univ. of Kansas Med. Center, Kansas City, KS 66103.

We have previously reported that high intensity treadmill running during the third trimester of pregnancy in the rat induces delays in neonatal reflex development and permanently impairs exploratory behavior. (Neurosc. Abst. 41.14, 1988). Copulatory potentials in adult male offspring were also impaired, with reduction in SDN-POA volume. The opioid system has been implicated as a mediator of sexual behavior differentiation as well as somatic and brain development. It is also known that ß-endorphins are released during exercise in the rat. The present study investigated the effects of blocking opiate receptors during prenatal exercise on neuromotor development. Third trimester pregnant rats were injected daily with 2 mg/kg naltrexone (N-EX) at 0900, 1300 and 1700. The running protocol began at 1330 daily. Exercised controls received saline injections (S-EX). Non-exercised naltrexone injected pregnant females (N-C) and saline controls (S-C) were also included. S-EX offspring showed impaired reflex and exploratory behaviors. N-EX offspring showed reflex development consistent with the S-C group. However, N-EX exploratory behaviors were as impaired as in the S-EX group. N-C offspring showed accelerated growth and reflex development, but did not display advanced exploratory skills. These results suggest that exercise-induced reflex acquisition delays, but not complex exploratory behaviors, may be mediated by the opioid system. Investigation of copulatory behavior potentials and morphometric analysis of the somatosensory cortex is underway. (NIH-HD22340)

POTENTIATION OF MORPHINE AND STRESS INDUCED ANALGESIA IN MICE BY ANTAGONISM OF MAMMALIAN FMRF-AMIDE RELATED PEPTIDES. M. Kavaliers and H.-Y. T. Yang, University of Western Ontario, London, Canada and NIMH, St. Elizabeths Hosp. Washington D.C.

Two mammalian FMRFamide-like peptides have been isolated from bovine brain; an octapeptide, FLFQPQRFamide (F-8-F-amide) and an octadecapeptide, AGEGLSSPFWSLAAPQRF-amide (A-18-F-amide). Results of previous studies with rodents have suggested that FMRFamide and endogenous mammalian FMRFamide-related peptides may function as opiate antagonists. In the present study determinations were made of the effects of intracerebroventricular administrations of antibody (IgG) prepared from antisera raised against these peptides on nociception and morphine- and immobilization-induced opioid analgesia in male mice. Both F-8-F-amide-IgG and A-18-F-amide-IgG antisera augmented nociception (thermal response latency) and increased the durations and levels of morphine- and immobilization-induced analgesia in a naloxone reversible manner, with F-8-F-amide-IgG antiserum having a greater effect than A-18-F-amide-IgG antiserum. These observations provide additional support for the proposal that mammalian FMRFamide-like peptides function as endogenous opiate antagonists and have a role in the mediation of antinociception.

PAIN MODULATION: AFFERENT MECHANISMS

341.1

CONDITIONED ANALGESIA IN THE SPINALIZED RAT. J.A.Salinas*, P.A.Illich, M.W.Meagher & J.W.Grau (SPON:R.A.King). Dept. of Psychology, Texas A&M Univ., College Station, TX 77843.

Pairing a neutral stimulus with an aversive event can endow the stimulus with the ability to elicit analgesia. It has been generally assumed that forebrain systems play a critical role in producing this conditioned analgesia. However, there is some evidence that classically conditioned responses can be established in spinalized subjects. The present study assesses whether conditioned changes in pain reactivity can be obtained in spinalized subjects. Six rats received a spinal transection at T2. Eight hrs after the surgery, subjects received differential conditioning (which controls for both pseudoconditioning and sensitization). One stimulus (CS+) was paired with intense tail shock (2-sec, 3-mA), while the other (CS-) was presented alone. Mild shock (10-sec, 1.0-mA) delivered to the left or right paw served as the CS+ and CS-. The subjects received 30 CS+ and 30 CS- trials spaced 1 min apart. Which stimulus served as the CS+ was counter-balanced across subjects. Pain reactivity was then tested one hour later with the tail-flick test. Subjects appeared analgesic during the CS+ relative to the CS-. This difference extinguished over the course of testing. A second experiment was then performed to determine whether the conditioned analgesia is naltrexone reversible. We found that a large dose of naltrexone (14 mg/kg) did not attenuate the conditioned analgesia. Supported by NSF grant BNS 881981 to JWG.

341.2

PREVIOUSLY FOOD DEPRIVED RATS EXHIBIT AN EXAGERATED MORPHINE ANALGESIA. M.K. Biles*, P.A. Illich, and J.W. Grau. Dept. of Psychology, Texas A&M University, College Station, TX 77843.

Previous research has shown that an extended exposure to inescapable shock elicits a strong hormonally mediated opioid analgesia. In addition, it sensitizes the opioid system to being reactivated, 24 hr later, upon exposure to a low dose of morphine (1 mg/kg) (Grau et al., Science, 203: 1409, 1981). Here we determined whether another manipulation which elicits a hormonally mediated opioid analgesia, food deprivation (Hamm et al., Physiol. & Beh., 35: 879, 1985), has a similar sensitizing effect.

Subjects had their food removed and after 24 hrs were given 9 grams of food. After an additional 24 hrs, food was returned. Twentyfour hours after food was returned, subjects were injected with 1 mg/kg morphine or saline. Pain reactivity was assessed 30 min later with the tail-flick test. We found that morphine elicited a much stronger analgesia in previously food deprived subjects. In a second experiment, we assessed pain reactivity over a 2.5 hr period following the injection. We found that previously food deprived subjects exhibited an exagerated analgesia for the entire 2.5 hrs of testing. In both experiments, food deprivation had no impact on the levels of pain reactivity observed in the saline controls.

SEROTONERGIC AGONISTS PRODUCE ANTINOCICEPTIVE EFFECTS IN RESPONSE TO COLORECTAL DISTENSION. R.M. Danzebrink and G.F. Gebhart. Department of Pharmacology, The University of Iowa, Iowa City, Iowa, 52242.

The antinociceptive effects of intrathecally administered 5-HT and other serotonin receptor agonists were examined in a model of visceral pain (colorectal distension, CRD) in conscious rats. CRD reliably elicits a vigorous pressor response and contraction of the abdominal and hindlimb musculature (a visceromotor response). Antinociception is characterized by inhibition of both pseudaffective responses.

5-HT dose-dependently elevated the visceromotor threshold and produced a slight facilitation prior to dose-dependent inhibition of the pressor response to CRD. The 5-HT_{1A} agonist 8-OH-DPAT, the 5-HT_{1B} agonist RU-24969, the 5-HT_2 agonists DOI, MK-212, and -methyl-5-HT and the 5-HT_3 agonist 2-methyl-5-HT all dose-dependently inhibited the pressor and visceromotor responses to noxious CRD. The antinociceptive effects of 5-HT, RU-24969 and DOI were antagonized by methysergide. Ketanserin antagonized the antinociceptive effects of MK-212 and MDL-72222 antagonized the effects produced by 2-methyl-5-HT in response to CRD. The antinociception produced by 8-OH-DPAT was not antagonized by methysergide and the effects produced by -methy-5-HT were not antagonized by either methysergide or ketanserin. These results demonstrate that 5-HT_1, 5-HT_2 and 5-HT_3 receptors in the spinal cord mediate antinociception in response to noxious CRD in conscious rats.

341.4

INFLAMMATION POTENTIATES RESPONSES TO COLORECTAL DISTENSION IN THE RAT. T.J. Ness and G.F. Gebhart. Departments of Anesthesia and Pharmacology, The University of Iowa, Iowa City, Iowa, 52242

Turpentine (25% in peanut oil) produces inflammation when applied to the gut mucosa of rats as judged by plasma extravasation (Evan's Blue) and neutrophil infiltration. Colorectal distension (CRD) produces behavioral (conditioned avoidance), cardiovascular, visceromotor (abdominal/hindlimb muscle contractions) and neuronal (T13-L2 spinal dorsal horn) responses and counter-inhibitory effects.

When compared with responses in untreated rats, responses in turpentine-treated (colorectal mucosa) rats are potentiated 1,2,6,24 or 48 hours following treatment:

(1) 30 mm Hg, 20 s CRD produces conditioned avoidance in turpentine-treated, but not untreated rats;
(2) resting heart rate is higher in treated rats;
(3) pressor responses to CRD are greater in treated rats;
(4) pressure thresholds for activation of visceromotor responses to CRD are lower in treated rats;
(5) graded neuronal responses are increased 50-300% two hours following treatment with turpentine;
(6) graded inhibition of the tail-flick reflex by conditioning CRD was greater in treated rats.

In the aggregate, these studies suggest that turpentine-induced inflammation increases visceral nociception.

341.5

HYPOGASTRIC AND PELVIC NEURECTOMY CONTRIBUTE DIFFERENTIALLY TO VAGINOCERVICAL STIMULATION-PRODUCED ANALGESIA IN RATS. ST Cunningham, JL Steinman & BR Komisaruk, Institute of Animal Behavior, Rutgers Univ., Newark, NJ 07102.

Vaginocervical stimulation (VS) has been shown to elevate both tail flick (TF) latency to radiant heat and vocalization (VOC) threshold to electric shock. The present study examined the relative contributions of hypogastric neurectomy (HX) and pelvic neurectomy (PX) to VS-produced analgesia (VS-PA) as measured by these tests. Bilateral HX, PX or HXPX were performed 5-10 days prior to behavioral testing. After baseline (BL) was established, VS (400g force) was applied for 5 sec. Values are expressed as % change from BL; * = $p<0.03$; t-tests comparing each treatment group to unoperated controls (n's = 7-10).

	CONTROL	HX	PX	HXPX
TF	347%	169%*	148%*	42%*
VOC	27%	-17%*	52%	-9%*

In summary, HX or PX reduced VS-produced elevation in TF, and HXPX produced the greatest reduction. By contrast, HX and HXPX, but not PX alone, significantly reduced the VOC elevating effect of VS. These findings suggest that the hypogastric and pelvic nerves subserve different components of VS-PA. (Supported by NIH NLS-2-1R01-NS22948 to BRK).

341.6

VAGINOCERVICAL STIMULATION-PRODUCED ANALGESIA AND CORRELATED SPINAL CORD AMINO ACID RELEASE ARE DISRUPTED BY NEONATAL CAPSAICIN TREATMENT. D. B. Masters, C. Beyer*, F. Jordan*^, J. L. Steinman and B. R. Komisaruk. Institute of Animal Behavior and ^Dept. of Chemistry, Rutgers University, Newark, N. J. 07102 USA.

We hypothesized that inhibitory amino acids (Gly, Tau) are released within the spinal cord in response to vaginocervical mechanostimulation **(VS)** and thereby produce analgesia. This hypothesis was tested by HPLC analysis of the amino acid content of microdialysates of the sacral dorsal horn before, during, and after VS (400g force) in the urethane-anesthetized rat. Furthermore, the neurotoxic effect of neonatal capsaicin treatment **(NCT)** was utilized in order to increase pain thresholds to a wide variety of noxious stimuli. Our strategy was to diminish vaginal afferent activity by NCT and observe any corresponding change in amino acid release.

Results from adult female rats show a significant elevation in the NCT group (n=37) compared to controls (n=24) in response thresholds on the following tests: vocalization to tail shock (55%), paw lick to hot plate (76%), and tail flick (20%). By contrast, leg-flexor reflex to hindpaw-pinch was unaffected. VS in control rats significantly increased pain thresholds on all these tests 90-300%. The effect of VS in NCT rats was significantly less than in controls on all four tests. Moreover, NCT rats show a significant decrease in vocalization threshold (10%) during VS compared to pre-VS levels.

The results from *in vivo* dorsal horn microdialysates show that Gly and Tau are significantly increased by VS in control (n=4) but not NCT rats (n=8). However, Asp and Glu increase in response to VS in both groups. All statistics used ANOVA ($p\leq0.05$).

In conclusion, the evidence that VS lowers vocalization threshold in NCT rats indicates that VS releases nociception-producing transmitters and analgesia-triggering transmitters, the former being preferentially spared in vaginal afferents after NCT. The idea that excitatory and inhibitory amino acids mediate these events is consistent with their spinal release demonstrated in this study. Support NIH :1RO1NS22948-02 (BRK)

VAGAL AFFERENT MODULATION OF NOCICEPTION: CENTRAL PATHWAY. K. Ren, A. Randich and G.F. Gebhart. Departments of Pharmacology and Psychology, The University of Iowa, Iowa City, Iowa, 52242

Vagal afferent stimulation (VAS) at low and high intensities produce facilitation and inhibition, respectively, of spinal nociceptive transmission. Central substrates involved in these VAS-produced effects were further examined in this study. Cold block of the thoracic spinal cord abolished VAS-produced effects on spinal units. VAS-produced inhibition of responses of lumbar dorsal horn units to 50°C thermal stimuli was significantly attenuated by either transection of thoracic dorsal lateral funiculi (DLF) or microinjection of lidocaine into the thoracic ventrolateral funiculi (VLF). VAS-produced facilitation of unit responses was unaffected by DLF transection. Decerebration at the collicular level had little effect on VAS-produced inhibition, but eliminated VAS-produced facilitation. Bilateral microinjection of lidocaine into the region of the locus coeruleus (LC) attenuated VAS-produced inhibition and abolished VAS-produced facilitation. These results indicate that descending pathways engaged by peripheral VAS are located in the VLF and DLF of the spinal cord and at least one relay for the descending modulation produced by VAS is the LC. A rostral forebrain loop appears to be required for VAS-produced facilitation. Supported by NS 24958.

341.8

RELAY BY NUCLEUS TRACTUS SOLITARII (NTS) OF NOCICEPTIVE MODULATION BY VAGAL AFFERENT STIMULATION (VAS). A. Randich, K. Ren and G.F. Gebhart. Departments of Psychology and Pharmacology, The University of Iowa, Iowa City, IA 52242

Both VAS and NTS stimulation (NTSS) modulate spinal nociceptive transmission. Since vagal afferent fibers terminate primarily in the NTS, the functional role of the NTS in VAS-produced nociceptive modulation was examined. Spinal dorsal horn units were recorded extracellularly in anesthetized, paralyzed rats. VAS was applied to the central end of the cut cervical vagus nerve and modulated neuronal responses to 50°C heating of the skin as reported before. NTSS either ipsi- or contralateral to the spinal unit inhibited neuronal responses with equal efficacy. The apparent latency to NTSS-produced inhibition was 50 ± 10ms. NTSS decreased the slope of the stimulus-response functions of spinal units to graded heating without altering the response threshold. Quantitative comparisons revealed similarity between the effects of NTSS and VAS on spinal nociceptive transmission. Microinjection of lidocaine into the NTS significantly attenuated VAS-produced inhibition. VAS-produced facilitation was eliminated by microinjection of lidocaine into the contralateral, but not ipsilateral NTS. The data suggest that the NTS is a relay for VAS-produced modulatory effects. A multisynaptic relay of VAS-produced effects is suggested by the apparent latency to NTSS-produced inhibition. Supported by NS 24958.

ANTINOCICEPTIVE EFFECTS OF INTRAVENOUS SEROTONIN IN RATS. III. ROLE OF NON-VAGAL AFFERENTS. G.F. Gebhart, S.J. Lewis*, S.T. Meller* and M.J. Brody. Dept. Pharmacology, The University of Iowa, Iowa City, Iowa, 52242.

We have reported that intravenous (IV) serotonin (5-HT) produces a dose-dependent inhibition of the nociceptive tail-flick (TF) reflex in Sprague-Dawley rats through activation of vagal afferent fibers capable of engaging descending inhibitory systems. The aim of this study was to determine whether non-vagal afferents participate in the antinociceptive effects of acute doses of IV 5-HT (6-192 µg/kg) in lightly-anesthetized rats with either bilateral removal of the superior cervical ganglion, or transection of either the carotid sinus (CSN) or glossopharyngeal nerve (glosso). There were no differences in baseline TF latencies between groups and all groups showed a dose-dependent inhibition of the TF reflex to IV 5-HT. Control rats had an ED_{50} of 40 µg/kg. Bilateral removal of the SCG, or transection of the glosso or CSN resulted in varying degrees of increased sensitivity to IV 5-HT (ED_{50} of 25, 10 and 12 µg/kg, respectively). These results suggest that these non-vagal afferents modulate the antinociceptive effect of IV 5-HT mediated by vagal cardiopulmonary afferents.

CHARACTERIZATION OF EFFECTS OF SEROTONIN ON CORTICAL SENSORY EVOKED POTENTIALS (SEP). K.A. Follett, S.T. Meller*, S.J. Lewis*, M.J. Brody and G.F. Gebhart. Departments of Neurosurgery and Pharmacology, The University of Iowa, Iowa City, Iowa, 52242.

Stimulation in nucleus raphe magnus in rats inhibits the tail-flick (TF) reflex and SEP. Intravenous (IV) serotonin (5-HT) produces profound antinociception as measured by changes in TF latency (Neurosci. Abstr., this volume). The purpose of this study was to determine whether 5-HT also attenuates SEP, thereby providing insight into whether IV 5-HT activates brainstem antinociceptive systems.

Sprague-Dawley rats were anesthetized, paralyzed and artificially respired. Ten cortical SEP produced by electrical stimulation of the hindpaw (10 mA, 0.5 msec, 1/10 sec) were recorded epidurally and computer-averaged. Graded doses (6-288 µg/kg) of 5-HT were administered IV, after which 10 consecutive SEP were again recorded. IV 5-HT produced a dose-dependent reduction of SEP amplitudes. The average dose required for 50% reduction was 32 µg/kg (>90% reduction at 64 µg/kg). The latency to onset of the effect (30-60 sec) and the duration of action (< 1 min to 7-8 min) were directly related to the magnitude of SEP reduction. The doses required and the duration of effect are comparable to those associated with TF inhibition by IV 5-HT, indicating that this effect may be due to activation of cardiopulmonary afferents, which in turn may activate brainstem antinociceptive centers.

341.11

ANTINOCICEPTIVE EFFECTS OF INTRAVENOUS SEROTONIN IN RATS. I. CHARACTERIZATION. S.T. Meller*, S.J. Lewis*, T.J. Ness, M.J. Brody and G.F. Gebhart (SPON: R. Schelper). Dept. Pharmacology, The University of Iowa, Iowa City, Iowa, 52242.

The aim of this study was to systematically examine the effects of intravenous (IV) serotonin (5-HT) on nociception and blood pressure (BP) as 5-HT has been shown to be algesic, and there are 5-HT receptors on cardiopulmonary afferents. IV 5-HT produced a dose-dependent (6-192 µg/kg) inhibition of the tail-flick (TF) reflex (ED_{50}=40 µg/kg). A variety of anatomical and pharmacological manipulations were performed to characterize the antinociceptive effect of IV 5-HT and associated changes in BP. Removal of reflex apnea by artificial respiration did not alter inhibition of the TF reflex by IV 5-HT. Chlorisondamine pretreatment abolished depressor responses to IV 5-HT, but did not significantly alter inhibition of the TF reflex. Acute BP changes of similar magnitude and duration observed with 5-HT were produced by IV nitroprusside, phenylephrine or trimethaphan but did not change TF latency from baseline. Bilateral vagotomy abolished up to 70% of the antinociceptive effect of IV 5-HT. Finally, low thoracic spinal cord transection abolished inhibition of the TF reflex produced by IV 5-HT. These results indicate that the antinociceptive effect is not secondary to apnea, or BP changes and support the notion that IV 5-HT is a potent noxious stimulus capable of activating vagal afferents and eliciting antinociception by engaging descending inhibitory systems.

341.12

ANTINOCICEPTIVE EFFECTS OF INTRAVENOUS SEROTONIN IN RATS. II. ROLE OF VAGAL AFFERENTS. S.J. Lewis*, S.T. Meller*, M.J. Brody and G.F. Gebhart (SPON: J. Godersky). Department of Pharmacology, The University of Iowa, Iowa City, Iowa, 52242.

We have reported that intravenous (IV) serotonin (5-HT) produces a dose-dependent inhibition of the nociceptive tail-flick (TF) reflex in Sprague-Dawley rats through activation of vagal afferent fibers capable of engaging descending inhibitory systems. In that study, bilateral vagotomy abolished about 70% of the antinociceptive effect of 72 µg/kg 5-HT. The aim of this study was to examine which specific vagal afferent nerves might mediate this effect. The antinociceptive effects of acute doses of IV 5-HT (6-192 µg/kg) was examined in lightly-anesthetized rats with either bilateral vagotomy, aortic depressor (ADN), or superior laryngeal nerve (SLN) transections. There were no differences in baseline TF latencies between groups and all groups showed a dose-dependent inhibition of the TF reflex. Control rats had an ED_{50} of 40 µg/kg. Following bilateral vagotomy there was a dramatic shift to the right (ED_{50}=90 µg/kg) of the 5-HT dose-response curve. In contrast, bilateral transection of either the ADN or SLN resulted in a greatly enhanced sensitivity to 5-HT (ED_{50}=15 and 17 µg/kg, respectively). These results indicate that there is a complex interaction between these vagal cardiopulmonary afferents in response to IV 5-HT.

EFFECTS OF HYPERBARIC STRESS ON RESPONSE PATTERN AND MORPHINE-INDUCED ANALGESIA IN THE FORMALIN TEST. O.-G. Berge, K. Furset* and I. Garcia-Cabrera*, Dept. of Physiol., Univ. of Bergen, N-5009 Bergen, Norway.

Rats administered formalin (0.1 ml, 5 %) in a hind paw, and saline or morphine subcutaneously, were exposed to ambient pressure of either 1 or 48 bar in a helium-oxygen atmosphere. The behavior of the animals was monitored for 35 min at stable pressure, starting 25 min after the injections. The 48-bar groups showed an increase in total motor activity and a dramatic reduction in pain-related behavior, due to reduced licking, biting, sustained lifting and protection of the injected paw. Brief paw-lifting was not altered and there was no increase in freezing at 48 bar. Significant effects of morphine on accumulated time of total pain-related activity were only present at 1 bar. The total number of pain-related responses was much less affected by pressure and was dose dependently reduced by morphine at both pressures. The results demonstrate the advantage of evaluating several criteria in the formalin test, show that hyperbaric exposure alters the response pattern in this test and provide evidence against pressure reversal of morphine analgesia.

OPIOID MEDIATED DEPRESSION OF NOCICEPTION BY HYPERCAPNIA IN THE RAT.

G.D. Gamble* & R.J. Milne, Dept. of Physiology, University of Auckland, New Zealand. (SPON: S.Pockett)

Moderate hypercapnia elevates pain thesholds in human subjects. We have administered CO_2 in the inspired gas mixture to conscious rats. CO_2 in the range 5 to 10% produced moderate hypercapnia (P_ACO_2 : 40±8 to 90±9 mmHg) and elevated tail flick and leg flexion latencies 2 to 3 fold in both intact and spinalised animals. Tail skin temperatures were unchanged. The effects on withdrawal reflex latencies but not on P_ACO_2 or $P_AO_2$were blocked by naloxone (2mg/kg), and were not present in morphine tolerant animals. The effects were reduced by dexamethasone but were not changed by adrenalectomy or by guanethidine, propanolol or phentolamine. Hypercapnia delayed the onset of the late phase of behavioural responses to formalin injected into the plantar surface of the hindpaw. We conclude that moderate hypercapnia powerfully depresses flexor withdrawal responses to noxious stimuli, by a mechanism involving release of endogenous opioids but not systemic catecholamines. This effect may account in part for the elevation in pain threshold during impaired respiration.

EFFECTS OF DORSAL COLUMN (DC) STIMULATION ON C_8-T_5 SPINOTHALAMIC TRACT (STT) CELLS. **M.J. Chandler, T.J. Brennan, D.W. Garrison, K.S. Kim and R.D. Foreman. Depts. Physiol. and Physical Ther., Univ. Okla. HSC, Okla. City, OK 73190.**

We hypothesized that inhibition of spinothalamic tract (STT) neurons may provide a neural mechanism for attenuation of pain observed clinically with epidural spinal electrical stimulation of dorsal columns (DC). In 11 α-chloralose anesthetized monkeys, extracellular potentials were recorded for neurons (C_8-T_5) antidromically activated from the ventral posterior lateral thalamus. Effects of stimulating ipsilateral DC at C_3-C_5 (30-300 µA, 50-200 Hz, 250 µs) were determined on spontaneous cell activity and on activity evoked by cardiac and by innocuous or noxious somatic stimuli. DC stimulation reduced spontaneous or somatic-evoked activity in 2 of 2 cells excited only by noxious pinch (HT), in 4 of 11 cells excited by both pinch and brushing hair (WDR) and in 6 of 7 cells excited by pinch but inhibited by brushing hair (HTi). Conditioning stimuli from DC at intervals of 20-160 ms reduced spikes evoked by electrical stimulation (1-35 V, 1 Hz, 100 µs) of cardiopulmonary A-δ spinal afferents in 11 cells. Intracardiac bradykinin (BK) increased activity in 5 of 9 STT cells. DC stimulation reduced BK-evoked activity in 3 cells, excited and then inhibited 1 cell, and did not affect 1 cell. Thus, DC stimulation may attenuate pain by reducing activity of STT neurons which receive nociceptive somatic or visceral input. (Medtronics; HL22732)

TREATMENT WITH B-VITAMINS ENHANCES DIFFUSE NOXIOUS INHIBITORY CONTROLS OF NOCICEPTIVE NEURONS IN THE RAT SPINAL CORD. Q.-G. Fu *, J. Sandkühler and M. Zimmermann (SPON: A.F. HAASE). II. Physiol. Inst. Univ., 6900 Heidelberg, FRG

Diffuse noxious inhibitory controls (DNIC) produce spinal inhibition via a supraspinal loop involving serotonergic mechanisms. We studied the possibility that the analgesic effect of B-vitamins may be related to DNIC.

Rats were treated daily for 7 days with 1 ml/kg s.c. of vitamin B compound (B_1/B_6/B_{12}, 100 mg/100 mg/ 1 mg in 3 ml) or isotonic saline. On day 8, discharges were recorded with microelectrodes from lumbar spinal dorsal horn neurons under pentobarbital anaesthesia. Neurons were activated by noxious radiant heat (50°C, 10s) applied to the hindpaw. DNIC was induced by 35 s of repetitive electrical stimulation (1 ms, 0.8-8.0 mA, 500 ms trains at 50 Hz) starting 5 s before heating, via pairs of needles inserted at tail, ipsilateral forepaw or contralateral hindpaw.

In both groups of treatment the heat-evoked responses were inhibited by electrical stimulation of ipsilateral forepaw or contralateral hindpaw. The degree of inhibition increased at increasing intensity of transcutaneous stimulation. However, in the animals treated with B-vitamins the inhibitory effect was greater than in control animals, and the increment of inhibition with increasing current of stimulation was much steeper than in the controls. Thus B-vitamins enhance DNIC of spinal nociceptive neurons.

EFFECTS OF HIGH FREQUENCY TENS ON HEAT PAIN DISCRIMINATION. S. Marchand, M.C. Bushnell and G.H. Duncan. Cent. rech. sci. neurol. and Fac. méd. dent., Univ. Montréal, Canada H3C 3J7.

Numerous clinical reports have demonstrated that high frequency TENS can reduce patients' complaints of pain. We have recently verified, in a controlled laboratory setting, that TENS reduces subjects' evaluations of experimental heat pain (Marchand et al., 1988). In order to further evaluate the role of TENS in modulating sensory-discriminative aspects of nociception, this study assessed subjects' ability to detect small changes in noxious heat stimuli before, during and after high frequency TENS.

Ten subjects detected small differences in the intensity of painful heat stimuli applied to the cheek. Subjects participated in one TENS session and one placebo session, in which they discriminated small changes in painful heat (47°C to 47.1°, 47.25°, 47.4°, 47.55° and 47.7°C) and nonpainful visual stimuli, before, during and after the application of 100 Hz nonpainful TENS or placebo TENS.

When compared with the placebo sessions, nonpainful TENS significantly decreased the subjects' mean percent success for detecting the temperature changes during treatment (21% reduction during TENS, 2.9% *increase* during placebo TENS, $P<0.001$); in addition, this effect persisted after the treatment was terminated (12.2% reduction after TENS, 6.7% *increase* after placebo TENS, $P<0.05$). Correspondingly, the latency to detect the temperature changes was significantly increased during TENS compared to the placebo condition (11.5% increase versus 3.0% decrease, respectively, $P<0.01$), as well as after TENS (13.1% increase versus 4.5% decrease, respectively, $P<0.01$). Neither the percent success nor the latency to detect changes in the visual stimuli was altered by TENS.

These data show that the TENS treatment selectively altered the heat pain discrimination, thus indicating that activity in sensory-discriminative pain pathways is modulated by high frequency nonpainful TENS.

DOES A COULOMETRIC RELATION DETERMINE WHETHER ANALGESIA IN THE DECEREBRATE RAT IS OPIOID OR NONOPIOID IN FORM? M.W. Meagher, J.W. Grau, & R.A. King, Depts. of Psychology, Texas A&M University, College Station, TX 77843, and UNC, Chapel Hill, NC 27514.

Terman et al. (Science, 226: 1270, 1984) have suggested that the coulometric relation (mA*sec) determines whether shock directly activates an opioid or nonopioid analgesic system at the level of the brainstem: low coulometric products elicit an opioid analgesia, while high coulometric products elicit a nonopioid analgesia. Here we test this hypothesis by evaluating whether a coulometric relation determines the form of the analgesia (i.e. whether its opioid or nonopioid) observed in the decerebrate rat. We first identified the minimum coulometric products required to elicit analgesia in the decerebrate rat on the tail-flick test. We found that either 3, 25-sec, 0.5 mA or 3, 12.5-sec, 1.0 mA shocks were required. We then compared the form of the analgesia elicited by these shock schedules to that elicited by 3, 25-sec, 1.0 mA shocks. (Elsewhere we have shown that the analgesia observed after these shock schedules depends upon supraspinal systems.) All 3 shock schedules induced significant antinociception. However, naltrexone (14 mg/kg) had no effect on the analgesia observed in any of the groups. This suggests that only the nonopioid brainstem analgesic systems may be directly activated by shock. Supported by NIDA grant DA04259-01 to JWG.

INDEPENDENCE OF MOOD ELEVATION AND ANTINOCICEPTION INDUCED BY RUNNING IN MAN. M. Glusman, W.C. Clark*, M.N. Janal*, and J. Kuhl*. Lab. of Behavioral Physiology, New York State Psychiatric Institute, New York, N.Y. 10032.

Running produces stress induced analgesia and mood elevation in man (Janal, M.N., et al, Pain, 19:13-25, 1984). The present study shows that these effects are independent of each other. Antinocicept-ion requires prolonged hard running for its production, whereas mood elevation is elicited sooner and at lower levels of stress. Furthermore, under particularly stressful circumstances, e.g., a long hard run at an uncomfortably hot temperature, antinociception occurs without mood elevation.

In an initial experiment 37 Ss (13 trained runners and 24 sedentary Ss) ran the Bruce Protocol to 90% of maximal heart rate on a treadmill. Mean duration of exercise was 11.7 min. Mood, measured by visual analog scales, was significantly elevated postrun, whereas pain perception, measured by the ischemic arm pain test, was not significantly altered. In another experiment a 50 min outdoor run at near racing speed produced both antinociception and mood elevation in 12 trained runners. Lastly, a similar run by 5 trained runners in uncomfortably hot weather (mean temp. 30.9 C) produced antinociception and a decrease in mood ratings.

341.20

NOVELTY-INDUCED ANALGESIA IN THE NAPLES HIGH- AND NAPLES LOW-EXCITABLE RAT LINES. A.G. Sadile, H. Welzl*[2] and B. Siegfried*[3]. Inst. Human Physiol. & Med. Biophys., Univ. Naples, Italy; Insts. [2]Behav. Biol. & [3]Pharmacol., ETH & Univ. ZUrich, Switzerland.

Naples High-Excitable (NHE) and Naples Low-Excitable (NLE) rat lines are genetically selected for arousal in response to a novel environment (activity in a Lät-maze). Exposure to a spatial novelty has been reported to induce analgesia (Siegfried, B. et al., Behav.Neurosci., 101:436, 1987). If a differential reactivity to novelty underlies the behavioral differences found in the NHE and NLE rats, differences in novelty-induced analgesia (NIA) between the 2 lines should also occur. Therefore, we measured NIA by the tail-flick latency (TFL) method in NHE/NLE rats and in their controls (random bred and F_2 hybrids) before and at different times after exposure to a complex tunnel maze. All groups did not differ in their baseline TFL. After the exposure to novelty NLE rats increased their TFL to a larger extent than controls whereas the TFL of NHE rats remained close to baseline levels. These differences disappeared with ageing. Since, however, adult (6mo.) as well as ageing (15mo.) NHE/NLE rats were different in activity upon exposure to a novel environment, different mechanisms might underlie novelty-induced analgesia and novelty-induced hyperactivity.

PSYCHOTHERAPEUTIC DRUGS: ANTIDEPRESSANTS

342.1

LITHIUM FACILITATION OF SYNAPTIC TRANSMISSION DEPENDS ON PROTEIN KINASE C (PKC). M.S. EVANS*, D.B. CLIFFORD and C.F. ZORUMSKI. Depts. of Neurology and Psychiatry, Washington University Sch. of Med., St. Louis, MO 63110.

Lithium is a commonly-used psychotherapeutic agent, but how it influences nervous system function is unclear. Lithium facilitates excitatory synaptic transmission in hippocampus. This is likely to be important for seizure syndromes caused by lithium, but it may also be important for lithium's therapeutic effects. Because lithium affects G proteins and PKC in other systems, we asked if this effect of lithium on synaptic transmission might involve one of these second messengers. We studied lithium's effect on extracellular EPSPs at the Schaffer collateral/CA1 synapse in rat hippocampal slices. Pretreatment of rats with intraventricular pertussis toxin did not alter synaptic facilitation by lithium. Activation of PKC by phorbol esters enhanced synaptic transmission, and occluded the facilitatory effect of lithium. Inhibition of PKC by H7 or spingosine did not markedly affect synaptic tran smission, but these treatments also eliminated lithium's facilitation of synaptic transmission. Lithium facilitates ecitatory synaptic transmission by enhancing transmitter release (Evans, et. al., Soc. Neuro sci. Abstr. 14:1094, 1988); In cultured pituitary cells lithium facilitates corticotropin release by a mechanism involving PKC (Zatz, M. and T.D. Reisine Proc. Nal. Acad. Sci. U.S.A. 82:1286-1290, 1985). suggesting that lithium may have a widespread effect on secretory processes involving PKC. This may account for some of lithium's psychotherapeutic and toxic effects.

342.2

EFFECTS OF CHRONIC LITHIUM TREATMENT ON PROTEIN KINASE C (PKC) AND PKC-MEDIATED PH CHANGES IN HL60 CELLS. J. A. Bitran,* F. Gusovsky, H. K. Manji,* and W. Z. Potter* (SPON: A. J. Nazarali). Lab. of Clin. Sci., NIMH, and Lab. of Bioorg. Chem., NIDDK, NIH, Bethesda, MD 20892.

Lithium effects on signal transduction are of great interest. We studied the effects of chronic LiCl treatment on dibutyryl cyclic AMP differentiated HL60 cells. Chronic treatment (7 days) with 1 or 10 mM LiCl markedly attenuated both the agonist (fMLP) and phorbol ester induced pH changes (thought to be mediated by PKC regulation of the Na/H antiporter activity). In contrast, chronic LiCl did not affect phosphoinositide turnover or agonist induced intracellular [Ca^{2+}] increases. These results suggested a selective LiCl effect on PKC, which we further investigated.

Chronic LiCl treatment resulted in decreases in both cytostolic and membrane associated PKC activity. In addition, immunoblot analysis demonstrated decreased PKC amounts in both fractions following chronic LiCl treatment. Thus, alterations in PKC function may represent a mechanism for the therapeutic actions of lithium. The possibility that modification of PKC function represents a primary (rather than a compensatory) effect of chronic LiCl treatment is currently under investigation.

342.3

THERAPEUTIC DOSES OF LITHIUM ENHANCE HYPOTHALAMIC SEROTONIN TURNOVER IN RATS: A MICRODIALYSIS STUDY. T. Baptista*[2], L. Hernandez*[2], J. L. Burguera*[3], M. Burguera*[3] & B.G. Hoebel[1] (SPON: D. Chou). [1]Dept. Psychol., Princeton Univ., Princeton, NJ 08544-1010, [2]Laboratorio de Fisiologia de la Conducta, Escuela de Medicina, Merida, Venezuela, [3]Departmento de Quimica, Facultad de Ciencias, Merida, Venezuela

Chronic administration of lithium salts improves the symptoms of bipolar disease; however, the mechanism of action of lithium is not well known. Some *in vitro* and *postmortem* studies strongly suggest that central serotonergic neurons might be involved in lithium therapeutic effects. In the experiments reported here microdialysis with removable probes and high pressure liquid chromatography with electrochemical detection were used to assess amphetamine-induced release of serotonin (5-HT) and its metabolite 5-HIAA in the perifornical hypothalamus (PFH) and hippocampus (HP) of freely moving rats before and after chronic lithium chloride administration (2 meq/kg, by intragastric daily injections for 14 days). With this treatment, the serum levels of lithium, as measured by atomic absorption spectrometry were 0.65 $\pm$ 0.2 meq/l. These levels are within the therapeutic window for humans. After lithium treatment, amphetamine-induced 5-HT release was significantly enhanced in the PFH but not in the HP. The basal levels of 5-HIAA in the PFH but not in the HP were also enhanced. We speculate that this effect of lithium on the hypothalamus could be related to the improvement in autonomic and cyclic symptoms of manic-depressive patients undergoing lithium therapy.

342.4

THE TRICYCLIC ANTIDEPRESSANT DESIPRAMINE HAS BIPHASIC EFFECTS ON THE GROWTH OF RAT PHEOCHROMOCYTOMA (PC12) CELLS IN VITRO. D.A. Tanen*, P. Montpied* and S.M. Paul*, (SPON:H. Khachaturian). Section on Molecular Pharmacology, Clinical Neuroscience Branch, NIMH, Bethesda, MD 20892 and Howard Hughes Medical Institute.

Rat pheochromocytoma (PC12) cells have proven useful as in vitro models of adrenal chromaffin cells and can differentiate in response to growth factors to assume the phenotypic properties of sympathetic (noradrenergic) neurons. Tricyclic antidepressants, such as desipramine (DMI), are believed to produce their therapeutic effects by altering the activity of central noradrenergic neurons, although their precise mechanism(s) of action remain obscure. Consequently, we have studied the effects of desipramine on a number of cellular properties of PC12 cells that are related to catecholamine release, biosynthesis, uptake, and metabolism. In the course of our experiments, we observed that incubation of PC12 cells with varying concentrations of desipramine (0.1-20 μM) results in a biphasic effect on cell growth.

PC12 cells were grown (1-14 days) in DMEM supplemented with 7% horse and fetal calf serum. Cells were incubated for various times in the presence and absence of desipramine, harvested, and counted using a Coulter Counter. Cell growth was also monitored by pulse labelling with [^{3}H] thymidine.

Desipramine (2-20 μM) resulted in an increase in cell number following long-term (5-14 days) incubation; whereas lower concentrations of desipramine tended to inhibit cell growth. Desipramine did not appear to alter the differentiation of PC12 cells. Experiments measuring [^{3}H] thymidine incorporation revealed an early (24 hour) effect of desipramine (1-20 μM) on DNA synthesis. These data suggest that desipramine may have an heretofore undescribed effect on PC12 cell growth. Studies on the effects of other chemically-related (and unrelated) antidepressants on PC12 growth will be presented.

342.5

THE EFFECT OF CHRONIC ADMINISTRATION OF ANTIDEPRESSANTS ON α_2 ADRENOCEPTORS IN THE LOCUS COERULEUS (LC). CE Aronson*[1], and GB Kovachich[2,3] (Spon: C O'Brien). Univ. of Penn. Sch. of Vet. Med.[1], Univ. of Penn. Sch. of Med.[2], Vet. Admin. Med. Ctr.[3], Phila., PA 19104.

Many antidepressants acutely suppress the firing rate of the LC, but the suppressed activity returns towards control values with repeated administration of these drugs. This "escape" of the suppressed firing rate may be accompanied by subsensitive responsiveness of the LC to α_2 adrenoceptor agonists. To determine if such reduced responsiveness could be accounted for by changes in α_2 adrenoceptors in the LC, we used the technique of quantitative autoradiography to measure these receptors (ligand: ^{3}H-idazoxan, 3nM, $\pm$ phentolamine, 5μm.) Antidepressants, administered to rats for 14-21 days, were protriptyline, phenelzine, mianserin, citalopram and sertraline. Protriptyline, phenelzine and mianserin produced statistically significant (about 15%) reductions in the binding of ^{3}H-idazoxan whereas neither citalopram nor sertraline caused this effect. Thus, antidepressants that acutely affect the functioning of noradrenergic nerves may reduce α_2 adrenoceptors in the LC. **(Supported by Research Funds from the Vet. Admin.)**

342.6

EFFECTS OF ANTIDEPRESSANTS ON LOCUS CERULEUS (LC) DISCHARGE: COMPARISON BETWEEN A NORADRENERGIC REUPTAKE INHIBITOR AND A SEROTONERGIC REUPTAKE INHIBITOR. A. L. Curtis, D. Parris* and R. J. Valentino. Department of Pharmacology, George Washington University Medical Center, Washington D.C. 20037.

Corticotropin-releasing factor (CRF) which has been hypothesized to be hypersecreted in depression, activates LC neurons and disrupts LC responses to phasic sensory stimuli. The hypothesis tested was that antidepressants have effects on LC discharge characteristics that are opposite to those of CRF. Acute administration of the norepinephrine reuptake inhibitor, desmethylimipramine (DMI, 0.1 and 0.3 mg/kg, i.v.), decreased LC spontaneous discharge rates of halothane-anesthetized rats and altered the response of LC cells to phasic sensory stimuli such that the ratio of evoked-to-tonic discharge was increased. These effects are opposite those produced by CRF. However, tolerance occurred with chronic DMI administration. In contrast, acute administration of the serotonin reuptake inhibitor, sertraline (SER, 1.0 and 3.0 mg/kg, i.v.), had no effect on LC spontaneous discharge, and decreased the ratio of evoked-to-tonic discharge during repeated phasic sensory stimulation. Chronic administration of SER resulted in an enhanced response of LC cells to phasic sensory stimuli and thus an increased ratio of evoked-to-tonic activity. The present results suggest that chronic administration of antidepressants that selectively inhibit serotonin reuptake may oppose the effects of CRF on LC responses to phasic sensory stimuli. The net effect of these drugs may be to enhance LC responsiveness to phasic sensory stimuli and this may be one mechanism of their antidepressant action. Supported by NIH grants MH 40008 and MH42796.

CHRONIC ANTIDEPRESSANT ADMINISTRATION ATTENUATES STRESS-INDUCED ACTIVATION OF NORADRENERGIC LOCUS CERULEUS (LC) NEURONS. Rita J. Valentino and Andre L. Curtis. Department of Pharmacology, George Washington Univ. Med. Ctr., Washington D.C., 20037.

Corticotropin-releasing factor (CRF) increases LC spontaneous discharge. Likewise, i.v. infusion of nitroprusside increases LC spontaneous discharge by releasing CRF. Because CRF is thought to be hypersecreted in depression, it was hypothesized that chronic antidepressant administration would either antagonize CRF or block stress-elicited CRF release. To test this hypothesis, LC spontaneous discharge was recorded in halothane-anesthetized rats that were chronically administered the norepinephrine reuptake inhibitor, desmethylimipramine (DMI, 10 mg/kg/day, i.p. for 21 days), or the serotonergic reuptake inhibitor, sertraline (SER, 10 mg/kg/day, i.p. for 21 days). I.C.V. administration of CRF (3.0 μg, i.c.v.) increased LC spontaneous discharge rate of chronic DMI and SER rats by a similar magnitude as reported for untreated rats. However, LC activation by nitroprusside infusion was greatly attenuated in rats chronically administered DMI indicating that stress-induced CRF release was decreased in these rats. This effect was not apparent in rats acutely administered DMI (0.3 mg/kg, i.v.), or in rats chronically administered SER. Chronic DMI did not alter the magnitude or time course of nitroprusside-elicited hypotension. The present results suggest that chronic administration of antidepressants which are selective in blocking norepinephrine reuptake may attenuate the hypersecretion of CRF in depression, and this may be one mechanism for their antidepressant effects. Supported by NIH Grants MH 40008 and MH 42796.

ELECTROPHYSIOLOGICAL EFFECTS OF THE ANTIDEPRESSANT CANDIDATE, NEFAZODONE, ON MONOAMINERGIC NEURONS IN RATS. C.P. VanderMaelen and J.P. Braselton. Bristol-Myers Company, Preclinical CNS Research, 5 Research Parkway, Wallingford, CT 06492.

Nefazodone, an antidepressant candidate chemically related to trazodone, is currently undergoing clinical evaluation. In the present series of experiments, the effects of systemically administered nefazodone on the spontaneous firing rates of noradrenergic neurons in the locus coeruleus (LC), serotonergic neurons in the dorsal raphe (DR) nucleus, and A9 dopamine neurons in the substantia nigra were assessed in male Sprague-Dawley rats anesthetized with chloral hydrate. Standard techniques for extracellular single-unit recording using glass microelectrodes were employed. Nefazodone (0.1-10.0 mg/kg, i.v.) produced a mild excitation of LC neurons (ED_{25} = 2.4 mg/kg, i.v.), while desipramine (1.0 mg/kg, i.v.) produced the expected suppression of firing. In the DR, nefazodone (0.1-3.2 mg/kg, i.v.) produced variable effects, with the predominant effect being a weak inhibition (ED_{25} = 1.3 mg/kg, i.v. for cases where inhibition occurred). By comparison, clomipramine (0.8 mg/kg, i.v. or greater) effectively inhibited DR neuronal firing. No consistent effect of nefazodone was seen for A9 dopamine neurons. These results when compared to results reported in the literature suggest that nefazodone has a unique electrophysiological profile compared to antidepressants of the MAOI, TCA, and 5-HT uptake inhibitor classes.

ANTIDEPRESSANT-LIKE EFFECTS OF TRAZODONE ON DIFFERENTIAL-REINFORCEMENT-OF-LOW RATE 72-S (DRL 72-S) BEHAVIOR IS MEDIATED BY THE PARENT COMPOUND, NOT THE METABOLITE M-CHLOROPHENYLPIPERAZINE. Gerard J. Marek, Timothy H. Hand, Abby A. Li* and Lewis S. Seiden. Dept. Pharmacological & Physiological Sciences, Univ. of Chicago, Chicago, IL 60637.

The atypical antidepressant drug trazodone tests similar to other antidepressant drugs (increased reinforcement rate and decreased response rate) on a behavioral screen for antidepressant drugs (the DRL 72-s schedule of reinforcement; Seiden et al.,1985). One of the most potent pharmacological actions of trazodone is antagonism of 5-HT_2 receptors. The main metabolite of trazodone in both humans and rodents is the 5-HT_{1B} agonist m-chlorophenylpiperazine (m-CPP). The present experiments were designed to determine if the antidepressant-like effects of trazodone on the DRL 72-s schedule are due to the parent compound or the major metabolite m-CPP. Administration of m-CPP (1-10 mg/kg,ip) to Sprague-Dawley rats 60, 30 or 10 min. before the behavioral session did not mimic the reinforcement rate increasing effects of trazodone (10-20 mg/kg). Next, the enzyme inhibitor proadifen (SKF 525 A; which blocks conversion of trazodone into m-CPP) was administered 3 hrs prior to trazodone. Proadifen (50 mg/kg,ip) by itself was without effect on DRL 72-s behavior. Proadifen administration prior to trazodone caused a > 30-fold leftward shift in the dose response curve for both the reinforcement rate and the response rate. These results suggest that the parent compound, and not the trazodone metabolite mCPP, mediates the antidepressant-like effects of trazodone on DRL 72-s behavior. This research is suppo ted by PHS MH-11191; RSA MH-10562 (L. Seiden) and MSTP Grant GM-07281 (Marek).

EFFECTS OF ANTIDEPRESSANTS ON BASAL & NE-STIMULATED ^{3}H-INOSITOL PHOSPHATE FORMATION IN RAT CORTICAL SLICES. L.E. Dyck and A.A. Boulton, Neuropsychiatric Research Unit, Dept. of Psychiatry, Univ. of Sask., Saskatoon, Sask., Canada S7N 0W0.

Some antidepressants (ADs) possess considerable affinity for α_1-antagonist receptors, and thus might be expected to interfere with NE-stimulated inositol trisphosphate formation, which is an α_1-receptor-mediated response. We investigated this possibility by incubating rat cortical slices (50 µl, ~1 mg protein) with ^{3}H-inositol (1 µCi) for 1 h to label phosphoinositides, and then measured the formation of ^{3}H-inositol phosphates (IPs) during a 1 h incubation in the presence of 10 mM LiCl. IPs were isolated by adsorption onto an anion exchange column. NE-stimulated IP formation was inhibited dose-dependently by tricyclic ADs, mianserin, citalopram and tranylcypromine (IC_{50}'s, ~ 3-200 µM). By contrast, basal rates of IP formation were stimulated by higher concentrations (≥ 0.1 mM) of the tricyclic ADs, but not by the other ADs. Prazosin did not block tricyclic AD-stimulated IP formation; therefore, the tricyclics did not seem to be acting either as inhibitors of the reuptake of endogenous NE or as partial α_1-agonists. An examination of the types of IPs formed by ADs showed increased amounts of inositol monophosphate and decreased amounts of inositol bisphosphate compared to control. The mechanism(s) of the latter effects is unknown; however, the efficacy of the ADs at inhibiting NE-stimulated IP formation correlated to their reported affinities for of α_1-antagonist-receptors. Supported by Rhone Poulenc Pharma Inc. and Sask. Health.

ANTIDEPRESSANT DRUG TREATMENT WITH AN MAOI DECREASES HYPOTHALAMIC TEMPERATURE IN SYRIAN HAMSTERS. B. Gao* and W. Duncan* (SPON: J. Passonneau). Clinical Psychobiology Branch, NIMH, Bethesda, MD 20892

We have previously observed that chronic treatment of Syrian hamsters with the antidepressant drug clorgyline (CLG), a type A monoamine oxidase inhibitor, results in REM sleep suppression and a decrease in peritoneal temperature (T_p). Both decreased T_p and REM sleep suppression may be related to altered hypothalamic temperature regulation. The current experiment measured hamster hypothalamic temperature (T_h) and motor activity during baseline (BL) and 3 weeks of CLG or saline (SAL) treament. Using Alzet mini-osmotic pumps, CLG (2mg/kg/day, n=4) or SAL (n=2) was administered s.c. to hamsters housed in LD 14:10 at 22°C. T_h and motor activity (A_m) were monitored continuously during the hamster activity-rest cycle using the Mini-Mitter telemetry system. Compared to the light phase BL, CLG decreased T_h by 0.4°C, 0.3°C and 0.3°C during weeks 1, 2 and 3. Light phase A_m was decreased by 27% during weeks 1, 2 and 3. Compared to the dark phase BL, CLG decreased T_h by 0.2°C and A_m by 17% during week 1. T_h normalized and A_m tended to normalize during weeks 2 and 3. These effects were not observed in SAL-treated hamsters. These results suggest that CLG decreases the hypothalamic temperature set-point during the light (or rest) phase of the hamster circadian cycle.

342.12

NEONATAL DESIPRAMINE ADMINISTRATION TO RATS AFFECTS IMMOBILITY IN THE PORSOLT SWIM TEST AND DIURNAL RHYTHM OF RUNNING WHEEL ACTIVITY. K.D. Dwyer*, K.S. Albrecht* and E.J. Roy. Neural & Behavioral Biology Program, University of Illinois, Champaign, IL 61820.

Neonatal administration of antidepressants to rats has been proposed as an animal model of depression. In the present study we measured behavioral and biochemical indices to examine the validity of this proposed animal model of depression.

Neonatal rats were treated with saline or 5mg/kg desipramine (DMI) each day for 11 days. At 1 mo of age, open field behavior of the rats was examined. At 2 mos of age the animals were tested for immobility in a 15 min Porsolt swim test. 24 hrs later immobility was measured again in a 5 min swim test. Between the 2 swim tests the animals were administered antidepressants or saline. At 4 mos of age the female rats were placed in running wheels to assess diurnal rhythms. Several biochemical indices were measured post-mortem.

Consistent with previous studies, rats treated neonatally with DMI showed increased immobility in the first swim test. However in the second swim test animals failed to increase immobility. The rats treated neonatally with DMI showed a phase-advance in running wheel activity on proestrus, similar to the changes in diurnal rhythms associated with depression. The results of this study indicate that neonatal DMI administration produces changes in the Porsolt swim test and changes in diurnal running activity suggestive of a useful animal model of depression, but further validation is necessary.

342.13

BEHAVIORAL CHARACTERIZATION OF THE NOVEL ANXIOLYTIC/ANTIDEPRESSANT AGENT WY-50,324 H. Morris*, S.M. White, A.T. Shropshire*, M. Abou-Gharbia, C.A. Boast and J.A. Moyer. Wyeth-Ayerst Research, CN 8000, Princeton, NJ 08543-8000

Wy-50,324 [N-(2-(4-(2-pyrimidinyl)-1-piperazinyl)ethyl)tricyclo(3.3.1.1(3,7) decane-1-carboxamide] is a novel adamantyl piperazine derivative that has been shown to have both 5-HT1A partial agonist and 5-HT2 antagonist activity (Moyer et al., Soc. Neurosci. Abstr. 1989). Wy-50,324 reduced mouse isolation-induced aggression (MED = 10 mg/kg i.p.) and in rats weakly reduced avoidance responding (AB50 = 25, 30 mg/kg i.p.), and produced hypothermia. This profile is similar to that of some nonbenzodiazepine anxiolytics. Unlike these agents, Wy-50,324 produced significant effects in Geller-Seifter conflict in rats by increasing punished responding at a dose which did not reduce VI responses (10 mg/kg i.p.). In ancillary studies, Wy-50,324 did not produce catalepsy or antagonize apomorphine-induced effects; it produced limited sedation/ataxia, and showed no ethanol interaction effects in mice. These results indicate that Wy-50,324 has a unique anxiolytic behavioral profile with limited CNS side effects.

342.14

PSYCHOPHARMACOLOGICAL PROFILE OF WY-50,324 - A NOVEL ANXIOLYTIC/ANTIDEPRESSANT AGENT. J.A. Moyer, R.F. Kucharik*, T.H. Andree, S.M. White, D. Grimes*, R.A. Scerni*, R.L. Fenichel* and M. Abou-Gharbia. Wyeth-Ayerst Research, CN 8000, Princeton, NJ 08543-8000

Wy-50,324 [N-(2-(4-(2-pyrimidinyl)-1-piperazinyl)ethyl)tricyclo(3.3.1.1(3,7)) decane-1-carboxamide] is a novel adamantyl piperazine derivative. Like non-benzodiazepine (BZ) anxiolytics, Wy-50,324 has very high affinity at 5-HT1A receptors *in vitro* (Ki = 1nM) and demonstrates partial 5-HT1A agonist activity *in vivo* in rat serotonin syndrome tests (agonist ED50 = 13 mg/kg i.p., antagonist ED50 = 8 mg/kg i.p.). Unlike most non-BZ anxiolytics, Wy-50,324 also has high affinity at 5-HT2 receptors (Ki = 66nM) and shows 5-HT2 antagonist activity in functional tests (quipazine-induced head shakes in rats ED50 = 0.6 mg/kg i.p.; platelet aggregation IC50 = 4.4 µM; isolated rabbit aorta pKa = 6.5). These results indicate that Wy-50,324 has both 5-HT1A partial agonist and 5-HT2 antagonist activity. This combined activity suggests Wy-50,324 is a unique anxiolytic/antidepressant agent. Wy-50,324 has low activity at D2, Alpha 1, Alpha 2, and BZ receptors suggesting a favorable side effect profile.

342.15

IMIPRAMINE AS A DISCRIMINATIVE STIMULUS IN PIGEONS. L. Zhang and J.E. Barrett, Dept. of Psychiatry, Uniformed Services University of the Health Sciences, Bethesda, MD 20814-4799.

Although the major mode of action of imipramine (IMI) is to block the uptake of norepinephrine (NE) and serotonin (5-HT), IMI also affects other neurotransmitter systems. The role of these different systems in determining the behavioral effects of IMI was investigated using a drug discrimination procedure with IMI as the training drug. Key pecking by pigeons was reinforced with food following the completion of 30 pecks on one key following IMI (3.0 or 5.6 mg/kg, i.m.); following saline, pecks on a second key produced food. The tricyclic antidepressants, amitriptyline, doxepin and desipramine all produced drug-appropriate responding. Substitution for IMI also occurred with cocaine and amphetamine, as well as with the NE uptake inhibitors tomoxetine and nomifensine. The 5-HT_{1A} receptor ligand 8-OH DPAT also produced responding on the IMI key. Generalization did not occur with the following drugs: fluoxetine, clonidine, ritanserin and GBR 12909; substitution for IMI was obtained with some pigeons with gepirone, buspirone, and scopolamine. These results confirm that the IMI discriminative stimulus in pigeons is complexly mediated and is based in large part on drugs interacting with NE and 5-HT systems. Effects with 8-OH-DPAT suggest that compounds with activity at the 5-HT_{1A} site may be clinically effective antidepressants and that the activity of IMI may be mediated in part through this receptor site.

342.16

THE ANTIDEPRESSANT PHENELZINE AND METABOLISM OF γ-AMINOBUTYRIC ACID AND ALANINE IN RAT BRAIN. G.B. Baker and I.L. Martin*. Neurochemical Res. Unit, Dept. of Psychiatry, Univ. of Alberta, Edmonton, Canada T6G 2B7 and *MRC Molecular Neurobiology Unit, Univ. of Cambridge Medical Sch., Cambridge CB2 2QH, UK.

Phenelzine (phenylethylhydrazine) is a monoamine oxidase-inhibiting antidepressant effective in treating panic disorder. In addition to elevating brain biogenic amines, this drug has been reported to cause an increase in concentrations of GABA and alanine in rat brain. In our laboratories, the effects of phenelzine on rat whole brain activities of GABA transaminase and alanine transaminase were investigated. Male Sprague-Dawley rats were injected with phenelzine (15mg/kg ip) and killed 1, 2, 4, 8 or 16h after injection. Significant inhibition of both enzymes was still evident at 16h after injection. A study at 4h of doses of phenelzine ranging from 2.5 to 30mg/kg indicated dose-dependent inhibition of both enzymes. Such inhibition may contribute to the overall clinical profile of this drug and to its behavioural and physiological effects in laboratory animals. Funds provided by the British and Canadian Medical Research Councils.

342.17

CHRONIC ANTIDEPRESSANT DRUG (AD) TREATMENT ATTENUATES HYPOTHERMIA CAUSED BY ELECTROCONVULSIVE SHOCK (ECS). C. H.Gleiter[1,2] K.M. Wozniak[1] and J.DeJong[1]*. [1]NIAAA/LCS, Bethesda, MD 20892; [2]HPI Ciba-Geigy, D-7400 Tübingen, FRG.

ECS-induced body temperature decrease in mice has been shown to be markedly attenuated following chronic ECS[1]. Therefore we investigated the effect of acute and chronic AD treatment on ECS-induced hypothermia in NIH Swiss mice. Animals received desipramine (DMI), fluoxetine (FLUOX), amitryptiline (AMI), pargyline (PARG) (all 10 mg/kg i.p.) or saline. Rectal temperature was recorded at 0, 15, 30, 45, 60 ,90 min following a single ECS. ECS (8 mA, 1 s, no anesthesia) was applied 24 h after a single drug injection, and 24 h, 1 week and 2 weeks after the last of 14 once-daily injections. Hypothermic response to a single ECS at the various time points of AD treatment (expressed as area under the temperature-time curve):

	SALINE	DMI	FLUOX	AMI	PARG
single	188±16	235±53	188±63	223±32	203±44
chronic	200±39	82±11**	52±28**	94±28**	87±27**
1 week	174±44	201±32	143±45	163±51	132±37
2 weeks	154±41	137±22	162±40	125±11	165±25

(mean ± SD; n = 9/group; °C x min; ** $p < 0.001$)
Conclusions: 1. Chronic AD treatment attenuates the hypothermic response to a single ECS in a similar way as repeated ECS[1]. 2. This resembles the attenuation by chronic ECS or AD treatment of 8-OH-DPAT or clonidine-induced hypothermia (see [1]). 3. The (common ?) mechanism remains unclear. [1]Gleiter et al. Convul. Ther. 5: in press (1989).

342.18

USE OF S-ADENOSYL-METHIONINE, A NATURALLY OCCURRING METHYL DONOR, IN THE TREATMENT OF DEPRESSION. N.Z. Rosenlicht*,B.L.Kagan*,D.L.Sultzer* and R.H.Gerner. West Los Angeles V.A. Medical Center, Dept. of Psychiatry, UCLA Sch. of Med. and UCLA Neuropsychiatric Inst., Los Angeles, CA 90024.

18 inpatients meeting DSM-III criteria for major depression were randomly assigned to receive 21 days of oral S-adenosyl-methionine (SAM) or placebo. All patients underwent an initial 7 day drug-free washout period. Clinical status was monitored using Hamilton, Caroll, and global rating scales at 0, 3, 7, 14, and 21 days of treatment. Of the 15 patients who completed the study, the SAM treated group showed significant improvement in their depressive symptoms, as measured by the above scales. Other than 1 patient who became manic, despite no prior history of bipolar affective disorder, virtually no side effects were noted.

This study indicates that oral SAM is a safe and effective antidepressant, and that the role of methylation in the pathophysiology of affective disorders is an an area deserving of further study.

342.19

CHRONIC ANTIDEPRESSANT TREATMENT AUGMENTS COUPLING OF THE GTP BINDING PROTEIN, Gs, TO THE CATALYTIC MOIETY OF ADENYLATE CYCLASE. H. Ozawa and M.M. Rasenick, Physiology and Biophysics, University of Illinois College of Medicine, Chicago, IL 60680.

Despite nearly two decades of research, a clear molecular locus for antidepressant action has not been defined. This laboratory and others have postulated that G proteins formed a part of that locus, but additional data were required to make a more clear hypothesis. This study demonstrates that chronic treatment of rats with antidepressant drugs (iprindol or amitryptilline) or electroconvulsive shock, increases activation of adenylate cyclase in membranes prepared from various regions of rat brains. Inhibition of adenylate cyclase is not affected by these treatments and the chemical elimination of Gs abolishes all differences between treated and control groups. Non-neuronal tissues from treated animals showed no differences in adenylate cyclase than those tissues from control animals. The dissociation constant (K_d) and maximal binding (B_{max}) for [^{32}P] AAGTP (an hydrolysis-resistant, photoaffinity GTP analog) to synaptic membrane G proteins was unchanged after antidepressant treatment. Thus, it is unlikely that there was any change in the quantity or GTP-binding capacity of Gs. However, the transfer of [^{32}P] AAGTP from Gi/o to Gs was accelerated by chronic antidepressant treatment. Our findings are consistent with chronic administration of ECS inducing enhanced coupling between Gs and the adenylate cyclase enzyme as well as increasing the interaction between Gs and Gi/o. Supported by MH 39595.

A DOUBLE-BLIND PLACEBO CONTROLLED STUDY OF CAPTOPRIL IN THE TREATMENT OF MAJOR DEPRESSION. L. Germain*, G. Chouinard*, L. Annable*, (Sponsor: Y. Lamarre), Clinical Psychopharmacology Unit, Department of Psychiatry, McGill University, Montreal, Quebec.

Captopril is a potent inhibitor of the brain converting enzyme (CE). The CE is located in the human hippocampus, septum, amygdala, hypothalamus, frontal cortex, caudate nucleus and mid-temporal cortex, and it degrades several neuropeptides. In order to assess the effect of captopril on mood we studied 14 patients with major depression (DSM-III). Following diagnostic screening, all patients were voluntarily admitted to a research ward for 7 weeks. They were randomly assigned to treatment with captopril (C) or placebo (P) in a double-blind parallel group clinical trial. The dosage of their medication was doubled weekly from 37.5 to 150 mg/day. Their mental status was assessed weekly with the Hamilton Rating Scale for depression (HAM-D) and dexamethasone suppression tests were performed (DST). Analysis of covariance with baseline scores as covariate revealed that the C group (n=8) had significantly ($p=0.06$) lower mean HAM-D scores than the P group (n=6) after two weeks. A significant ($p<0.05$) change of the DST was observed in the C group but not in the P group. These results suggest that captopril may have an antidepressant effect with an early onset of action. Further study is necessary to clarify its long-term effect.

342.21

LONG-TERM TRICYCLIC AND ELECTROCONVULSIVE TREATMENT INCREASES RESPONSIVENESS OF DORSAL HIPPOCAMPUS 5-HT$_{1A}$ RECEPTORS: AN ELECTROPHYSIOLOGICAL STUDY IN THE RAT.

C. de Montigny, Y. Chaput and P. Blier. Dept. of Psychiatry, McGill University, Montréal, Canada H3A 1A1.

Suranyi-Cadotte et al. (Can. Coll. Neuropsychopharm., 10:O-22,1988) have reported an increased number of [^{3}H]8-OH-DPAT binding sites in the rat dorsal hippocampus following long-term tricyclic antidepressant treatment but no change following 5-HT reuptake blocker administration. In the present study, the responsiveness of CA$_3$ dorsal hippocampus pyramidal neurons to microiontophoretically-applied 5-HT and 8-OH-DPAT was compared in control rats and in rats which were administered one the following treatments: the tricyclic imipramine (10 mg/kg, i.p.), the selective 5-HT reuptake inhibitor paroxetine (5 mg/kg, i.p.), the monoamine oxidase inhibitor clorgyline (1 mg/kg, s.c.) daily for 21 days or 7 electroconvulsive shocks (ECS). For the latter group, controls were administered subconvulsive shocks. The efficacy of the stimulation of the ascending 5-HT pathway in suppressing the firing activity of the same postsynaptic neurons was also studied in the same rats. The responsiveness to both 5-HT and 8-OH-DPAT was increased in the ECS and in the imipramine groups whereas it was unchanged in the paroxetine group and decreased in the clorgyline group. In all four treatment groups, however, the efficacy of the stimulations of the 5-HT pathway was increased, thus indicating an enhanced 5-HT transmisssion by all these antidepressant treatments.

Consistent with the demonstration that 5-HT$_{1A}$ receptors mediate the hyperpolarizing effect of 5-HT on dorsal hippocampus pyramidal neurons (Andrade and Nicoll, J. Physiol., 394:99,1987), and the radioligand binding data of Suranyi-Cadotte, the present results provide further evidence that antidepressant-induced modification of the postsynaptic responsiveness of dorsal hippocampus pyramidal neurons to 5-HT is attributable to an alteration of 5-HT$_{1A}$ receptors.

BEHAVIORAL AND BIOCHEMICAL EVIDENCE FOR DOWNREGULATION OF 5HT1A RECEPTORS BY SERTRALINE.

L.S. Reynolds, M.H. Connolly*, S. McLean and J. Heym. Central Res. Div., Pfizer Inc., Groton, CT 06340.

Clinical trials have shown sertraline, a potent and selective inhibitor of 5HT reuptake, to be an effective antidepressant (AD). As with all ADs, however, there is approximately a 2 week latency before a therapeutic response is achieved. This observation has prompted examination of the effects of chronic AD treatment on monoaminergic function in brain. Our most recent experiments have studied the effect of chronic sertraline treatment on postsynaptic 5HT1A receptors.

Sertraline (10 mg/kg/day) or vehicle was continuously infused into adult male rats via subcutaneously implanted minipumps. After 14 days of treatment, the sensitivity of postsynaptic 5HT1A receptors was assessed by examining the potency of 8-OH-DPAT, a 5HT1A agonist, to elicit reciprocal forepaw treading (RFT). Animals were sacrificed 24 hours later for *in vitro* analysis of 5HT1A receptors in forebrain using radioligand binding with [^{3}H]-8-OH-DPAT. Chronic but not acute administration of sertraline shifted the dose-response curve for 8-OH-DPAT-elicited RFT to the right with nearly a 2 fold decrease in potency. This attenuated behavioral response was accompanied by an 18% decrease in the number of 5HT1A receptors in hippocampus without a change in receptor affinity.

These data further indicate that chronic treatment with sertraline produces changes in monoaminergic function that are not apparent after administration of a single dose and these adaptations may be fundamental for alleviation of clinical depression.

342.23

CHRONIC IDAZOXAN (IDZ) ATTENUATES ISOPROTERENOL - INDUCED CYCLIC AMP PRODUCTION IN C6 GLIOMA CELLS.

H. K. Manji,* J. A. Bitran,* F. Gusovsky, and W. Z. Potter* (SPON: N. Buckholtz). Lab. of Clin. Sci., NIMH, and Lab. of Bioorg. Chem., NIDDK, NIH, Bethesda, MD 20892.

Chronic treatment with a number of antidepressants produces a subsensitivity of rat adrenoceptor linked adenylate cyclase. This effect has generally been attributed to increased synaptic norepinephrine; however, a direct postsynaptic effect has also been implicated by recent in vitro studies (Fishman and Finberg, J. Neurochem. 49:282-9, 1987).

We undertook the present study to investigate the effects of chronic IDZ (a selective alpha-2 antagonist, and a putative antidepressant) on signal transduction in C6 glioma cells. Incubation of C6 cells with 1 or 10 uM IDZ for 5 days resulted in a significant decrease in isoproterenol-stimulated cAMP production. In contrast, forskolin-stimulated cAMP production was unaffected. The effects of chronic IDZ at the receptor and G protein level were also examined, and the results suggest an uncoupling of the beta adrenoceptor from the adenylate cyclase.

BRAIN METABOLISM AND BLOOD FLOW II

LOCAL CEREBRAL PROTEIN SYNTHESIS IN THE CAT DURING NORMAL DEVELOPMENT.

J. F. Kerrigan*, H. T. Chugani*, D. A. Hovda, J. R. Villablanca, S-C. Huang*, J. Barrio*, and M. E. Phelps. UCLA School of Medicine, Los Angeles, CA 90024, USA

We have measured local cerebral protein synthesis rates (lCPSR) in normal cats using in vivo incorporation of L-(1-^{14}C)-leucine and quantitative autoradiography. Animals were studied at 15 (n=1), 30 (n=1), 45 (n=3), 60 (n=5), 90 (n=3), 120 (n=2), and 180 days(n=1). lCPSR was calculated for 50 brain regions representing visual, auditory, motor, extrapyramidal, cerebellar, thalamic, limbic and brainstem subsets. lCPSR changed over the course of development with most brain regions increasing during early time points, reaching a metabolic peak by 45 days of age, when leucine incorporation rates were up to 2.7x those seen at 15 days. lCPSR for most brain regions then declined, approaching 15 day values by 180 days of age. Some structures, including those involved in motor and visual function, showed a second metabolic peak at 90 days. Although lCPSR for virtually all structures peaked at 45 days, changes in protein synthesis rates with time showed many individual characteristics. Absolute values of lCPSR varied widely from structure to structure, ranging from 2.0 nmole/min/gm in septum to 6.8 nmole/min/gm in medial habenula (45 days). In many structures the maturation of lCPSR correlated well with previosly established developmental neurobehavioral milestones. We plan to use these normative data to evaluate metabolic response during recovery in brain-lesioned animals.

VASCULAR EFFECT OF ACETAZOLAMIDE ON THE CHOROID PLEXUS.

F.M. Faraci*, W.G. Mayhan and D.D. Heistad. Depts. of Internal Medicine and Pharmacol., VA Medical Ctr., Univ. of Iowa Coll. of Med., Iowa City, IA 52242.

Acetazolamide inhibits carbonic anhydrase and produces a marked reduction in cerebrospinal fluid (CSF) production. Studies in vitro suggest that acetazolamide also constricts blood vessels of the choroid plexus. The goal of the present study was to examine effects of acetazolamide on blood flow to the brain and choroid plexus. We measured blood flow (microspheres) to the brain and choroid plexus and production of CSF (ventriculo-cisternal perfusion) in anesthetized rabbits. Under control conditions, blood flow to brain and choroid plexus was 49±5 (mean±SE) and 402±48 ml/min × 100 g, respectively, and CSF production was 9.4±0.9 μl/min. Acetazolamide (25 mg/kg, i.v.) decreased production of CSF by 55±5% but increased cerebral blood flow and blood flow to the choroid plexus more than two-fold. Acetazolamide also produces hypercapnia. In animals in which the hypercapnia was prevented by increases in ventilation, blood flow to choroid plexus tended to increase even further. Thus, acetazolamide decreased production of CSF but, in contrast to predictions based on studies in vitro, acetazolamide produced a marked increase in blood flow to the choroid plexus. These findings indicate that blood flow to the choroid plexus and production of CSF are uncoupled under some conditions.

IN-VIVO CREATINE KINASE REACTION RATES IN HYPOXIC BRAIN. D. Holtzman, M. Offutt*, L.J. Neuringer*. Neurology, Children's Hospital, Boston, MA 02115 and Nat'l Magnet Lab, MIT, Cambridge, MA 02139.

Brain creatine kinase (CK) forward reaction rates [phosphocreatine (PC) to ATP] were studied in young adult mice made hypoxic with cyanide (KCN) using high field (8.45T) NMR spectroscopy and the saturation transfer technique. pH was measured from chemical shift of the inorganic phosphate (P_i) peak. Sublethal KCN produced one of two responses: 1) no change in PC, 60% increase in P_i with two P_i peaks present, and a transient doubling of the CK rate constant; or 2) a transient 35% decrease in PC, increased P_i with two peaks (pH 7.16 and 6.70), and a 3-fold decrease in CK rate constant. Lethal KCN doses produced a 40-60% decrease in PC followed by a fall in both PC and ATP. There were two P_i peaks (pH 7.15 and 6.4) and a 6-fold increase in CK rate constant. The two P_i peaks suggest two intracellular pools including one with a stable concentration and pH of 7.15 under severe hypoxic conditions. Phosphate flux (PC to ATP) doubles with mild hypoxia but is markedly decreased with moderate hypoxia. [NRSA (NS 08039) and Milton Fund grants to DH, NIH Resource Grant (RR 00995) to LN, and a Mental Retardation Center Grant from NICHD (P 30 - HD 18655)].

343.4

INCREASED CEREBRAL CORTICAL TISSUE WATER CONTENT AFTER 3-4 WEEKS OF HYPOBARIC HYPOXIA (0.5 ATM). J.C. LaManna, M. Cullen*, L.M. Vendel*, W. Austin*, and K.P. Strohl. Depts. Neurology, Medicine and Physiol./Biophys., Case Western Reserve University, Cleveland, OH 44106, U.S.A.

We have previously reported that regional cerebral blood flow is not suppressed by the hypocapnia that accompanies hyperventilation in response to hypobaric hypoxia, demonstrating cerebrovascular adaptation to long term mild oxygen deficit. In this study we report the long term effects of hypoxia on brain water and ion content. Adult male Wistar rats (n=5) were kept in a hypobaric chamber for 3-4 weeks at 0.5 ATM, littermate rats were used as normoxic (n=10) and acute hypoxic (n=12) contols. Rats were anesthetized with chloral hydrate (400 mg/kg, i.p.) for placement of arterial and venous cannulae, and allowed to recover in an hypoxic environment, except for the normoxic controls which were kept in room air at normal pressure. After 3 hrs rats were sacrificed and the mid-brain and bilateral samples of the frontal and occipital cortex were removed and frozen. Acute hypoxic (PaO_2: 47±2 vs 93±2 mmHg) rats were hypocapnic ($PaCO_2$: 23±1 vs 34±1 mmHg) and alkalotic (pH: 7.50±.01 vs 7.38±.01), but otherwise were not different from normoxic controls. Chronic hypoxic rats (PaO_2: 50±3 mmHg) were also hypocapnic ($PaCO_2$: 19±2 mmHg), but had normal arterial pH (7.38±.03) and elevated hematocrit (71±2) compared to normoxic (46±1) or acute hypoxic (49±1) rats. The water content of the cerebral cortical structures was increased to 82% compared to 79% in the control groups. Na^+ and K^+ were also elevated in these cerebral cortical samples. There was no increase in water or ion content of the mid-brain samples. Thus, rats exposed to chronic hypoxia of up to 1 month demonstrated a tendency toward development of cerebral edema in spite of compensatory cerebrovascular responses.

343.5

FACTORS AFFECTING LACTATE RELEASE FROM HIPPOCAMPAL SLICES. H.M.Assaf*,A.J.Ricci*,T.S.Whittingham, J.C. LaManna,R.A.Ratcheson,and W.D.Lust. Lab. of Exper. Neurological Surgery, Case Western Reserve Univ. School of Medicine, Cleveland, OH 44106

Intracellular lactic acid (L) accumulation has been implicated in the evolution of brain damage after ischemia. Since compartmentation of L may play a role in acid-base balance during a number of metabolic stresses, L release was examined in hippocampal (H) slices under a variety of conditions. Gerbil H slices were preincubated for 1 h in artificial cerebrospinal fluid (ACSF) equilibrated with 95%O_2/5%CO_2 (pH 7.4 at 37°C) and then transferred to tubes containing 300 ul of test media. 15 ul aliquots were taken at various times of incubation and assayed for L. The initial rate of L release in cont slices was 6.5 nmol/min/mg prot and increased 2-and 4-fold under conditions mimicking ischemia and anoxia, respectively. Elevated K^+ (60 mM) increased L release by nearly 3-fold. Release was temperature-dependent. Removing Ca^{++} or adding D-Lactate (5mM) to the ACSF had only a minimal effect. Pyruvate (10 mM) decreased L release by more than 50% in cont and anoxic ACSF. If L is released in the uncharged form, loss of cellular protons would tend to minimize large pH fluctuations among the various CNS compartments.

343.6

LACTATE TRANSPORT PROBABLY DOES NOT MEDIATE THE HIGHLY TEMPERATURE-SENSITIVE FALL IN pH_0 EVOKED BY ANOXIA IN HIPPOCAMPAL SLICES. W.Walz[1] and K.Krnjević. Anaesthesia Research Department, McGill University, Montréal, H3G 1Y6. P.Q., Canada.

At 21-22°, brief anoxia (95% N_2 + 5% CO_2 for 2 min) causes inconsistent changes in pH_0 (+0.042 ± 0.034), recorded in CA1 pyramidal layer with pH-selective microelectrodes; but at higher temperatures, it produces an increasing acidosis, reaching 0.092 ± 0.037 pH units at 34-35°. This acidosis depends on anaerobic glycolysis, being abolished by superfusion with glucose-free medium. The possibility that it is directly caused by anaerobic lactate production and its efflux via specific lactate transport was tested by applications of DL-p-hydroxyphenyl-lactic acid (HPL), a selective antagonist of lactate efflux in cultures of hippocampal cells (Walz and Mukerji, 1988, Glia 1, 366). In slices at 33-35°, 8 mM HPL failed to reduce the Δ pH_0's evoked by 2 min anoxic tests. In conclusion, the transient fall in pH_0 produced by 2 min of anoxia is probably not mediated by specific lactate transport, but rather by some other mechanism, such as Na^+-H^+ exchange (Supported by Canadian Medical Research Council).

ENERGY METABOLITES IN THE ISCHEMIC PENUMBRA. B. A. Kaplan* and W.A.Pulsinelli. Dept.of Neurology, Cornell Univ. Sch. of Med.,New York, NY 10021

The penumbra of evolving brain infarction has been defined as a region with reduced cerebral blood flow (CBF), impaired synaptic transmission but preserved ionic gradients and cell morphology. The quantitative relationship between penumbral CBF and energy metabolism is not well defined. We measured CBF with laser doppler probes and energy metabolites fluorometrically at sites in the core and periphery of ischemic cortex in Spontaneously Hypertensive rats subjected to middle cerebral/common carotid artery occlusion for 15, 60 or 240 min. Sites with CBF values between 15-35% of preocclusion values were sampled from both the periphery and core zones of ischemia.

Metabolites (μmol/g) at CBF 15-35% of Preocclusion Values

	CBF(%)	Lactate	Glucose	ATP	PCr
Sham	100	1.67	2.06	2.81	4.89
(n=15)		±0.17	±0.10	±0.11	±0.13
Core	21.4a	8.81a,b	0.27a,b	0.24a,b	0.57a,b
(n=11)	±1.49	±1.14	±0.09	±0.05	±0.09
Periph.	25.7a	5.21a	1.98	2.23	3.86a
(n=10)	±1.81	±0.92	±0.34	±0.28	±0.62

a $p \leq 0.05$ vs.sham, b $p \leq 0.05$ vs. periph. (ANOVA, Bonferroni correction)

Despite the similar degree of ischemia in the core and periphery, high energy metabolites and glucose levels were severely reduced in the core while in the periphery they were maintained near normal. These data are consistent with the supression of energy demands in the periphery of evolving infarcts.

343.9

COMBINED qEEG AND NMR SPECTROSCOPIC ANALYSIS OF BRAIN IN A RABBIT MODEL OF HYPOGLYCEMIC COMA.
K. H. Taber, M. J. Herold* and J. D. Frost*.
Dept.s of Radiology, Neurology and Magnetic Resonance Center, Baylor College of Medicine, Houston, TX 77030.

Combined 31 phosphorus NMR spectroscopic and qEEG measures were used to delineate the metabolic and functional changes that occur in brain during and following induction of hypoglycemic coma. All NMR aquisitions were performed on a Bruker 2.35T MSL Spectrometer utilizing a 1.5 cm surface coil. Physiologic parameters were monitored with a Lifescope II telemetry system (Nihon Kohden). Blood glucose was tested every 5-10 min utilizing a Glucometer II (Ames) glucose meter. EEG was recorded with a modified Neuropak II recording system (Nihon Kohden). Hypoglycemic coma was induced by injection of insulin and reversed following a set duration of coma by infusion of glucose. Blood glucose and EEG changes preceeded 31P spectral alterations in all rabbits. Correlation analysis was used to identify related measures and provide insight into how metabolic alterations are reflected in electrical activity as well as indicate parameters associated with permanent tissue damage.

343.10

THE ROLE OF HEMATOCRIT IN THE REDUCTION OF CEREBRAL BLOOD FLOW MEASURED DURING HYPERGLYCEMIA.
R. B. Duckrow, Department of Medicine, Division of Neurology, The Pennsylvania State University, Hershey, PA 17033.

Cerebral blood flow (CBF) is reduced during hyperglycemia in awake-restrained rats. However, the hematocrit may increase in rats made acutely or chronically hyperglycemic, and this may reduce CBF by increasing blood viscosity. This hypothesis was tested by measuring regional CBF in normoglycemic and hyperglyemic rats after normalizing the hematocrit by isovolemic hemodilution. Chronic hyperglycemia (33 mM) was induced by treatment with streptozotocin. Vascular catheters were placed using halothane/nitrous oxide anesthesia. Wounds were injected with procaine and swabbed with xylocaine ointment. The hip girdle was immobilized with a plaster cast and anesthesia was withdrawn. After a one hour recovery period blood was withdrawn and centrifuged. The red cell fraction or the plasma was resuspended in a glucose solution and reinjected to cause no change or to reduce the large vessel hematocrit by 5. Thirty minutes later CBF was measured using [^{14}C]iodoantipyrine and dissection of brain regions. Normalization of hematocrit by hemodilution increased CBF in all brain regions by 15%. Despite equal hematocrit, hyperglycemia reduced CBF by 20%. This reduction was more prominent in nontelencephalic regions. CBF is reduced during hyperglycemia independent from the effects of large vessel hematocrit. (Supported by PHS NS24109 and an AHA EI Award)

343.11

EFFECTS OF SEVERE HYPOGLYCEMIA ON SYNAPTIC TRANSMISSION AND CARBOHYDRATE METABOLISM IN THE GUINEA-PIG HIPPOCAMPAL SLICE.
J. Waalen* & P. Lipton (Spon. K. Raley), Dept. of Physiol., Univ. of Wisconsin, Madison, WI 53706.

Hypoglycemia profoundly affects cerebral activity but the mechanism is not yet understood. There are significant EEG changes prior to measured changes in ATP but the localizations of the two measurements are not the same. Here we assess the role and control of glucose metabolism in the dentate gyrus of the guinea-pig hippocampal slice. Population spikes were evoked by stimulation of the perforant path at 1/8 Hz. After removing glucose, synaptic transmission is maintained for 10-15' then decreases to zero with a t1/2 of about 8'. ATP and PCr in the molecular layer are still at control levels at the time of complete transmission failure as is Ca^{2+}-dependent K^+ stimulated release of endogenous glutamate from dentate gyrus. Thus, transmission loss due to severe hypoglycemia is not due to energy failure or functional neurotransmitter depletion.

Studies with lactate provide further evidence that glycolysis per se is necessary for synaptic transmission. 20 mM lactate rapidly re-activates transmission abolished by hypoglycemia without changing high energy phosphate levels. This effect is blocked by 2-DOG (20 mM) and by IAA (.2 mM). Thus, return of transmission is a result of re-activating one or more steps in glycolysis. The result suggests there is at least partial gluconeogenesis in the glucose-deprived slice.

MULTIPLE-QUANTUM COHERENCE IN VIVO NMR SPECTROSCOPY OF 9L GLIOSARCOMA CELLS IMPLANTED INTO ATHYMIC MICE.
T. Nakada and I. L. Kwee. Neurochem Res Lab, VA Med Ctr, Martinez, CA 94553 and Dept of Neurology, Univ of California, Davis, CA 95616.

Multiple-quantum coherence experiments involve precessional and relaxation properties of phenomena arising from transitions between levels with $\Delta m_1 > 1$. Additional spectral editing capability arising from multiple-quantum coherence experiments compared to the single-quantum coherence experiments have been subject of various in vivo spectroscopic studies (Sotok CH, Magn Reson Med 7:364, 1988, Ueshima Y. et al., Magn Reson Imaging 7 (suppl): 190, 1989). Among the various proposed applications of multiple-quantum coherence experiments in vivo, zero-quantum (ZQ) experiments of lactate editing and double-quantum editing (DQ) of adenosine diphosphate (ADP) appears most promising. In this study, we have applied ZQ lactate editing and DQ ADP editing to study the in vivo metabolism of 9L rat gliosarcoma cell lines using subcutaneous implantation of cultured 9L cells into athymic mice. These techniques appear to be useful for monitoring tumor metabolism under various treatment regimens.

MAGNETIC RESONANCE MICRO-IMAGING OF BLOOD OXYGENATION IN BRAIN.
S. Ogawa*, T-M. Lee*, D.W. Tank and A.R. Kay*. (SPON: C.A. Taylor) AT&T Bell Laboratories, Murray Hill, NJ 07974.

Regional differences in O_2 utilization are currently used in PET imaging to localize brain activity during cognitive tasks. ^{1}H MRI has primarily been used as an anatomical tool. We now demonstrate that gradient echo images at high spatial resolution exhibit contrast dependent on blood oxygentation. The contrast results from the effect of paramagnetic deoxyhemoglobin and manifests as dark lines in the image (SeeFig.), corresponding to blood vessels. High magnetic field (7.0 and 8.4 T) images of rat brain were formed at high resolution (pixel=70x70 microns; slice thickness=700 microns). Coronal sections of the neocortex reveal dark radiating lines corresponding to blood vessels (diameters < 60 microns). During states of deep anesthesia the lines disappear, consistent with decreased oxygenation of the blood as a result of depressed neuronal activity. Results suggest that gradient echo images at high field may serve as a non-invasive method of measuring brain activity at the resolution of cortical columns.

In vivo gradient echo image (coronal section) including neocortex and hippocampus. Scale Bar=500 microns.

343.14

IN VIVO 13C{1H} NMR SPECTROSCOPIC MONITORING REVEALS FORMATION OF BRAIN [1-13C]2DG GLYCOGEN IN ANESTHETIZED RATS.
J.J. Kotyk*ƒ R.K. Deuel†, J.E. Mathisen*†, T.A. Woolsey†, J.S. McCaslandt, and J.J.H. Ackerman*† (SPON R. Sohn†) Washington University School of Medicine†, College of Arts and Sciences*, and Monsanto Co.ƒ, St. Louis, MO 63110.

Recently it has been proposed that brain glycogen is utilized during normal brain activity. 1-[^{13}C] 2DG glycogen can be identified and observed simultaneously with ^{13}C2DG/DG6P by ^{13}C{^{1}H} NMR spectroscopy. We monitored inclusion of [^{13}C]2DG into brain glycogen in Na pentothal anesthetized (35 mg/kg iv) adult rats after an iv bolus of [1-^{13}C]2DG (500mg/kg). Experiments were conducted in a Bruker WH-360 spectrometer (8.5 Tesla) using a two coil coaxial surface coil antenna. Body temperature, respirations, and brain intracellular pH were monitored and control spectra obtained. Ten min. spectral averages were analyzed. [1-^{13}C]2DG/DG6P was detected at 0-10 min., and [1-^{13}C]2DG glycogen first observed in one rat 20-30 min. after iv 2DG; it disappeared and was next detected at 50-60 min. In another rat it appeared at 100-110 min., again at 120-130, and 160-170 min. after iv 2DG. The highest glycogen concentration at any time was 8% of total maximum DG analog pool. No brain intracellular pH or other indications of physiological distress were noted. The data demonstrate formation of brain ^{13}C2DG glycogen in the living rat. Supported in part by NS 17663, NIH RO1GM30331, and the McDonnell Center for Studies of Higher Brain Function.

343.15

pH$_i$ COMPARTMEMTATION IN HIPPOCAMPAL SLICES INDICATED BY SNARF-1 AND NEUTRAL RED. T.J. Sick and J.C. LaManna, Depts. of Neurology, Univ. of Miami, Miami, FL 33101 and Case Western Reserve Univ., Cleveland, OH 44106.

Intracellular pH (pH$_i$) was measured in rat hippocampal slices by absorption spectrophotometry of neutral red (NR) and by spectrofluorometry of SNARF-1. Slices were incubated in either 100 μM neutral red or 20 μM of the acetoxymethylester form of SNARF-1. pH$_i$ was estimated from standard curves determined with either neutral red or the free acid form of SNARF-1 in brain homogenate, titrated to known pH with a standard glass pH electrode. Resting (95% O_2 - 5% CO_2) pH$_i$ by SNARF-1 was more acidic than pH$_i$ measured by NR. Changes in pH$_i$ during anoxia (95% N_2 - 5% CO_2) also differed when measured by SNARF-1 and NR. Following 10 min of anoxia pH$_i$ by SNARF-1 acidified to 0.14 pH units while pH$_i$ by NR did not change significantly from control values. Both pH$_i$ indicators showed large acid shifts upon administration of high CO_2. The data suggest that at least two proton compartments exist in brain and that these compartments differ in their responses to anoxia. It is not yet clear whether the pH$_i$ measurements indicate two different cellular compartments (e.g. neurons and glia) or subcellular compartments (cytosol or organelles).

343.16

KINETIC MODEL OF ^{14}C-2-DEOXYGLUCOSE METABOLISM IN BRAIN SLICES. C.S.Patlak, G.C.Newman, F.E.Hospod, Depts. of Neurology and Neurological Surgery, SUNY at Stony Brook, Stony Brook, N.Y. 11794.

The metabolism of 2DG in brain slices has been analyzed using a kinetic model with five compartments: 1) perifusate, 2) tissue 2DG, 3) 2DG6P, 4) 2DG1P + UDP-2DG, and 5) 2DG-glycogen + 2DG-glycoproteins.

Hippocampal or hypothalamic brain slices, 540μ or 1000μ thick, were incubated in 0.28μCi/ml of ^{14}C-2DG for varying times for uptake and washout experiments. After rapid freezing, the slices were extracted with perchloric acid and the supernatant separated by anion exchange chromatography. Tissue 2DG and acid-labile 2DG1P and UDP-2DG thus are determined as a single fraction. Each data set is derived from 104 to 149 slices from 12 to 18 Sprague-Dawley rats. The results have been analyzed using the solutions of the differential equations of our kinetic model and least squares analysis and will be presented in graphical and tabular form.

Our results reveal the following: 1) Influx and efflux of 2DG from 540μ brain slices proceed with K_1^* and k_2^* similar to those *in vivo*; 2) the 2DG6P-phosphatase reaction rate constant, k_4^*, is about 0.011 min^{-1}, similar to *in vivo*; 3) the rate constant of 2DG6P-2DG1P phosphoglucoisomerase, k_5^*, is similar to k_4^*, but radioactivity is trapped in the tissue; 4) significant amounts of glycogen and glycoproteins accumulate during long incubations consistent with studies *in vivo*. In 1000μ brain slices: 1) K_1^* and k_2^* are reduced; 2) k_3^* increases; 3) there is little or no changes in the other rate constants; 4) but 2DG1P, UDP-2DG and 2DG-glycogen accumulate at a greater rate because of increased tissue 2DG6P.

Analysis of total radioactivity, C_i^*, of uptake experiments 45 min or less with a three parameter model reveals excellent agreement with the calculated rates based upon the analysis of all data with the eight parameter model.

343.17

THE EFFECTS OF PROPOFOL ON LOCAL CEREBRAL GLUCOSE UTILIZATION (LCGU) IN THE RAT. C. Ori*, M. Dam*, G. Richieri*, G. Pizzolato*, G.P. Giron* and L. Battistin* (SPON. N. L. Shinowara). Ist. Anestesiologia e Rianimazione e Clinica Neurologica, Universita di Padova, 35100 Padova, Italy.

Propofol (ICI 35268; 2,6-di-isopropylphenol), an intravenous anesthetic, decreases intracranial pressure, cerebral blood flow, and $CMRO_2$. Therefore, propofol may be a suitable anesthetic to use in patients who suffer from intracranial disorders. In the present study the autoradiographic 2-deoxy-D-[^{14}C]glucose (2-DG) method was used to investigate the LCGU responses to propofol anaesthesia.

Male Fischer-344 rats (3 months old) were anesthetized with propofol (20 mg/kg) 30 min before 2-DG injection. Anaesthesia was maintained with a propofol infusion rate of 12.5, 25, or 50 mg/kg/h and LCGU evaluated as previously described (J. Neurochem. 28: 897, 1977). Propofol decreased LCGU in the auditory, visual, sensory-motor, precentral, and prefrontal cortices, thalamic nuclei, extrapiramidal system (caudate-putamen, globus pallidus, red n. and substantia nigra) and limbic system (hippocampus, presubiculum, medial habenula, and interpeduncularis n.). LCGU decreases were dose-dependent, except for the LCGU reduction in the reticular formation, which was maximum when the lowest propofol dose was used. This effect may be related to the anesthetic state which also occurs with low propofol doses

343.18

BIOCHEMICAL DISTRIBUTION OF PLASMA DERIVED 18F-DL-ERYTHRO-9,10-DIFLUOROPALMITATE IN RAT BRAIN. J.G. Noronha, J.J. DeGeorge*, B. Schmall*, T. Nariai*, J. Bell*, R.D. Finn*, and S.I. Rapoport. Lab. of Neurosci, NIA and Nuclear Medicine, NIH, Bethesda, MD 20892

We previously examined the incorporation of [9,10-3H] palmitate from plasma into brain and now compare its brain distribution with that of [9,10-18F]palmitate, a positron emitter, to determine whether such a probe has potential for imaging brain lipids using positron emission tomography (PET). 18F-palmitate was synthesized with a sp. ac. of 500-1000 mCi/mmol and was infused over 5 min into rats implanted with arterial and venous femoral catheters. After 20 min, rats were killed by a pentobarbital overdose and brains were removed and extracted. Neutral or acidic chloroform:methanol (2:1) extracts were prepared and partitioned with KCl. In the absence of acid, 43% of brain label is in the lipid phase, 25% in the aqueous phase, and 32% in the pellet. Extraction with acid yielded 57% of label in lipid, 43% in aqueous and < 1% in pellet. These results indicate that polar metabolites of 18F-palmitate, both lipid and water-soluble, contribute substantially to brain label. Work is in progress to determine whether 18F-palmitoylCoA or -acetylCoA are aqueous metabolites. [9,10-18F]Palmitate may prove to be a sensitive probe of membrane components using PET.

343.19

HPLC-EC DETERMINATION OF FREE PRIMARY AMINO ACID CONTENT OF CAT CISTERNAL CEREBROSPINAL FLUID. V.R. Roettger, F. Costello*, T.R. Bumbalough*, and M.D. Goldfinger, Department of Physiology & Biophysics, Wright State University, Dayton, OH 45401-0927.

The objective of this work was to assess the primary amino acid content of cat CSF. Adult cats were anesthetized with Nembutal. The dura beneath the atlanto-occipital membrane was exposed. A 27ga needle was inserted through the dura overlying the obex; approx. 2 ml of cisternal CSF was gently withdrawn and stored at -70°C for subsequent analysis. Osmolality of thawed CSF was 310 mOsm/Kg(N=5, range:303-325).

Isocratic reverse-phase HPLC-EC was as in (1) (using MPI) with these modifications: flow-rate - 1.8 ml/min; column temp. = 40°C. Elution times were under 19 min (GABA). Derivatization was as in (1) (25µL sample: 25µL DS; 1.5 min) with these modifications: thiol content was X110; excess thiol was eliminated by post-derivatization/pre-column reaction with Iodoacetamide (5.0µl of 140 mg/ml water). The high thiol content optimized derivatization; Iodoacetamide removed the thiol peak and allowed detection of rapidly-eluting derivatives (eg, Aspartate). Detection limits were between 0.3 (Glutamine) and 2.3 (GABA) picomoles derivatized. CSF was studied as a 50% water dilution. Detector sensitivity was switched during elution with a schedule designed to accommodate the wide ranges of CSF amino acid content.

A water mixture of amino acids (31 mOsm/Kg) simulated CSF amino acid levels. With serial dilution testing, detection with switching was linear (slopes: mixture, 0.99; range .95-1.02; CSF, 1.00, range .93-1.05). CSF components were identified by co-elution and 'spiking' of 50% CSF with standards (up to 2X load). Several peaks were not identified. In spiking tests, observed peak heights varied linearly with expected heights; for each of 3 experiments, all component values were used to generate 1 observed vs expected regression line: avg. slope = 0.97, range:.95-.99.

In 5 cats, CSF concentrations (µmole/L) of identified components had these averages (ranges): Glutamate, 4.1(2.9-5.5); Asparagine, 12.2 (10.0-13.4); Glutamine, 681.5(620.0-827.3); Glycine, 15.1(13.5-16.5); Taurine, 7.1(4.8-12.9); Alanine, 37.5(24.0-52.8); Tyrosine, 10.5 (6.9-17.2); GABA, <0.1.

CEREBRAL METABOLIC EFFECTS OF *SIGMA* LIGANDS IN THE RAT. A.Della Puppa and E.D. London. Neuropharmacology Laboratory, Addiction Res. Ctr., NIDA, Baltimore, MD 21224.

The 2-deoxy-D-[1-^{14}C]glucose method (Sokoloff, L., et al., J. Neurochem. 28:897, 1977) was used to map and quantitate the cerebral metabolic effects of *sigma* (σ) ligands. Drugs tested included *d*-pentazocine, (±)BMY 14802 and (±) BW 234U.

Male Fischer-344 rats, 4-6 months of age, were used as previously described (London, E.D., et al., J. Neurochem. 37:217, 1981). Drugs were administered i.p. at a dose of 30 mg/kg. In general, BMY 14802 significantly increased LCGU in the substantia nigra compacta and reticulata, paraventricular hypothalamic nucleus, lateral habenula, facial and cochlear nuclei, locus ceruleus, pontine nuclei, supramammillary nucleus, medial mammillary nucleus, VTA, lateral vestibular and interpositus cerebellar nuclei and cerebellar vermis. *d*-Pentazocine increased LCGU in the substantia nigra compacta and reticulata, paraventricular hypothalamic nucleus, layer 5 of the somatosensory cortex, medial habenula, anterior cingulate cortex, posterior piriform cortex, CA1 and CA3, and subthalamic nucleus. In contrast, BW 234U reduced LCGU in the superficial gray layer of the superior colliculus, inferior colliculus, substantia nigra compacta, lateral habenula, medial geniculate body, abducens and lateral vestibular nuclei and in the auditory cortex. Most of the areas that showed changes in LCGU are known to contain σ receptor sites (Largent, B.L, et al., J. Pharmacol. Exp. Ther. 238:739, 1986). Differences in pharmacological properties, including effects on neuronal excitability, may have resulted in different distributions and effects of the drugs on LCGU.

MEASUREMENT OF FREE AND TRANSFER RNA AMINO ACYL SPECIFIC ACTIVITIES AND PROTEIN SYNTHESIS IN RAT BRAIN IN VIVO. K.M. Hargreaves*, J.B. Buciak*, and W.M. Pardridge. Department of Medicine and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024-1682.

Measurement of cerebral protein synthesis requires the determination of amino acid specific activities in both the intracellular-free pool and the amino acyl transfer RNA pool. Following development of methods for measuring these two parameters, brain protein synthesis was measured in ketamine-anesthetized, male Sprague-Dawley rats by an internal carotid artery infusion technique. The brain was perfused for 0.5-30 minutes with buffer containing 10 mM glucose, 3% bovine albumin, 1X concentration of plasma amino acids, 30% rat erythrocytes, and 100 μCi/ml [^{3}H]-leucine. The free-intracellular pool and the tRNA pool of leucine completely equilibrated within 2 minutes, but these two pools did not reach equilibrium with the plasma pool until 10 minutes of perfusion. Moreover, after this point of equilibration, the specific activity of the plasma amino acid pool remained three-fold higher than the specific activity of the free-intracellular and tRNA pool. Protein synthesis rates were constant between 10 and 30 minutes of perfusion and averaged 0.62 ± 0.06 nmol/min/g (mean ± S.E., n = 11) for the whole cerebral hemisphere. Conclusions: The specific activity of the amino acyl tRNA pool is in rapid equilibrium with the free-intracellular pool, but is markedly overestimated by the specific activity of the plasma amino acid pool.

REGIONAL CEREBRAL GLUCOSE UTILIZATION IN FREELY-RANGING AND RESTRAINED RATS. R.M. Bryan, Jr. Departments of Surgery (Neurosurgery) and Physiology, M.S. Hershey Medical Center, Hershey, PA, 17033.

Regional cerebral glucose utilization (rCMRgl) was measured in freely-ranging and restrained rats to determine the effects of restraint on rCMRgl. Three groups of rats were used in this study: (1) freely-ranging controls; (2) rats restrained by fitting a plaster cast around the pelvis (hindlimb restraint); and (3) rats restrained by immobi- lizing all four limbs with tape (four-limb restraint).

Hindlimb restraint significantly elevated heart rate (35%), blood pressure (19%), plasma glucose (75%), plasma epinephrine (1400%), plasma norepinephrine (458%), and significantly decreased $PaCO_2$ (40.0 mm Hg to 37.4 mm Hg) compared to the freely-ranging controls. These changes are indicative of a stress response. Regional CMRgl decreased significantly in the sensory cortex (9%), motor cortex (9%), and the inferior colliculus (7%). However, CMRgl measured in fourteen other brain regions was not statistically different from the freely-ranging controls. Four-limb restraint did not significantly alter rCMRgl measured in five brain regions. I conclude that restraint stress has very little effect on rCMRgl. Cerebral energy metabolism appears to be controlled differently during restraint stress than during other forms of stress where rCMRgl increases throughout the brain.

343.23

EFFECTS OF HIGH-DOSE *d*-SKF 10047 ON CEREBRAL METABOLISM IN RATS. G.R. Hill*, A. Della Puppa and E.D. London (SPON: D. Jasinski) Neuropharmacology Lab., Addiction Research Center, NIDA, Baltimore, MD 21224.

The effects of high-dose *d*-SKF 10047 (5 mg/kg i.v.) and its potential PCP-like activities on local cerebral glucose utilization (LCGU) were studied by using the 2-deoxy-D-[1-^{14}C]glucose ([^{14}C]DG) method (Sokoloff, L., et al., J. Neurochem. 28:897,1977)

Male Fischer-344 rats were prepared with indwelling femoral and venous catheters (London, E.D., et al., J Neurochem. 37:21, 1981). *d*-SKF 10047 was given i.v. at 2, 5, 10 and 15 min before [^{14}C]DG and LCGU calculated as described elsewhere. *d*-SKF 10047 increased LCGU in the anterior cingulate cortex, retrosplenial granular and agranular cortex, visual cortex, molecular layer of the dentate gyrus, presubiculum, nucleus accumbens, globus pallidus, anterior dorsal, reuniens and reticular thalamic nuclei, zona incerta, subthalamic nucleus, medial and lateral mammillary bodies, substantia nigra reticulata, oculomotor, abducens and pontine nuclei. However, LCGU was decreased in the auditory cortex, inferior colliculus, medial geniculate body, lateral habenula and layer 1-3 of the frontal cortex. The effects of a 5 mg/kg i.v. *d*-SKF 10047 dose widely reproduced cerebral metabolic patterns observed after PCP administration (Weissman, A.D., Brain Res. 435:29, 1987). The similarities between *d*-SKF 10047 and PCP effects on LCGU may be a function of the *d*-SKF 10047 dose. Indeed, such a dose may have stimulated the PCP receptors for which *d*-SKF 10047 has low affinity. Therefore, it is suggested that some of the cerebral activities of PCP and *d*-SKF 10047 high-dose are mediated through common mechanisms.

343.24

REGIONAL ANALYSIS OF [9,10-^{3}H] PALMITATE INCORPORATION IN A METASTATIC BRAIN TUMOR MODEL. T. Nariai*, J.J. DeGeorge*, N. Greig*, S. Genka* and S. I. Rapoport. Laboratory of Neuroscience, NIA, NIH, Bethesda, MD 20892.

We have developed a procedure to examine brain phospholipid synthesis and turnover in vivo, using radiolabelled palmitate (Noronha et al. Trans. Am. Soc. Neurochem. 20:142, 1989). In the present study, we used this technique to investigate lipid metabolism of neoplastic tissue and normal brain following intracerebral tumor cell implantation in Fischer-344 rats. Walker 256 carcinosarcoma, 250 cells in 5 ul EMEM containing 1% low melting point agar, were implanted into the caudate nucleus. Control animals were injected with the same amount of agar to evaluate implantation damage. Seven days after tumor cells were implanted, awake rats were infused intravenously with [9,10-^{3}H] palmitate(^{3}H PA)(6.4 mCi/Kg) for 5 min. Twenty minutes after the start of infusion, rats were killed and brains were removed and prepared for autoradiography and histology. The tumor cell mass (2-10 ul in volume) was well demarcated histologically from surrounding gliotic brain tissue. Incorporation of ^{3}H PA into tumor was heterogeneous, 3.1-6.8 fold greater than in corresponding contralateral brain regions. The area of reactive gliosis surrounding the tumor and the control lesion sites showed less than 1.3 fold increase of ^{3}H PA incorporation. The results indicate that radiolabelled palmitate can be utilized for imaging brain tumors in vivo.

ALZHEIMER'S DISEASE: TRANSMITTERS AND BEHAVIOR

344.1

EVIDENCE FOR NEUROFIBRILLARY TANGLES (NFT'S) IN PONTINE 5-HT NEURONS IN ALZHEIMER'S DISEASE (AD) J.M. Lee* & N.W. Kowall (SPON: E.T. Hedley-Whyte). Department of Pathology & Neurology, Mass. General Hospital, Boston MA 02114.

Midbrain and pontine raphae nuclei were investigated in patients with AD and age-matched controls using the mouse monoclonal antibody PH8. This antibody recognizes similar epitopes of the 3 aromatic amino acid hydroxylase enzymes; tyrosine, phenylalanine and tryptophan hydroxylase (Haan et al., Brain Res.(1987) 426:19-27). Tissue was taken within 24 hours of death and placed in a periodate-lysine-paraformaldehyde fixative. Fifty micron sections were incubated with a 1:1000 dilution of PH8 followed by incubation with a goat anti-mouse peroxidase conjugated secondary (1:300) and developed using DAB as a substrate. Under the conditions described above, controls as well as AD brainstems showed intense reproducible PH8 positive cell body staining in the dorsal raphae (DR,B7), median raphae (B8) and B9 nuclei. Staining of the neuromelanin neurons of the locus ceruleus and substantia nigra was variable and less intense. Counterstaining with 1% thioflavine S revealed that a number of PH8 positive neurons showed a green-yellow fluorescent material under UV light consistent with NFT's in both the dorsal as well as median raphae nuclei of the AD group. The distribution was similar to Tau positive immunoreactive neurons in separately stained sections. In addition, preliminary cell counts and analysis of cell areas revealed trends toward a decreased PH8 positive cell number in the caudal DR and B9 nuclei and a decreased cell area of caudal DR neurons in AD patients.(PH8 antibody available courtesy of Dr. R.G.H. Cotton)

PRESYNAPTIC PROTEINS IN THE PERFORANT PATHWAY TERMINAL ZONE ARE DEPLETED IN ALZHEIMER'S DISEASE. L.M. Cabalka, B.T. Hyman, T.C. Ritchie, C.R. Goodlett, J.D. Coulter and G.W. Van Hoesen. Depts. of Anatomy and Neurology, Univ. of Iowa, Iowa City, IA, and Dept. of Neurology, Harvard Medical School, Boston, MA.

The perforant pathway arises from layers II and III of the entorhinal cortex and is the source of cortical afferents to the hippocampal formation, terminating in the outer 2/3's of the molecular layer of the dentate gyrus and along distal dendrites of hippocampal pyramidal cells. In experimental animals, entorhinal lesions cause loss of synaptic markers in this terminal zone. A consistent alteration in Alzheimer's disease (AD) is the presence of neurofibrillary tangles in layer II of entorhinal cortex. We have examined the distribution of nerve terminal proteins in the hippocampal formation of five AD patients, three controls, monkeys, and rats, to determine the effect of this pathology on synaptic markers. Tissue was stained using antibodies against synaptophysin (p38), a synaptic vesicle membrane protein present in virtually all nerve terminals, and against NT75, a selectively distributed nerve terminal protein. Control patients, monkeys and rats showed similar patterns of p38 immunoreactivity, with dense staining throughout the molecular layer of the dentate gyrus. All AD patients had neurofibrillary tangles in layer II of entorhinal cortex, and in these patients p38 staining was depleted in the perforant path terminal zone. This suggests that the loss of p38 immunoreactivity in AD is related to entorhinal pathology. Moreover, both p38 and NT75 immunoreactivity were associated with some neuritic plaques in the dentate molecular layer. This result suggests that neuritic plaques may be a focus of aberrant sprouting of nerve terminals, and that normally present nerve terminal proteins may play a role in this process. FOUR CLASSES OF ALZHEIMER'S DISEASE: NEOCORTICAL NEUROPATHOLOGY AND ALTERATIONS IN NEUROTRANSMITTER RECEPTOR BINDING. B.A. Vogt, G.W. Van Hoesen, L.J. Vogt* & P.B. Crino. Depts. Anatomy & Behavioral Neurology, Boston Univ. Sch. Med., Boston, MA 02118, Depts. Anatomy and Neurology, Univ. Iowa, Iowa City, IA 52242 & V.A. Hospital, Bedford, MA 01754.

Cases of dementia of the Alzheimer type (DAT) were classifiéd according to which layers had the greatest proportionate loss of neurons in posterior cingulate cortex.These four classes did not differ by age at disease onset, length of disease nor density of thioflavin S-stained neuritic plaques or neurofibrillary tangles.

Pirenzepine binding to cryostat sections was reduced in layers V and VI of all cases but was most pronounced in cases with greatest loss of neurons in these layers. Oxotremorine-M binding was normal in all DAT cases except in the class where neuronal loss was most pronounced in layer IV. This latter class also had greatest up regulation of beta adrenoceptors. Muscimol binding was normal in all layers but layer I, where reduced binding did not appear to be class related. Finally, ketanserin binding was unaltered in any layers in all cases.

In conclusion, neocortical neuron loss is not the same in all DAT cases and alterations in receptor binding are not a generalized response to such changes. Future receptor binding studies will require more detailed assessments of underlying neuropathological alterations.

RELATIONSHIP OF NGF-RECEPTOR AND NADPH-DIAPHORASE CONTAINING BASAL FOREBRAIN NEURONS IN MONKEYS, AGED NORMAL ELDERLY AND ALZHEIMER'S DISEASE PATIENTS. E.J. Mufson and J.H. Kordower. Inst. for Biogerontol. Res., Sun City, AZ and Univ. of Illinois, Sch. Med., Chicago, IL

Interspersed within the basal forebrain continuum of large magnocellular cholinergic neurons which express the receptor for nerve growth factor are smaller NADPH-diaphorase positive neurons. We determined the relationship between these neuronal populations and whether NADPH-d positive perikarya are involved in the pathologic process of AD. Sections from basal forebrain of normal aged patients obtained postmortem and adult Cebus monkeys were processed for NADPH-d, nerve growth factor receptor (NGFR) and concurrently for both proteins. In both species, NADPH-d positive neurons were seen scattered throughout the basal forebrain with many more located within the region of the nucleus basalis as compared to the septal and diagonal band nuclei. Although a few NADPH-d neurons intermingled within the aggregates of NGFR expressing neurons, most were located either adjacent to or surrounding NGFR neuronal subgroups. In AD patients, many of the small ovoid, fusiform or bipolar NADPH-d neurons appeared shrunken or dystrophic. Sections concurrently stained for NADPH-d, NGFR immunoreactivity and Thioflavin-S revealed numerous tangle bearing NGFR expressing neurons whereas virtually all NADPH-d neurons were Thioflavin-S negative. NADPH-d positive neurons in close proximity to basal forebrain NGFR expressing neurons degenerate in AD, but do not exhibit NFTs as do NGFR containing neurons. Support: Amer. Hlth. Ass. Fdn., ADCRC, NS26146, NS25655.

BRAIN CHOLINERGIC RECEPTORS IN HUMAN NEURODEGENERATIVE DISEASES. I. Aubert, D. M. Araujo, S. Gauthier, & R. Quirion. Douglas Hospital Res. Ctr. & McGill Univ., Montreal, Quebec, Canada H4H 1R3.

In the present work, we determined whether cholinergic receptor sites are altered in various brain regions of certain neurodegenerative diseases such as Alzheimer's(AD), Parkinson's(PD), and Parkinson's with AD-type dementia(PD/AD). Thus, we characterized the binding of muscarinic and nicotinic ligands to homogenates of human brain. Our results show that in all three disease categories, the maximal density of nicotinic sites, assessed using ^{3}H-methylcarbamylcholine (MCC) as ligand, is markedly reduced in cortical regions and in hippocampus. In PD and PD/AD brains there is also a decrease in the Bmax for ^{3}H-MCC binding to homogenates of caudate-putamen. In contrast, the total density of muscarinic receptor sites,characterized using ^{3}H-QNB, was increased in the caudate-putamen of all brains and in the hippocampus of AD brains (81%). This increase in ^{3}H-QNB binding may be due to an up-regulation of the muscarinic-M1 subtype, since the Bmax for ^{3}H-pirenzepine binding was enhanced (by 20-85%) in these brain regions. The density of muscarinic-M2 sites, assessed with either ^{3}H-AF-DX 116 or ^{3}H-ACh was significantly reduced in all brain regions except caudate-putamen of PD/AD and AD brains, but was not affected in any region of the PD brains. In summary, cholinergic receptors are differentially altered in different brain regions in diseases.(MRC, Canada)

HETEROGENEITY OF CHOLINERGIC INNERVATION IN SUBFIELDS OF HUMAN HIPPOCAMPUS AS REVEALED BY CHOLINE ACETYLTRANSFERASE ACTIVITY. K. L. Tenebruso*, W. Hoss and R. W. Hamill. Monroe Comm. Hosp./Univ. of Roch., Rochester, N. Y. 14603, Univ. of Toledo, Col. Pharmacy, Toledo, OH 43606.

The distribution of cholinergic innervation of human hippocampus was examined utilizing a radiochemical assay for choline acetyltransferase (ChAT) activity, a marker of cholinergic synapses. Subregional and micropunch dissection of transverse cryostat sections (240-300 microns) were performed in order to isolate CA1, CA2, CA3, CA4/DG, subicular regions, and adjacent cortex (parahippocampal or entorhinal). Micropunch analyses permitted characterization of hippocampal laminae in some cases. Adjacent cresyl violet or acetylcholinesterase (AChE) stained sections provided correlative morphological observations. ChAT activity was highest in the CA4/DG region, relatively midrange and uniform levels existed throughout CA1, CA2 and CA3, and lower levels were found in adjacent cortical regions. Micropunch studies of laminae confirmed the subregional studies: ChAT specific activity appeared highest in the granular cell layer of the dentate gyrus and the polymorphic layer within the hilus of the dentate gyrus (CA4). Thus, the CA4/DG region received the richest cholinergic innervation. Preliminary studies in Alzheimer's disease patients indicate severe ChAT depletion in all hippocampal subregions and laminae. (Rochester Alzheimer Disease Project, PHS Grant, AG 03644).

344.7

BRAIN GANGLIOSIDES IN ALZHEIMER'S DISEASE AND IN RATS WITH FOREBRAIN LESIONS. N.M.K. Ng Ying Kin*, L.H. Pan*, J.H. Louvaris*, Y. Robitaille* and N.P.V. Nair. Douglas Hospital Research Centre, McGill University, Montreal, Canada.

Rats with quinolinic acid-induced lesions of the nucleus basalis magnocellularis (nbm) exhibit central cholinergic dysfunctions and are putative animal models for Alzheimer's disease (AD). Since ganglioside deficiencies have been reported in AD brains, it would be of interest to determine whether that was also the case in the lesioned rats. Unilateral lesions of the rat's nbm were performed as described by El-Defrawy et al. (Neurobiol. Aging, 6, 325, 1985). Cortical tissues from the ipsilateral (affected) and contralateral (controls) sides of the lesions were used in our studies. Gangliosides, assayed for their sialic acid contents, were found to be significantly reduced in affected tissues when compared to controls (N=5). Decreases range from 8 to 26 percent. Similarly, in human post-mortem cortical tissues, ganglioside contents were decreased in different anatomical regions of AD brains (N=11) when compared to controls (N=6). Regional reductions ranging from 6 to 22 percent were observed and were statistically significant . Deficits in younger patients were more pronounced. In summary, deficiencies in gangliosides, which have been reported to possess trophic properties, suggest a role for these compounds in the pathophysiology of AD and the animal model. Studies on the metabolism of gangliosides in the lesioned rats should be informative.

HUMAN CORTEX HAS THREE SUBTYPES OF NICOTINIC RECEPTORS. E. Giacobini[1], K. Sugaya*[1], V.A. Chiappinelli[4], B. Clark[2] and R. Struble[3]. Depts. Pharmacology[1], Pathology[2] and Psychiatry[3], Southern Ill. Univ. Sch. Med., Springfield, IL and [4]Dept. Pharmacology, St. Louis Univ. Sch. Med., St. Louis, MO

Kappa-bungarotoxin (K-BTX) is a selective antagonist that facilitated characterization and localization of central nicotinic receptors. We have examined brain samples of human frontal and parietal cortex obtained from biopsies and autopsies, using three different ligands of nicotinic receptors, ^{125}I-alpha-BTX, ^{125}I-K-BTX and L-^{3}H-nicotine. In human frontal cortex of neurological controls (21-57 yrs), elderly controls (64-94 yrs) and Alzheimer disease (AD) patients (67-78 yrs), we demonstrated two binding sites for both bungarotoxins, with high and low affinity. With alpha-BTX, there was no statistical difference between young controls, old controls and AD patients. With K-BTX there was a significant decrease in low affinity binding sites between young and old controls and AD patients (42% and 47%, respectively). Computer assisted image analysis and autoradiography mapped out specific localizations of these three binding sites in brain areas. The functional significance of K-BTX sites was investigated by studying ^{3}H-acetylcholine release in human and rat cortex slices. Our results suggest the presence in human brain of three nicotinic receptor subtypes with different localizations which are recognized by bungarotoxins or nicotine. (Supported by NIA AG05416; NINDS NS17574; and R.J. Reynolds Tobacco Co.)

VISUO-SPATIAL AND MEMORY FUNCTION FOLLOWING ARECOLINE INFUSION IN PATIENTS WITH DEMENTIA OF THE ALZHEIMER TYPE. K.C. Raffaele, J.V. Haxby*, P. Morris*, T.T. Soncrant, and S.I. Rapoport. Laboratory of Neurosciences, National Institute on Aging, NIH, Bethesda, MD 20892.

Decreases in cholinergic markers have been demonstrated in brains of patients with dementia of the Alzheimer type (DAT). DAT patients treated with arecoline, a muscarinic receptor agonist, have shown some improvement in picture recognition, but not on other memory measures. In order to examine further possible performance improvements following arecoline treatment, patients with DAT (with mild to moderate dementia, mean Mini-mental Exam score = 13.8+4.8) were treated with a single infusion of arecoline (5 mg over 30 min.), one hour following methylscopolamine (0.5 mg p.o.). Psychometric testing was performed at 5 time points: the day before the infusion, during methyl-scopolamine pretreatment and at 0, 90, and 330 min. following the arecoline infusion. Patients were tested on 3 memory tasks (Digit Supraspan, Block Supraspan, and Buschke Selective Reminding) and a test of visuo-spatial ability (accuracy in copying figures). Blood samples from several time points during and after the infusion were analyzed to determine plasma levels and half-life of arecoline. Preliminary results from four patients show no significant improvement in memory measures. However, drawing accuracy was improved in two patients.

344.10

COMPARISON OF TETRAHYDROAMINOACRIDINE (THA) AND PHYSOSTIGMINE (PHY) AT INCREASING ACETYLCHOLINE (ACh) IN RODENT BRAIN. D. R. Liston, D. S. Chapin*, S. B. Jones* and J. A. Nielsen. Pfizer Central Research, Groton, CT.

Senile dementia of the Alzheimer type (SDAT) is a neurodegenerative brain disorder characterized by a decrease in neurochemical markers associated with cholinergic neurons. Of the acetylcholinesterase (AChE) inhibitors that have been used to ameliorate the cholinergic deficits present in SDAT, THA is proving to be the most effective clinically. Previously we demonstrated that THA is readily distributed to brain (Liston et al., Soc. Neurosci. 14:1224, 1988). The present studies have examined the effects of THA and PHY on ACh levels in brain. THA and PHY increased ACh concentration in the striatum and frontoparietal cortex of rats. THA induced statistically significant elevation of ACh at 5.6-17.8 mg/kg i.p.(LD50=31 mg/kg), while PHY was effective only at 1 mg/kg i.p., one-half of its LD50. THA increased ACh for at least 120 min, returning to baseline at 240 min, whereas PHY increased ACh at 30 min, but was without effect at 60 min. after dosing. THA increased ACh and had an LD50 in mice similar to that in rats. In both mice and rats, THA reversed the decrease in ACh levels induced by scopolamine. These data in rodents indicate that THA has a broader effective dose range and longer duration of action than PHY. These properties, in conjunction with THA's ability to achieve high drug concentrations in brain, may explain the favorable clinical results obtained with THA in the treatment of SDAT.

344.11

NOVEL PHYSOSTIGMINE ANALOGS FOR ALZHEIMER'S DISEASE THERAPY: PHARMACOKINETIC AND BIOCHEMICAL STUDIES. **D.B. Ellis*, G.M. Bores*, R.S.Hsu*, R.R.L.Hamer* and F.P. Huger.** Depts. Biological and Chemical Research, Hoechst-Roussel Pharmaceuticals, Somerville, NJ 08876.

The recognition of a central cholinergic deficit in Alzheimer's disease (AD) has prompted interest in acetylcholinesterase (AChE) inhibitors as a means of therapy. While cognitive and behavioral effects have been seen with physostigmine, a short duration of action, marked peripheral side effects, narrow therapeutic window and modest cognitive improvement after oral administration limit its use. We present several new physostigmine derivatives with better stability, improved bioavailability, longer duration of action and greater AChE inhibitory selectivity. Substitution of the carbamate nitrogen with a phenyl, cyclooctyl, isoquinolinyl or (R*) α-methylbenzyl yielded selective inhibitors of AChE while a phenethyl group was selective for butyrylcholinesterase. The (S*) α-methylbenzyl and phenylpropyl analogs were non-selective. Stability of these derivatives in acid and plasma was excellent. When given to rats, all were well absorbed and rapidly penetrated the blood-brain barrier. Duration of AChE inhibition in rat brain varied markedly, (R*) α-methylbenzyl >>> cyclooctyl, (S*) α-methylbenzyl, phenyl, isoquinolinyl >> physostigmine. The 3-chlorophenyl and α-methylbenzyl analogs were also active inhibitors of NE re-uptake. The increased duration of action, better stability, decreased acute toxicity and additional noradrenergic activity provide encouraging lead compounds with potential clinical implication for the symptomatic treatment of AD patients.

EVIDENCE THAT AF-DX 116, A MEMORY FACILITATING MUSCARINIC-M2 ANTAGONIST, CROSSES THE BLOOD BRAIN BARRIER. W. Regenold M.G. Packard and R. Quirion. Depts. of Psychiatry and Psychology, McGill University, Douglas Hospital Research Centre, 6875 La Salle Blvd., Verdun, P.Q., Canada, H4H 1R3.

The cholinergic hypothesis of geriatric memory loss predicts that a muscarinic-M2 autoreceptor antagonist may improve cognitive function in Alzheimer's disease (AD) by increasing acetylcholine (Ach) release. Previous work in our labs has shown that AF-DX 116 binds an M2-like receptor site and enhances in vitro Ach release. Furthermore, on both a win-shift radial maze task (sensitive to hippocampal lesions) and a win-stay task (sensitive to caudate lesions) systemic post-training injections of AF-DX 116 improved memory. In view of these findings and the importance of peripheral drug delivery in AD pharmacotherapy, we investigated the ability of AF-DX 116 to cross the blood brain barrier (BBB). Anaesthetized rats received 1 mCi/kg injections of [^{3}H]AF-DX 116 in 0.4 ml EtOH(45%)-saline soln. Half of the rats were perfused prior to decapitation, and brains were dissected and homogenized. Mean CPM from perfused (P) brain homogenate aliquots were, e.g., 801(cortex) to 382(brain stem) above background and consistently lower than nonperfused(NP) brain, e.g., 801(P) vs. 2022(NP) in cortex and 382(P) vs. 936(NP) in brain stem. These results suggest that AF-DX 116 crosses the BBB, supporting a central action of AF-DX 116 on memory. (Supported by the Medical Research Council of Canada)

LOCUS COERULEUS CELL LOSS IN NEURODEGENERATIVE DISEASES: COMPUTER IMAGING. K.F. Manaye, W.K. Smith, D.J. Woodward, D.M.A. Mann* and D.C. German. Depts. of Psychiat. & Cell Biol., U. of Texas Southwestern Med. Cntr., Dallas, TX 75235 and Dept. of Pathol., U. of Manchester, UK.

The locus coeruleus (LC) cells are markedly reduced in number in patients with Alzheimer's disease (AD), Parkinson's disease (PD) and Down's syndrome (DS). The purpose of the present study was to examine the topographical pattern of LC cell loss in the above diseased brains. Cell locations were mapped in horizontal sections (10-14) from rostral to caudal using the CARP system from Biographics Inc. 10 AD, 6 PD and 2 DS and 8 age-matched normal brains were examined. Data analysis consisted of calculating the number of cells per section, and the area of the nucleus in the XZ (mediolateral X rostrocaudal) and XY planes (mediolateral X dorsoventral). The cell loss in AD and DS was primarily confined to the rostral portion of the nucleus whereas the loss in PD was comparable from rostral to caudal and markedly destroyed the peripheral cells. These data suggest that cell loss in AD and DS is greatest among the forebrain-projecting cells whereas in PD the loss is more uniform. CSF LEVELS OF VASOPRESSIN, OXYTOCIN, AND NEUROPHYSINS ARE REDUCED IN ALZHEIMER'S DISEASE. William G. North*, Robert Harbaugh*, and Teddie Reeder*(SPON: H. L. Borison). Departments of Physiology and Neurosurgery, Dartmouth Medical School, Hanover, NH 03756.

The well-documented observation that vasopressin, oxytocin, and related neuropeptides affect behavior, and the finding that vasopressin protects against age-related changes in cholinergic function, prompted us to examine the levels of these peptides, and of neurophysins, in the CSF of patients suffering from Alzheimer's Disease. Neurophysins are gene-related products secreted by vasopressin and oxytocin neurons. For nine (9) such patients (6 men, 3 women) CSF samples wee obtained from a Selker reservoir placed into the right ventricle and attached to a continuous infusion pump for delivering bethanacol chloride. Protein concentrations of the CSF samples were evaluated from differential absorbance at 215 nm and 225 nm. The levels of vasopressin, vasopressin-associated neurophysin (VP-HNP), oxytocin, and oxytocin-associated neurophysin (OT-HNP) were determined for unextracted CSF using our specific RIAs for these substances. Values obtained were compared with those for CSF from 60 mentally healthy patients who were being treated for back pain.

All four substances measured by RIA were reduced in the patients with Alzheimer's Disease. For these patients vasopressin levels (3.6±0.7 fmol/ml) and VP-HNP levels (21.7±1.6 fmol/ml) were less than half of those for control subjects (7.8±0.4 fmol/ml; 54.0+2.0 fmol/ml). Oxytocin levels (2.7±0.6 fmol/ml) and OT-HNP (104.1±3.4 fmol/ml) were 75% and 58% of those for control subjects (3.6±0.3 fmol/ml; 180.1±1.9 fmol/ml). We conclude from these data that Alzheimer's Disease is associated with decreased activity of both vasopressin neurons and oxytocin neurons with axons terminating in the central nervous system.

344.15

IMMUNOHISTOCHEMICAL STUDY OF SUBSTANCE P (SP) AFTER UNILATERAL FRONTAL LOBECTOMY IN THE HUMAN BRAIN. C. Bouras*, P.R. Hof[1], P.G. Vallet*, F. Tagliavini*, Y. Charnay*, J. Constantinidis*. (SPON. P.L. Magistretti). Div. of Morphological Psychopathology, Dept. of Psychiatry, Univ. of Geneva, CH-1225 Geneva, Switzerland, and [1]Research Institute of Scripps Clinic, BCR-1, La Jolla, CA 92037, USA

In a previous study of cases of Alzheimer's disease presenting an asymmetric cortical atrophy, striking differences in SP immunoreactivity between the two hemispheres were described (Bouras et al., in press). In the present study we report on the asymmetric changes in SP distribution in the pallidum (P) and the substantia nigra (SN) of five brains with unilateral frontal surgical ablation for tumoral pathology. The time between surgery and death varied from one week to two years. We performed a quantitative analysis of the staining intensity of the SP-immunoreactive profiles using computer-assisted micro-densitometry. In all five investigated cases the staining intensity was asymmetric and significantly higher in the P (up to 31 %) and the SN (up to 24 %) ipsilaterally to the lobectomy. There were no changes in the SP-immunoreactive cell bodies visualized in the striatum. These data, as compared to previous results obtained in Alzheimer's disease cases, suggest that a loss of cortico-striatal afferents may influence the SP content in the terminal areas of the striato-pallidal and striato-nigral pathways.

THE VASOACTIVE INTESTINAL POLYPEPTIDERGIC DORSAL AMYGDALOFUGAL PATHWAY IS NOT ALTERED IN ALZHEIMER'S DISEASE. P.B. Cipolloni B.J. Quigley Jr.*, and N.W. Kowall. Dept. Anatomy, Boston Univ., ENR Memorial VA Hosp., Bedford MA 01730 and Neurology Service, Mass.General Hospital, Boston MA 02114.

We have previously shown that several classes of peptidergic neurons in the amygdala including those containing neuropeptide Y, cholecystokinin, substance P and somatostatin, develop dysmorphic features and contribute to senile plaque formation in Alzheimer's disease (AD). In the present study we used immunoperoxidase methods and a commercial antiserum (INCstar) to determine the distribution of vasoactive intestinal polypeptide (VIP) immunoreactivity in the amygdala of normal aged humans and patients with AD. VIP immunoreactive fibers, terminals and cells define the lateral division of the central nucleus more clearly than do other peptide stains. The stria terminalis is also intensely VIP immunoreactive. In Alzheimer's disease there is no change in the intensity or distribution of staining in the central nucleus of the amygdala or the stria terminalis. Occasional dystrophic VIP positive neurites are seen in the central nucleus. Despite the severity of changes affecting the amygdala in AD, the dorsal amygdalofugal pathway as defined by VIP immunocytochemistry is largely unchanged. This finding underscores the selectivity of neuronal degeneration in AD and supports the notion that projection systems to cerebral cortex are preferentially affected in AD.

344.17

GALANIN IMMUNOREACTIVE NEURONS OF THE TUBEROMAMMILLARY NUCLEUS IN NORMALS AND PATIENTS WITH SENILE DEMENTIA OF THE ALZHEIMER TYPE. V.Chan-Palay and B.Jentsch*. Neurology Clinic, University Hospital, CH-8091 Zürich, Switzerland.

The tuberomammillary nucleus in man contains a significant number of variably galanin immunoreactive neurons in a dense field of terminals. The location, quantity and morphological features of these peptide neurons are distinctive and have been studied using interactive computer systems. By these means the galanin containing neurons in this nucleus in six persons, neurologically and psychiatrically unaffected, were studied, quantified and three dimensional reconstructions were made of the entire region. These results were compared to the same nucleus in brains of clinically, psychometrically tested and neuropathologically confirmed cases of senile dementia of the Alzheimer type taken from the Zürich longitudinal study of dementia. There are significant alterations in the morphology of the remaining galanin immunoreactive neurons, and a loss of galanin containing cells. The immunoreactivity of the galanin neurons range from deeply intense to a very light reaction within the same groups of neurons suggesting that there may be co-existence of galanin with other neuroactive substances. We are investigating the probability that they are a subset of the histamine containing neurons of the tuberomammillary nucleus.

344.18

CORTICAL GLUTAMINASE, β-GLUCURONIDASE AND GLUCOSE UTILIZATION IN ALZHEIMER'S DISEASE. E.G. McGeer, H. Akiyama* and P.L. McGeer. Kinsmen Lab. of Neurol. Res., Univ. British Columbia, 2255 Wesbrook Mall, Vancouver, B.C., V6T 1W5, Canada.

Large cortical pyramidal neurons, known to be affected in DAT, stain positively with an antibody to phosphate-activated glutaminase (PAG). Cortical PAG, measured biochemically, is reduced in DAT more than is choline acetyltransferase (ChAT) in the same samples. β-Glucuronidase, a possible marker for reactive astrocytes, is elevated. PET studies show significant deficiencies in cortical glucose metabolism in DAT and serial scans show an exascerbation of the defect over time. In 4 cases, no correlation was found within each brain between the levels of ChAT determined postmortem in various cortical regions and the premortem local cerebral metabolic rates (LCMRs). In the 3 cases with <2 years between scan and death, the LCMRs correlated positively with PAG and negatively with β-glucuronidase activities. Such results are consistent with the hypothesis, advanced initially on the basis of morphological studies on a PET-scanned DAT that the progressive deficiencies in glucose metabolism reflect degeneration of cortical neurons with replacement by glial scar tissue.

344.19

ALTERATIONS IN THE DENSITY OF [^{125}I]PEPTIDE YY BINDING SITES IN THE HIPPOCAMPUS IN ALZHEIMER'S DISEASE. J.R. Unnerstall, B.J. Wilcox and P.J. Whitehouse. Dept. Neurology and Alzheimer Research Labs, Case Western Reserve Univ. Sch./Med., Cleveland, OH 44106.

Alterations in neuronal systems that contain neuropeptide-Y (NPY) have been described in the cortex and hippocampus of Alzheimer's Disease patients. Here, we have utilized the potent NPY analog [^{125}I]Peptide YY ([^{125}I]PYY) to label NPY binding sites in frozen sections of hippocampus taken from 9 AD cases and 7 age-matched controls at autopsy. Quantitative receptor autoradiography was used to assess the distribution and density of binding sites in these tissues. In tissue section, [^{125}I]PYY binds to two sites with K_D's of approximately 50 pM and 6 nM. Sections were labeled with 150 pM [^{125}I]PYY in the absence or presence of 500 nM human NPY to assess the high-affinity binding in autoradiographic assays. The distribution of [^{125}I]PYY binding sites parallels the distribution of NPY cell bodies and terminals described in the literature, with the highest binding seen in CA4 and the molecular layer of CA1-3. High levels of binding were also seen in the stratum radiatum and oriens. Moderate levels of binding are seen in the subiculum. Low levels of binding are seen in the molecular layer of the dentate gyrus. 50% decreases in [^{125}I]PYY binding in the AD cases were seen in the subiculum and the molecular layer of the dentate gyrus. Modest changes in other subregions can be related to the disruption of the laminar organization of the hippocampus. Thus, the greatest changes in [^{125}I]PYY binding can be related to subregions receiving afferents from intrinsic NPY neurons.

CIRCADIAN RHYTHMS OF MELATONIN AND CORTISOL IN NORMAL AGEING AND ALZHEIMER'S DISEASE. M. Thakur, M. Sharma*, G. Schwartz,*R. Quirion and N.P.V. Nair. Douglas Hosp. Res. Centre & McGill Univ. Montreal, Quebec, Canada H4H 1R3.

We investigated circadian rhythms of cortisol and melatonin in normal ageing and Alzheimer's disease (AD). Control subjects (19-89 yrs) were physically and mentally normal. AD patients (57-76 yrs) were diagnosed as "probable" or "definite" AD cases according to Reisberg Scale. All subjects were admitted to an investigation unit, where hourly blood samples were drawn from 8 a.m. until 8 a.m. the next day. The indoor illumination was restricted to 300 lux during the day and 50 lux during the night. Melatonin and cortisol were estimated by radioimmunoassay. The data was analyzed both for quantitative (24 hrs secretion and peak level) and time related functions (cosinor analysis for acrophase, mesor and amplitude). Preliminary results show significantly higher secretion of cortisol (264.1±55.9µg/dl vs 155.5±65.0µg/dl for controls) and melatonin (488.7±142.1pg/ml vs 295.5±137.6pg/ml for controls) in AD patients. On the contrary mean secretion of cortisol and melatonin decreased with age. However the acrophases of the two hormonal rhythms showed different relationships to age (positive correlation, $r=0.38$, $p<0.001$ for melatonin; and negative $r=-0.56$, $p<0.001$ for cortisol). This may suggest a weakened responsiveness of the circadian system to the day-night cycle and an altered relationship between the two pacemakers in the elderly.

COMPUTER QUANTITATED ALL NIGHT SLEEP/WAKE EEG IN EARLY ALZHEIMER'S DISEASE. P.N. Prinz, L.H. Larsen*, and M.V. Vitiello*. Dept. of Psychiatry, Univ. of Washington, Seattle, WA 98195.

Waking (clinical) EEG frequencies, while highly variable, average lower in Alzheimer's dementia (AD) than controls. Here we replicate this finding in the all night sleep EEG using computer techniques that minimize unwanted variance (muscle, eye and state influences) by selecting ideal tonic REM or slow wave sleep (SWS) epochs for analysis. Nine hour EEGs from 36 early AD (Mini Mental = 23 ± 3.) and 36 controls were digitized (256 Hz) and processed (AR filter smoother and fourier transform) using a Compaq 386. Results showed that 1) ADs had more slow (0.5 to 6 Hz) and less fast (8-30 Hz) energy during REM than controls; e.g., 16-20 Hz. REM energy (as % of total 2-20 Hz REM energy) averaged 1.82 ± .18 (SD) and 3.49 ± .32 for AD and controls ($F(1,70)=58$; $p<.0000$). 2) ADs have less energy in all frequency bins during SWS than controls; e.g., 0.5-2 Hz SWS energy averaged 7.01 ± 1.37 and 10.85 ± 1.82 for AD and controls ($F=22.6$; $p<.0000$). 3) Alpha frequency shifts toward lower values in AD; e.g., the ratio, [6 to 8 Hz ÷ 8 to 9 Hz] averaged 1.675 ± .39 and 1.447 ± .52 for AD and controls ($F=24.0$; $p<.0000$). These 3 measures together correctly classify >90% of control vs. early AD subjects in discriminate analyses. Supported by PHS Grants MH33688, RR37 and the VA.

344.22

FORGETTING IN ALZHEIMER'S DISEASE (AD): DMS VS DNMS RECOGNITION. D.M. Freed and A.J. Saraj*. Dept. of Psychology, Univ. of Southern Calif., Los Angeles, CA 90089.

Huppert and Piercy (1978) devised a procedure to evaluate rate of forgetting in memory-impaired individuals. Using this technique, control subjects (N=19) and patients with AD (N=19) were shown a set of 90 color slides taken from foreign language magazines. AD patients were provided with additional study time in order to equate their initial recognition performance with that of control subjects. Delayed-match-to-sample (DMS) and delayed-non-match-to-sample (DNMS) recognition was assessed 10 min and 24 hrs after learning.

Overall, AD patients displayed normal rates of forgetting in both DMS and DNMS recognition. A subgroup of AD patients (N=6) displayed an anomalous improvement in DNMS recognition 24 hrs after learning, replicating the findings of an earlier study (Freed et al., 1989). These results suggest that DMS and DNMS recognition are uncoupled in a subgroup of patients with AD. The existence of subgroups of AD patients has important implications for research. Supported in part by a grant from USC's Faculty Research Innovation Fund.

CHARACTERISTICS OF ODOR MEMORY IN ALZHEIMER'S DISEASE C.S. Seery* and C. Murphy. San Diego State Univ., San Diego, CA, 92182 & UCSD Medical Center, San Diego, CA 92103.

Recent neuroanatomical evidence for damage to the olfactory areas in Alzheimer's Disease suggests that patients with the disease may show selective olfactory dysfunction. Prior research has suggested that Alzheimer's patients show impairment in both olfactory threshold and memory. The present study was designed to investigate olfactory memory in Alzheimer's patients, and to compare types of responses made by patients to those made by controls. Ten patients who met the NINCDS ARDA criteria for probable Alzheimer's Disease were matched according to sex, age, and odor threshold to ten normal controls. Subjects performed a recognition memory task for odors and visual stimuli. ANOVA was conducted to compare odor and symbol hits and false-alarms in the two groups. A significant interaction was found between group and the within subject measure of hits and false alarms. A Newman-Keuls test revealed that patients had significantly more odor false alarms than did the controls, whereas the number of odor hits did not significantly differ between the two groups. Furthermore, patients had significantly more symbol false-alarms than did controls, whereas, once again, the number of symbol hits did not differ between the two groups. Interestingly, although patients had more symbol false-alarms than did the controls, within the patient group, there were significantly more odor false-alarms than symbol false-alarms. These results show that not only are the Alzheimer's patients impaired on odor memory tasks relative to controls, but they also make qualitatively different types of responses--more false-alarms, especially in the olfactory domain. Analysis of odor memory false-alarms may prove to be of diagnostic value, and may be consonant with the idea of olfactory intrusion errors. Supported by NIH grant #AG04085 and #AG08203 to C.M. We acknowledge the assistance of the Alzheimer's Disease Research Center at UCSD.

GEOGRAPHICAL KNOWLEDGE IN PATIENTS WITH ALZHEIMER'S DISEASE. W.W. Beatty and N. Bernstein*. Alzheimer Disease Research Center, UCSD.

Geographical knowledge, a measure of remote memory for visuospatial information, was studied in 24 mildly or moderately demented patients who met NINCDS-ADRDA criteria for Alzheimer's disease (AD). Patients and age, education, and gender-matched controls completed the US and California-Nevada (CA-NV) maps from the Fargo Map Test (FMT, Beatty, J Clin Psychol, 1988, 44, 61). AD patients were moderately impaired in locating the absolute positions of the gross geographical features emphasized on the US map and more profoundly impaired in locating the specific features (e.g., cities) emphasized on the CA-NV test. When the CA-NV map was scored for relative accuracy, performance by patients and controls improved to the same degree. Regression analyses indicated that patients' performance on the FMT was best predicted by neuropsychological measures that reflect remote memory; measures of anterograde memory and visuospatial function were not as strongly predictive. Our results suggest that AD patients lose the ability to access spatial information stored as a cognitive map at a stage in their disease when capacities for visuospatial analysis and wayfinding by taxon strategies may be relatively well preserved.

CLASSICAL CONDITIONING OF THE EYELID RESPONSE IN NORMAL ELDERLY AND IN PATIENTS DIAGNOSED WITH ALZHEIMER'S DISEASE. D. S. Woodruff-Pak, R. G. Finkbiner*, and I. Katz*. Dept. of Psychology, Temple University, Philadelphia, PA 19122 and Philadelphia Geriatric Center, Philadelphia, PA 19141.

The model system of classical conditioning of the eyelid response in rabbits has led to significant progress in the neurobiology of learning and memory. There are striking parallels in learning and retention of this response between rabbits and humans. Age differences in learning this response are large in both species. Two brain structures of demonstrated involvement in eyelid classical conditioning are the cerebellum and the hippocampus. The ipsilateral cerebellum is essential for eyelid conditioning, and the hippocampus plays a modulatory role. Loss of Purkinje cells with age correlates with poorer learning in rabbits and might also be involved with poorer acquisition in older humans. Since the hippocampus is severely damaged in senile dementia of the Alzheimer's type (SDAT), we suspected that patients with SDAT might condition more poorly than normal elderly adults. Medical records of Philadelphia Geriatric Center residents were screened, and patients diagnosed with standard criteria for SDAT (e.g., McKhann et al., Neurology, 34, 1984) were identified and contacted to participate. Age-matched control subjects from PGC were also run. An 80 dB, 500 msec tone conditioned stimulus (CS) was followed 400 msec after its onset with a 5 psi, 100 msec corneal airpuff unconditioned stimulus (US). All subjects demonstrated that they could hear the tone clearly. They also demonstrated that they had a blink reflex to the airpuff. Eyeblinks were measured with an infrared detector, mounted on a headpiece with the air tube. Ninety trials were presented to the subject in a session lasting about 45 minutes. By the end of the session, normal older adults were producing an average of 57% conditioned responses, while patients with SDAT were producing an average of 10% responses. These differences were statistically significant. This simple form of learning is seriously impaired in SDAT. In this regard, classical conditioning of the eyelid response may be useful as a behavioral assessment technique in SDAT.

344.26

LONGITUDINAL MENTAL STATUS CHANGES IN ALZHEIMER'S DISEASE. S.T. DeKosky , F.R. Schmitt,* and C.Knox.* Dept. of Neurology, Lexington VA and Univ. Kentucky Med. Ctrs. and Sanders Brown Center on Aging, Lexington, KY 40511.

Studies of the natural history of Alzheimer's disease (AD) are needed as baselines for assessing effective treatment. Such research also provides information on reliability and validity of brief rating scales used to follow disease progression and response to therapy. Neurotransmitter enhancement might produce improvement in cognition but long term effectiveness of such therapy, or treatments to delay structural changes (e.g., gangliosides or trophic factors) require data on long-term cognitive stability or decline. Longitudinal data from our NIA-Alzheimer's Disease Research Center has allowed for the assessment of cognitive rating scales in a large cohort (N=125) of AD patients meeting NINCDS-ADRDA criteria for diagnosis. Six month followups for up to 18 months show progressive impairment in the Mini-Mental State (MMS; -3.2 points/yr), Memory Information Test (MIT; 3.2 points/yr), and cognitive portion of the AD Assessment Scale (ADAS; 6.2 points /yr). Non-cognitive ADAS scores did not change significantly; use of medications for "non-cognitive symptoms" (e.g., restlessness, anxiety, depression) appeared to stabilize some behavioral ratings. We found slight correlations between level of education with cognitive scores but stronger associations with duration. The three mental status exams were highly correlated with each other. No differences in mental status scores based on family history of AD were seen.

344.27

MEMORY IMPAIRMENTS OF ALZHEIMER'S DISEASE CHARACTERIZED BY THE CERAD PSYCHOMETRIC BATTERY. K.A. Welsh, N. Butters, R.C. Mohs, J.P. Hughes, A. Heyman & CERAD neuropsychology investigators. Alzheimer's Disease Research Center, Duke University, Durham, North Carolina, 27705. CERAD has developed a reliable neuropsychological assessment battery for the evaluation of patients with the clinical diagnosis of Alzheimer's disease (AD). In this study we examined the memory measures of the battery in order to establish the utility of this instrument in characterizing the memory impairments of Alzheimer's disease. Enrolled cases (N=358) were stratified by stage of dementia (mild vs moderate) and were compared to normal controls (N=327) on the list learning task and the delayed recall and recognition procedures. The results of the analyses indicate (1) an attenuated learning rate (slope from linear regression), (2) severely impaired retention, defined as percent savings between the delay recall trial and the last learning trial, and (3) deficient recognition memory in the dementia groups. In addition, retention correlated well with other neuropsychological measures of the CERAD battery, particularly the tests involving verbal retrieval. These data using CERAD measures conform closely to the well documented changes reported in AD using other neuropsychological assessment instruments. The results provide some of the validation information necessary before theoretically important studies applying the CERAD battery to other populations can be addressed.

344.28

CORRELATES OF DEMENTIA: AN EPIDEMIOLOGICAL STUDY IN THE AREA OF BORDEAUX (FRANCE). J.F. DARTIGUES*, C. MESSIER, M. GAGNON*, R. SALAMON*, P. BARBERGER-GATEAU*, M. ORGOGOZO*, and the PAQUID GROUP. Département d'Informatique Médicale, Université de Bordeaux II, 146 rue Léo Saignat, 33076 Bordeaux, FRANCE.
PAQUID is an epidemiological study designed to gather and follow-up a cohort of 4,000 elderly (65 years and older) subjects living at home. These subjects were randomly chosen in the general population of 80 well-defined communities of Gironde and Dordogne (two large districts in the area of Bordeaux, FRANCE). The major goal of PAQUID is to study normal and pathological brain aging. We present the results of the data collected on 2792 subjects who accepted to participate in Gironde. The DSM-III criteria for dementia was met by 99 subjects, corresponding to a 3.55% prevalence. The prevalence increased with age, but more interestingly, the prevalence of dementia also decreased dramatically as educational level increased. Prevalence is 11.6% for subjects with no education, 4.3% for subjects with grade school level of education, 1.3% for subjects with high school level, and 0% for subjects with university degrees. Within the same educational level, the prevalence of dementia decreased as the level of intellectual demands of the subjects' principal occupation increased.

344.29

NEUROLOGICAL FINDINGS IN ALZHEIMER'S DISEASE AND NORMAL AGING. L.J. Thal and D. Galasko (SPON: K. Madden). Dept. Neurosciences, UCSD, La Jolla, CA 92093; Neurology Ser., VA Med. Ctr. San Diego, CA 92161

Abnormal neurological findings including primitive reflexes, parietal sensory deficits, extrapyramidal signs and myoclonus occur in Alzheimer's disease (AD). In order to determine their potential value as markers of AD and their relationship to the stage of AD, we compared standardized neurological examinations in 135 community-dwelling patients with AD and 91 nondemented elderly controls. After correcting for differences in age and education between the two groups, we found that rigidity, stooped posture, graphesthesia, neglect of simultaneous tactile stimuli (face-hand test) and snout, grasp and glabella reflexes were present significantly more often in AD than controls. These findings increased in prevalence in AD patients according to the severity of their cognitive impairment. However, in a multivariate logistic regression model we found that only the grasp reflex, graphesthesia and face-hand test were statistically significantly associated with the degree of cognitive impairment. Although abnormal neurological findings occur regularly in AD, their frequency of occurrence overlaps with normal aging, resulting in a low sensitivity for the early diagnosis of AD. Prospective studies are necessary to identify whether patients with the early onset of neurological abnormalities, particularly extrapyramidal findings, form a distinct subgroup of AD such as those with diffuse Lewy body disease.

344.30

COVERT ATTENTIONAL SHIFTS AND CEREBRAL METABOLISM IN ALZHEIMER'S DISEASE AND NORMAL AGING. P.M.Greenwood*,R.Parasuraman* and J.V.Haxby*(SPON:J.Moran). Cognitive Science Lab.,Catholic Univ.,Washington, DC 20064 and Lab. of Neurosciences, N.I.A.,Bethesda, MD 20892.

Right-left asymmetries in cerebral metabolism of parietal association areas are seen in early dementia of the Alzheimer type (DAT) (Haxby et al.,1985). Since the posterior parietal plays a role in visual attention (Mesulam, 1981), we hypothesized that DAT-induced parietal dysfunction might effect the costs and benefits of cue validity on covert orienting (Posner, 1980). A directed attention task was administered to normal young and old Ss and to DAT patients, in whom resting regional cerebral metabolic rates for glucose were measured by PET. A target letter appeared after a valid, invalid or neutral location cue. In the Detect condition, Ss made a speeded response when the "X" was detected. In the Encode condition Ss made a speeded categorization of the target as a consonant or vowel. The difference in RT between invalid and valid cues was largest for the DAT group ($p<.001$). The normal young and old performed similarly (Nissen & Corkin 1985). Furthermore, RT differences were larger in the DAT group in the Encode condition ($p<.05$) suggesting costs and benefits increase with increased target processing. Results are discussed in relation to asymmetric parietal metabolism in DAT and impaired disengaging of attention after right parietal damage (Posner et al.,1984). (Supported by grants from ADRDA and NIA).

344.31

NEUROPSYCHOLOGICAL CHARACTERISTICS OF A LEWY BODY VARIANT OF ALZHEIMER'S DISEASE. D. Salmon, L. Hansen*, E. Masliah*, D. Galasko*, N. Butters and R. Katzman. Alzheimer's Disease Research Center, UCSD Sch. of Med., San Diego, CA 92103.

A variant of Alzheimer's disease (AD) has recently been described in which neuropathological changes typical of AD occur concomitantly with diffusely distributed neocortical and brainstem Lewy bodies and temporal lobe spongiform changes (Lewy body variant: LBV). The neuropsychological test performance of 9 patients with autopsy verified LBV was compared to that of 9 patients with autopsy verified AD.

Although the two patient groups were matched for age, education and overall severity of dementia (Blessed scores LBV=16.56 errors; AD=17.56 errors), the LBV patients were more impaired than the AD patients on measures of attention, visuospatial/constructional ability, and verbal fluency. The groups did not differ significantly on tests of confrontation naming or memory. The present results suggest that LBV produces a pattern of neuropsychological deficits typical of cortical dementia such as AD (e.g., memory, language impairment), with additional, uncharacteristically severe deficits in cognitive processes usually affected in subcortical dementia (e.g., attention, verbal fluency). This pattern of deficits may be useful for clinically differentiating LBV from AD.

Non-radioactive detection of NGF-receptor mRNA with digoxigenin-UTP labeled RNA probes. F. Baldino, Jr., E. Robbins, D. Grega[1], S. L. Meyers, J.E. Springer[2], and M. E. Lewis. Cephalon, Inc., West Chester PA. [1]Boehringer Mannheim, Indianapolis, IN., and [2]Hahnemann Univ., Phila., PA.

Non-radioactive detection of mRNA has become an important new histochemical strategy to study the regulation of gene expression. Autoradiographic detection of specific mRNAs with radiolabeled probes has been limited by several factors including exposure time and the degree of cellular resolution. Here we report a method to detect mRNA coding for the NGF receptor (NGFR) with an RNA probe labeled with digoxigenin-UTP.

A NGFR cDNA (3400 bases) was blunt end inserted into the polylinker site of a pGEM vector containing an Sp6 promotor and linearized at an EcoRI restriction site. In situ hybridization was performed on 25 um tissue sections according to previously published methods. Hybrids were detected with anti-digoxigenin-alkaline-phosphatase conjugate reacted with NBT.

Hybridization positive cells were identified along the base of the forebrain extending dorsally along the vertical diagonal band into the medial septum. The distribution of labeled perikarya is consistent with in situ hybridization studies using radiolabled probes complementary to the NGFR message (see J.E. Springer Neurosci. Abs.), and was convergent with the distribution of cholinergic neurons in these regions. Background labeling was barely visible in these sections.

The ability to detect NGFR mRNA with RNA probes labeled with digoxigenin-UTP (dig-UTP) will greatly enhance our ability to better understand the factors which regulate the expression of this gene. Furthermore, RNA probes labeled with dig-UTP permits the high level of resolution required to study the regulation of relatively rare transcripts at the single cell level. We thank Boehringer Mannheim GmbH for their continued support and collaboration.

345.2

LOCALIZATION OF NGF RECEPTOR mRNA IN EARLY CHICKEN EMBRYOS USING IN SITU HYBRIDIZATION J.G. Heuer* and M.A.Bothwell (SPON: O. Smith) Dept. of Physiology & Biophysics, University of Washington, Seattle, Wa. 98195.

We have previously described the cloning of a chicken NGF receptor cDNA (Bothwell et al., Neurosci. Abstr. 14:684, 1988) and its use in detecting NGF receptor mRNA in embryonic day 6 chick embryos. We demonstrate here the localization of NGF receptor mRNA in 40, 55 and 72 hour chick embryos using in situ hybridization. Chick embryos were removed from their eggs, fixed in 4% paraformaldehyde, dehydrated and embedded in paraffin. 8um sections were cut and collected onto polylysine coated slides and in situ hybridization was carried out according to Wilkinson et al., (Development 99:493, 1987) with the omission of the high stringency wash steps. NGF receptor sense and antisense cRNA probes were made using SP6 and T7 RNA polymerases from a cDNA fragment subcloned into a pGEM vector (Promega). We find NGF receptor mRNA expression on a wide variety of non-neuronal cell types including head mesenchymal cells, segmental mesoderm cells, mesenchymal cells entering developing wing and leg buds as well as sclerotome and dermatome cells of developing somites. In addition, we find NGF receptor mRNA expression on several neuronal populations including cells of cranial ganglia 5,7,8,9 and 10, presumptive motoneurons in the spinal cord, cells of the ventral myelencephalon and a subpopulation of cells in the diencephalon. Our findings indicate the presence of NGF receptor mRNA expression on a wide variety of cell types at stages earlier than those previously examined, suggesting that NGF may play other roles in development aside from the classical neurotrophic role.

345.3

KAINIC ACID - INDUCED SEIZURES STIMULATE INCREASED EXPRESSION OF ß-NGF mRNA IN ADULT RAT FOREBRAIN. C.M. Gall, K.D. Murray*, and P.J. Isackson, Department of Anatomy and Neurobiology, University of California, Irvine, CA 92717.

Recent work in our laboratories has demonstrated the recurrent limbic seizures, induced by an electrolytic lesion of the dentate gyrus hilus, result in a rapid bilateral increase in mRNA for nerve growth factor (NGF) in hippocampal neurons and a more delayed increase in neurons of olfactory cortex, neocortex, and amygdala. In the present study, the influence of seizures induced by intraventricular injection of 0.5µg kainic acid (KA) on mRNA for NGF was examined by *in situ* hybridization using riboprobes complementary to ß-NGF and the full preproNGF sequence (Whittemore et al., 1988). Hybridization was localized with both film and emulsion autoradiographic techniques.

The greatest KA-induced increase in hybridization was observed in the dentate gyrus granule cells. As early as 2 hrs post-KA there was a 35-fold increase in the density of hybridization within this cell layer (as evaluated by densitometric analysis of film autoradiograms). By 5 hrs post-KA, this had declined to 10-fold control values. At both of these time points virtually all of the dentate gyrus granule cells appeared to be densely labeled with the ^{35}S-cRNA probe. As in control rats, the majority of neurons within stratum pyramidale of hippocampal regions CA3 and CA1 were not labeled in KA-treated animals. By 12 hrs post-KA, hybridization density within the granule cell layer had declined further and there was a clear increase in the density of hybridization in superficial layers (II, III) of the piriform and entorhinal cortices and more modest increases in superficial neocortex. These data provide further support for the conclusion that seizure activity serves as a powerful stimulant for increased expression of NGF in adult rat forebrain neurons.

CELLULAR LOCALIZATION OF ß-NGF mRNA IN RAT FOREBRAIN. J.C. Lauterborn, P.J. Isackson, and C.M. Gall, Dept. of Anatomy and Neurobiology, University of California , Irvine CA 92717.

Nerve growth factor (NGF) is thought to be a neuronally derived trophic factor which has been implicated to be important for the survival of basal forebrain cholinergic neurons. In the present study, the distribution of ß-NGF mRNA was analyzed in rat forebrain by *in situ* hybridization techniques using a ^{35}S-labeled RNA probe complementary to a 771 base sequence encoding the complete preproNGF peptide (Whittemore et al., 1988). Hybridization was visualized by emulsion autoradiographic (AR) methods.

The highest density of labeled cells was seen in the hippocampus with individual well-labeled cells observed in all principal fields as well as the subiculum. In the dentate gyrus, well-labeled cells were scattered within the hilus and a much lower density of AR grains was observed overlying the granule cell layer. Interestingly, a small number of labeled cells were also seen in the tenia tecta. In regio inferior, numerous labeled cells were observed uniformly scattered within both stratum pyramidale and stratum radiatum. By comparision, in regio superior the vast majority of labeled cells were seen within stratum pyramidale. It should be noted that the labeled neurons comprised a small portion of total neurons in each of these areas. Beyond hippocampus, scattered labeled cells were observed within the amygdaloid complex with greatest densities in the cortical amygdaloid nucleus and the anterior amygdaloid area. In addition, a small number of labeled cells were seen in the ventral pallidum and the magnocellular preoptic nucleus; two basal forebrain areas which contain cholinergic neurons. Finally, a moderate density of AR grains was also observed in layer 2 of the entorhinal and cingulate cortices and layers 2 & 3 of piriform cortex. These data provide further information on the distribution of ß-NGF synthesizing cells in limbic brain regions. Moreover, the presence of ß-NGF synthesizing cells in cholinergic-containing ventral forebrain areas is intriguing in light of NGF's probable trophic effect on CNS cholinergic neurons. Supported by NS26748 to C.M.G. and NS24747 to P.J.I.

CHARACTERIZATION OF TRUNCATED, SOLUBLE FORMS OF THE HUMAN NERVE GROWTH FACTOR RECEPTOR. A.A. Zupan, P.A. Osborne*, and E.M. Johnson, Jr. Department of Pharmacology, Washington University, St. Louis, MO 63110.

We report the purification, by sequential ammonium sulfate precipitation and immunoaffinity chromatography, of at least three truncated forms of the human nerve growth factor receptor ($NGFR_t$) from amniotic fluid with yields of 80 µg/L of starting material. Using ^{125}I-$NGFR_t$ as a tracer in the purification, a recovery of 40% was calculated. The three glycoproteins, with molecular masses of 45, 40, and 35 kDa on SDS/PAGE-12%, were confirmed to be $NGFR_t$'s by amino-terminal sequencing of individual species isolated by electroelution and were designated $NGFR_t$-1, -2, -3, respectively. The apparent binding affinities of these species for NGF were comparable to that of the low-affinity, cell-surface receptor. Isoelectric points ranged from 3.3 - 3.95 with intraspecies microheterogeneity. Each of these proteins retained a complex-type carbohydrate modification on Asn-32 and demonstrated varying degrees of sialation. We propose these molecules to be portions of the receptor's extracellular domain generated by differential proteolytic cleavage proximal to the membrane-spanning sequence. The potential to isolate milligram quantities of human $NGFR_t$ permits structural studies of the intact receptor and the generation of polyclonal antibodies to study its biological function(s). Supported by a Monsanto grant.

CIRCUMVENTRICULAR ORGANS AND CHOROID PLEXUS OF ADULT RAT CONTAIN HIGH LEVELS OF NERVE GROWTH FACTOR (NGR) RECEPTOR. [1]Qiao Yan,[1]Akio Wanaka,* [2]H. Brent Clark, and [1]Eugene M. Johnson, Jr., [1]Department of Pharmacology, Washington University Medical School, St. Louis, MO 63110 and [2]Department of Laboratory Medicine, Memorial Medical Center, Springfield, IL 62781

Immunohistochemical examination of adult rat brain demonstrated the presence of high levels of NGF receptor in circumventricular organs: Subfornical organs, median eminence, area postrema, and posterior pituitary. Dense staining was also seen in choroid plexus. Biochemical study of the NGF receptor in these tissues by crosslink/immunoprecipitation showed a band at a molecular weight of 90 kDa, consistent with intact receptor. No truncated species of receptor was observed. These tissues also contained significant levels of the 3.9 Kb NGF receptor mRNA, indicating that the receptor is synthesized locally. Immunoelectronmicroscopy indicates that the receptor resides on un-identified fusiform cells which lie both inside and outside the basal lamina in proximity to blood vessels. The NGF receptor in the circumventrical organs were further studied by in vivo labeling of ^{125}I-ligands. Intravenously injected ^{125}I-NGF was specifically accumulated in the area postrema and the posterior pituitary (only areas examined), but ^{125}I-cytochrome C was not. Labeling of ^{125}I was blocked by injection of unlabeled NGF. Experiments are currently underway to identify the cell type(s) bearing the NGF receptor in these tissues.

DEVELOPMENTAL EXPRESSION OF NERVE GROWTH FACTOR RECEPTOR (NGFR) IN THE RAT VISUAL SYSTEM. M.C. Comelli*, L. Cavicchioli*, P. Candeo*, G. Carmignoto* and L. Maffei*°. (SPON.: G. Calderini). Fidia Research Laboratories, 35031 Abano Terme (PD) and °Istituto di Neurofisiologia, CNR, 56100 Pisa, ITALY.

Retinal ganglion cells of rat retina have been recently proven to be rescued from degeneration by NGF intraocular administrations (Carmignoto, G. et al., J. Neurosci., in press). Since the action of NGF involves a receptor-coupling event, we analyzed the possible expression of the NGFR and its mRNA in the retina and optic nerve of Long Evans hooded rats. The presence of NGFR was detected immunocytochemically in cross sections of the retina by using the monoclonal antibody 192-IgG, which specifically recognizes rat NGFR. NGFR immunoreactivity was present in the retina as well as optic nerve of neonatal rats, whereas it was present only in the retina of adult rats. The pattern of staining is consistent with Müller cells, although it can not be completely ruled out that retinal ganglion cells (RGCs) are also positive. The mRNA for NGFR was also found to be present in the retina both at postnatal day 2 and in adult rats, thereby indicating that the immunoreactivity represents authentic NGFR. These results suggest that the effect of NGF on RGC survival is mediated indirectly through Müller cells and raises the possibility of a specific role of NGF in the development of the visual system.

REVERSE PHASE-HPLC CHARACTERIZATION OF NGF AND NGF RECEPTOR. C.E. Beck*, D.E. Shan*, J.I. Teng*, K. Werrbach-Perez* & J.R. Perez-Polo, (Spon: L.W. Thorpe) HBC&G Dept., Univ. of Texas Medical Branch, Galveston, TX, 77550.

The first obligatory step to the action of the neuronotrophic factor NGF is binding to a cell surface receptor, NGFR. Murine beta-NGF, here called NGF, is a glycoprotein. NGF purified by reverse phase HPLC was attached to nitrocellulose membranes, reacted with biotinylated lectins and reactions visualized with an avidin-biotin complex coupled to horseradish peroxidase that yielded several monosaccharides. Hydrolysis of NGF followed by analysis by high pressure anion exchange chromatography with pulsed amperometric detection (AE-PAD) gave d-glucose, fucose, mannose, d-galactose and glucosamine. NGFR present on PC12 cells was partially purified by lectin chromatography and RP-HPLC followed by immunoprecipitation with a monoclonal antibody to rodent NGFR and SDS-PAGE analysis. Our results suggest that there is a receptor associated protein of 16 KDa. Supported in part by grants from NINDS and ONR.

345.9

NERVE GROWTH FACTOR (NGF) REGULATES EXPRESSION OF THE NGF-RECEPTOR GENE IN ADULT RAT SENSORY NEURONS R.M.Lindsay, E.M.Shooter, G.Dechant*, H.Thoenen and D. Lindholm. Regeneron Inc., 777 Old Sawmill River Road, Tarrytown, NY 10591-6707

Adult rat dorsal root ganglion (DRG) sensory neurons can be maintained in culture in the absence of NGF. We have therefore used these neurons to study the effect of NGF on the regulation of expression of mRNA encoding the NGF-receptor (NGF-R). In the absence of NGF, NGF-R levels remained constant for 7 days in cultures of adult rat DRG neurons. In the presence of NGF, NGF-R mRNA levels rose 2-3-fold after 2 days, reaching plateau levels (5-6-fold increase) after 5 days. NGF-induced up-regulation of NGF-R mRNA could be shown even after prior NGF-deprivation for 5 days. NGF had no effect on NGF-R mRNA levels in DRG non-neuronal cells. Other polypeptide growth factors (EGF, CNTF, FGF) had no effect on adult rat DRG neuron NGF-R mRNA levels, but 8-bromo-cAMP treatment decreased NGF-R mRNA levels by 65% (cf. controls) after 2 days. NGF also induced a rapid rise in c-fos in DRG neurons but not in non-neuronal cells. These results suggest that levels of expression of the NGF-receptor in vivo may be regulated by endogenous levels of NGF.

IDENTIFICATION AND CLONING OF ANTISENSE mRNA FOR NERVE GROWTH FACTOR RECEPTOR. A.G. Yakovlev,* E. Costa and I. Mocchetti+. Fidia-Georgetown Institute for the Neurosciences and +Department of Anatomy & Cell Biology, Georgetown University, Washington D.C. 20007.

Northern blot hybridization analysis of rat brain poly(A)$^+$ RNA with pNGFR.1 cDNA (Radeke et al. 1986) clone revealed the presence of two mRNA species related to nerve growth factor receptor (NGFR) one of 3.8 kb and the other of about 1.7 kb. The 1.7 kb hybridization pattern fails to occur in poly(A)$^+$ RNA prepared from PC12 cells or dorsal root ganglia which highly express the 3.8 kb NGFR mRNA. Furthermore, the presence of 1.7 kb band could be detected by hybridizing with a single strand probe containing the coding sequence of NGFR cDNA and not by its antisense strand. These observations prompted us to investigate whether an endogenous antisense NGFR RNA could be present in rat brain. cDNA library of rat brain was constructed and screened with pNGFR.1 probe. Several positive clones were isolated and further analyzed by Northern blot hybridization analysis. One of the positive clone, pBS3 which hybridized to 1.7 kb brain RNA, was partially sequenced. The 3' region of this clone revealed high homology with a segment of NGFR mRNA. pBS3 cDNA was used to hybridize poly(A)$^+$ RNA from rat brain at different stage of postnatal development. We found that the zenit of pBS3 mRNA expression is associated to the nadir of NGFR mRNA expression. We are currently investigating whether the BS3 mRNA is involved in the modulation of NGFR mRNA expression at the translational level.

345.11

TRANSSYNAPTIC REGULATION OF NERVE GROWTH FACTOR GENE EXPRESSION. M. Fabrazzo*, E. Costa and I. Mocchetti+. Fidia-Georgetown Institute for the Neurosciences and +Department of Anatomy & Cell Biology, Georgetown University, Washington D.C. 20007.

The regulation of nerve growth factor (NGF) gene expression in rat brain has been studied to assess the hypothesis deriving from our *in vitro* studies that beta-adrenergic receptor (BAR) stimulation increases NGF gene expression. The hypothesis was verified *in vivo* by investigating whether the acute or prolonged stimulation of BAR by isoproterenol (20ug i.c.v.) increases NGF mRNA content. While BAR activation failed to change NGF mRNA content of various brain structures, the depletion of catecholamine stores by reserpine induced a specific increase of NGF mRNA in cerebral cortex. The time course of this effect shows that a single dose of reserpine (2 mg/kg s.c.) elicits an increase on NGF mRNA content which peaks at 9 hr after the injection. However at 24 hours the content of NGF mRNA return to the control value . Injecting the same dose for two days, the NGF mRNA increase caused by reserpine last longer. In fact, 3 days after the last injection NGF mRNA and protein content are still significantly increased. Therefore, reserpine either might remove a transsynaptic tonic inhibition exerted by a depleted monoamine or increase the content of corticosteroids which, in turn, can positively affect NGF gene expression.

DETECTION OF NERVE GROWTH FACTOR (NGF) mRNA IN HUMAN BRAIN USING THE POLYMERASE CHAIN REACTION (PCR). M. Fahnestock and L. B. Taylor*. Molecular Biology Department, SRI International, Menlo Park, CA 94025.

We have previously shown that NGF mRNA can be detected in human frontal cortex using sensitive Northern blotting techniques, and that the relative amounts of NGF mRNA in various cortex samples can be estimated using dot blotting. However, the amount of NGF mRNA in human brain is extremely low, and in order to load sufficient mRNA on Northern or dot blots to generate a signal, we have been forced to start with many grams of tissue. This has made the study of NGF in smaller structures of the brain impossible.

We now show that, starting with small amounts of tissue from human cortex or hippocampus, polyA+ mRNA can be purified and tested for the presence of NGF mRNA. One microgram of polyA+ mRNA is sufficient template for the synthesis of cDNA; then NGF-specific primers and Taq polymerase are used to amplify the NGF cDNA by the polymerase chain reaction (PCR). A standard, amplified simultaneously in each sample, allows relative amounts of NGF mRNA to be compared between samples. We show that NGF mRNA can be detected by PCR in human cortex.

SITE SPECIFIC MUTAGENESIS OF TRP-21 TO LEU-21 IN β-NERVE GROWTH FACTOR (NGF) RETAINS BIOLOGICAL ACTIVITY. Y. Luo* and K.E. Neet. Department of Biochemistry, Case Western Reserve University, Cleveland, Ohio 44106.

Oxidation of Trp-21 with N-bromosuccinimide produces a significant decrease in both biological and binding activity of NGF (Cohen et al. J. Biol. Chem. 255, 2949, 1980; Frazier et al. Biochemistry 12, 3281, 1973). In order to test further the involvement of Trp-21 in the biological and binding activity of NGF, we have replaced the tryptophan with leucine by oligonucleotide-directed mutagenesis. The mutated NGF cDNA was confirmed by dideoxy DNA sequencing and was highly expressed in *E. coli* with a gene fusion vector pRIT2T (Luo & Neet, 18th Ann. Soc. Neurosci. Mtg, 14, 276.7, 1988). The fusion protein was present in inclusion bodies of *E. coli* and was purified through a DE52 anion exchange column in the presence of 6 M urea. Intact mutant NGF protein, NGF(W21L), was cleaved from the fusion protein by trypsin treatment at 0^0 C and purified to homogeneity by reverse phase FPLC. NGF(W21L) was found to promote neurite outgrowth of PC12 cells in defined medium and this biological activity was inhibitable by polyclonal anti-NGF antibodies. Our result indicates that alteration of Trp-21 to a smaller hydrophobic residue, leucine, does not eliminate the biological response of PC12 cells to NGF. Further biochemical characterization and quantitation of this mutant protein are in progress. (Supported by an NIH grant, NS24380)

345.14

SRC AND RAS RELATED ANTIGENS ARE REQUIRED FOR NEURONAL DIFFERENTIATION OF PC12 BY NGF AND b-FGF. N. E. Kremer, J. S. Brugge,* and S. Halegoua*, Dept. of Neurobiology & Behavior, S.U.N.Y. at Stony Brook, Stony Brook, NY 11794, and *Howard Hughes Medical Institute, Dept. of Microbiology, Univ. of Penn., Philadelphia, PA, 19104.

We have used antibody microinjection into multinucleated fused PC12 cells to study signal transduction of NGF and basic FGF (see Hagag et al., 1986, Nature, 319:680). We report that microinjection of a monoclonal antibody against the protooncogene c-src product pp60, or of monoclonal antibody Y13-259 against protooncogene c-Ha-ras product p21, blocks neurite outgrowth induced either by NGF or b-FGF.

Cells were pretreated with NGF for 24 hr, or with b-FGF for 4 days, then microinjected, and scored for neurites 24 hr later. In a typical experiment with NGF, 75% of uninjected control cells or cells injected with a non-specific control antibody exhibited neurites. Only 17% of cells had neurites after microinjection of the anti-src antibody. Similarly, treatment with b-FGF resulted in a neurite frequency of 71%. Injection of the anti-src antibody resulted in a frequency of 26%. Injection of anti-ras antibody similarly inhibited both NGF and b-FGF induction of neurites. Both anti-src and anti-ras antibodies prevented and reversed neurite outgrowth. All antibody injected cells were capable of producing neurites, since they all produced neurites in response to dibutyryl cAMP. Furthermore, antibody injected cells regrew neurites at times beyond 40 hr post-injection.

Our results suggest that a src-related tyrosine kinase and a ras-related G-protein are essential components of both the NGF and b-FGF signal transduction pathways. The relationship between these components and others involved in NGF action, such as C-kinase and A-kinase, are being investigated.

PROCESSING OF RECOMBINANT NERVE GROWTH FACTOR P.J. Isackson, M. Blaber*, K. Cavanaugh* and R.A. Bradshaw. Dept. of Biological Chemistry and Dept. of Anatomy and Neurobiology, Univ. of California, Irvine, CA 92717.

Beta-NGF and the associated glandular kallikreins, alpha-NGF and gamma-NGF, of the mouse submandibular gland have each been expressed as fusion proteins in E. coli using a plasmid vector containing the araB and araC genes. Induction with arabinose results in the expression of each of these fusion proteins at a level of greater than 1 mg per liter of media. The kallikrein fusion proteins can be solubilized with guanidine-HCl followed by refolding with a glutathione-based redox buffer. Limited digestion of the gamma-NGF fusion protein with trypsin produces a two-chain form of the molecule which has been purified to homogeneity, is enzymatically active against synthetic ester substrates, and recombines with alpha- and beta-NGF to form the 7S NGF complex. In contrast to the kallikreins, the beta-NGF fusion protein is not soluble in neutral pH buffer after the refolding procedure. Treatment of the refolded fusion protein with trypsin produces a form of beta-NGF which is soluble and promotes neurite extension of PC12 cells. Supported by NS24747 to P.J. Isackson and NS19964 to R.A. Bradshaw.

345.16

RAPID AND SPECIFIC INDUCTION OF IMMEDIATE EARLY GENES BY NERVE GROWTH FACTOR IN PC12 CELLS. Jeffery L. Twiss* and Gary E. Landreth. Department of Neurology, Medical University of South Carolina, Charleston, SC 29425

Nerve growth factor rapidly stimulates the expression of a number of "immediate early genes" which encode putative transcriptional regulators. We have screened a cDNA library from NGF-treated PC12 cells and have detected four cDNAs representing mRNA species whose abundance is dramatically increased on NGF treatment of PC12 cells. Two of these clones have been characterized. NGF treatment resulted in the dramatic elevation of mRNA levels of 1N19 within 1 hr, which was sustained for at least 24 hrs. The mRNA levels of a second clone, 7N56, are induced within 10 hrs of NGF treatment and subsequently declined within 24 hrs. EGF and TPA treatment of the cells had no effect on mRNA levels of these genes. Cross hybridization studies demonstrated that these clones are unrelated to other NGF induced genes including c-fos, c-myc, PC2, PC3, PC4. Partial sequence analysis revealed no sequence homology with other gene sequences in Genbank. We have detected a novel gene, 1/5N3, which was maximally induced within 15 min of NGF addition, mRNA levels then fell rapidly in the following 30-60 min. The accumulation of 1/5N3 mRNA was blocked by ā-amanitin. The expression of this gene was also stimulated by EGF and TPA to similar levels. No significant homology within the Genbank database was detected using partial sequence data.

Induction of 1,2-diacylglycerol by nerve growth factor and basic fibroblast growth factor in PC12 cells is primarily from phospholipids other than the phosphoinositides. J. G. Altin* and R. A. Bradshaw, Dept. of Biological Chemistry, California Coll of Med., Univ. of Calif., Irvine, CA 92717.

Nerve growth factor (NGF) and basic fibroblast growth factor (bFGF) induce differentiation and neurite outgrowth in PC12 cells. In these cells, NGF stimulates an increase in the production of inositol phosphates (IPs) from the cleavage of phosphoinositides with the concomittent release of 1,2-diacylglycerol (DAG). However, compared to carbachol, the amount of IPs produced by both NGF and bFGF are inadequate to account for the DAG, suggesting that other phospholipid pools may also be hydrolyzed. The addition of NGF and bFGF to cells pre-labelled with ^{3}H-inositol and incubated in the presence of 10 mM LiCl, each increased the production of IPs by 120-200% within 30 min. Approximately 85% was recovered as IP, the remainder as inositol bisphosphate and inositol trisphosphate. Under similar conditions carbachol induced a 10-fold increase in IPs. NGF and bFGF also induced a Ca^{2+}-dependent increase in the mass level of DAG; the increase was about 2-3 fold after 15 min and was sustained for at least 30 min. Stimulation of DAG production by 0.5 mM carbachol was similar to that induced by 200 ng/ml NGF and 50 ng/ml bFGF. As the production of IPs by carbachol was 5-10-fold greater than that induced by NGF and bFGF, this suggests that both factors stimulate the production of DAG primarily from a source(s) other than the phosphoinositides. Moreover, since carbachol stimulates the production of DAG but does not induce neurite outgrowth in PC12 cells, it raises the question as to the role of protein kinase C in the signal transduction cascade leading to neurite outgrowth in PC12 cells, and whether the species of DAG produced by the action of NGF, bFGF and carbachol might activate different forms of protein kinase C. Supported by USPHS research grant NS19964 and ACS research grant BC273.

345.18

DIFFERENTIAL INHIBITION OF NGF RESPONSES BY PURINE ANALOGS. C. Volonté, A Rukenstein*, D.M. Loeb* and L.A. Greene*. Department of Pathology,College of Physicians and Surgeons, Columbia University, New York - N.Y., 10032.

Purine analogs are used in this study to dissect specific steps in the mechanism of action of nerve growth factor (NGF). We have previously shown that protein kinase N (PKN), an NGF-activated serine protein kinase that is active in the presence of Mn^{++}, is inhibited in vitro by purine analogs, the most effective of which was 6-thioguanine (apparent K_i = 6 μM). Several different criteria indicated that 6-thioguanine was not a general inhibitor of protein kinases and that it was relatively specific for PKN. Since purine analogs rapidly and effectively enter cells, they were assessed for their actions on both transcription-dependent and -independent responses to NGF. NGF-promoted neurite regeneration is reversibly suppressed, both in PC12 cells and in cultured sympathetic neurons, by the analogs, at concentrations very similar to those that inhibit PKN. Comparable concentrations of the purine analogs also block NGF- and cyclic AMP analog-stimulated induction of ornithine decarboxylase activity. This effect is prevented by pre-exposing the cells to NGF for a very short time (1-3 min). In contrast to its inhibition of neurite regeneration and ornithine decarboxylase induction, 6-thioguanine does not suppress NGF-dependent induction of c-*fos* mRNA expression and in fact, appears to enhance this effect. c-*fos* mRNA induction is transient in the presence of 6-thioguanine and NGF, peaking at about 1 hr and being undetectable by 4 hrs of treatment. Thus, purine analogs such as 6-thioguanine appear capable of differentially suppressing some, but not other actions of NGF. These findings suggest the presence of multiple pathways in the NGF mechanism of action and the possibility of dissecting them with the use of purine analogs. Moreover, these data are compatible with a causal role for protein kinase N in certain of these pathways.

345.19

EFFECTS OF NERVE GROWTH FACTOR (NGF) AND MONOSIALOGANGLIOSIDE GM1 ON NEUROTRANSMITTER RELEASE IN VIVO. D. Maysinger, M. Herrera-Marschitz*, U. Ungerstedt and A.C. Cuello Dept. of Pharmacology & Therapeutics, McGill University, Montreal and Dept. of Pharmacology, Karolinska Institutet, Stockholm, Sweden.

The release of acetylcholine, (ACh), choline, dopamine (DA), DOPAC, 5-HIAA, HVA and adenosine was studied in the rat cortex and striatum by using microdialysis combined with highly sensitive HPLC systems. The release of neurotransmitters and their metabolites was investigated in animals with unilateral cortical devascularizing lesions causing partial retrograde degeneration of cholinergic neurons in the nucleus basalis magnocellularis. Cortically lesioned rats were chronically treated with either NGF or the monosialoganglioside GM1. The drugs were delivered into the lateral ventricle via permanent installed canulae. Thirty days following the treatment, animals were anaesthesized with halothane and microdialysis probes were implanted into the intact or remaining cortex and the left caudate putamen (ipsilateral to the lesion). Unstimulated ACh release was only measurable in the presence of neostigmine. This AChE inhibitor produced transient but significant increase of DA release in the corpus striatum. High KCl concentration caused significant increase in release of all neurotransmitters. Both NGF and GM1 partially or totally (GM1) reestablished the recovery of stimulated ACh release in lesioned rats.

EFFECTS OF NGF AND/OR GM1 ON HIGH AFFINITY CHOLINE UPTAKE IN THE RAT BRAIN FOLLOWING UNILATERAL DECORTICATION. L. Garofalo* and A.C.Cuello(SPON: E.Pioro). Dept. of Pharmacology, McGill University, Montreal,Canada H3G-1Y6.

Previous studies in our laboratory have shown that treatment with NGF and/or GM1 increases ChAT activity above control levels in the remaining ipsilateral cortex of adult rats following unilateral devascularizing cortical lesions. In order to examine further the effects of such a lesion and factor administration on the functional state of cholinergic terminals we assessed high affinity choline uptake(HACU) in the remaining ipsilateral cortex of rats 1,5, 15 and 30 days post-lesion. Adult male Wistar rats were cortically lesioned unilaterally and treated immediately intracerebroventricularly with either: vehicle, NGF(12ug/day), GM1(5mg/kg/day) or both these factors simultaneously for 7 days using osmotic minipumps. Cortical HACU in the remaining ipsilateral cortex of vehicle treated rats did not differ, at any time examined post-lesion, from control values. Significant increases over control values in HACU were observed 15 days post-lesion only in rats which received both NGF and GM1. At 30 days post-lesion, a 22% and 30% increase over control cortical HACU was noted in synaptosomes from NGF or GM1 treated rats respectively and a 66% increase was obtained in rats which received NGF and GM1 simultaneously. Immunocytochemical studies are currently underway to determine whether these increases may be due to sprouting of cortical cholinergic terminals.

TROPHIC AGENTS VI

AN APPARENT ABSENCE OF NERVE GROWTH FACTOR RECEPTORS ON MIGRATING NEURAL CREST CELLS *IN VIVO*. J. Speight* and P. Bernd (SPON: J. Jakway). Dept. of Anatomy and Cell Biology, SUNY Health Sci. Ctr., Brooklyn, NY 11203.

Binding studies on relatively undifferentiated short-term (0 & 24 hr) neural crest (NC) cultures have demonstrated that premigratory and early migratory NC cells do not bind ^{125}I-NGF indicating that they do not possess NGF receptors; differentiating, long-term (>5 day) cultures do bind ^{125}I-NGF via specific receptors and are potentially responsive to NGF. 72-hr (stage 19-20) quail embryos were used to examine the presence or absence of NGF receptors on early migratory NC cells *in vivo*. Serial cryostat (10 µm) sections were exposed to ^{125}I-NGF (50 ng/ml in PBS, 90 min, 37°C); controls included an excess of nonradioactive NGF (5 µg/ml). Radioautography was used to localize NGF receptors, while migrating neural crest cells were identified using HNK-1. Preliminary results revealed low levels of specific binding uniformly throughout the embryo; however, the density of silver grain accumulations over the HNK-1+ cells was not greater than that over surrounding tissues, indicating that early differentiating NC cells *in vivo*, as *in vitro*, do not possess receptors for NGF. 8 day (stage 35) embryos were used as a positive control; as expected, there was specific ^{125}I-NGF labelling of dorsal root ganglia. These results further confirm *in vitro* studies and imply that NGF does not play a role in the migration and early differentiation of NC cells. Supported by grants from the March of Dimes (#1-1090), NSF (BNS-8896101), and the Dysautonomia Foundation.

346.2

SELECTIVE EXPRESSION OF NERVE GROWTH FACTOR RECEPTORS ON SENSORY NEUROBLASTS IN NEURAL CREST CULTURES. P. Bernd. Dept. of Anatomy and Cell Biology, SUNY Health Sci. Ctr., Brooklyn, NY 11203.

Previous studies have shown that long-term neural crest cultures (7 days past explantation) contain a subpopulation of cells exhibiting NGF receptors. We have found, however, that the phenotype of cells expressing NGF receptors is dependent upon the culture conditions. In cultures maintained in the absence of exogenous NGF, the primary cell phenotype binding ^{125}I-NGF appears to be Schwann cell precursors, while neuron-like cells do not bind ^{125}I-NGF. In contrast, if cultures are maintained in the continuous presence of exogenous NGF (50 ng/ml), catecholaminergic neuron-like cells with high affinity NGF receptors can be identified. The current study investigated whether sensory neuroblasts, identified by the presence of vasoactive intestinal polypeptide (VIP) or substance P (SP), are likewise affected by culture conditions. Combined radioautographic and immunocytochemical results indicate that VIP-like immunoreactive cells do not have NGF receptors if maintained in the absence of NGF. Preliminary co-localization studies with cultures maintained in the continuous presence of exogenous NGF revealed NGF receptors on cells immunoreactive for SP. Studies are under way to determine whether these receptors are of the high affinity subtype. These findings suggest that sensory neuroblasts may be responsive to NGF, depending upon the microenvironment. Supported by grants from the March of Dimes (#1-1090), NSF (BNS-8896101), and the Dysautonomia Foundation.

346.3

PATTERNS OF IMMUNOREACTIVITY IN CNS AND GENETICALLY ENGINEERED CELL LINES VISUALIZED WITH ANTIBODIES AGAINST NATIVE NGF AND SYNTHETIC PEPTIDE SEQUENCES WITHIN NGF AND PRO-NGF. C. Wetmore[1], T. Ebendal*[2], M. Bygdeman*[3], M. Eriksdotter-Nilsson*[1], L. Strömberg[1], H. Persson*[4], L. Olson[1], Depts. of [1]Histology & Neurobiology and [4]Molecular Neurobiology, Karolika Institute, S-104 01 Stockholm; [3]Dept. of Obst-Gyn, Karolinska Hospital, S-104 01 Stockholm; [2]Biomedicum, Uppsala Univ., S-751 23 Uppsala, Sweden.

We have raised antibodies against purified mouse salivary NGF and against synthetic peptide sequences within NGF and pro-NGF. Two peptides (P5, P6) represent sequences in rat and mouse pro-NGF, one peptide (P3), a highly conserved region of mature NGF (identical in man, mouse, rat and chicken) and one peptide (P4) the presumed loop region of mature NGF. Monoclonal peptides against P3 were also generated. Polyclonal antibodies against native NGF were raised in four different species (mouse, rabbit, sheep, chicken). Antibodies were affinity-purified using the appropriate antigens and were tested in adult male mouse submandibular glands. In adult rat brain P3-IR cells were found in several other regions including cortex and hippocampus. P3-IR was distributed in peripheral cytoplasm. Antibodies against pro-NGF peptides P5 and P6 bound to a similar set of cells in cortex, hippocampus and elsewhere. P5-IR had a perinuclear distribution. P6-IR was prominent both in brain and in spinal cord neurons and in oligodendroglial cells. Antibodies against native NGF raised in rabbit and sheep bound mainly to myelinated fibers. After colchicine treatment, one such antibody also revealed many nerve cells in cortex. Additionally, cells in human fetal spinal cord were strongly immunoreactive with P3 antibodies. 3T3 fibroblasts transfected with the rat NGF gene also contained high numbers of P3-IR cells. Interestingly, antibodies raised against native NGF in chicken bound to the membranes of a rich network of varicose nerve terminals in cortex and hippocampus and to cholinergic nerve cell bodies. This observation suggests the possibility of obtaining anti-idiotypic antibodies recognizing the NGF receptor following immunization with NGF. Further studies including preabsorption tests and experimental perturbations will define the possibilities and limitations of using immunohistochemistry to study NGF in CNS.

CORRELATIONS BETWEEN GAP43 EXPRESSION AND THE NGF RECEPTOR IN PRIMARY SENSORY NEURONS. V.M.K. Verge*, W. Tetzlaff, M. Bisby and P.M. Richardson. McGill University and University of Calgary, Canada.

Expression of the gene for GAP43 in normal and injured rat sensory neurons was studied by in situ hybridization with a cDNA probe in correlation with NGF-receptor radioautography or immunocytochemistry on adjacent sections. In normal lumbar DRG, some neurons were heavily labelled by the GAP43 probe while others had labelling near background levels. The highest cytoplasmic concentrations of GAP43 mRNA were found in neurons with high-affinity NGF receptors: much lower concentrations were found in neurons without such receptors. Another NGF-responsive population, sympathetic neurons in the superior cervical ganglion, also displayed high basal levels of GAP43 mRNA. One week following sciatic nerve transection, GAP43 mRNA was increased in all L_4 DRG neurons except for approximately 10%, presumed to lack projections into the sciatic nerve. It is suggested that i) NGF may regulate the synthesis of GAP43 in normal adult sensory neurons. ii) one consequence of the relatively strong expression of the GAP43 gene in NGF-responsive sensory neurons might be superior capacity for collateral sprouting in response to partial denervation. iii) following nerve injury, GAP43 is induced in both NGF-responsive and unresponsive neurons by some unknown signal.

NERVE GROWTH FACTOR RECEPTOR IMMUNOREACTIVITY IN THE SKIN AND ITS RELATIONSHIP TO SENSORY AND SYMPATHETIC FIBERS. A. Ribeiro-da-Silva*, R.L. Kenigsberg*, I. Mazzoni* and A. Claudio Cuello. Dept. of Pharmacology & Therapeutics, McGill University, Montreal, Quebec, Canada H3G 1Y6.

In the rat skin, nerve growth factor receptor (NGFR) immunoreactivity (IR) has been shown to occur in nerves, sensory receptors and patchy areas of the epidermis associated with intraepithelial nerve fibers (Ribeiro-da-Silva, et al., Neurosci. Abstr. 14:903, 1988). In the present study, double labelings for NGFR-IR and substance P (SP)-IR, and NGFR-IR and dopamine beta-hydroxylase (DBH)-IR were carried out using exclusively monoclonal antibodies. Nerves with NGFR-IR often contained fibers with SP-IR. These fibers were observed crossing the NGFR-IR patchy areas of the epidermis, ending closer to the surface of the epithelium. Nerves with both DBH-IR and NGFR-IR occurred mainly in nerve fibers associated with blood vessels. Sensory denervation caused a complete disappearance of SP-IR, and sympathetic denervation a complete depletion of DBH-IR. In the denervated skin, increased NGFR-IR was observed in peripheral nerves containing degenerated axons. This study reveals that most of the NGFR-IR in the skin is associated with sensory fibers.

EXPRESSION OF NERVE GROWTH FACTOR RECEPTOR IN FOLLICULAR DENDRITIC CELLS OF LYMPHOIDAL TISSUES. S J Thompson*, A M Gown*, M A Bothwell, (SPON: D. Nochlin Department of Physiology & Biophysics, University of Washington School of Medicine, Seattle, WA. 98195.

Nerve growth factor receptor (NGFR) has been localized to follicular dendritic cells (FDC), which are antigen- presenting cells within the germinal centers of lymphoidal tissues. Monoclonal antibodies against human NGFR developed in this laboratory were used to characterize, by immunocytochemical method, the induction of NGFR expression by FDC in response to antigen challenge. FDC immunoreactivity in lymph node, tonsil, spleen, and lymphoid nodules within gut and lung has been noted. In spleen, trabeculae and sinusoids are also immunoreactive. Cross-linking experiments with radiolabelled NGF in one available dendritic cell line have been negative. Preliminary evidence suggests that unactivated lymphoidal tissues in humans and primates do not express NGFR.

NGFR expression in FDC is shared in common with several other cell types which are dendritic in morphology and are thought to be growth-regulatory to associated proliferating cells, including sustentacular cells of the adrenal medulla and myoepithelial cells of mammary tissue.

Spatial and temporal expression of NGF Receptor on the mesenchymal cells of embryonic rat lung in vivo and in organotypic lung culture. E. F. Wheeler*, S. L. Patterson*, and M. Bothwell. Dept. of Phys. and Biophys., U. of Washington, Seattle, WA. 98195.

The NGFR has been shown to express on a wide variety of neuronal and nonneuronal tissues as a function of development. In a number of developing epithelial organs, NGFR has been observed to express in a temporal manner on mesenchymal cells associated with developing epithelial tissue. Using immunocytochemical analysis and in situ hybridization on whole rat embryos, we have observed precisely timed expression (day 15- 17) of NGFR on the mesenchyme associated with developing bronchio-epithelium of the lung. Organotypic lung culture of day 16 embryonic lung prolongs the period of receptor expression. When whole 14 day rat lungs are subjected to organotypic culture, the expression of NGFR is delayed. However, once expressed on the mesenchyme in 14 day organotypic lung cultures, NGFR is maintained on the cell surface long after it would have disappeared in vivo. Preparation of monolayer lung cell cultures derived from different embryonic lung stages contain a population of mesenchyme cells that maintain receptor expression. The role epithelial cells play in the timed expression of NGFR on these mesenchymal cells will be discussed.

ELECTRON MICROSCOPY SHOWS NGF RECEPTOR LABELING OF GLIAL-LIKE CELLS IN OLFACTORY BULB. H. Vickland*,[1] J. N. Kott,[2] L.E. Westrum,[1,2,3] S.L. Patterson*,[4] and M. Bothwell[4] (SPON: K. Chan). Depts. Biol. Struct.,[1] Neuro. Surg.,[2] Restor. Dent.,[3] and Physiol. and Biophys.,[4] Univ. of Wash., Seattle, WA 98195.

We have used MAB 192 IgG to localize nerve growth factor receptor (NGFR) in the rat olfactory bulb (OB) in early postnatal (PN) stages and in the adult, and have observed age-related differences in NGFR expression with light (LM) and electron microscopy (EM). In PN ages 2 to 12, intense NGFR immunoreactivity (IR) was observed surrounding the olfactory fila, though the axons themselves appear negative. In adults no comparable NGFR staining was seen in this location, but the OB glomeruli show intense staining and the label appears strongest in a sheath surrounding the glomerulus. By EM, NGFR-IR appeared strongest on the exposed membrane surfaces of glial-like cells that resemble astrocytes. These have long processes surrounding axon fascicles of the fila, and some of the processes appear to contact blood vessels. A similar pattern of glial cells and processes exhibiting NGFR-IR surround the OB glomeruli. This supports the speculation that astrocyte-like cells are possibly involved in the distribution of NGF to other cells of the olfactory system. We are in the process of investigating the pattern of distribution of NGF. (Supported by Grant No. NS09678 to LEW and NS23343 to MB. LEW is an affiliate of CDMRC.)

NGF IN CHOROID PLEXUS AND CSF. S.L. Patterson* and M. Bothwell (SPON: C.A. Livingston). Dept. of Physiology and Biophysics, Univ. of Washington, Seattle, WA 98195.

In addition to its well characterized role in the development and maintenance of sympathetic and sensory neurons, nerve growth factor (NGF) may also be important in some central neural systems. NGF responsiveness is well documented in the magnocellular cholinergic neurons of the basal forebrain. These neurons project to the hippocampus and the neocortex, which provide NGF trophic support. These two brain regions are generally believed to be the primary source of NGF to these neurons. However, the efficacy of intraventricular infusions of NGF in alleviating age or injury related deficits in cholinergic function suggests the possibility that there might be an endogenous source of NGF associated with the ventricles. We report here the presence of NGF associated with the choroid plexus, and with the CSF, of rat brain. The NGF was localized immunocytochemically, assayed for the ability to promote neurite outgrowth from PC12 cells, and quantitated using antibodies against murine *B* NGF in a two-site enzyme-linked immunoabsorbant assay (ELIZA). The results suggest that the epithelial cells of the choroid plexus are producing biologically active NGF and releasing it into the the CSF in physiologically significant quantities.

1,1,3, TRICYANO-2-AMINO-1-PROPENE POTENTIATES NERVE GROWTH FACTOR-INDUCED PROTEIN PHOSPHORYLATION IN THE PC-12 CELL LINE. J. West Paul and John P. DaVanzo. Dept. of Pharmacology, School of Medicine, East Carolina University Greenville, NC 27834.

Our laboratory has recently shown that 1,1,3, tricyano-2-amino-1-propene (Triap) potentiates the actions of NGF on the PC-12 cell line. Nanomolar concentrations of Triap potentiate the induction of neurite outgrowth by NGF as well as the induction of tyrosine hydroxylase and choline acetyltransferase. To further investigate the mechanism for this potentiation we examined Triap's effect on protein phosphorylation in NGF treated and untreated PC-12 cells. NGF alone caused a detectable increase in the phosphorylation of proteins with molecular weights of 101, 62, 38, and 21 kilodaltons (Kd) and a decrease in phosphorylation of a protein at 65 Kd. Triap alone increased the phosphorylation of only one protein at 38 Kd. Cells treated with both NGF and Triap increased the phosphorylation of proteins at 101, 62, and 21 Kd with no change in the phosphorylation of the 38 Kd protein. The combination also decreased the phosphorylation of the 65 Kd protein as compared to NGF alone. Triap and NGF together also induced the phosphorylation of proteins at 55 and 17 Kd. Experiments with immunopurified tyrosine hydroxylase showed that Triap alone had no effect on tyrosine hydroxylase phosphorylation but Triap potentiated NGF's induction of protein phosphorylation. These results suggest that Triap's interaction with NGF is more complex than a simple potentiation of phosphorylation. (Our thanks to Hoechst-Roussel Pharmaceuticals Inc. for financial support.)

DETECTION AND PARTIAL CHARACTERIZATION OF AN NGF-ACTIVATED MICROTUBULE ASSOCIATED PROTEIN 1.2 (MAP 1.2) KINASE ACTIVITY IN PC12 CELLS. H. Tsao*, J.M. Aletta, L.A. Greene (SPON: D. Burmeister). Dept. of Pathology, College of Physician and Surgeons, Columbia Univ. New York,NY 10032

The addition of NGF to intact PC12 cells leads to a rapid increase in the phosphorylation of high molecular weight (HMW) MAP 1.2, also designated MAP 1B and MAP 5. The phosphorylation of this protein in intact cells has been well described (Aletta et al, JCB 106: 1573-1581) and may play a role in neurite outgrowth. In order to further elucidate the mechanism underlying the in vivo observations, an in vitro system was developed. Here we describe the cell free detection of an NGF-stimulated kinase activity capable of phosphorylating both endogenous PC12 cell and exogenous brain MAP 1.2. Nontreated cultures of PC12 cells or replicate cultures exposed to NGF for 1 hr are homogenized at 4 deg in MES/EGTA/$MgCl_2$ pH 6.8 and spun at 100,000g. The supernatants are then incubated either with or without exogenous MAPs for 15 min at 37 deg. Both ATP and GTP can serve as phosphate donors and results indicate that the NGF-stimulated MAP 1.2 kinase activity can be inhibited by either μM levels of heparin or mM concentrations of 2-aminopurine. When bovine brain MAPs are isolated for the assay, MAP 1A, MAP 1.2 and MAP 2 are all present in the preparation. Each of these MAPs appears to be phosphorylated by an NGF-sensitive mechanism in our assay system. However, MAP 1 and MAP 2 appear to have differential sensitivities to heparin and 2-aminopurine. These differences therefore suggest that more than one NGF-regulated kinase may be involved in the phosphorylation of different HMW MAPs.

346.12

NERVE GROWTH FACTOR (NGF) REGULATION OF ARACHIDONIC ACID METABOLISM IN PC12 CELLS. J.G. Webb* (SPON: H. Martin). Dept. of Pharmacology, Medical University of South Carolina, Charleston, SC 29425

The effect of NGF on basal and hormone-stimulated prostaglandin (PG) formation was examined in cultured PC12 cells. PGE_2 and PGI_2 (measured as 6-keto $PGF_{1\alpha}$) released into the incubation buffer were quantitated by RIA. In control PC12 cells, basal production of PGE_2 (630 ± 83 pg/min/mg prot.) was 5-fold greater than PGI_2 (134 ± 26 pg/min/mg prot.) synthesis. Synthesis of both PGs was eliminated by the cyclooxygenase inhibitor indomethacin. Neither norepinephrine (NE) nor bradykinin (BK) stimulated PG synthesis in undifferentiated control cells. Addition of NGF (50 ng/ml) to the culture media for up to 7 days produced time-dependent changes in arachidonic acid metabolism. Basal rates of production of PGE_2 and PGI_2 were increased to 2122±400 and 355±56 pg/min/mg prot., respectively. PG formation from exogenous arachidonic acid (10μM) was also enhanced 4-fold in NGF treated cells. Further, after 7 days of treatment with NGF addition of BK or NE now stimulated PG synthesis. BK (1μM) produced a 2-fold increase in PGE_2 and PGI_2 production and NE (1μM) produced a 50-60% increase in PG synthesis. The results indicate that NGF induced differentiation in PC12 cells promotes the expression of cyclooxygenase activity and imparts responsiveness to hormones which regulate arachidonic acid metabolism.

SUPRESSION OF NGF ACTIONS BY THE 5-LIPOXYGENASE INHIBITOR CGS 8515. D.J. Steel, J.W.F. Wasley*, and L.A. Greene. Dept. of Pathology, Columbia Univ. Coll. of P & S, New York, NY 10032 and *CIBA-Geigy Corp., Pharmaceutical Div., Summit, NJ 07901.

Recent work suggests that arachidonic acid metabolites may mediate NGF-induced responses in PC12 cells (DeGeorge et al, J. Neurosci Res. 21:323, 1988). Our investigations with selective cyclooxygenase inhibitors indicate no role for this pathway in the NGF-induced differentiation of PC12 cells, using induction and regeneration of neurite outgrowth, and induction of ornithine decarboxylase (ODC) as criteria. However, we find that a selective inhibitor of the 5-Lipoxygenase (5-LO) pathway, CGS 8515 (Ku et al, Biochim. Biophys. Acta 959:332,1988) reversibly antagonizes several NGF-mediated responses in PC12 cells. CGS 8515 blocked both NGF-induced neurite initiation (transcription-dependent) and regeneration (transcription-independent) with an IC_{50} of 900 nM after 2 days of treatment. Similiar doses of CGS 8515 also inhibited the NGF induction of ODC, with a maximal effect between 2 and 6 hours of pretreatment. Examination of protein phosphorylation indicates that an 18 kD protein that is less phosphorylated in response to NGF is more heavily phosphorylated in the presence of CGS 8515, (+/-NGF). A structural analog of this compound that does not inhibit 5-LO had no effect on any NGF-mediated responses examined; other analogs with 5-LO inhibitory activity also blocked NGF effects. However, parallel experiments with other reportedly selective 5-LO inhibitors that are structurally distinct from CGS 8515 did not block responses to NGF. Thus, the role of eicosanoids in the NGF mechanism and the mechanism by which CGS 8515 blocks NGF actions remain to be defined. To this end, PC12 cell eicosanoid composition is being determined with and without exposure to this compound.

INHIBITION OF NERVE GROWTH FACTOR-INDUCED NEURITE OUTGROWTH OF PC12 CELLS BY A PROTEIN KINASE INHIBITOR WHICH DOES NOT PERMEATE THE CELL MEMBRANE. Y. Matsuda, S. Nakanishi*, H. Kase*, and G. Guroff. Kyowa Hakko Kogyo Co., 3-6-6 Asahimachi, Machida-shi, Tokyo 194, Japan and Section on Growth Factors, National Institute of Child Health and Human Development, Bethesda, MD20892.

Previous studies have shown that K-252a, an alkaloid-like kinase inhibitor isolated from the culture broth of Nocardiopsis sp., selectively inhibits the actions of nerve growth factor on PC12 cells (Koizumi, S., J. Neurosci., 8 : 715, 1988). The present experiments were designed to inspect the action of K-252b, the 9-carboxylic acid derivative of K-252a, on nerve growth factor-iduced neurite outgrowth. K-252b is water-soluble and does not permeate the cell membrane of PC12 cells, whereas K-252a clearly does. On the other hand, K-252b is as potent as K-252a itself in inhibiting nerve growth factor-induced neurite outgrowth. In the same concentration range as K-252a, K-252b also can severely block protein kinase activity in vitro assay system. (Kase. H., Biochem. Biophys. Res. Commun., 142 : 436, 1987). These data can be interpreted to suggest that the site of action of K-252 compounds to block the neurite elongation is located on the cell surface of PC12 cells. Furthermore, K-252b provides a new tool for the dissection and study of ecto-protein kinase-requring process.

REGULATION OF NERVE GROWTH FACTOR (NGF) AND NGF-RECEPTORS BY CHOLINERGIC DRUGS. J. Alberch*, M. Carman-Krzan* and B.C. Wise. Fidia-Georgetown Institute for the Neurosciences, Georgetown Univ., Washington, D.C. 20007

It is well documented that NGF and its receptor are present in brain and that NGF may be a neurotrophic factor for brain cholinergic neurons. In the present studies, we investigated whether the levels of the NGF protein and NGF receptor are pharmacologically regulated by drugs that affect cholinergic neurotransmission. Membranes prepared from the cortex of 28 day old rats have both high and low affinity binding for ^{125}I-NGF. Scatchard analysis indicated a high affinity site with a K_D of 26 ± 4 pM and B_{max} of 0.65 ± 0.03 fmol/mg protein. A lower affinity site with an estimated K_D of 37 ± 10 nM and B_{max} of 125 ± 33 fmol/mg protein was also detected. Treatment of young rats with scopolamine (5 mg/kg, twice daily for 7 days) resulted in the loss of detectable high affinity binding sites and a decrease in the number of low affinity sites in cortical membranes. The K_D of the low affinity site did not change. The hippocampus (2.2 pg NGF/mg tissue) and cortex (1.2 pg/mg) have the highest levels of NGF in the rat brain as measured with the two-site NGF enzyme immunoassay. After 7 days of scopolamine treatment, there was little change in the levels of NGF in the cortex and hippocampus. In contrast, treatment with physostigmine (1 mg/kg/day for 7 days) resulted in about a 45% decrease in NGF levels in both the cortex and hippocampus. These results suggest that the dynamic state of the NGF system in brain can be modulated by treatment with cholinergic drugs.

346.16

HUMAN B-LYMPHOCYTES EXPRESS FUNCTIONAL NERVE GROWTH FACTOR RECEPTORS.
P. Ehrhard*[1], R. Peck*[2] and U. Otten[1] (SPON: W. Fischli).
[1] Dept. of Pharmacology, Biocenter, University of Basel, CH-4056 Basel, and [2] Central Research Unit, Hoffmann-La Roche & Co., Ltd., Basel, CH-4002 Basel, Switzerland

In addition to its characteristic effects on peripheral sympathetic and sensory neurons and subsets of centrally located neurons, there is increasing evidence that nerve growth factor (NGF) may play an essential role in the modulation of the immune system and the inflammatory response. By using a monoclonal antibody directed against the human NGF receptor a sensitive immunoprecipitation assay for the quantification of human NGF receptors has been established. Our results show that in addition to neural cells, non-neuronal tissues also express significant amounts of NGF receptors: e.g. human spleen and lymph nodes contain 8, respectively 6, fmole receptor/mg protein. Moreover, we found that human B- and (to a smaller extent) T-cells isolated from the blood of healthy donors express specific NGF receptors. These receptors are functional as demonstrated by the findings that NGF induces a dose-dependent proliferation of both B- and T-lymphocytes and immunoglobulin production by the B-cells. Thus, in addition to its specific neurotrophic effects, NGF plays a role in immunoregulation.

346.17

SPECIFIC LECTIN-BINDING RADIOIMMUNO- AND BIOASSAY METHODS FOR DETECTION OF 53 kDa NGF. J. Lakshmanan*, R. Lam*, A. Reviczky*, M. Grodin*, A. Abo-Bakr*, S. Soinila, D. North* and D.A. Fisher* (SPON: M. Weichsel, Jr). Department of Pediatrics, UCLA School of Medicine, Harbor-UCLA Medical Center, Torrance, CA. 90509.

In 1988 using an immunoblot analysis, we reported the presence of a 53 kDa NGF, in addition to 13 kDa NGF, in submaxillary glands of adult male and female mice (BBRC 152:1008-1013). In subsequent investigations we characterized the 53 kDa NGF as a glycoprotein (Clin Res 37:181A, 1989), secretory in nature (FASEB J 3:1572A, 1989) and biologically active (Neurosci Lett, in press, 1989). More recently, we documented that 53 kDa NGF, but not 13 kDa NGF, is present in the salivary glands of immature and young adult male and female mice; 13 kDa NGF appears only late in development (Pediatr Res 25:313A, 1989). We now describe specific lectin- binding radioimmunoassay and bioassay methods for quantifying 53 kDa NGF. These methods in conjunction with immunoblotting should prove useful in determining the tissue distribution and purification of 53 kDa NGF.

346.18

EFFECTS OF TWO PROTEIN KINASE INHIBITORS (STAUROSPORINE AND K252a) ON NGF-MEDIATED PC12 CELL SURVIVAL. D.L. Needels, L.A. DiNatale*, and T.L. Martin. CNS Biology, Bristol-Myers, Wallingford, CT 06492.

In addition to its well known effects on cell morphology, nerve growth factor (NGF) also supports the survival of PC12 cells under serum-free conditions. We have established a colorimetric bioassay for PC12 cell survival based on the metabolism of MTT by viable cells, and used it to quantify the effects of two related protein kinase inhibitors (staurosporine and K252a). These molecules have opposing, but not antagonistic, effects on PC12 cell morphology [*Martin et al., this meeting*].

Although it is thought that at least some of the morphological responses of PC12 cells to NGF are mediated by protein kinases, much less is known about the role of kinases in the NGF survival response. Neither staurosporine (which promotes neurite formation) nor K252a (which inhibits NGF-induced neurite formation) was active at supporting PC12 cell survival at concentrations of up to 200 nM, suggesting separate pathways for neurite-promotion and survival. K252a half-maximally inhibits NGF-induced neurite formation at a concentration of ~100 nM, apparently by blocking a kinase located within an NGF-specific pathway. K252a also inhibited NGF-induced survival, but with the half-maximal response occuring at ~1 nM. The observed cell death was not due to cytotoxicity, since cells supported under other growth conditions died only at much higher concentrations of K252a (≥400 nM). In contrast, staurosporine was incapable of inhibiting NGF-mediated survival of PC12 cells at less than cytotoxic concentrations.

These data suggest a multiplicity of protein kinases involved in the responses of PC12 cells to growth factors, with some specificity in terms of both the stimulating growth factor and the biological endpoint. Interestingly, K252a completely blocked NGF's survival effects at concentrations that have little effect on the morphological response, suggesting distinct pathways. Moreover, K252a is active at concentrations well below its reported K_i for inhibition of protein kinase C (25 nM). Identification of the enzymatic systems affected by these molecules should provide insight into the mechanism of NGF's effects on PC12 cell survival and morphological differentiation.

346.19

THE PARADOXICAL EFFECTS OF TWO PROTEIN KINASE INHIBITORS (STAUROSPORINE AND K252a) ON PC12 CELL MORPHOLOGY. T.L. Martin, J.K. Dickey*, M.P. Rosser*, and D.L. Needels. (Spon: L.A.Riblet). Depts. of CNS Biology, and Screening & Biochemistry, Bristol-Myers Co., Wallingford, CT 06492.

The capacity of PC12 cells to transform from a chromaffin-like cell to one resembling a fully differentiated sympathetic neuron on exposure to nerve growth factor (NGF) or basic fibroblast growth factor (bFGF) is well documented. It has been postulated, based on studies with modulators of kinase activity, that protein kinases play a role in this process of cellular differentiation. For example, the protein kinase inhibitor K252a inhibits the neurite outgrowth response of PC12 cells to NGF [*Koizumi et al. (1988) J. Neuroscience 8, 715-721*]. We report here that a closely related protein kinase inhibitor (staurosporine) has the opposite effect, inducing the morphological differentiation of PC12 cells in the absence of NGF.

PC12 cells were cultured in the presence or absence of growth factors and/or protein kinase inhibitors and visually inspected 48 hr later for the presence of neurites. As previously reported, 50-200 nM K252a blocked the ability of NGF to induce neurite formation, but was inactive in bFGF-treated cultures. Staurosporine, in contrast, was unable to block the NGF response. In fact, staurosporine alone had a robust neurite-promoting effect on PC12 cells at concentrations ranging from 20-200 nM. In an attempt to block this morphological response, staurosporine-exposed PC12 cells were challenged with K252a. In contrast to what would be expected for agents acting through a common effector pathway, K252a did not inhibit staurosporine-induced neurite formation.

These data indicate that more than one kinase plays an important role in the process of neurite elaboration and suggests that there are multiple pathways leading to the common endpoint of neurite outgrowth. Although staurosporine is an inhibitor of protein kinase C, the concentrations of staurosporine required to induce neurites are considerably higher than the K_i for enzyme inhibition (0.7 nM). Identification of the putative protein kinases (or other enzymes) inhibited by these molecules should advance our knowlege of growth factor-mediated neurite outgrowth in PC12 cells.

346.20

MECHANISMS OF NERVE GROWTH FACTOR ACTION IN H_2O_2 RESISTANCE G.R. Jackson*, K. Werrbach-Perez*, and J.R. Perez-Polo. Dept. Human Biol. Chem. and Genet., Univ. of Texas Medical Branch, Galveston, TX 77550.

Nerve growth factor (NGF) regulates neuronal cell death in developing sympathetic and embryonic sensory ganglia, as well as injured magnocellular cholinergic neurons of the basal forebrain. PC12 cells treated with NGF doses ranging from 1 ug to 1 ng/ml display resistance to peroxidative injury generated by H_2O_2. Acquisition of resistance occurs within 24 hr of NGF treatment and requires de novo protein synthesis. Treatment with retinoic acid, which upregulates the low affinity NGF receptor, or the protein kinase inhibitor K252a mimics the resistance conferred by NGF. Pretreatment with a sublethal dose of H_2O_2 (0.5 mM) provides resistance to further insult; NGF treatment of survivors enhances this resistance. NGF increases the specific activity of catalase by 30% in control PC12 cells and by 500% in the survivors of 0.5 mM H_2O_2. Thus, injury and NGF enhance the capability of NGF responsive populations to withstand peroxidative stress. Supported in part by NINDS grant NS-18708.

REGENERATION: CNS II

347.1

AGE-RELATED RECOVERY AFTER NERVE REPAIR IS PROBABLY NOT DUE TO REGENERATION OF NORMAL PERIPHERAL ORGANIZATION. J.T. Wall, P.E. Garraghty, S.L. Florence, and J.H. Kaas. Vanderbilt University, Nashville, TN 37240.

The best examples of sensory recovery after nerve repair are seen in children. Is this recovery due to mechanisms involving peripheral regeneration and/or mechanisms relating to adaptation in the brain? To test if recovery is due to a peripheral capacity of immature nerves to regenerate normal connections with the skin, this study assessed patterns of somatotopic organization of primary afferent terminations in the cuneate nucleus and spinal cord following early repair of a hand nerve. Cutaneous injections of HRP conjugates were made into reinnervated thumb (D1) and normally innervated little finger (D5) locations in a 3.3 year old macaque monkey which had undergone anesthesia and wrist-level median nerve section and repair at 10 days of age. The resulting patterns of transported label were compared to patterns in normal monkeys. The termination patterns of regenerated D1 inputs are highly abnormal in both the cuneate nucleus and dorsal horn. Tightly focussed, rostro-caudally oriented columns of label typical of normal D1 terminals are replaced by more broadly distributed patterns of label. This suggests that immature nerves do not have a general capacity to regenerate normal connections, and that central mechanisms of adapting to changed peripheral organization contribute to sensory recovery after early nerve repair. FURTHER EVIDENCE THAT DEVELOPMENTAL PLASTICITY OF THE RUBROSPINAL TRACT RESULTS PRIMARILY FROM THE GROWTH OF NEW AXONS. X.M. Xu, R.R. Pindzola and G.F. Martin. Department of Anatomy and Neuroscience Program, The Ohio State University College of Medicine, Columbus, OH 43210.

Rubral axons can grow around a lesion of their spinal pathway in developing opossums and a critical period exists for that plasticity (Martin and Xu, Dev. Brain Res., 39:303-308). In the present experiments we sought to determine if the axons which grow around the lesion are those originally cut or later growing ones. Pouch young opossums were injected with Fast Blue (FB) into the caudal thoracic cord during the critical period to label rubrospinal neurons. 3-4 days later, the rubrospinal tract was transected 4-5 segments rostral to the injection. The animals were maintained for about 1 month before a second marker, Diamidino Yellow (DY) was injected into the cord between the FB injection and the lesion. Four days later, the animals were sacrificed and the tissues prepared for microscopic examination. Only a few neurons were labeled by FB in the red nucleus contralateral to the lesion, indicating that most axotomized rubrospinal neurons degenerated. In contrast, neurons were labeled by DY alone, indicating that axons which were not present at the time of the FB injection had grown around the lesion to incorporate DY. A few double labeled neurons were also found, however, suggesting that axons of some FB labeled neurons that survived the lesion grew around it to incorporate DY. We conclude that developmental plasticity of the rubrospinal tract results primarily from the growth of new axons around the lesion but that true regeneration may also occur. (Supported by NS-25095).

THE EFFECTS OF THE FETAL SUBSTANTİA NİGRA GRAFTS ON THE SYMPATHETIC GANGLİA. S.Uysal*, E.Korfalı*, T.Özmen*, İ.H.Ulus, W.D. Knowles. Dept. of Neurosurgery and Pharmacology, Uludağ Univ. Bursa, Turkey and CCF, Cleveland Ohio, USA

In the present study, after the destruction of the nigrostriatal dopaminergic pathways by intraventricular injection of 6-OHDA, fetal substantia nigra graft tissues which were obtained from 15-17 days old fetusus were transplantated into cavities overlying caudate nucleus were investigated for demonstration of the effect of graft tissues on the sympathetic ganglions.

Three months after grafting tyrosine hydroxylase activity of the adrenal, celiac and lomber sympathetic ganglions of grafted rat groups showed an increase of 121% and this increase has been found significant. These results indicate that fetal nigrostriatal dopaminergic grafts has also positive effects upon the distant CNS tissues.

SCHWANN CELLS AND SCHWANN CELL CONDITIONED MEDIUM SUPPORT SURVIVAL AND NEURITE OUTGROWTH OF LONG-PROJECTION NEURONS OF THE NUCLEUS LOCUS COERULEUS. B.Baharloo* and M.B.Clark. Dept. of Anatomy, Univ. Md. Sch. of Med., Baltimore, MD 21201

Using dissociated cell cultures we have compared the survival and neurite outgrowth of locus coeruleus neurons from postnatal rats in environments of 1) Schwann cells (SCs), 2) Schwann cell conditioned medium (SCM), 3) SCM prebound to the culture dish and on 4) laminin, 5) collagen and 6) polylysine. After 3d in culture neurons were identified by double immunostaining for neurofilament protein and tyrosine hydroxylase. Neurite length and branch points were determined from micrographs of individual neurons. Since initial experiments indicated that neuronal survival and neurite outgrowth were similar on SCs whether or not they assembled a basal lamina, conditioned medium was always prepared from SC cultures which had not assembled basal lamina. Neuronal survival was 3-5x greater in the presence of SCs than on laminin, collagen or polylysine. SCM, either prebound to the culture dish or included in the culture medium as a soluble component, supported the survival of 70-75% as many neurons as Schwann cell beds. Neurite promotion (neurite bearing neurons/total neurons) was greater in the presence of SCs (62%) or prebound SCM (50%) than in soluble SCM (30%) or defined medium (6-20%). Mean neurite length on prebound SCM was approximately 2x that on SCM-soluble or laminin, and 5x that on polylysine; the number of branch points associated with neurons on prebound SCM or on laminin were similar, with an average of 6/neuron as compared to 3/neuron from soluble SCM and 0-1 for neurons on polylysine in defined medium. Finally, 50-75% of neurons in cultures with SCM were TH positive, indicating the survival of specific noradrenergic neurons. Taken together these results suggest that SCs support survival and outgrowth of long projection locus coeruleus neurons and that the products released by SCs may be responsible for these effects. (Supported by NIH NS24252 to MBC.)

INVOLVEMENT OF SEPTOHIPPOCAMPAL PATHWAY IN COLCHICINE-INDUCED COMPENSATORY RESPONSES IN HIPPOCAMPUS. P. Tandon, M. Bonner, S. Barone Jr., and H.A. Tilson. LMIN, NIEHS/NIH, Res. Tri. Pk, NC 27709.

Our lab has shown that intradentate administration of colchicine produces a hyperstimulation of agonist-induced PI turnover. This response has been related to the process of compensation in the hippocampus occurring in response to neurodegeneration and can be observed one year after the lesion. As the main cholinergic input to the granule cells and pyramidal cells of the CA3 region in the hippocampus is via the septohippocampal pathway, it has been suggested that regeneration of this pathway occurs after the lesion. To further study this hypothesis we stereotaxically injected 2.5 ug of colchicine in the hippocampus and/or septum in various groups of male Fischer-344 rats. Twelve wks after the injection, the animals were sacrificed and hippocampus dissected out. Agonist-induced turnover of PI showed that septal lesions alone did not have any effect on PI turnover in the hippocampus while hyperstimulation of IP release was observed after hippocampal lesion as reported earlier. However, when both the hippocampus and the septum were lesioned, the hyperstimulation of agonist-induced release of IP was reduced. These data demonstrate the importance of the septohippocampal pathway for the persistent hyperstimulation of IP release after intradentate colchicine.

BINDING PROPERTIES OF A NEWT RETINAL PIGMENT EPITHELIUM ANTIBODY DURING RETINAL DEVELOPMENT AND REGENERATION. *Lisa R. Klein*, P.R. MacLeish and Torsten N. Wiesel* Laboratory of Neurobiology, The Rockefeller University, New York, NY, 10021.

The binding of RPE-1, a mouse monoclonal antibody selective for newt retinal pigment epithelium, was followed in eyes undergoing embryonic development and retinal regeneration. Using the indirect immunofluorescence technique on frozen sections, bright and continuous staining was observed exclusively in the retinal pigment epithelium of normal adult newts but staining became diminished near the ora serrata region and stopped abruptly at the ciliary margin. During development, staining was not detected in the retinal pigment epithelium until the formation of photoreceptor outer segments and was not observed in any other ocular tissue. There was no correlation between the formation of pigment in retinal pigment epithelial cells and their labelling with the RPE-1 antibody. Furthermore, albino salamander embryos showed the same pattern of labelling with RPE-1 as that seen in age-matched pigmented animals. During retinal regeneration, retinal pigment epithelial cells were stained less intensely by the antibody. The newly formed retinal cells were brightly stained and retained varying degrees of pigmentation during the early phase of regeneration. With time, staining in regenerated retina receded so that by the end of regeneration, staining by RPE-1 was once more restricted to the RPE cells. The identification of RPE-1 as a marker for post-mitotic retinal neurons about to undergo differentiation provides a promising approach for further studies of regeneration using molecular tools. (Supported by NIH grants NS22789, and EY05201)

TECTAL REGULATION OF NEURITIC OUTGROWTH AND EXPRESSION OF NEUROFILAMENT PROTEINS IN GOLDFISH RETINAL EXPLANTS. C.M. Hall*, C.K. Else*, and N. Schechter. Departments of Biochemistry and Psychiatry, SUNY at Stony Brook, NY 11794

Goldfish retinal explants were used to study the regulatory influence of the optic tectum on neurofilament expression during optic nerve regeneration. Neuritic outgrowth was quantitated and the expression of the neurofilament proteins (ON_1 and ON_2) was characterized by immunohistochemistry and by labeling with ^{35}S-methionine, followed by 2D-gel electrophoresis, autoradiography and densitometry. Retinas were explanted at various times after optic nerve crush and were characterized during a two week time period. We demonstrate that the relative expression of ON_1 and ON_2 varied with time after crush and with the time that the explants were kept in culture. Removal of the contralateral optic tectum prior to optic nerve crush enhanced neuritic outgrowth when compared to control explants after sham operation. In these experiments, the expression of ON_1 and ON_2 in the explants was significantly diminished at a time when tectal innervation normally takes place. One interpretation of these results is that tectal contact sustains the expression of the neurofilament proteins. (NIH grant EY-05212 to N.S.)

347.8

GROWTH OF INJURED RABBIT OPTIC AXONS WITHIN THEIR OWN DEGENERATING ENVIRONMENT: POSSIBLE SEQUENCE OF EVENTS.

V. Lavie, A. Solomon*, M. Murray, S. Ben-Bassat*, M. Belkin* and M. Schwartz. Dept. of Neurobiol., Weizmann Inst. of Sci., Rehovot, Israel, Goldschleger Eye Res. Inst., Tel Hashomer, Israel, and Dept. of Anatomy, Med. Coll. of Pennsylvania, Philadelphia, PA, USA.

Spontaneous growth of axons after injury is limited in the mammalian central nervous system (CNS). We have previously shown apparent regenerative growth of injured adult rabbit optic axons into their own degenerating environment. The newly growing axons, including growth cones, unmyelinated and thinly myelinated axons, were compartmentalized. The present study examines the possible sequence of events leading to this compartmentalized growth using electron microscopy and immunocytochemical analysis. Unmyelinated axons, as a single profile or as bundles, appear preferentially at the margins of the compartment in collagenous tissue under the dura and are channeled by glial processes. The processes protrude from unidentified cells and from astrocytes stained with antibodies to glial fibrillary acidic protein. Myelinated axons are preferentially located at the center of the compartment. Their myelin lamellar periodicity measured by diffractometry is characteristic of CNS myelin. We suggest that the initial protrusion of the axonal tip is into extracellular matrix channeled by glial processes, which then group together into bundles to form a compartment. This growth is reminiscent of developmental growth through intercellular channels. At a site, 2mm distal to the lesion, 8 weeks postoperatively, 14068 axons were counted, (20387, corrected for the grid bar), representing 7% of that in an intact nerve. This offers the possibility for further growth leading to reconnection with the target.

347.9

CHARACTERIZATION OF THE ENVIRONMENT OF REGENERATING AXONS IN THE GOLDFISH OPTIC NERVE: DIFFERENTIAL EXPRESSION OF HNK-1, EMBRYONIC N-CAM (EN-CAM) AND CHONDROITIN SULPHATE PROTEOGLYCAN (CSPG). Yael Shinar*, W. Battisti, M. Schwartz, P. Levitt, and M. Murray. Dept. Anatomy, Med. College of PA, Philadelphia, PA.

The goldfish optic nerve can be used to characterize molecular interactions leading to succesful regeneration within a CNS environment. Here we demonstrate expression of membrane and extracellular epitopes in the goldfish optic nerve that may play a role axonal outgrowth. Using ELISA on nerve homogenates and immunocytochemistry on longitudinal sections reactivity of laminin, CSPG, N-CAM and HNK-1 was observed in both intact and regenerating nerve 22 days post crush. In intact nerves, CSPG and laminin staining showed a linear pattern of staining reminiscent of the fascicular boundaries and suggesting a non-neuronal location. In contrast eN-CAM and HNK-1 appeared to stain the entire fascicle, and thus stain areas containing both axons and non-neuronal cells. In injured nerves, 22 days post crush the normal pattern was conserved proximally to the crushed area. The crush site was intensely and rather uniformly stained by all antibodies. Distally, CSPG and laminin expression is increased and appear to be associated with non-neuronal cells while HNK-1 and en-CAM are also elevated and may be associated with regenerating axons as well. The increased expression of these molecules in the regenerating nerve suggests that they contribute to successful axonal growth. The expression of these epitopes in the intact nerve may contribute to the regenerative potential of the goldfish optic nerve.

STUDIES OF MISROUTED REGENERATING IPSILATERAL RETINOTECTAL AXONS IN RANA PIPIENS. D.J. Stelzner and J.A. Strauss, Dept. of Anatomy and Cell Biology, SUNY Health Science Center, Syracuse, New York 13210.

After optic nerve crush injury in Rana pipiens, misrouted regenerating optic axons project to the ipsilateral (ipsi) optic tectum and overlap with the normal intact projection from the other eye. Many collaterals are formed in the optic nerve early in regeneration which retract by 5 mo. p.o. To test whether misrouted optic axons form synaptic connections in the ipsi tectum, these axons were labeled anterogradely with WGA-HRP at 8 wks (N=5), 3 mo (N=5) and 6 mo p.o. (N=3) and processed for LM and EM (Joosten et.al., '87). To test whether misrouted ipsi optic axons are collaterals of normally projecting axons, the retrogradely transported fluorescent labels fast blue (FB) and rhodamine (Rh) were applied to the centrolateral dorsal tectum of each tectal hemisphere at 3 mo (N=4) and 6 mo (N=8) p.o. Labeled synaptic profiles were observed in ipsi tectum at all survival times tested after nerve crush injury but were in greatest number at 6 mo. p.o. A large percentage of retinal ganglion cells were double labeled with FB and Rh 3 mo p.o. but few remain double labeled 6 mo. p.o. Thus, misrouted ipsi axons form and maintain contract in the already innervated tectum but collaterals of axons also projecting to normal targets are lost as reinnervation is completed (Grant NS14096).

FROG TECTAL AXONS FAILING TO REGENERATE WITHIN THE CNS DO SO WITHIN PERIPHERAL NERVE IMPLANTS. Y.-H. Hung and D.J. Stelzner(SPON: J.A. Horel). Dept. of Anatomy and Cell Biology, SUNY Health Science Center, Syracuse, New York 13210.

Tectal efferent axons, located adjacent to the optic tract, fail to regenerate past diencephalic lesions in Rana pipiens even though optic axons regenerate after the same injury (J. Comp. Neurol. 255: 511-525). We tested whether tectal efferents can regenerate within peripheral nerve implants. Segments of frog sciatic nerve were implanted into the anterolateral (N=13) or centrolateral (N=13) dorsal surface of the optic tectum using an angled micropipette. After 12 p.o. wks, the distal end of the nerve was cut and HRP applied. All animals survived for 3-7 d.p.o., were perfused with mixed aldehydes, brains frozen sectioned in the transverse or sagittal plane, and reacted with DAB or TMB histochemistry. Labeled cells were not seen in control cases (N=6) where the nerve was crushed before HRP applied, but were found in all experimental operates. The vast majority of labeled cells were in close proximity to the graft insertion site. Most were located in laminae 5 or 8, the origin of the tectal efferent projections, but a smaller number were labeled in lamina 2. In several cases labeled neurons could also be identified in the posterior thalamus and rostral midbrain tegmentum. Like the mammalian CNS, tectal neurons unable to regenerate within the CNS, can grow within peripheral nerve implants. (Supported by grant NS 14096).

SURVIVAL OF DISPLACED RETINAL GANGLION CELLS AFTER OPTIC NERVE REGENERATION IN THE FROG HYLA MOOREI. S.A. Dunlop, M.F. Humphrey and L.D. Beazley. Psychology Dept., University of Western Australia, Australia.

Approximately 50% of orthotopic retinal ganglion cells (RGCs) die following extracranial optic nerve crush in Hyla moorei. The remaining RGCs form functional contacts in the optic tectum. Some RGCs are located in the inner cell layer of the inner nuclear layer. Here we investigated whether these "displaced" RGCs were similarly affected by optic nerve crush. Displaced RGCs were identified in retinal wholemounts and sections after retrograde transport of HRP applied to the optic nerve.

In normal retinae (N=5) the displaced RGCs comprised 0.55% of the orthotopic population. Densities of displaced RGCs were highest in the area centralis and horizontal visual streak similarly to the orthotopic population. In addition the displaced cell density was higher in the naso-ventral and tempero-dorsal peripheries.

In retinae at least 70 days after nerve crush (N=4) the orthotopic RGCs were reduced by a mean of 47% compared to the unoperated partner retinae. The mean proportion of displaced cells was similar to that in normals at 0.62%. Therefore a similar degree of cell death had occurred in the displaced RGCs. In both normal and regenerate retinae the displaced cells were made up of several distinct types. This provides further evidence that all RGCs undergo a similar proportion of death, rather than the death being confined to specific classes.

347.13

FUNCTIONAL SYNAPSES BETWEEN REGENERATED RETINAL GANGLION CELL AXONS AND SUPERIOR COLLICULUS NEURONS IN ADULT HAMSTERS. S.A. Keirstead, M. Rasminsky, Y. Fukuda, D.A. Carter*, A.J. Aguayo and M. Vidal-Sanz*. Montreal General Hospital and McGill University, Montreal, Quebec, H3G 1A4.

An autologous peripheral nerve graft was anastomosed to the ocular stump of the transected right optic nerve in adult hamsters. The other end of the nerve graft was inserted into the ispsilateral superior colliculus (SC) at week 7-8 and the left optic nerve transected at week 9-11.

Extracellular recordings were made near the site of graft insertion in the SC at week 21-26, several weeks after retinal ganglion cell (RGC) axons that regenerate through such grafts form synapses in the SC (Carter et al, Soc. Neurosci. Abstr. 14:654,1988). Units responding to light flashed at the right eye were found in the superficial 500 um of the SC in all 8 animals tested. 25 units responding to light were identified as SC neurons and not RGC axons since they responded more consistently to paired electrical stimulation (ES) of the graft than to single pulses at the same intensity, indicating postsynaptic summation of afferent inputs. Light flash and ES of the graft decreased ongoing activity in another 7 SC neurons.

Regenerated RGC axons were the only possible sources of visual input to SC neurons responding to light. This study demonstrates that axons regenerated over long distances from adult mammalian CNS neurons can form functional synapses with neurons in other regions of the CNS.

347.14

EXTENSION AND PERSISTENCE OF REGENERATED RETINAL GANGLION CELL AXONS IN THE SUPERIOR COLLICULUS OF ADULT HAMSTERS. D.A. Carter*, G.M. Bray, and A.J. Aguayo. Montreal General Hospital and McGill University, Montréal, Québec, Canada, H3G 1A4.

Two months after placement of a peripheral nerve (PN) graft connecting one eye and the superior colliculus (SC) in adult hamsters, regenerated retinal ganglion cell (RCG) axons, which have regrown through the PN graft, extend up to 0.5 mm into the SC and make synaptic contacts with neuronal targets (Soc. Neurosci. Abstr. 14: 654, 1988). Four months after placement of such grafts, SC neurons can be activated transynaptically by stimulation of the retina by light (Keirstead et al., Soc. Neurosci Abstr., 1989). To investigate the morphology of the regenerated projection at 4 months and its later persistence, RGC axons of similarly prepared hamsters were labelled with HRP orthogradely transported from the eye and examined 4-10 months after PN graft insertion into the SC. By light microscopy, labelled axons remained confined to the superficial SC but extended further (up to 1 mm) into the SC. The extension of some axons towards the surface of the SC resembled that of normal retino-collicular arbors. By electron microscopy, the regenerated retino-collicular terminals had a normal appearance. Thus, over intervals of several months, these regenerating CNS axons extend into the neuropile of adult animals and appear to persist.

347.15

RECROSSING OF RETINAL AXONS AFTER EARLY TECTAL LESIONS IN HAMSTERS OCCURS ONLY WHERE VIMENTIN- AND GFAP-POSITIVE MIDLINE CELLS ARE DAMAGED.

D.-Y. Wu*, S. Jhaveri* and G. E. Schneider (SPON: N. Y. Kiang). Dept. of Brain and Cognitive Sciences, M.I.T., Cambridge, MA 02139.

The midline in the developing tectum contains vertically-oriented cells stretching between the ventricle and the pial surface. The cells express vimentin and GFAP and may form a ***barrier*** to keep retinal axons from crossing the midline (Wu, D.-Y. *et al.*, *Soc. Neurosci. Abstr.*, 1988, *14*:1110).

As an initial test of the "barrier" hypothesis, we studied the fate of the midline cells in regions where retinal axons recross abnormally at the dorsal midline following ablation of the right SC and removal of the right eye. Lesions were made in P1 hamster pups and animals were sacrificed on P2, P8, P13, and P15 — 18 hours after HRP was injected into the remaining eye. One series of sections was reacted for visualizing the HRP; adjacent series were immunostained with antibodies to vimentin or to GFAP.

A tectal lesion was always accompanied by withdrawal of midline processes from the pial surface and a deviation of processes away from the lesion site. By P2, retinal axons had crossed the dorsal midline either along a newly-formed bridge above the necrotic tissue, or more ventrally, over the surface of the lesioned SC. The ventral route was present ***only where midline processes were abnormal***, but did not span the entire rostro-caudal extent of the midline damage. Thus, disruption of midline cells is permissive but may not be instructive for retinal axons to spread from one SC to the other.

PROCESS OUTGROWTH, GROWTH CONES AND GUIDANCE MECHANISMS V

348.1

LOCALIZATION OF TUBULIN DURING AXON OUTGROWTH FROM CHICK TRIGEMINAL NEURONS. M. Sisk, M. Lee, P. Gass, S. Moody and A. Frankfurter. (SPON: S. Klein) Depts. of Anatomy, Biology and Neuroscience, University of Virginia, Charlottesville, VA 22908.

During development tubulin gene expression is differentially regulated. The modulation in abundance of different gene products raises the question of whether specific classes of cells construct biochemically distinct microtubules to perform specific functions. To answer this question we compared the staining patterns in the developing chick trigeminal system produced by two anti-β-tubulin monoclonal antibodies. TuJ1 recognizes exclusively the neuron-specific β-tubulin isotype (Class III) encoded by the gene cβ4 (Sullivan et al. '86, Molec. Cell. Biol. 6:4409). This antibody stains only postmitotic neurons and their processes as early as st13. The only extra-CNS structures that are immunoreactive in the head are epibranchial placodes. In contrast, the other antibody (5H1), which recognizes an epitope common to Class III and at least one other isotype,does not stain cells in the V area until st15. At this time, only axons in the hindbrain marginal zone and in the V ganglion are immunoreactive. In addition, apparently all ventricular processes of hindbrain neuroepithelial cells are 5H1-positive. Furthermore, 5H1 is not brain specific; the entire epidermis is brightly immunoreactive, as are a few mesenchyme cells in the mandibular arch. All neuroepithelial and epidermal staining is lost by st 20, whereas axonal staining persists at least until D10. As development procedes, more and more axons, both in the brain and V ganglion, stain with TuJ1. Within any particular fascicle only a subset of these also stain with 5H1. The fact that 5H1 localizes only to cell processes in select cells suggests that it recognizes a posttranslational modification, whose site we are investigating. NEURONAL MATURATION AND AXON GUIDANCE IN THE MOUSE TRIGEMINAL SYSTEM: AN IMMUNOHISTOCHEMICAL STUDY. D.Y.R. Stainier* and W. Gilbert. Bio. Labs, Harvard Univ., Cambridge, MA 02138.

We are investigating the outgrowth and pathfinding characteristics of the trigeminal sensory neurons in the mouse, using several specific mAb's. MAb B30 (Stainier and Gilbert, J. Neurosci., 1989) stains the surface of mesencep. trig. neurons (mesV) as well as some sensory neurons in the PNS. MAb E1.9 labels growing axons of various sensory neurons.

By early E9, sparsely distributed E1.9 positive neurons in the trig. ganglion send out short axons. The first outgrowth defines the ophthalmic (oph.) projection and axons grow out as individual fibers, each growth cone growing independently in a common direction. By late E9, B30 immunoreactivity (IR) defines mesV neurons as they send axons from their midbrain location to the brainstem where they exit the CNS at the pontine region. These central axons mix with B30 positive neurons and axons of the trig. ganglion and join one of the three (oph., max. and mand.) projections. By early E10, the oph. projection has already reached past the eye cup where axons are sending short collaterals. While leading axons still behave as pioneers, later ones seem to join nerve bundles.

By late E10, early E11, the leading axons seem to have reached the vicinity of their targets and more axons can be seen joining the nerve bundles as they leave the ganglion. Indeed, B30 IR clearly shows at this stage three distinct axon bundles leaving the ganglion and also reveals the segregation of the trig. neurons according to their general target area. Shortly after that, E1.9 IR disappears while the B30 Ag is detectable throughout synaptogenesis and until P15.

348.3

THE PRIMARY AFFERENT INNERVATION OF THE TRIGEMINAL BRAINSTEM COMPLEX OF FETAL RATS AS DEMONSTRATED BY ANTEROGRADE TRANSPORT OF DI-I. R.S. Crissman, L.L. Parsons, N.L. Chiaia and R.W. Rhoades (SPON: A.V. McGrady). Dept. of Anatomy, Medical college of Ohio, Toledo, OH 43699.

Deposits of Di-I into the trigeminal (V) ganglion were used to trace the primary afferent projection to the brainstem, primarily V nucleus principalis (PrV), in rats killed on embryonic (E-) days 16, 18, 20, the day of birth (P-0) and P-7. On E-16, Di-I labelled fibers were visible throughout PrV. Most of these axons were very simple and followed radially oriented paths from the V spinal tract into the nucleus. Some fibers ended in growth cones and many also gave off side branches at several points along their course. In addition to the radially oriented fibers, some axons left the tract in the rostral part of PrV and coursed through the length of the nucleus, parallel to its long axis. A few of these could be followed as far as the rostral portion of V subnucleus interpolaris and many of them also gave off branches along much of their length. Organization of the primary afferent projection to PrV on E-18 was generally similar to that on E-16. However, at this age, many of the primary afferents that followed radial trajectories into PrV were organized into fascicles that exited the tract at periodic intervals. All of the fibers within a given fascicle appeared to terminate in the same portion of PrV. By E-20, most primary afferent axon arbors were still fairly simple, but some fibers had arborizations that appeared considerably more widespread than those observed in older animals. Organization of radially oriented collaterals into fascicles was also apparent at this age. By P-0, most primary afferents terminating in PrV had fairly restricted arbors, but a few widespread axons were still visible. By P-7, most well-labelledprimary afferents in PrV had formed dense and highly circumscribed arbors.

FACIAL NERVE DEVIATION AFTER OTOCYST REMOVAL IN CHICK EMBRYOS. W. Yang*, C.S. Von Bartheld, and E.W Rubel (SPON: R.L. Hyson). Hearing Development Laboratories RL-30, Univ. of Washington, Seattle, WA 98195.

The otocyst was extirpated unilaterally in E3 chick embryos. At E9-12, the embryos were perfusion-fixed and the fluorescent tracer DiI was injected into ipsilateral middle ear structures to label the facial nerve. The tissue was cryosectioned 2-3 months later. After otocyst removal the facial nerve takes an unusual route to the brain. It courses rostrally outside the cranium, penetrates the skull adjacent to the trigeminal ganglion and then turns caudally inside the cranium to enter the brain in the usual location, i.e. at the level of the vestibular nuclei. Motor fibers of the facial nerve appear to make the same detour as the sensory fibers. Auditory brainstem nuclei do not receive projections from the facial or paratympanic nerve when the vestibular or cochlear nerves are absent.

The abnormal course of the facial nerve was also found in some cases with partial otocyst removal, when only a rudimentary cochlea and cochlear nerve remained. However, the facial nerve follows its normal route along the vestibular nerve when a portion of the vestibular endorgan and nerve persisted. In all cases, the facial nerve projections in the brainstem appear similar to normal controls.

We conclude that the vestibular nerve, but not the cochlear nerve normally provides guidance cues for ingrowing facial sensory nerve processes. In the absence of this pathway the trigeminal nerve appears to attract facial nerve axons. The fact that once inside the cranium the nerves are able to find their normal site of entrance into the brain and their normal termination sites suggests highly specific guidance cues. Such cues, apparently, are effective beyond the normal distance from the ingrowing sensory axons. Supported by NIH grants NS 24522 and NS 08578.

DEVELOPMENTAL EVOLUTION IN THE DISTRIBUTION OF RADIAL GLIAL FIBER GROWTH CONES IN THE MURINE CEREBRAL WALL. T.Takahashi*,J-P. Misson* VS. Caviness Jr.,(Spon.: P.Bhide).Dept. Neurology, Mass. Gen. Hospital, Boston, MA 02114
Bipolar radial glial cells of the developing murine cerebral wall are proliferating population which continually adds fibers during the course of cerebral histogenesis. A quantitative study during the 3rd week of gestation, the principal period of neuronal migration, suggests, however, that a substantial proportion of the fibers extends only as far as the outer IZ-deep subplate zone of the cerebral wall (Gadisseux et al., in prep.). The present analysis, based upon glial immunostaining with RC2 antibody (Misson et al.,Dev.Br.Res,1988,44,95), is a re-examination of this possibility. Specifically this analysis is a quantitation of the density of glial fiber growth cones in relation to depth in the cerebral wall through the interval E17-P2. The glial cell growth cones,as visualized by RC2 staining,are polymorphic. For the purpose of the present analysis two growth cone forms are recognized: a simple rounded or club shaped form, on the one hand, a heterogeneous set of forms made complex because of multiple filopodial extensions and branches, on the other. Only the simple form is considered in the analysis on the assumption that it is related to fiber extension while the complex form is probably a reflection of glial process arborization and astrocytic transformation (Caviness et al., Neurosci. Abstr. 1989). Through P0, growth cones of the simple form are abundant in the cerebral wall but subsequently decline sharply in density. By E17 their distribution is disproportionate with respect to the strata of the cerebral wall. Specifically, the concentration in the ESS is 2X that of the adjacent subplate and 4X that of the overlying CP. By P0, the disparity has lessened such that the concentrations in the ESS through the lower half of the cortex are approximately equalized though still somewhat greater than that in the outer zone of the CP. These observations, consistent with findings of the quantitative study of RGF cited above, suggest that fiber tips amassed within the ESS at E17, surge into the CP during the final days of gestation. The interval of the surge corresponds to the time of assembly of supra- granular cortical layers by neuronal migration.

SEROTONIN IMMUNOREACTIVE FIBERS YIELD A COMPLETE MAP OF THE BODY SURFACE IN SOMATOSENSORY CORTEX OF PERINATAL RATS. L.M. Yarris, N.L. Chiaia, C.A. Bennett-Clarke, M.F. Jacquin, J.H. Haring, G.J. Macdonald and R.W. Rhoades (SPON: E.C. Johnson). Depts. of Anatomy, Medical College of Ohio, Toledo, OH 43699 and Robert Wood Johnson Medical School, Piscataway, NJ 08854, and Dept. of Anatomy and Neurobiology, St. Louis University School of Medicine, St. Louis, MO 63104.
Serotonergic fibers in developing rats pass through a period during which they are very dense in primary sensory cortical areas (D'Amato, R.J. et. al. PNAS, 84:4322, 1987). We have extended this observation by determining the age at which differential localization of serotonin immunoreactive (SI) fibers can first be detected in the primary somatosensory cortex and whether neonatal peripheral nerve damage alters the organization of the serotonergic innervation of this cortical region. Pups from timed pregnant rats were sacrificed one hr after birth (P-0) and at the beginning of each of the next nine postnatal days and their cortices were processed for the demonstration of SI using conventional techniques. Some of these animals sustained transection of the left ION within 2 hrs of birth. Dense SI was present in the presumptive primary somatosensory cortex by the beginning of P-1. At this age, the region in which these fibers were most dense provided a crude representation of the body surface. By the start of P-2, the map of the body surface defined by areas of high density SI was much more refined. In the region representing the vibrissa pad, an organization related to the rows of whiskers could be seen clearly. By, the beginning of P-3, all of the patches representing the individual vibrissae could be readily seen as well as the representation of the buccal pad, lower jaw, forelimb and hindlimb. Transection of the ION on the day of birth and examination of the cortex on P-9 demonstrated a marked disruption of the vibrissa-related pattern in the somatosensory cortex.

MODEL OF OCULAR DOMINANCE COLUMNS AND PATTERN FORMATION: ANALOGY TO FERROMAGNETIC DOMAINS. H. Potter, (SPON: M. Livingstone). Dept. Neurobiology, Harvard Med. Sch., Boston, MA 02115.
The formation and behavior of the patterns of functional domains of two biological tissues—the ocular dominance columns in the vertebrate visual cortex and the dermal condensations that will give rise to feathers in the developing chick skin—bear a striking resemblance to the behavior of the pattern of alternating magnetic domains in ferromagnetic crystals. In all three cases, striped patterns can be interchanged with patches or blobs by altering the competitive advantage of one type of domain over the other—for instance, by suturing one eye closed at birth, by disrupting cell-cell interactions with antibodies, or by exposing the crystals to an external magnetic field. These similarities suggest a general model for pattern formation during development, that is based solely on cell or synapse adhesion and motility as governed by the same simple energy relationships that underlie the formation and behavior of ferromagnetic domains.

EARLY INGROWTH OF INDIVIDUAL CALLOSAL AXONS INTO RAT NEOCORTEX. S. Catalano * and H.P. Killackey, Depts. of Anatomy and Neurobiology and of Psychobiology, University of California, Irvine, CA 92717 (SPON: R. Josephson)
The morphology of single callosal afferents in rat neocortex at various timepoints in development were examined using the fluorescent tracer DiI. Rat pups were sacrificed and then perfused transcardially with 4% buffered paraformaldehyde. Crystals of DiI were then implanted in neocortex, and the brains stored in fixative for up to six months. During this time the DiI diffuses through the lipid membranes of cells in the aldehyde fixed tissue (P. Godement et al, Development 101:697, 1987), labeling callosal axons anterogradely and callosally projecting cells retrogradely in the contralateral cortex. Brains were then sectioned with a vibratome, and sections were counterstained with bisbenzamide to visualize the cortical laminae, allowing direct identification of fiber position within the laminae.
By the nineteenth day of gestation, cortex can be subdivided into a marginal zone, cortical plate, subplate, and intermediate zone. At this stage, presumptive callosal afferents can be observed which have penetrated the subplate and reached the lower border of the cortical plate. These fibers exhibit a simple morphology; most are unbranched along their entire length, and are tipped by a distinctively small growth cone. Given that the subplate contains cells destined to become layers V and VI (layers in which callosal axons will terminate), it appears as though some callosal axons reach the vicinity of their target much earlier than has been previously demonstrated. (Supported by NSF grant BNS 87-19311).

DEVELOPMENT OF CALLOSAL ARBORS IN THE HAMSTER SM CORTEX. C.R. Norris* and K. Kalil. SPON: J. Lilien. Neuroscience Program & Dept of Anatomy, University of Wisconsin, Madison, WI 53706.
We have followed the extension of callosal axons into the cortex and their transformation into axonal arbors. First, at the LM level, we are interested in the role of lateral branching in the development of topographic connections. Second, at the EM level, we are examining the time course of synapse formation by callosal axons.
We used DiI to label callosal growth cones arising from the sensorimotor cortex in infant hamsters. Callosal growth cones begin to extend across the callosum at birth and first enter the contralateral cortex at about 48 hours postnatal. Axons then grow perpendicular to the cortical layers with little lateral branching until they reach layer 1, at about 9 days postnatal. Thus, in the initial stages of growth into the cortex, growth cones appear to establish their cortical territory with straight unbranched axons before the axons give rise to the lateral branches. Furthermore, the site at which growth cones enter the cortical target corresponds topographically to their neurons of origin in the contralateral cortex. Therefore, initial callosal connections are point to point connecting reciprocal regions of the cortex, as in the adult. The present results are not inconsistent with previous studies using retrograde tracers to study the development of callosal connections, which suggested that early callosal arbors spread over a wider cortical territory than those in the adult; rather it is likely that pruning of widespread arbors is a later developmental event.
To examine the time course of transformation of callosal growth cones into synapses, combined HRP-EM methods were used. Preliminary data suggest that at 3-4 days postnatal callosal axon tips in the deep layers of cortex do not establish synaptic contacts. Moreover, even at 10 days postnatal, callosal axons still exhibit small but identifiable growth cones. Taken together, these results suggest that axons first establish their cortical topography and then branch laterally to form synaptic connections with cortical targets. AXON TRAJECTORY AND GROWTH CONE MORPHOLOGY IN THE DEVELOPING CORPUS CALLOSUM. Dale Hogan* and N.E.J. Berman (SPON: S.R. Nelson). Dept. of Anatomy and Cell Biology, University of Kansas Medical Center, Kansas City, KS 66103.
Visualizing the pattern of growth of CNS tracts is an important step in gathering evidence for putative axonal guidance mechanisms. The developing corpus callosum was studied in neonatal rats by inserting the carbocyanine tracer DiI into the visual cortex of fixed brains. This technique allows visualization of pioneer axons, individual axons in the growing front and complex growth cone morphologies. On the day of birth, the growing fascicle is just crossing the midline with the pioneers .5-1 mm. ahead of the fascicle. The pioneers are seen in both the dorsal and ventral aspects of the callosum. The axons in the bundle appear to remain parallel to each other implying that they are arranged topographically as they enter the callosum. In the most rostral regions of the visual callosum, more axons have crossed the midline and the pioneers extend further into the contralateral hemisphere than in the more caudal region. Many of the growth cones in the main fascicle show complex filopodial and lamellepodial morphologies suggesting that they are growing slowly and actively sampling their environment. Pioneer axon growth cones were observed to be smaller and rounder, implying that they are growing faster and following a preexisting substrate. (Supported by MH38399 and BNS8819971)

HEREDITY OF COLLISIONS BETWEEN ANTERIOR COMMISSURE AND COLUMNS OF THE FORNIX IN MOUSE BRAIN. B. Cassells and D. Wahlsten. Dept. of Psychology, University of Waterloo, Waterloo Ontario, CANADA N2L 3G1. Axons of the anterior commissure (AC) normally pass anterior to the columns of the fornix (CF) in a compact cylindrical bundle. However, BALB/c inbred mice show a high incidence of CF-AC collisions (Wahlsten, Brain Res. 68: 1-18, 1974) in which part or all of the anterior part of the AC passes through the CF. To more fully describe the inheritance of the collision, C57BL/6 CRBL mice, which do not show this anomaly, and BALB/cCRBL mice were bred to produce reciprocal F1 hybrids and backcrosses. These mice were perfused as adults and every other 25 µm sagittal section throughout the extent of the septum was stained with Sudan Black B for myelin and examined at 40 X for CF-AC collisions and related morphology. The defect showed nearly complete (94%) penetrance in inbred BALBs. Collision risk was increased additively by incompletely penetrant recessive BALB/c autosomal (64%) and X-linked (30%) factors. The inheritance of corpus callosum defects, also seen in BALBs, was entirely independent of the inheritance of CF-AC collisions. Study of morphology related to the collisions led to the hypothesis that hereditary factors produced premature differentiation of neurons sending axons via the AC; this produced an increased rate of growth in the anterior but not posterior limbs of the AC due to differences in primary axonal outgrowth/guidance mechanisms and the resulting dyscoordination produced the CF-AC collisions.

GROWTH AND BRANCHING OF CORTICAL AXONS: IMPLICATIONS FOR TARGET SELECTION BY DEVELOPING AXONS. D.D.M. O'Leary and T.Terashima, Dept of Neurosurg, Washington Univ, St. Louis, MO. 63110

Layer 5 of the mammalian neocortex is the source of projections to a number of subcortical targets. We have studied the elaboration of these projections from two distinct regions of cortex, motor and visual, and find that subcortically projecting layer 5 neurons have similar axon extension and branching programs, although their mature projections are quite distinct. Cortical axons and their collateral branches were labeled by injections of the axon tracer, DiI, made in vivo into motor or visual cortex of E20 to adult rats. The primary axons arising from layer 5 neurons extend out of cortex through the internal capsule, cerebral peduncle, pyramidal tract and into the spinal cord. The subcortical targets of layer 5 neurons are later innervated by collaterals which branch from the primary axons. We have focused on 5 major branch points: tectal (which innervates several targets, with the superior colliculus as its distal target), mesencephalic (which innervates the midbrain nuclei such as the red nucleus, etc.), pontine (innervates basilar pons), inferior olive, and dorsal column nuclei. Each collateral forms well after the parent axon grows past the future branch point, with the more rostrally located branches forming first. Both motor and visual cortical axons form and extend all 5 branches, but those from visual cortex are delayed. We have yet to observe any indication that the growth cones of the primary axons recognize the future branch points, nor do we see any filopodial remnants left behind that may mark them. At a later stage, certain components of the initially similar axon trees are eliminated: Motor cortical axons lose most of their tectal collateral, while visual cortical axons lose the primary axon and all collaterals caudal to the pontine branch point. Thus, the development of layer 5 subcortical projections has 3 phases: extension of primary axons, delayed formation of collateral branches, and selective loss of axon segments. These findings indicate that in this system target selection is not the responsibility of the growth cone of the primary axon.

SEROTONIN AGONISTS DECREASE BRANCHING OF FRONTAL CORTEX NEURONS. L. Sikich*, J. Hickok*, and R.D. Todd. (SPON: K. Isenberg). Department of Psychiatry, Washington University School of Medicine, St. Louis, MO 63110.

Serotonin (5HT) has long been known to influence neurite elongation in identified invertebrate neurons. However, the morphological effects of 5HT upon individual neurons in mammals has not been previously examined.

Various serotonergic drugs were added to dissociated cultures of fetal rat cortex after one day in vitro. Following 90 hours of drug exposure, the number of neurites and branch points along each neurite, the somal area and the total neuritic extent were measured in 100 cells from each treatment group. Treatment with 5HT or the $5HT_{1A}$ agonist 8-OH-2-(Di-*n*-propylamino)-1,2,3,4-tetrahydronaphthalene (8-OH DPAT) decreased the mean number of branches and mean neuritic extent by ~50% and ~25% respectively. These effects were blocked by coculture with the $5HT_{1A}$ antagonist spiperone. Results were similar in cultures from both E17 and E19 animals.

These results demonstrate that 5HT acts via $5HT_{1A}$ receptors to modify specific facets of neuronal morphology. Whether these changes represent decreases in all cortical neurons or in specific subgroups of neurons is currently unknown. Such morphological modifications could influence the pattern of connections and synaptic contacts and the survival of neurons in the mammalian frontal cortex.

DIBUTYRYL cAMP REDUCES THE INHIBITORY EFFECT OF AMITRIPTYLINE ON NEURITE OUTGROWTH OF CHICK EMBRYONIC CEREBRAL EXPLANTS. K. L. Wong*, E. Gonzales*, and A. I. Farbman. Department of Neurobiology and Physiology, Northwestern University, Evanston, IL 60208.

Recent data from this laboratory have shown that: 1) dibutyryl cAMP (dbc AMP), or phosphodiesterase inhibitors such as isobutylmethylxanthine and theophylline, enhance neurite outgrowth of chick embryonic olfactory explants [J. Neurobiol. (1988) 19: 681], and 2) amitriptyline (AMI), a typical tricyclic antidepressant, inhibits neurite outgrowth of both chick embryonic olfactory and cerebral explants in a dose-dependent manner [Brain Res. (1988) 457: 281]. These data lead to the possibilities that cAMP could be involved in neurite outgrowth, and that AMI may inhibit neurite outgrowth via the alteration of the intracellular level of cAMP.

In chick embryonic cerebral explants, 1 or 10 µM of dbc AMP results in a significant 19 and 27% increase, respectively, in the percentages of explants that expressed neurite outgrowth relative to the controls (1 µM: $t=2.93$, $df=8$, $p<0.025$; 10 µM: $t=4.42$, $df=8$, $p<0.005$). More importantly, combined treatment of AMI and dbc AMP reduces the inhibitory effect of AMI treatment alone. For example, 1 or 10 µM of dbc AMP (in the presence of 8 µM of AMI) results in a significant 26 and 37% increase in neurite outgrowth over that of 8 µM of AMI treatment alone. (1 µM: $t=3.57$, $df=6$, $p<0.015$; 10 µM: $t=5.06$, $df=6$, $p<0.0025$). Likewise, both 1 and 10 µM of dbc AMP (in the presence of 4 µM of AMI) noticeably reduce the inhibitory effect of of 4 µM of AMI (1 µM: $t=2.96$, $df=6$, $p<0.05$; 10 µM: $t=3.43$, $df=6$, $p<0.015$).

PROCESS OUTGROWTH, GROWTH CONES AND GUIDANCE MECHANISMS VI

349.1

ANALYSIS OF CELLULAR INTERACTIONS THAT MEDIATE THE DEVELOPMENT OF MOTOR AXON SEGMENTATION. R. A. Oakely and K. W. Tosney. Neurosci. Program & Biol. Dept., Univ. of Michigan, Ann Arbor, MI 48109

Motoneurons extend axons only through the anterior half of each somite and the development of this segmental pattern is dependent on sclerotome. We have developed an *in vitro* assay to investigate the cellular mechanisms responsible for motor axon segmentation. We remove the viscera, notocord, and spinal cord and cut strips of several consecutive somites that are cultured ventral side up on a laminin substratum. These conditions expose the sclerotome and yet retain the physical relationships among anterior and posterior populations. Motoneurons are labeled with DiI, dissociated and deposited on the explants.

We find a clear hierarchy of substratum preference as detected by the extent of labeled neurite outgrowth after 20 hours of culture. Neurite outgrowth is minimal on the posterior half sclerotome and is more extensive on the anterior half sclerotome. In addition, the behavior of neurites at tissue borders indicates that the posterior sclerotome is impervious to axon invasion from somata on the spinal cord basal lamina or on the anterior sclerotome, consistent with the role of the posterior sclerotome as a barrier to axon advance. Our results suggest that a contact mediated mechanism may be responsible for motor axon segmentation. A preliminary analysis of the trajectory of neurites suggests that a long distance cue may also contribute.

Despite a clear preference for anterior over posterior as a substratum, axons grow much more robustly on the laminin substratum than on any portion of the explant. In addition, outgrowth is extensive on the remaining spinal cord basal lamina and on the myotome. These results suggest that the sclerotome is a relatively hostile environment for motor axon outgrowth and that the posterior sclerotome is more hostile than the anterior.

TWO GROWTH ASSOCIATED PROTEINS: CHANGES IN MEMBRANE LOCALIZATION DURING DEVELOPMENT. M. Merline*, E. Floor, and K. Kalil. (SPON: E. Schweitzer). Dept of Anatomy and Neurosciences Training Program, University of Wisconsin, Madison, WI 53706.

We previously described a 33kDa brain-specific membrane protein whose expression during development is well correlated with axon outgrowth in the hamster CNS (Kalil and Perdew, *J. Neurosci.*8:4797-4808, 1988). To gain insight into the functional role of this protein, we examined how its subcellular localization changes during development and compared this localization with that of another growth associated protein, GAP-43, which is thought to play a role in axon outgrowth.

Subcellular fractionation was carried out on hamster brains ranging in age from 3 days postnatal to adult. Brains were homogenized and a low-speed supernatant run on Sephacryl S-1000 columns to separate subcellular particles according to size. Membrane particles from each column fraction were pelleted and their proteins separated by SDS-PAGE. The proteins were analyzed by Western blotting with a monoclonal antibody to the 33kDa protein and a polyclonal antibody to GAP-43 (kindly provided by L. Benowitz). In young animals the 33kDa protein appeared to be distributed over membrane particles of a wide range of sizes. By contrast, in adult brains the protein was enriched in a fraction containing small particles 30 nm in diameter, a size somewhat smaller than synaptic vesicles. Results with GAP-43 suggest that in young brains this protein is associated primarily with large membrane particles.

The results suggest that these proteins may play a role in intracellular membrane processing during axon outgrowth. The residual stores of the 33kDa protein on a population of small particles in the adult brain could perhaps be involved in further synaptic changes once axon outgrowth is completed. (Supported by NIH Grants NS 24890 to E. Floor and NS 14428 to K. Kalil.)

349.3

NEW MACRO-EXPLANT (ME) TISSUE-CULTURE MODEL TO STUDY SPINAL-CORD (SC) NEURONS. C.Mariotti*, V.Askanas, W.K.Engel, C.S.Lee*. Neuromuscular Ctr, U. of So. Cal., L.A., 90017.

We have developed a system for culturing separately the entire longitudinally-cut ventral and dorsal parts of the whole SC of 12-14 day rat embryos, on polylysine-collagen mixture, in F14 medium + 10% FBS. At the time of explantation and throughout the period of culturing (up to 21 days) CAT activity in dorsal MEs (DMEs) was negligible (2% of that in the ventral MEs (VMEs). In 5 experiments, neurite outgrowth, measured by computerized video image analysis (CVIA) (RAS, Amersham), at 12 days was 3-fold in VMEs and 2-fold in DMEs ($p<.02$) that of 5-day-old explants. Optical-density (OD) analysis of neuron-specific enolase (NSE) immunostain showed that at 5 days 37% of neurites in VMEs and 31% in DMEs belonged to the highest OD bin (indicating strongest staining) vs. 19% and 21% of 12-day VMEs and DMEs ($p<0.05$). To the contrary, 44% of 12-day VME-neurites and 43% of DME-neurites belonged to the lowest OD vs. 30% and 35% in 5-day VMEs and DMEs. About 35% of all neurites belonged to the middle OD level. CAT activity was the lowest in 5-day VMEs. It increased 113% ($p<0.05$) at 12 days, 50% at 16 (p=NS) days, and 106% ($p<0.05$) at 21 days. This new system allows study of motor neurons and the influence on them of putative growth, survival and maturation factors in an SC milieu more closely resembling the in vivo condition. Our established parameters can now serve as a basis for such studies.

349.4

CARBON FILAMENTS PROMTE AXONAL GROWTH ACROSS THE SITE OF SPINAL CORD TRANSECTION IN ADULT RATS. M. Dauzvardis* and T. Khan, (SPON: G. Gaik) Neuro-Regeneration Lab., RR&D Center, VA Hospital, Hines, IL 60141.

Small diameter (4-8μ) carbon filaments have been used in the orthopedic repair of ligaments in the knee (Weiss, A.B. et al., Clin. Orthop. & Related Res., 196:77, 1985). In these studies, fibroblasts apparently used the filaments as framework for the laying down of new collagen. Carbon filaments have also been shown to support the growth of embryonic spinal cord in tissue culture (Khan, T. et al. Abtrc. Soc. Neurosci. 11:586, 1985). In the present study, we analyzed the ability of carbon filaments to function as a "scaffolding" for the growth of regenerating axons in spinalized rats.

Seven 200g Wistar rats sustained total spinal cord transection at level T8-T9 with the use of a #11 scapel blade followed by withdrawal of fine wire hook through the transection site. In five of these animals the resulting transection gap was then filled with a 5mm long bundle of approximately 10,000 carbon filaments of 4.0μ diameter. Two rats served as surgical controls. After a six-week survival period, all animals received bilateral cortical injection of 1% WGA-HRP. No fibers were observed below the lesion area in the two surgical control animals, while the spinal cords of 2 out of 5 animals with carbon filament implants were found to contain labeled axons as far as two spinal segments below the transection site.

Carbon filaments, by providing a favorable adhesion surface and also a possible guiding function, may prove useful in the treatment of spinal cord injury. Supported by funds from Veterans Affairs, Rehabilitation R&D Service, Rehab. R&D Grant #B423R.

CELLULAR ELEMENTS ARE REQUIRED FOR AXONAL REGENERATION IN THE LAMPREY SPINAL CORD. **D.I. LURIE* AND M.E. SELZER. DAVID MAHONEY INST. OF NEUROL. SCIENCES AND DEPT. OF NEUROLOGY, U. OF PENN., SCH. OF MED., PHILA., PA 19104.**

Larval sea lampreys recover from complete spinal transection. This involves axonal regeneration across the zone of injury. We wish to determine whether cellular elements in the injury zone are required for this regeneration. A 3mm freeze lesion was performed which severed axons and destroyed neurons and glia but left the connective tissue components of the meninges intact. The lesion was devoid of cellular elements after 4 weeks. The remaining connective tissue formed a continuous bridge between the proximal and distal stumps of the cord. Nine Petromyzon marinus larvae received a freeze lesion at the level of the 7th gill and were allowed to recover for at least 10 weeks. Muller and Mauthner axons were injected intracellularly with HRP. Whole-mounts of brain and spinal cord were prepared. None of the animals recovered coordinated swimming even after 19 weeks. Fifty-five branches of 29 axons were labelled with HRP. Although these neurites regenerated in a directionally specific manner in the proximal stump, none of them grew into the lesion site. We conclude that regenerating spinal neurites will not grow into a connective tissue matrix devoid of both neurons and glia. (NIH grants NS 14837 and NS 25581).

349.6

ADHESION AND NEURITE OUTGROWTH ON THROMBOSPONDIN AND A 140 kDa FRAGMENT. K.S. O'Shea, L-H.J. Liu*, & V.M. Dixit* Anatomy & Cell Biology, Univ Mich, Ann Arbor, MI 48109.

To assay the effects of thrombospondin (TSP), a trimeric glycoprotein constituent of extracellular matrices, on adhesion, neuroepithelial cells isolated from spinal cords of day 13 mouse embryos were cultured on TSP (1-50 ug/ml), its NH_2-terminal heparin-binding domain (25 ug/ml), a 140 kDa fragment containing the COOH domain but lacking the heparin-binding amino-terminal region (25 ug/ml), laminin (25 ug/ml), or BSA (25 ug/ml), in serum-free N2 medium. Anti-TSP (50 ug/ml) or GRGDS (500 ug/ml) was added to additional wells coated with TSP. After 2h, coverslips were washed, the Hoescht dye was added and adherent cells counted. Neurite outgrowth from anti-alpha-MSH stained cells was determined after eight h in vitro. TSP, like laminin, supported both attachment and neurite outgrowth as did the 140 kDa fragment, but not the heparin-binding domain. Anti-TSP antibodies inhibited attachment and neurite outgrowth on TSP; GRGDS had no effect. Interestingly, neurite outgrowth on the 140 kDa fragment was nearly as efficient as on laminin, while on the intact molecule, outgrowth was slightly less.

AXONIN-1, AN AXONALLY SECRETED GLYCOPROTEIN: I. IMMUNOHISTOCHEMICAL LOCALIZATION IN DEVELOPING NERVE FIBER TRACTS. E.T. Stoeckli*, P. Streit#. M.A. Rüegg* and P. Sonderegger. Biochemisches Institut & #Hirnforschungsinstitut, Universität Zürich, CH-8057 Zürich.

Axonin-1 is a glycoprotein that is released from axons of cultured neurons, as revealed by metabolic labeling in a compartmental cell culture system (Stoeckli, E.T. et al., Eur. J.Biochem., 180:249-258, 1989). It has recently been purified from the ocular vitreous fluid of the chicken embryo (Rüegg, M.A. et al., EMBO J., 8:55-63, 1989). In the present study, the expression of axonin-1 in the developing nervous system of the chick was investigated immunohistochemically at the light and electron microscopic level. In both the developing retina and spinal cord, axonin-1 was found mainly associated with nerve fiber tracts. In the spinal cord, the staining disappeared after hatching. Immunoelectron microscopy of the optic fiber layer of the retina located the axonin-1 immunoreactivity of axon bundles to the surface of the axonal membrane. The specific location in bundled axons and the early disappearance after birth suggests implication in the formation of nerve fiber tracts.

349.8

AXONIN-1, AN AXONALLY SECRETED GLYCOPROTEIN: II. IDENTIFICATION OF A MEMBRANE-ASSOCIATED HOMOLOGUE INVOLVED IN NEURITE FASCICULATION. M.A. Rüegg*, E.T. Stoeckli*, R.B. Lanz*, P.Streit# and P. Sonderegger (SPON: H.-C.Bauer). Biochemisches Institut und #Hirnforschungsinstitut der Universität Zürich, CH-8057 Zürich.

The location of axonin-1 immunoreactivity at the surface of developing nerve fiber tracts (Stoeckli, E.T. et al., accompanying abstract) closely parallels the tissue distribution of cell adhesion molecules involved in neurite fasciculation. The presence of anti-axonin-1 Fab fragments during axon growth in vitro resulted in antibody binding to the axonal surfaces and in a marked perturbation of the fasciculation pattern. Hence, a fraction of axonin-1 is associated with axonal membranes and, by operational criteria, qualifies as a cell adhesion molecule. The major proportion of membrane-associated axonin-1 co-solubilized with the integral membrane proteins. Structurally, the integral membrane form was found to be highly similar to soluble axonin-1, hence, adhesive properties are postulated for secreted axonin-1. As a soluble adhesive protein, it may function as a regulator of cell adhesion around its most likely site of secretion, the growth cone.

349.9

A SMALL SUBPOPULATION OF MYOCYTES MAY BE REQUIRED FOR PROPER MORPHOGENESIS OF IDENTIFIED MOTONEURONS IN EMBRYONIC ZEBRAFISH. B. Debu, S.H. Pike*, R. Bremiller*, C.B. Kimmel and J.S. Eisen. Institute of Neuroscience, University of Oregon, Eugene, OR, 97403

Identified primary motoneurons (PMNs) innervate cell-specific regions of each muscle segment in the zebrafish. En route to their targets, PMN growth cones extend along a common pathway until they reach a choice point where each growth cone selects a cell-specific pathway.

Labeling with the anti-engrailed antibody, 4D9 reveals a set of 3-6 muscle cells, termed primary medial myocytes (pmms) at the choice point; these cells differentiate hours before adjacent muscle cells. Pmms are absent from trunk segments and PMNs project abnormally in embryos bearing the spt-1 mutation in which somitogenesis is disrupted. Mosaic analysis involving transplantation of single PMNs showed that PMN phenotype depends on the genotype of the host, not on the genotype of the PMNs. These observations suggest that pmms may be required for proper pathfinding by the PMNs.

To test this hypothesis, we ablated pmms in wild type embryos using laser-irradiation. PMN pathfinding was abnormal in segments in which pmms were ablated, but was normal in segments in which muscle fibers adjacent to the pmms were ablated. These results support the hypothesis that pmms are required for proper pathway navigation by the PMN growth cones. Supported by HD22486 and NS23915.

349.10

FORMATION OF THE MAUTHNER CELL LATERAL DENDRITE IN ZEBRAFISH IS INDEPENDENT OF ITS EARLIEST SENSORY CONTACTS. K. Hatta*, W.K. Metcalfe, M.S. Curry * and C.B. Kimmel. Inst. of Neuroscience, U. of Oregon, Eugene, OR 97403.

Are specific axo-dendritic contacts required for correct dendritic development of a postsynaptic cell? The lateral dendrite of the Mauthner cell (M-cell) receives synaptic inputs from sensory neurons located in the trigeminal (Vg), vestibular (VIIIg), and lateral line (LLg) cranial ganglia. Axons from the Vg are the first of the inputs to contact the M-cell, and they eventually synapse most proximally on the lateral dendrite. They are followed by the VIIIg and then LLg inputs, which make contacts progressively more laterally on the dendrite. Thus the spatial positions of the inputs precisely reflects their time of arrival at the dendrite.

At the time the first Vg axons arrive at the M-cell, its lateral dendrite has not yet formed, and Vg growth cones contact the M-cell body. This relation suggested the hypothesis that the Vg contact is necessary for the M-cell to initiate proper differentiation or to develop its lateral dendrite.

To test this hypothesis, we used a laser to ablate Vg cells 1-2 hr before they contact the M-cell. The lateral dendrite and other morphological features of M-cells deprived of their early Vg inputs and examined 5 days later appeared normal. Thus, the outgrowth of the lateral dendrite may either be programmed intrinsically in the M-cell, or dependent upon some environmental signal other than its first input. GROWTH CONE MORPHOLOGY OF COMMISSURAL INTERNEURONS IN THE CHICK SPINAL CORD. H. Yaginuma*, S. Homma*, R. Künzi* and R. Oppenheim (SPON: N. Okado). Dept. of Anatomy, Wake Forest Univ. Medical School, Winston-Salem, NC 27103.

Previous studies have shown that spinal commissural interneurons (CI) located in dorsolateral and intermediolateral regions are one of the earliest developing populations in the chick spinal cord. To study the mechanisms involved in axonal guidance in this pathway, we have examined the morphology, trajectory, and interaction with the substrate, of commissural growth cones. Growth cones were labelled in vitro with HRP or DiI and observed by light and electron microscopy.

Developing growth cones showed different shapes depending on their position in the pathway. Both before and after passing through the floor plate, growth cones were lamellepodial or filopodial in shape. By contrast, within the floor plate, the majority exhibited blunt or varicose shapes, with only one or a few filopodia at the leading edge and small protrusions on the sides. Within the longitudinal fiber tracts of the marginal zone (MZ) growth cones were lamellepodial or spindle shaped with filopodia. When observed with the electron microscope, most growth cones in the floor plate were found to contact the basal lamina. Close contacts between growth cones and longitudinal axons in the MZ were also observed. The present results indicate that different guidance mechanisms are used along the CI pathway.

FLOOR PLATE ANTIGEN P84 SUPPORTS ADHESION AND OUTGROWTH OF CULTURED CEREBELLAR NEURONS. W. Chuang and C. Lagenaur. Dept. of Neurobiology, Anatomy, and Cell Science. Ctr. for Neuroscience, Univ. of Pittsburgh, Sch. of Med., Pittsburgh, PA 15261.

We have previously described a novel adhesion molecule, P84, which is restricted to the floor plate of mouse embryonic spinal cord, but is widely expressed in postnatal CNS. Previous studies showed that nitrocellulose immobilized P84 supports adhesion and outgrowth from postnatal cerebellar neurons. Both monoclonal and polyclonal anti-P84 antibodies stained the surfaces of cultured postnatal central neurons. Addition of polyclonal Fab fragments directed against P84 to the growth medium inhibited cell adhesion and outgrowth on P84. Intact monoclonal antibodies to P84 also inhibited adhesion and outgrowth on P84 antigen. Taken together, these findings suggest that the adhesive activity of isolated P84 antigen observed in vitro resides in a site exposed on the surface of living cells. Immunoaffinity purified P84 is composed of proteins with molecular weights of 167, 85, and 66 kD. In Western blot, polyclonal antibodies to P84 stain these three proteins. Affinity purified antibodies eluted from each P84 band also stained all P84 proteins indicating that these bands all share common antigenic determinants. When these same affinity purified antibodies were used to stain sections of embryonic spinal cord, they produced a staining pattern identical to that seen with monoclonal anti-P84 stainings. Cells taken from embryonic day 15 tectum (which does not yet express P84) were not able to attach and extend neurites on P84, but were able to grow on laminin, poly-L-lysine, and 8D9 antigens. Postnatal cortex shows weak staining for P84, and indeed, this tissue will grow on a P84 substrate. These findings indicate that the ability of neurons to grow on P84 is temporally and regionally regulated.

FLOOR PLATE CELL MORPHOLOGY REVEALED BY TRANSGENE EXPRESSION. R. Campbell*, R. McGowan*, C. Sapienza*, and A. C. Peterson. Ludwig Institute for Cancer Research, Montreal, Canada.

The neural tube floor plate is thought to participate in the guidance of a subset of axons (commissural axons) within the developing neural tube. We are studying a transgenic mouse line in which an *hsp68-lac* Z construct is ectopically expressed within the floor plate from E10 to E14. Staining for beta-galactosidase activity using chromogenic substrates reveals a subset of cells with a morphology suggesting an intimate association with decussating neurites.

In this same line, insertion of the transgene has caused a mutation of the *dystonia musculorum* (*dt*) locus, leading, in homozygous mice, to a profound degeneration of peripheral sensory axons soon after birth. The transgene's ectopic expression in this line appears to result from its site of insertion within the genome, as other lines made with the same contruct show no such expression (Kothary, R., Clapoff, S., Brown, A., Campbell, R., Peterson, A., and Rossant, J., *Nature*, **335**: 435, 1988.). Since this insertion site appears to be the *dt* locus, this raises the possibility that regulatory elements belonging to the *dt* gene itself are directing transgene expression to the floor plate.

ACTIVE MOVEMENTS OF MEMBRANE ANTIGENS TO THE EDGES OF GROWTH CONES OF CORTICAL NEURONS. **D.B. Wayne, N.L. Baumrind , A.L. Pearlman and M.P. Sheetz. Depts. of Cell Biol. & Neurol., Wash. Univ. Med. School, St. Louis, MO 63110.** **The neuron-specific antibody, 2A1, immunolabels the perimeter of murine cortical neurons in vitro (Baumrind et al., this volume). This distribution could result from either active concentration of the antigen at the cell's leading edge or passive trapping at the substrate surface. To distinguish between these we used antibody coated gold particles to follow the movements of antigen by video-enhanced DIC microscopy. 80% of 2A1-conjugated gold particles are found along the growth cone perimeter and many are located on filipodia. They exhibit diffusive movements indicating that their position is not fixed by substrate attachment. An antibody to N-CAM (abNCAM) is similarly distributed, whereas transferrin or rat IgG bind primarily to the central body of the growth cone. Gold particles coated with 2A1 or abNCAM move predominantly in a random manner, but occasionally move outward to the leading edge of lamellipodia or to the end of filopodia at 1-2μm/sec. Detailed position analyses indicate that the latter movements are active, not diffusive. The active forward movement of 2A1 and N-CAM and their preferential distribution at the growth cone edge suggest that membrane molecules involved in cell-cell or cell-substrate interactions may be actively concentrated at the leading edges of growth cones and filopodia (see Sheetz et al., this volume for a possible mechanism).**

ASTROCYTES MATURED IN VITRO SUPPORT RETINAL NEURITE OUTGROWTH. March D. Ard and Mary B. Bunge. Dept. Anatomy, U. Mississippi Med. Ctr., Jackson, MS, and Dept. Anatomy & Neurobiology, Washington U. Sch. Med., St. Louis, MO.

Short-term (5-10 d) astrocyte cultures consist of flat cells, but in long-term (28-40 d) cultures, astrocytes develop a stellate shape with thin processes and are packed with more glial filaments. Embryonic retinal neurite outgrowth appears to be supported equally well in both types of cultures.

Primary astrocytes from neonatal rat cerebral cortex were subcultured once onto collagen-coated coverslips in medium with 20% serum. Embryonic d 15-16 rat retinal explants were placed on 1 d subcultures. After 4 d, vigorous neuritic outgrowth reached a length of 2.1 mm (average length of longest bundle of neurites from 8 cultures). EM showed the neurites in fascicles within intercellular channels between cell layers or on the upper surface of the astrocytes. Neurites contacted astrocyte surfaces but neither the collagen substratum nor the abundant extracellular matrix (ECM). ECM formed in short-term cultures consisted of an occasional segment of basal lamina-like material, collagen fibrils near the substratum, and accumulations of a filamentous meshwork material.

When explants were added to long-term astrocyte subcultures, neuritic outgrowth was again vigorous, reaching 2.0 mm in 4 d (average of 10 cultures) As in younger cultures, neurites grew within intercellular channels or on top of the astrocyte layers, in contact with astrocyte surfaces but not with the collagen substratum or ECM. ECM in long-term cultures differed from that of short-term cultures in that the intercellular meshwork material had been replaced by more dispersed and widespread wispy material yet to be identified. Basal lamina-like material had formed into occasional ring structures enclosed by cellular processes, reminiscent of astrocytic end feet in CNS. The stellate shape of the astrocytes and their increased production of glial filaments together with the basal lamina-like structures may indicate polarization of the cells with maturity. Supported by NIH grant NS15020 and the National Multiple Sclerosis Society.

A ROLE FOR TENASCIN IN NEURITIC OUTGROWTH ON ASTROCYTES. **H. M. Geller, J. P. Grierson, R. E. Petroski. Department of Pharmacology, UMDNJ-Robert Wood Johnson Medical School, and The Graduate School, Rutgers University, 675 Hoes Lane, Piscataway, NJ 08854.**

In vivo, astrocytes are thought to play a key role in axonal guidance. *In vitro*, a monolayer of purified protoplasmic (type 1) astrocytes seems to model this function by providing an optimal substrate for the adhesion and process outgrowth of dissociated embryonic rat hypothalamic neurons at low density. We have found that the astrocyte monolayer is often inhomogeneous. Most of the culture consists of regions of very "flat" large astrocytes which support extensive neuritic processes as determined by immunoreactivity with anti-neurofilament antibody. Other regions contain smaller astrocytes which reach confluence at a higher density and have a variegated or "rocky" appearance under differential interference contrast microscopy; these regions display a virtual absence of neurites. We have conducted a detailed immunocytochemical investigation of the potential sources of heterogeneity in the GFAP$^+$ astrocyte monolayer by immunocytochemical techniques using antibodies directed against extracellular matrix and putative cell adhesion molecules. No correlation was found with the expression of NCAM, thrombospondin, laminin, or fibronectin and the presence or absence of neurites. A high correlation exists between the expression of the myotendinous antigen M1 (tenascin, cytotactin, J1) and the flat and rocky astrocytes type: flat astrocytes with many neurites express moderate levels of punctate M1 immunoreactivity whereas regions with a high level of fibrillar M1 immunoreactivity displayed low neuritic invasion and a rocky appearance. These results suggest a that there is coordinate expression of the "rocky" trait and tenascin and that tenascin expression may play a role in directing neural outgrowth. Supported by NIH NS 25168.

ANTIBODY AGAINST MYELIN-ASSOCIATED INHIBITOR OF NEURITE GROWTH DECREASES FREQUENCY OF NEURITE EXCLUSION AREAS R.D. TODD (SPON: E.H. Rubin). Department of Psychiatry, Washington U. School of Medicine, St. Louis, MO 63110.

Primary cultures of rat frontal cortex contain transiently present, large A2B5+, GFAP-, galC- cells (called CINEAS: cells in neurite exclusion areas) which do not support the movement of neurons or the growth of neurites across their surfaces (R.D. Todd, Soc. Neurosci Abst. 13:257). Caroni and Schwab (Neuron 1:85-96, 1988) have described monoclonal antibodies, IN-1 and In-2, which neutralize the effects of the CNS myelin-associated inhibitor of neurite growth. The effects of these two antibodies on CINEA number are reported here.

High density (8 x 10^5 cells per 35 mm poly-lysine coated plate) cultures of E17.5 rat frontal cortex cells were grown in the presence of serial dilutions of IN-1 or IN-2 hybridoma supernatants. Cultures were scored for CINEA number three days after plating. IN-1 had no effect on CINEA number with dilutions of 1:200 to 1:2. In contrast, IN-2 decreased CINEA number in a dose related manner for dilutions of 1:200 to 1:50 (from 240 CINEAs per 10^6 cells to 100 per 10^6 cells). Increasing IN-2 concentrations 25-fold (1:2 dilution) resulted in no further decrease in CINEA number. These results are compatible with factors related to myelin-associated inhibitor having a developmental role in neurite growth, neuron migration, or both.

[COLD] FUSION IN HYPOTONIC SALINES OF SEVERED MYELINATED AXONS. T.L. Krause* and G.D. Bittner. Dept. of Zool., Coll. of Pharm., and Inst. for Neurosci., U. Texas, Austin, TX 78712.

Severed nerve axons, myelinated or unmyelinated, typically take weeks to months to regenerate in invertebrates or vertebrates. Several years ago we (Bittner et al., Brain Res. 367: 351-355, 1986) reported that two severed segments of an unmyelinated invertebrate axon, the crayfish medial giant axon (MGA), dissected free of the animal could be morphologically and physiologically reconnected in vitro within minutes using polyethylene glycol (PEG). Morphological fusion was apparently successful in only 3-7% of all trials; physiological reconnection occurred even less frequently.

We now report a much more frequent ability to fuse severed segments of an invertebrate myelinated giant axon, the MGA of the earthworm (*Lumbricus terrestris*). Apparent morphological fusion has been achieved in 80-90% of all in vitro attempts by applying a 50% solution of 4000 MW PEG at 20°C. The PEG solution is introduced through a micropipette for one minute directly upon severed, apposed, MGA segments in a 30% hypotonic saline solution. Axoplasmic and axolemnal continuity have been used as two measures of morphological fusion success. In addition, we have often observed diffusion of Lucifer yellow dye between two axonal segments fused by this technique. However, Lucifer dye does not diffuse across the lesion site if severed segments are apposed, but PEG is not applied.

Unlike certain others, this [cold] fusion [bio] technology does not require palladium electrodes. Like other putative cold fusion technologies, unambiguous proof of complete fusion may be hard to demonstrate. We are presently examining the ability of PEG-fused axons to conduct action potentials across the lesion site and to move HRP and other markers across the lesion site by slow or fast axonal transport. Supported by Texas Advanced Technology Grant #14-2202 to GDB.

A CONDITIONING LESION ENHANCES THE RATE OF DEVELOPMENT OF MECHANOSENSITIVITY IN AN ACUTELY CUT NERVE. G.M. Koschorke*, R.A. Meyer, and J.N. Campbell. The Johns Hopkins Univ. School of Medicine, Baltimore, MD 21205

Myelinated afferents develop mechanosensitivity at the site of a peripheral nerve ligation within hours of the ligation. We postulate that a mechanical-to-electrical transducer is transported to the nerve ligation site. Since a nerve injury is known to amplify axonal transport, a conditioning lesion should enhance the rate of development of mechanosensitivity. In anesthetized monkeys, the sural nerve was crushed, ligated, and 1 cm of nerve was removed distal to the ligature. Seven days later, the nerve was again crushed, ligated and cut 1 cm proximal to the conditioning lesion. Small strands were dissected from the parent nerve 6 cm proximal to the ligature, and action potential activity from myelinated afferents was recorded. Control experiments were done in acutely ligated nerves without a conditioning lesion. The percentage of myelinated afferents that responded to mechanical stimulation at the site of the acute injury was significantly greater following a conditioning lesion (45% at 10 hours) than in the control experiments (23%, $p \leq 0.001$). These results support the hypothesis that a mechanical-to-electrical transducer is conveyed via axonal transport to the periphery and becomes functional in regenerating membranes. This transducer may account for the mechanosensitivity of myelinated, low-threshold mechanoreceptors.

350.3

LENGTH OF LESION HAS NO EFFECT ON SPEED OF REGENERATION IN THE RAT SCIATIC NERVE. J.J. Campbell* and B. Pomeranz. Dept. of Zoology, University of Toronto, Toronto, Canada, M5S 1A1.

This study was conducted to determine the effect of length of lesion and the corresponding loss of Schwann cells on the rate of regeneration.

Twelve adult male Wistar rats received lesions of the right sciatic nerve near the sciatic notch. Three lesions of different lengths were randomized amongst these animals: the crush lesion was 3 mm long; the short freeze lesion was 9 mm long; and the long freeze lesion was 18 mm long.

On post-operative days 25, 30 and 35, EMG's were recorded using one of two methods. Five animals (2 crush and 3 short freeze) underwent one EMG recording session with the sciatic nerve placed on stimulating hook electrodes, and pin recording electrodes inserted in 12 identified sites in the foot. Seven animals (4 crush and 3 long freeze) underwent a technique of repeated EMG recording sessions, modified from Kerns et al. (*J. Neurosci. Meth.*, 19:259-266, 1987). The sciatic nerve was stimulated transcutaneously through micro-alligator clips, firmly pinching the shaved skin of the rat in the upper thigh over the sciatic nerve, and EMG's were recorded through fine pin electrodes as before. This method permitted repeated EMG's to be recorded over several days, producing a time-course for regeneration.

There was no difference in the rate of regeneration between the three lesion groups, indicating that the destruction of Schwann cells does not affect the rate of regeneration of a lesioned sciatic nerve.

350.4

THE MODULATION OF FAST AXONAL TRANSPORT SPEED DURING NERVE REGENERATION. M.B. Atkinson* and A.C. Breuer. (SPON: A. Tramposch) Neurology and Brain and Vascular Research, Cleveland Clinic Foundation. Cleveland, OH 44195.

Axonal transport plays a critical role in neuronal regeneration after injury. Retrograde (RETRO) transport has been hypothesized as an injury signal mechanism to the cell soma. Synthesized molecules for regeneration are transported from the cell soma by either anterograde (ANTERO) fast axonal transport (FAT) (Eg. plasma membrane components, growth associated proteins) or slow axonal transport (cytoskeletal elements). The rate at which the components are delivered to the growth cone is likely the rate limiting step of regeneration. We report the rate for the FAT system at various time points following transection and anastomosis of male, Sprague-Dawley rat sciatic nerve as determined by video microscopy and computer image enhancement techniques. Time points include 24, 48, 72 hours and 1 week post anastomosis which resulted in ANTERO FAT speed *decreases* of 44.8% ($p<0.005$), 12.1% ($p<0.05$), 25.3% ($p<0.01$), and 20.7% ($p<0.01$) respectively and RETRO FAT speed *decreases* of 9.2% ($p<0.01$), 15.7% ($p<0.001$), 18.4% ($p<0.001$), and 22.1% ($p<0.001$) respectively. We hypothesize that the decrease of FAT speeds in both the ANTERO and RETRO directions may be related to a shift in molecular synthesis towards the production of cellular components needed for regeneration at the expense of other molecular species (including both ANTERO and RETRO translocator motor proteins). The decrease in FAT speeds reflects a reduced delivery rate. Augmenting FAT speeds using Ca^{++} channel agonists (Cell Calcium 9: 293-301, 1988) increases the organelle delivery rate and may enhance axonal regeneration.

350.5

ALTERED MICROTUBULE ASSOCIATED PROTEIN (MAP) PHOSPHORYLATION DURING OPTIC NERVE REGENERATION. Denis Larrivee, Dept. Physiology, Cornell Univ. Med. Coll., New York, NY 10021.

Many axonal phosphoproteins in the goldfish optic nerve show changes in phosphorylation related to the progress of regeneration (Larrivee & Grafstein, J. Neurosci. 9:574, 1989). One of these phosphoproteins, designated P9, undergoes a prominent pI shift that is first apparent 3 weeks after the nerve is injured and persists to at least 7 weeks. Because P9 is similar in molecular weight and pI to several low molecular weight MAPs, its association with microtubules was explored during regeneration. The protein a)could be precipitated with taxol, b) was immunoreactive with a chartin antibody (courtesy of Dr. F. Solomon), and c) copurified with tubulin on gel permeation columns. Thus, P9 is likely to be associated with microtubules and to contain epitopes shared with chartins. In regenerating nerves, ^{32}P labeling of P9 was highest in a tubulin fraction that was soluble in low-salt buffer: by contrast, its labeling in normal nerves was highest in the non-soluble tubulin compartment. Even extraction with high-salt buffer (0.3M NaCl) did not separate P9 from tubulin in normal and regenerating nerves. Intraocular injection of ^{3}H-proline during regeneration preferentially labeled P9 associated with non-soluble tubulin. Thus, changes in phosphorylation of P9 during regeneration may be involved in releasing tubulin into a soluble axonal pool.

Supported by NIH research grant NS14967 to B.Grafstein.

350.6

TRANSPORT OF SCb TUBULIN INTO AXON SPROUTS IS INCREASED BY A CONDITIONING LESION. I.G. McQuarrie and J.M. Jacob. Neural Regeneration Ctr., VA Med. Ctr., Cleve., OH 44106.

When axons are injured, the nerve cell body response includes an increase in tubulin synthesis associated with an increase in the amount of tubulin being carried by SCb, the faster subcomponent of slow axonal transport. When a conditioning lesion initiates these events, a second lesion can test the effect of supplemental SCb tubulin on the growth of newly-formed axons (Jacob & McQuarrie, J. Cell Biol. 107:454a, 1988). Rats received either a conditioning crush or sham-crush of distal sciatic nerve branches, followed after one week by injection of 35-S methionine into the lumbar spinal cord. One week later, a second crush was made immediately ahead of the labeled SCb wave. Nerves were harvested 4-12 days later for SDS-PAGE of consecutive 3 mm segments, fluorography, gel punching, and liquid scintillation counting. The SCb rate was normal (3.3 mm/d) in both conditioned and sham-conditioned axons, but tubulin labeling was 50-100% greater in conditioned axons. Actin, calmodulin, and MAPs participated in this increase. The outgrowth rate was 4.8 mm/d in conditioned axons vs. 4.3 mm/d in sham-conditioned axons. These findings support the idea that axonal outgrowth depends on the availability of tubulin, actin, and other cytomatrix proteins (McQuarrie & Lasek, J. Neurosci. 9:436, 1989).

Supported by NINDS grant NS-18975.

350.7

AXOTOMY INCREASES AXONAL TUBULIN TRANSPORT AT THE FRONT OF SCb. J.M. Jacob and I.G. McQuarrie. Neural Regeneration Center, VA Medical Center, Cleveland, OH 44106.

When peripheral nerve motor axons are interrupted in mammals, the nerve cell body response includes an increase in tubulin synthesis. This produces an increase in the amounts of 35-S methionine-labeled tubulin being carried by SCb, the faster subcomponent of slow axonal transport (Hoffman and Lasek, Brain Res. 202:317-333, 1980). We measured the rate and amount of transport of selected SCb proteins: tubulins, microtubule-associated proteins (MAPs) at 58-67 kD, actin, and calmodulin. Rats received either a crush or sham-operation of distal sciatic nerve branches, followed one week later by injection of 35-S methionine into the lumbar spinal cord. Nerves were harvested 1, 2, or 3 weeks later for SDS-PAGE of consecutive 3 mm segments, fluorography, gel punching to remove proteins, and liquid scintillation counting. There was no change in the rate of the SCb peak: 3.5 mm/d after crush vs. 3.4 mm/d after sham-operation. A 150% increase in SCb tubulin labeling was confined to faster-moving elements of the crushed axons, and formed a new peak which advanced at 5-6 mm/d. Actin, calmodulin, and MAPs participated in this localized increase. These findings define the increase in SCb transport that has been shown to accelerate axonal outgrowth at the site of a second nerve injury (Jacob and McQuarrie, J. Cell Biol. 107:454a, 1988).

Supported by NINDS grant NS-18975.

350.8

CYTOSKELETAL CHANGES DURING AXONAL GROWTH AND REGENERATION IN CULTURED SENSORY NEURONS. M.R. Gilbert*, B.L. Harding*, P.N. Hoffman, J.W. Griffin. Johns Hopkins Univ. Sch of Med., Baltimore, MD 21205

Previous studies have shown that axonal growth during development and regeneration is associated with changes in the levels of cytoskeletal mRNAs (Hoffman, PN, J Neurosci 9:893, 1989). In neonatal animals, levels of class II β tubulin and GAP-43 mRNAs are elevated, whereas levels of NF-L are low. Later in development, tubulin and GAP-43 mRNA levels decrease while NF-L mRNA levels increase. Axotomy of peripheral sensory fibers in mature rats results in a recapitulation of the developmental pattern of gene expression. We compared these in vivo properties with cultured neurons, utilizing DRG explant cultures grown in N2 defined media with NGF. For the study of growth-associated changes, mRNA levels for class II β tubulin, GAP-43, and NF-L were measured in ganglia at the time of dissection and at 2, 4, 6, and 8 weeks in vitro. There was a progressive decrease in tubulin and GAP-43 mRNA levels over the 8 weeks. In contrast to the in vivo system, NF-L mRNA levels in cultures did not increase with age. Axotomy of cultured DRG neurites, performed at 4 weeks in vitro, caused a prominent induction of tubulin mRNA, but little change in NF-L mRNA levels. These results indicate that many of the changes in cytoskeletal mRNA levels during growth and regeneration are similar in both the in vivo and in vitro models.

ASSOCIATION OF AXOTOMY - INDUCED CHANGES IN RAT DORSAL ROOT GANGLION NEURONS WITH THE PROGRESS OF AXONAL REGENERATION. M. R. Wells and U. Vaidya. Dept. of Neuroscience, New York College of Osteopathic Medicine, Old Westbury, N. Y. 11568 and Dept. of Neurology SUNY Stony Brook, N.Y. 11794-8121

A unilateral crush lesion of the sciatic nerve in rats produces a biphasic response in some metabolic and morphological parameters in the L5 and L6 dorsal root ganglia (DRG). The present study examined the possible association of the progress of axonal regeneration with these alterations. After unilateral crush lesions of the sciatic nerve at the level of the sciatic notch, the progress of the regeneration of axons in the nerve from the L5 ganglion was examined by axoplasmic transport of [^{3}H] labelled peptides 1-7 days after injury. The data demonstrate that a significant proportion of axons from the L5 ganglia enter the distal stump between 1-2 days after injury. The progress of regenerating axons was linear at approximately 2 mm/day thereafter. The timing of the regeneration of axons suggests that some components of the first of the two major phases of the L5 DRG neuronal reaction to axotomy may be associated with the entry of axons into the distal stump. The second phase may be associated with early contact of axons with hip muscles. Supported in part by the Veterans Administration and NYCOM.

TARGET AND GROWTH REGULATION OF PROTEINS SENSITIVE TO AXOTOMY. A. Buriani, M.J. Savage, D.W. Burmeister and D.J. Goldberg. Dept. of Pharmacology and Ctr. for Neurobiology & Behavior, Columbia U. Coll. of P&S, 630 W. 168th St, New York, NY 10032.

Among the changes a neuron undergoes after axotomy, variations in the synthesis or metabolism of specific proteins may play an important role in the regeneration of the axonal tree. Using SDS-PAGE, we identified 10 proteins whose incorporation of ^{35}S-methionine consistently changed 1 week after axotomy of the giant cerebral neuron of *Aplysia in vivo*. Axotomized GCNs were placed in culture, where they display vigorous axonal growth, to investigate the regulation of these changes. The labeling of one of the proteins that up-regulate (112 kDa; pI 5.6) was greatly reduced if all growth was blocked by either of 2 methods. The incorporation of label into two other proteins that up-regulate (116 kDa; pI 5.4 and 46 kDa; pI 6.3) was greatly decreased when cells with which GCN makes chemical synapses were included in the cultures, even though growth continues unabated. For the 116 kDa protein, target membranes mimicked the effect of the intact target, but medium conditioned by exposure to targets did not. These results indicate that membrane-membrane contact with target cells (or its loss) and growth (or its cessation) are involved in the initiation or termination of the increased output of certain proteins from the cell body after axotomy.

CHARACTERIZATION AND IMMUNOLOCALIZATION OF SOLUBLE EXTRACELLULAR GLYCOPROTEINS IN GOLDFISH BRAIN. Finnbogi Thormodsson, Stephen F. Lakos and Bernice Grafstein. Physiology Dept., Cornell U. Med. Coll., New York, NY 10021.

The goldfish brain contains a prominent group of soluble acidic glycoproteins consisting of 2 main subgroups, with MWs about 33K and 38K respectively. The proteins, which can bind to heparin, are largely extra- cellular. We have designated them "eXoGlycoProteins" (XGPs). Expression of XGPs is increased during optic nerve regeneration. Edman degradation sequencing of spots from 2-dimensional gels (performed by Dr. J. Labdon) showed that the first 15 N-terminal amino acids in the most abundant isoform of the 33K sub-group were identical with the sequence deduced from a cDNA clone of "ependymins" (Königstorfer et al., J. Neurochem 52: 310, 1989). The most abundant isoform of the 38K sub-group showed less homology. Antiserum to XGPs produced prominent immunostaining of the pial cells and the outer walls of capillaries, as well as a population of large granular cells in the thick reticular zone underlying the optic tectum, in the vicinity of the third ventricle, and occasionally under the pia. Immunopositive cells in the blood included lymphocytes, monocytes and macrophages. The XGPs therefore appear to be associated with a diverse population of cells of mesodermal origin in the brain and blood, at least some of which belong to the reticuloendothelial system. **[Supported by NIH Research Grant NS-09015 and Training Grant NS-07138.]**

CHANGES IN β-PREPROTACHYKININ (β-PPT) mRNA AND TACHYKININS IN RAT DORSAL ROOT GANGLIA (DRG) FOLLOWING PERIPHERAL OR CENTRAL AXOTOMY. D.B. Henken[1], A. Tessler[1,2], M.-F. Chesselet[1], and M. Murray[1]. [1]Anatomy Dept., Medical College of PA, and [2]VA Medical Center, Phila, PA.

In normal rat DRG, 15-20% of the total neuronal population contains tachykinins and mRNA for the tachykinins precursor, β-PPT. In order to determine whether peptide and message content change differentially after axotomy, we examined the numbers of cells labelled for tachykinins immunocytochemically or for β-PPT mRNA using in situ hybridization histochemistry following either sciatic nerve or dorsal root section. Neurons labelled for β-PPT mRNA or for tachykinins and unlabelled neurons were mapped, measured and compared in sections from operated and intact sides. One day following sciatic nerve section, no changes were detectable for either the message or the peptide. At 3 days the numbers of neurons labelled for the message had decreased to 4%, but the proportion of cells labelled for the peptide did not change. Two weeks following sciatic nerve axotomy 3.5% of the total neuronal population labelled for β-PPT mRNA while 8% stained for tachykinins. By 6 months following peripheral axotomy, the proportion of cells labelled for both the message and the peptide returned to control levels of 15%. After dorsal root section, at all post-operative intervals, both message and peptide remained at control levels of 15-20%. These results suggest that the DRG soma reacts differently to axotomy of its peripheral or central process at the level of gene expression. Supported by grants from NSF-BNS8616841, NIH-NS24707, USAMRDC-51930002 & VA Med Res Ser.

IN SITU HYBRIDIZATION DETECTION OF EARLY ALTERATIONS IN RIBOSOMAL RNA (rRNA) LEVELS FOLLOWING AXOTOMY OF HAMSTER FACIAL MOTONEURONS. N. B. Kinderman* and K. J. Jones. (SPON: M. Oblinger) The Chicago Medical School, North Chicago, IL 60064.

Adult hamster facial motoneurons (HFMN) represent a population of motoneurons that, when axotomized, undergo a reactive sequence geared toward survival and regeneration. One of the most robust changes demonstrated both morphologically and autoradiographically to occur after axotomy of HFMN involves alterations in nucleolar functioning at 2 days postoperatively (PO). In this study, we extended our investigation of the nucleolar response through the use of quantitative *in situ* hybridization and rDNA probes to detect how early after axotomy alterations in nucleolar functioning occur. Adult hamsters (100 days) were anesthetized by intraperitoneal injection of Nembutal and subjected to axotomy of the right facial nerve, with the left side serving as control. PO survival times were 6, 18, and 24 h, and 2 and 4 d, with each experimental group containing 3 animals. Fresh, frozen brainstem sections containing the facial nuclear groups were collected and postfixed. A nick-translated rDNA probe complementary to 28S rRNA was prepared and, following prehybridization, hybridized to the sections overnight at Rm T. The sections were subsequently washed, dried and processed for autoradiography. Quantitative analysis was accomplished using a computerized image analysis system to measure number of grains per cell, somal size, and grain density. At 6h, there was an axotomy-induced 10% increase in rRNA levels, relative to the controls. The peak increase (48%) in rRNA levels occured at 24 h, with a decline in the increase present at 2 and 4 d PO (35% and 31%, respectively), relative to the controls. Somal area was found to be initially increased (19%) at 18 h PO, with a peak at 24 h PO (28%), and a return to control values by 4 d PO. No changes in the concentration of rRNA were found at any time PO. Thus, the axotomy-induced changes in rRNA levels, as detected with quantitative *in situ* hybridization, 1) occur significantly earlier than previously thought using different methods and 2) indicate that initiation of the neuronal injury response occurs within hours PO. Supported by a SCRF grant (KJJ).

351.1

METABOLIC CHANGES IN MUSCLE FIBERS REGENERATING IN THE PRESENCE AND ABSENCE OF INNERVATION. S. Sesodia*, R. Choksi* and P.M. Nemeth. Dept. of Neurology, and of Anatomy & Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

We examined the influence of innervation on the energy-acquiring metabolism of muscle fibers in regenerating soleus muscles. In one group of Wistar rats, necrosis of the left soleus muscle was induced by a subdermal injection of Australian tiger snake venom (10μg in 100μl 0.9% NaCl) into the dorsolateral aspect of the lower hindlimb. In a second group, muscles were denervated immediately prior to venom injection by removing a 1 cm segment of sciatic nerve near the sciatic notch. Soleus muscles from both hindlimbs were removed at selected times after the venom injection and processed for histochemical and quantitative microchemical analyses. Fibers identified by myosin ATPase as type 1 in one section were located in, and dissected from, an adjacent lyophilized section. Individual dissected fibers were analysed by microanalytical biochemical techniques for enzymes representative of anaerobic (lactate dehydrogenase, LDH), aerobic (malate dehydrogenase, MDH) and high energy phosphate (adenylokinase, AK) metabolism. In innervated regenerating muscles, LDH was comparable to control levels by 3 days while the other enzymes returned to control levels more slowly. In denervated regenerating muscles, however, LDH returned to control levels with a similar time course as in the innervated regenerating muscles but MDH attained values only 30% of control while AK was 84% of control.

We conclude from these results that innervation is necessary for the restoration of aerobic metabolism in regenerating muscles while anaerobic metabolism seems to be independent of innervation. The results also imply that in the absence of contractile demands, the metabolic needs of denervated muscle fibers can be satisfied by anaerobic metabolism.

351.2

THE HYPER-REINNERVATION OF RAT SKELETAL MUSCLE. T.A. Kuiken*, W.Z. Rymer and D.S. Childress*. Depts. of Biomedical Engineering and Physiology, Northwestern University, Chicago, Illinois, 60611.

Rat MG muscles were hyper-reinnervated by: 1) cutting the MG nerve and implanting it onto the MG muscle together with additional hind limb nerves, thereby increasing the total number of regenerating motoneurons up to 11 fold (26 animals) or; 2) crushing the MG nerve and excising the medial portion (50-70%) of the muscle, thereby decreasing the number of muscle fibers (6 animals).

Muscles hyper-reinnervated with multiple nerves recovered more fully than did the self-reinnervated control muscles. Up to three times more motor units formed in the hyper-reinnervated muscles than were found in normal MG. The mean motor unit size was significantly smaller than in normal or control muscles. Moreover, the range of motor unit size was greatly increased; both normal sized and very small units were found in hyper-reinnervated muscles. Some of these motor units were extremely small, producing less than 200 mg. of tetanic force, which was a full order of magnitude smaller than units in normal muscle. Both fast and slow motor units were present in this population of small motor units. About 25% of the muscle fibers became polyneuronally innervated.

In the muscle reduction experiments, the number of motor units formed was not significantly larger than expected considering the mass of the muscles. However, the distribution of motor unit sizes in some of the experiments appeared to be bimodal, possibly implying that some motoneurons had an advantage in the reinnervation of these muscles. Cross-sections of the muscles were stained for ATPase activity after acid pre-incubation to determine myofiber type. The percentage of slow fibers was reduced by over 50% in these experimental muscles suggesting that fast motoneurons may have an advantage in competitive reinnervation.

351.3

HIGHLY SELECTIVE REINNERVATION OF XENOPUS PECTORALIS MUSCLE FOLLOWING NERVE CRUSH. Y. HARADA* and A.D. GRINNELL. Jerry Lewis Res. Ctr., UCLA Sch. of Med., Los Angeles, CA 90024.

In the pectoralis muscle of Xenopus, 95% of muscle fibers have two distinct endplates, and 80% of these are innervated by different branches of the same axon (mono-neuronal double innervation:MDI). This MDI can be thought to be the result of selective elimination and retention of synapses. To study this hypothesis, reinnervation during several months following nerve crush was investigated in adult Xenopus. Using formamide (up to 4M) to block contraction and reduced K^+ Ringer solution to block action potentials, even small EPP components could be recorded. MDI was judged from simultaneous occurance or failure of EPPs at both junctions at threshold stimulus strength. Reinnervation was mostly complete within 20 days after crush. Initially, one of the two endplates was occupied. Subsequently, the other became occupied selectively by the same axon, without polyneuronal innervation of one junction, or innervation of the two endplates by different axons, at more than control levels. But a foreign motor nerve appeared to innervate endplates randomly. These results indicate highly selective reinnervation from the beginning following nerve crush. Supported by a grant from the NSF.

351.4

ALL PERONEAL MOTONEURONS OF THE RAT SURVIVE CRUSH INJURY BUT SOME FAIL TO REINNERVATE THEIR ORIGINAL TARGETS. John E. Swett, Chang-Zern Hong*, Peter G. Miller*. Anat. & Neurobiol. & Phys. Med. & Rehab., Univ. Calif., Irvine, CA 92717

This is a quantitative study of the motoneurons of the rat's common peroneal nerve following severe unilateral, 2 mm-long crush injury of the sciatic nerve. Recovery from injury was allowed for 14 to 188 days and was measured behaviorally and electrophysiologically. The motoneurons were retrogradely labeled on both sides, the uninjured side serving as a control. On the injured side the nerves were labeled either distally or proximally to the crush site with HRP. Spinal segments L2 to L6 were cut in serial, frozen cross-sections. HRP was reacted using TMB as the chromogen. The normal peroneal nerve contains 634 ±26 motoneurons (22 cases). The number labeled distally from the crush site (22 cases) was 535 ±69 or 84.4% of normal. In cases where the nerve was labeled 5 mm proximally to the injury normal population numbers (648 ±30) were found. The unlabeled 15.6% had not vanished as a result of cell death. It was composed largely of small motoneurons whose axons may not have regenerated distally beyond the crushed zone. Mean soma size of injured neurons increased to maximum 3-6 weeks after injury and then gradually decreased in size over the following weeks to nearly normal values. This transient increase in size was due to two factors: 1) soma swelling in response to axonal injury, and 2) absence of many small motoneurons, presumably γ-motoneurons, that probably failed to regenerate beyond the injury zone long after larger motoneuron axons had reinnervated their targets. As all motoneurons survived, it is conceivable that they could all theoretically reinnervate their original targets under certain conditions providing that proper pathguides are available. (Supported by NIH Grant NS23707-03).

351.5

EXTENT AND PRECISION OF REINNERVATION OF MUSCLE SPINDLES IN THE CAT'S TENUISSIMUS MUSCLE. M.DeSantis. Dept. of Biol. Sci. & WAMI Prog., Univ. of Idaho, Moscow, ID 83843.

Cross-sections (X-sect.) through muscle spindles (ms.sp.) were studied microscopically. The area enclosed by the outer capsule of the spindle,the intracapsular area (ICA), served as the measure of the position at which a nerve terminal occurred along the length of the spindle.

In anesthetized cats the nerve to the muscle was destroyed unilaterally by freezing. A total of 75 X-sect. through ms.sp. were examined for regenerated terminals between 22 and 93 days after denervation. As controls the side contralateral to the denervation was sham-operated, and spindles from unoperated cats were also studied. A total of 118 X-sect. through control spindles were observed; 42% of them had nerve terminals present. The 29 X-sect. with sensory endings were located in regions of the spindle that had ICAs which generally exceeded those where the 18 with motor endings were present (Table 1). Fewer, 35%, of the X-sect. through ms.sp. that were allowed to be reinnervated had nerve endings. This difference between control and reinnervated spindles was due chiefly to fewer motor endings being present after axonal regeneration; the percentages with sensory endings were similar (Table 1). Most of the 21 X-sect. through ms.sp. with sensory endings had larger ICAs than the 8 profiles in which motor endings occurred (Table 1).

The data are consistent with the following two conclusions. Terminals of regenerated afferent and efferent axons redeploy in a way which resembles the innervation of intact ms.sp., and complete repopulation of the spindle by motor endings lags that of sensory endings. (Supported by USPHS grants NS-11026 & RR-05360).

Table 1

Type of	Control		Reinnervated	
Ending	%	ICA range (um^2)	%	ICA range(um^2)
sensory	24.6	3800 to 23000	24.0	2000 to 24000
motor	17.8	1100 to 4400	10.7	580 to 2200

351.6

DISTRIBUTION OF FIBER TYPES IN LONG-TERM SELF-REINNERVATED CAT MUSCLE. P.A. Nemeth*, T.C. Cope and P.M. Nemeth Dept. Physiology, Hahnemann Univ., Philadelphia PA 19102 and Dept. Neurology, Washington Univ., St. Louis, MO 63110 (PMN).

Histochemical studies of reinnervated muscle show clustering of like-type fibers distinct from the usual mosaic pattern. Our aim was to characterize the extent of type-grouping quantitatively.

Myosin ATPase-stained cross-sections from medial gastrocnemius muscles self-reinnervated for >2 years after complete nerve section were compared with those from the contralateral control muscle in 4 adult cats. The spatial relations between 3 muscle fiber types (I, IIa, IIb) were tested for randomness using the method of Venema (*Muscle and Nerve*, 11:301,1988). For 14 regions from reinnervated muscles (≥3 per muscle), 10 were similar to normal, i.e. differences between expected and observed numbers of adjacent fibers of like type fell within the normal range.

The fact that type-grouping was not prevalent in the majority of samples measured so far suggests that both recovery time and the source of reinnervation may be important for re-establishing the spatial distribution of fiber types. Restoration of a mosaic pattern raises the possibility of reorganization of synaptic connections made by regenerating motoneurons. (Supported by NS21023 (TCC) and DK38375 (PMN)).

351.7

ANTENNAPEDIA REGENERATES IN THE STICK INSECT, *Carausius morosus*: SENSORY PROJECTIONS II. W. P. Chan* and J. S. Edwards (SPON: R. D. Longley). Department of Zoology, University of Washington, Seattle, WA 98195.

Receptors on the antennapedia regenerate (AntpR) in the stick insect, *Carausius morosus* project to the deutocerebrum as with the normal antenna (Edwards et al., *Soc. Neurosci. Abstr.*, 12:1574, 1986). Nearly 40 % of the receptors on the flagellum of a normal adult antenna are chemosensory. On the more distal segments, ca. 50 % of these receptors are multiporous (olfactory). No such sensilla are found on the more proximal segments.

On the AntpR, ca. 20 % of the receptors are chemosensory but multiporous sensilla are absent. The anterior portion of the deutocerebrum in the AntpR is reduced (Edwards et al., *J. Neurobiol.*, In press, 1989). Single-sensillum cobalt-fills showed that chemoreceptors on the normal antenna always project to the anterior portion of the deutocerebrum. This condition is similar to the Lozenge^3 mutant in *Drosophila melanogaster* (Stocker, R. F. and Gendre, N., *Dev. Biol.*, 127:12, 1988). An inductive interaction of sensory neurons on deutocerebral target cells also operates during regeneration. Supported by NIH grant NS-07778 to JSE.

351.8

EFFECT OF MIDFIELD CUTS ON INTACT AND REGENERATING SYNAPSES IN THE CRAYFISH. J. S. Rhee* and S. J. Velez. Department of Biological Sciences, Dartmouth College, Hanover, New Hampshire 03755.

The superficial flexor muscle system of the crayfish Procambarus clarkii has been used to study how neurons reconnect with their appropriate target cells under a variety of experimental conditions (J.Neurobiol. 19: 127-152). We had reported that when the nerve was cut in the middle of the muscle field, and the lateral muscle fibers were removed, leaving the medial fibers with the normal complement of synapses, the medial synapses were repressed (no jp's could be recorded at physiological temperatures) as the axon without a target area (axon 4) grew over the medial muscle fibers (Soc. Neurosci. Abstr. 12: 1575). In the present work, similar surgery was done but this time the lateral fibers were left in place, providing a target area for the growth of axon 4. Now we do not observe the physiological repression observed earlier as jp's are detected for all axons at physiological temperatures over the medial fibers. Axon 4 spreads some contacts over the medial field but maximum growth occurs over the lateral fibers. By eight weeks all axons regenerate their normal connectivity patterns. These results suggest that intact synaptic contacts are not disturbed by partial axotomy if the nerve is able to grow over a denervated target area; when this is not possible, hyperinnervation of the remaining target field results in the repression of established synaptic contacts.

351.9

SUBSTRATE BOUND NERVE GROWTH FACTOR (NGF) ENHANCES AND DIRECTS THE REGENERATION OF ADULT RAT DORSAL ROOT AXONS. J.D. Houle and J.E. Johnson. Dept. of Anatomy, Univ. of Arkansas Med. Ctr., Little Rock, AR 72205

Severed adult rat dorsal roots were apposed to an intraspinal transplant of fetal spinal cord (FSC) tissue co-grafted with nerve growth factor (NGF) treated or untreated nitrocellulose strips to determine if substrate bound NGF could stimulate and guide the regrowth of centrally directed sensory axons. Axonal regrowth from the injured roots was assessed 1-3 months post transplantation by calcitonin gene-related peptide immunoreactivity (CGRP-IR).

In animals with untreated nitrocellulose implants individual CGRP-IR axons were observed in dorsal regions of the FSC tissue, primarily away from the nitrocellulose. In contrast, dense fascicles of regenerated CGRP-IR axons lined the entire length and depth of NGF treated nitrocellulose, with many axons extending beyond the graft-host interface ventrally into the adjacent host neuropil. Regeneration of CGRP-IR axons from severed roots was suggested by the retrograde labeling of dorsal root ganglion neurons with fluorescent dye injected into FSC tissue transplants. These results indicate that NGF can have a specific neurotrophic effect on the regeneration of sensory axons within the CNS, i.e. by promoting the extent of axonal regrowth and by directing regrowing fibers towards undamaged regions of the spinal cord. Supported by SCRF/PVA and NIH grants NS26380 and EY07584.

351.10

TROPHIC REGULATION OF GABA RECEPTOR EXPRESSION IN AXOTOMIZED DRG CELLS. R.B. Bhisitkul*, J.D. Kocsis and S.G. Waxman. Dept. of Neurology, Yale Sch. Med. and VA Med. Ctr., West Haven, CT. 06516. The effect of active regeneration on GABA receptor expression of axotomized rat sensory neurons was studied using current clamp and single electrode voltage clamp recording. Axotomy was produced without allowing normal axonal regeneration by transection and tight ligation of the sciatic nerve. 12-19 days post-transection, the GABA-mediated responses of excised L4 and L5 DRG cell bodies were attenuated; the mean depolarization was reduced to 7 mV from 16 mV in controls, and the mean GABA-induced current was 0.4 nA compared to 1.0 nA in controls. Decrements in GABA sensitivity produced by axotomy could be partially prevented by active regeneration of injured axons through the denervated distal nerve segment. Sciatic nerves were transected and ligated with the addition of a discrete nerve crush 3.0 cm proximal to the ligation site, allowing a delimited segment of regeneration without peripheral target reconnection. Under these conditions, the GABA-induced depolarization was considerably improved compared to transection alone. These results suggest that there is a trophic influence within the distal nerve segment which plays a role in maintaining somatic GABA receptors during axonal injury, consistent with the findings that Schwann cell-derived nerve growth factor exerts neurotrophic regulation in sensory neurons during regeneration.

351.11

DEVELOPMENT AND LESION INDUCED CHANGES IN FLUORIDE RESISTANT ACID PHOSPHATASE AND BINDING OF THE LECTIN BANDIRAEA SIMPLICIFOLIA-I IN THE RAT'S TRIGEMINAL BRAINSTEM COMPLEX. F.A. White, N.L. Chiaia and R.W. Rhoades. (SPON: J.G. Foy). Dept. of Anatomy, Medical College of Ohio, Toledo, OH 43699.

Binding of the lectin Bandiraea simplicifolia-I (BS-I) and expression of the enzyme fluoride resistant acid phosphatase (FRAP) identify the same population of dorsal root and trigeminal (V) ganglion cells (Silverman, J.D. and Kruger, L., Somatosensory Res., 5:259, 1988) and these primary afferents appear to be mutually exclusive from those that contain tachykinin immunoreactivity. We have previously shown that adult transection of the infraorbital nerve (ION) leads to a transient decrease in tachykinin immunoreactivity in the medullary dorsal horn (MDH) while neonatal transection of this V branch results in an expansion of the band of tachykinin immunoreactivity in this portion of the brainstem. In the present study, FRAP histochemistry and BS-I binding were used to assess the effects of neonatal and adult ION transection upon the innervation of the MDH by this population of sensory neurons. Transection of the ION in adulthood resulted in transient reduction in BS-I binding that was apparent by 7 days post-lesion, maximal at 30 days post-lesion, and nearly recovered by 60 days after the nerve transection. Neonatal ION transection resulted in a permanent loss of BS-I binding in the ipsilateral MDH. Because we were unable to consistently demonstrate BS-I binding in the brains of very young rats, we used FRAP histochemistry to evaluate the short-term effects of neonatal ION transection. These experiments showed that ION transection had no significant effect upon the density of FRAP staining in the MDH at 6 hrs after neonatal ION transection and that a clear reduction in staining density occurred within 16 hrs of the nerve transection.

351.12

ACCURACY OF REGENERATION OF VIBRISSA-RELATED PRIMARY AFFERENT NEURONS AFTER NEONATAL TRANSECTION OF THE RAT'S INFRAORBITAL NERVE. P.S. McCann*, N.L. Chiaia and R.W. Rhoades (SPON: R. Waziri). Dept. of Anatomy, Medical College of Ohio, Toledo OH 43699.

A sequential double labelling paradigm was used to determine the accuracy with which vibrissa-related trigeminal primary afferent neurons reinnervated the correct follicle after infraorbital nerve (ION) transection on the day of birth. Pups were anesthetized by hypothermia and true blue (TB) was injected into the A1 vibrissa follicle bilaterally within 6 hrs of birth. After an additional 6-8 hrs, the ION on the left side was transected. When these rats reached at least 6 wks of age, the A1 vibrissa follicle on both sides was injected with diamidino yellow (DY). Three days later, animals were anesthetized with ether, perfused with formalin, and tissue was processed for fluorescence microscopy. In normal ganglia (N=10), 80% (sd.=8.1) of the TB labelled cells also contained DY. In ganglia ipsilateral to damaged nerves (N=13), 17% (sd.=7.7) of the TB labelled cells also contained DY. This value was significantly lower than that for the normal ganglia, but significantly greater than that which would be expected by chance. Analysis of the areal distributions of labelled cells also indicated that reinnervation of the A1 vibrissa follicle was not random. In mid-horizontal sections through normal ganglia 92% (sd.=6.9) of cells labelled with DY only were located within the mediolateral distribution of the TB labelled neurons. In ganglia ipsilateral to damaged nerves, this value was 68% (sd.=7.8). Thus, the majority of the "foreign" innervation of the A1 follicle after neonatal ION transection came from neurons in the portion of the ganglion that would normally supply it. All of these data indicate that reinnervation of vibrissa follicles after neonatal ION transection, while not completely accurate, is also not random.

NGF PROMOTES NEURITE REGENERATION FROM NERVE CUT ENDINGS OF ADULT DORSAL ROOT GANGLIA CULTURES IN A COLLAGEN GEL.
HORIE,H.,BANDO,Y.*,TSU,H.*, ITO,S.*, FUKUDA,N.* AND TAKENAKA,T. Dept. of Physiol., Yokohama City University, School of Medicine, Yokohama 236, Japan

Dorsal root ganglia with nerve fibers dissected from 3-month-old mice were embedded in a collagen gel.The ganglia were cultured in serum free defined media. Regenerating neurites appeared from nerve cut endings 12 h after in culture.This result shows that neurons could start to regenerate neurites from the ending more quickly than dissociated ones. When ganglia were cultured in a NGF-free medium, average lengths of regenerating neurites were 133±55 um from the short distance nerve cut endings ($d \leq 1$ mm) apart from a ganglion and 106±24 um from the long distance endings ($d > 1$ mm) 24 h after in culture.When the ganglia were cultured in the NGF containig medium (100 ng/ml), the lengths were 174±58 um in the short and 162±98 um in the long 24 h after in culture. The effect of NGF to promote the regeneration were clealy shown from these results.At 96 h after cultured in a NGF containing medium, the average length of neurites from the long distance endings was 575±300 um and 364±176 um from the short.It is said from these results that NGF promotes regeneration more strongly from longer distance nerve endings than short ones.

351.14

PREVENTION OF PRIMARY SENSORY NEURON LOSS FOLLOWING PERIPHERAL NERVE TRANSECTION DOES NOT DEPEND ON AXONAL REGENERATION.
S. Melville, T. E. Sherburn, and R. E. Coggeshall. The Marine Biomedical Institute, Dept. of Anatomy and Neurosciences and Dept. of Phys. and Biophysics, The University of Texas Medical Branch, Galveston, Texas, 77550.

Transection of a major peripheral nerve usually causes the loss of a significant number of sensory cells. The present study shows that placing stumps of a transected nerve in an impermeable tube prevents this loss. We now show that this preservation does not depend on axonal regeneration. In one group of rats, the sciatic nerve was sectioned and left in situ. In another group the stumps, were placed 8 mm apart in an impermeable tube. In a second group the stumps were separated by a 15 mm gap. Thirty days after surgery DRG cells were counted bilaterally. Results show a 27-28% loss of DRG cells after simple sciatic nerve transection, with no loss of cells in the tubed animals. There was a difference in the tubed animals, however, in that regeneration took place with the 8 mm gap but not with the 15 mm gap. We conclude that placing transected rat sciatic nerve stumps in an impermeable tube protects those cells that normally would be lost and this is not dependent upon regeneration of axons. These findings may have clinical significance. Supported by grants NS11255, NS 10161, and NS 07185.

CYTOLOGY OF REGENERATED SENSORY TERMINALS IN ALLOGRAFTED AND AUTOGRAFTED PRIMATE SKIN.
D. D. Samulack, B. L. Munger*, and R. W. Dykes. Dept. of Anatomy, Penn. State Univ., Hershey PA 17033, Dept. of Physiology, McGill Univ., Montreal, Canada H3G 1Y6

The present study was designed to evaluate the regeneration of cutaneous sensory axons into allografted skin in immunosuppressed (cyclosporin and methylprednisolone) baboons. Autografted skin served as a surgical control. Single axons serving grafted skin were identified electrophysiologically at the forearm level and characterized on the basis of receptive fields and adaptive properties at 5-8 mo after grafting. At necropsy skin was prepared for light and electron microscopy. Regenerated axons were smaller in diameter and had a slower conduction velocity. Both rapidly and slowly adapting responses were identified. Meissner corpuscles only infrequently regenerated in all grafted skin and were often abnormally innervated. Normal sensory innervation of hairs was also never observed in all grafted skin. In the case of severe allograft rejection, no papillary ridges or hair follicles were present and few cutaneous nerves could be identified. To date, Merkel cells have not been identified in any allo-grafted specimen. The apparent lack of cytological specialization of sensory terminals in the face of identifiable adaptive properties implicates the axon is the site of mechanoelectric transduction in cutaneous mechanoreceptive afferents.

351.16

A COMPARISON OF CRYOPROBE AND CRUSH LESIONS IN THE RAT SCIATIC NERVE.
J.M. Kerns, B. Braverman*, A.D. Ivankovich*, A. Mathew* and C. Lucchinetti*, Depts. of Anatomy and Anesth., Rush Med. Coll., Chicago, IL 60612.

Cryoanalgesia has been used for pain treatment because the neural damage is limited and reversible. This experimental study examines the sensory, motor, behavioral and structural recovery following two types of nerve lesions. The sciatic nerve in anesthetized rats was frozen (CP) with a Westco Neurostat 1H3E cryoprobe or crushed (C) with forceps for 60 sec. Sensory tests indicated an earlier and improved mean withdrawal time from a heat source during the first month in the CP group. The CP index of motor recovery (digital twitch tension) returned to normal (96%) by 35dpo, but remained subnormal (81%) in the C group. The recovery of locomotion (SFI) was complete and nearly equal in the two groups by 42dpo. There were no significant group differences in the morphometric results at 63dpo; the fiber number increased 10-15% and the fiber size decreased 24-36% compared to the control side. While the functional recovery following a CP lesion may be earlier than a C lesion, the recoveries are nearly identical after two months. Support by NIH N519769 and BRSG 507RR05477 grants

351.17

ELECTRICAL FIELD EFFECTS ON CRUSHED NERVE REGENERATION.
C. Lucchinetti* and J.M. Kerns (SPON: C. Robinson). Dept. Anat., Rush Med. Coll., Chicago, IL 60612.

Previous studies have demonstrated enhanced recovery following the delivery of an electrical field to a transected nerve. This study examines the effects of such fields on the regeneration of crushed rat sciatic nerve during the first month. The treated (T) nerve group received a battery implant delivering 10uA with the cathode distal. The recovery was compared to an untreated (UT) group and unoperated controls (C). The loss of locomotion behavior and partial recovery (SFI) is identical for the T and UT groups. The index of motor recovery (twitch tension) is also similar (T/C=48% and UT/C=53%) by 28dpo. However, a "window" of enhancement occurs 2-4 days earlier in the T group. Qualitative histology at 28dpo suggests some improvement in the T group, but there are no significant group differences for fiber number. Similarily, the mean number of HRP labeled motoneurons is not significantly different (T=1393, UT=1658, C=1746). We conclude that despite an earlier motor recovery in the T group, no group differences in functional or structural recovery are observed at 28dpo. Support by BRSG 507 RR05477 and the Enelow Fund.

351.18

EARLY STAGES OF REGENERATIVE GROWTH OF ADULT RAT CNS AXONS INTO PERIPHERAL NERVE GRAFTS.
G.Campbell, P.N.Anderson*, M.Turnaine* and A.R.Lieberman*. Dept. of Anatomy & Dev. Biol. University College London.

Grafts of peripheral nerve into adult rat thalamus are invaded by large numbers of regenerating axons from thalamic neurons, as shown by retrograde HRP labelling (Bentley et al., J. Neurocytol. 1985; Campbell et al., unpublished). We have investigated early stages of this regenerative growth. Autografts of sciatic nerve were implanted into caudolateral thalamus of anaesthetised rats. The distal, free end was laid beneath the scalp. Between 5d and 4wk later the brains were processed for EM.

A regenerative response in the CNS, characterised by the production of large numbers of axonal sprouts, is well established around the proximal end of the graft by 5d. The sprouts accumulate below the forming glia limitans often in association with glia. Sprouts cross the limitans, many in contact with glial processes, to enter the border zone between host brain and graft tissue. By 8d, regenerating axons are associated with Schwann cells and astrocytes within the graft and at 2-4 wk the proximal portion of the graft contains large numbers of regenerating axons in Schwann cell or Schwann cell-astrocyte bundles. By 4 wk many axons have grown at least 6 mm along the graft. Most regenerating axons, at both proximal and distal levels of the graft, lay in simple contact with Schwann cells: very few were deeply invaginated into Schwann cell processes. Thus the relationship between them resembled that seen in very early stages of PNS regeneration, which may be due to either slow growth of regenerating CNS axons or abnormal axon-Schwann cell interactions.

AN IMPROVED MODEL TO STUDY RAT SCIATIC NERVE REGENERATION. K. Harman, J.C. de la Torre. Physiotherapy Program, Univ. of Ottawa Health Sci., Ottawa, Ont. K1H 8M5.

Quantifying sciatic nerve axons in the regenerated distal stump after transection may be used as an indicator of the nerve's response to a treatment. We have improved our rat nerve guide model and developed a simpler, more quantifiable and efficient axon counting technique. To make the nerve firmer, it is rapidly cooled to 0°C, transected with one stroke of a razor blade, creating an interstump gap of 2.5 mm. A marker is butted against each nerve stump and the gap is filled with collagen matrix (CM). The markers provide an accurate reference to the cut nerve end. Cross-sections 1 um thick are taken 5 mm distal to the transection site. The image of the slide is projected directly onto the digitizing tablet using a camera lucida attachment. An image analyzer computes quantity, density and size of regenerated axons at this site. This approach is being applied to test putative growth promoting factors. This model will also be used in studies with longer observation periods to correlate findings in the distal stump to target muscle reinnervation.

A QUANTITATIVE BIOCHEMICAL ASSAY FOR CATECHOLAMINERGIC NEURITE OUTGROWTH. D.S. Bell,* I.J. Kopin, M.A. Palmatier. HHMI-NIH Research Scholars and CNB, NINDS, Bethesda, MD, 20892.

Catecholaminergic neurons have an uptake and storage mechanism for catecholamines, which is present in neurites. Catecholamine uptake may thereby provide a rapid, quantitative assessment of in vitro neurite outgrowth.

Timed-pregnant Sprague-Dawley rats are euthanized at E-20, according to NIH Animal Care guidelines. Superior cervical ganglia (SCG) are dissected from the fetuses, dissociated, and cultured in serum-free medium with various amounts of NGF. After 24 h in vitro, uptake of ^{3}H-dopamine (DA) is measured. Parallel cultures can be processed for tyrosine hydroxylase (TH) immunocytochemistry.

Low concentrations of NGF are sufficient to support full cell survival for 24 hours with minimal neurite outgrowth. At higher NGF concentrations, DA uptake correlates linearly with increased neurite length. Therefore, dopamine uptake in SCG neurons cultured in serum free medium and low NGF concentrations can provide a quantitative measure of neurite outgrowth. This bioassay is presently being used to characterize and isolate neurite promoting factors from several sources.

CELL LINEAGE AND DETERMINATION III

DIFFERENTIAL CYTOCHROME OXIDASE STAINING OF DEVELOPING QUAIL NEURAL CREST CELLS IN CULTURE. S. Liu*, D.A. Wilcox*, M. Sieber-Blum and M. Wong-Riley (SPON: T. Trusk). Dept. Anatomy & Cellular Biology, Med. College of Wis., Milwaukee, WI 53226.

The neural crest, a transient tissue of the vertebrate embryo, gives rise to sensory neurons, autonomic ganglia, pigment cells, and other cell types. In quail neural crest cell cultures, there are two populations of sensory cells: non-migrating/early-differentiating and early-migrating/late-differentiating (Sieber-Blum, *Science* 243:1608,'88). In order to determine whether these different types of cells undergo changes in energy demands during cell development, cytochrome oxidase (C.O.) histochemistry was performed on day 1(E3) to day 19 cell cultures. At all stages, pigment cells were negative for C.O. staining. However, sensory neuroblasts increased their C.O. activity significantly ($p<0.0001$) with development. By days 12 and 19, the centrally located sensory neuroblasts were well differentiated and were much larger and more C.O. reactive than the priepheral ones ($p<0.0001$). A heterogeneous pattern of C.O. activity also existed among centrally located neuroblasts. We further distinguished sensory and autonomic neuroblasts by immunostaining C.O.-reacted cultures for the stage specific embryonic antigen-1 (SSEA-1) and dopamine-ß-hydroxylase (DBH), respectively. Sensory neuroblasts were dramatically more C.O. reactive than autonomic cells. We conclude that neuronal energy demands increase during development, indicating that functional activity increases with neuronal maturation. Different C.O. activity between the two populations of sensory cells may be due to their different time course of development and/or different level of functional activity. The autonomic neuroblasts have much lower C.O. staining than sensory neurons, suggesting that at least under these culture conditions and time period, developing sensory neurons may have higher spontaneous or synaptic activity than autonomic ones. Supported by USPHS grants NS18122 (MWR) and HD21423 (MSB).

A VITAL DYE ANALYSIS OF TRUNK NEURAL CREST CELL MIGRATION IN MICE. George N. Serbedzija, Scott E. Fraser, and M. Bronner-Fraser. Developmental Biology Center, U.C. Irvine, Ca. 92717

Analysis of neural crest cell migration in the mouse has been difficult due to the lack of reliable cell markers. Recently, we found that injection of DiI into the chick neural tube marks premigratory neural crest cells whose endfeet are in contact with the neural tube (Serbedzija, etal., 1988, Soc. Neurosci. 18:427). Here, we use this appraoch to describe neural crest migratory patterns in the trunk of the mouse. Embryos were removed from the mother between E8 and E10, labelled with DiI, cultured for 12 to 24 hours, and then analyzed at the level of the forelimb. 12 hours after DiI injection into E8 embryos, Labelled cells were observed exclusively in the neural tube. 12 hours after DiI injection into E8.5 embryos, labelled cells were found in the neural tube, in large clusters between the dorsal neural tube and the epidermis, and sparsely within the sclerotome. Embryos injected at E9 and incubated for 12 hours contained numerous DiI-labelled cells between the neural tube and the dermamyotome and in the region of the sympathetic ganglia. When E9 embryos were incubated for 24 hours, DiI-labelled cells were found in both the spinal and sympathetic ganglia. In contrast, embryos labelled at E10 contained DiI-labelled cells only in the spinal ganglia. These findings indicate that trunk neural crest cells in the region of the forelimb: 1) initiate their migration at approximately the 15 somite stage (E8.5), 2) populate their derivatives in a ventral to dorsal order, and 3) appear to be restricted to the rostral portion of each sclerotome. This pattern of neural crest migration closely resembles that previously observed in the avian embryos. (Supported by USPHS HD-25138 and BNS 8608356).

MONOCLONAL ANTIBODY, B-1A11, TO A CELL SURFACE EPITOPE RECOGNIZES A SUBPOPULATION OF EARLY NEURAL CREST CELLS. D.A. Wilcox*, and M. Sieber-Blum (SPON: F.D. Anderson). Department of Anatomy and Cellular Biology, Medical College of Wisconsin, Milwaukee, WI, 53226.

In order to develop a tool for isolating and/or manipulating subpopulations of precursor cells, monoclonal antibodies (mab) were raised against quail neural crest cells. One of them, B-1A11, belongs to the IgG1 subclass and recognizes a trypsin-resistant cell surface epitope on a subset of early neural crest cells in vitro. Positive cells were present in 2 day old cultures. By day 3, about 10% of the neural crest cells within the explant were B-1A11$^+$, whereas in selected areas at the periphery 40-60% were immunoreactive. In older cultures, a subset of sensory neurons, occasional immature pigment cells, and cells resembling nerve supporting cells were immunoreactive, while adrenergic and mature pigment cells did not bind detectable levels of the mab. Using mab against bromodeoxyuridine (BrdU) in day 3 cultures, we determined that during a 2 hr incubation period with BrdU >30% of the B-1A11$^+$ cells were in S-phase. When live, stained cells in primary explants were resuspended and seeded out at clonal density, they reattached and continued to proliferate. The data suggest that B-1A11 recognizes a differentiation antigen and may be useful for analyzing subpopulations of neural crest cells. Supported by USPHS grant HD21423.

Evidence for death of committed neuronal precursors in the developing adrenal gland. P.D. Henion and S.C. Landis. (SPON: V. Lemmon) Center for Neurosciences, Case Western Reserve Univ. Sch. Med.; Cleveland, OH 44106

The sympathoadrenal lineage of the neural crest gives rise to sympathetic neurons and adrenal chromaffin cells. Cell culture studies have raised the possibility that sympathetic neurons and chromaffin cells derive from a bipotential precursor cell population whose fate is determined by the local environment; consistent with this hypothesis, a subpopulation of clustered cells are present in embryonic adrenal which express the neuronal markers SCG-10 and B2 (Anderson and Axel, 1986).

To define further the properties and fate of the neuronal precursor cells, we stained embryonic and postnatal adrenals with antibodies against other neuronal markers and determined the time course of their expression. SCG-10/B2-IR cells express the neural adhesion molecules L1 and NCAM on E15. B2-IR was no longer observed on E18-19 while SCG-10/L1/NCAM-IR clusters of cells were evident until P6-7. To determine whether the disappearance of staining with SCG-10, L1 and NCAM in the first postnatal week was due to the death of neuronal precursors or the loss of expression of these molecules, we examined plastic sections of P0-P7 adrenals. During this period, clusters of cells in the medulla appeared to degenerate. Analysis of P5 adrenals revealed ultrastructural evidence of degeneration including dilated mitochondria, lack of rough endoplasmic reticulum and granular, electron-dense cytoplasm in numerous granule-containing cells. Thus, our observations confirm the existence of a neuronal precursor cell population in the developing adrenal and provide evidence that at least some of these cells die.

352.5

AN ISOLATED MESENCEPHALIC NEURAL CREST SUBPOPULATION DEVELOPS NEURONAL CHARACTERISTICS IN CULTURE. K. F. Barald Dept. Anatomy and Cell Biology, U.Michigan Med. Sch. Ann Arbor, MI 48109.

Although neural crest cells are known to be very responsive to environmental cues during their development, recent evidence indicates that at least some subpopulations may be committed to a specific differentiation program prior to migration. To address this problem, we have isolated a pure subpopulation of chick mesencephalic neural crest cells by no-flow cytometry after labelling them with monoclonal antibodies (Mabs) to a 75kD cell surface antigen associated with high affinity choline uptake. The Mabs also label all of the neurons of the embryonic chick and quail ciliary ganglion (CG) in vivo and in vitro, suggesting that the neural crest subpopulation that labels with these Mabs may be precursors of CG neurons. Pure populations of antigen-positive (A^+) cells were grown in a variety of media, each of which differently affected its characteristics and development. A^+ cells proliferated in 15% fetal bovine serum (FBS) and high concentrations (10-15%) of chick embryo extract, but did not differentiate, although they retained basal levels of choline acetyltransferase (ChAT) activity. However, in chick serum and high (25 mM as opposed to 7mM) K^+, and heart-, iris- or lung-conditioned media, all of which are known to promote survival &/or cholinergic development of CG neurons, the cells ceased to proliferate and "neuron like" cells indistinguishable from cultured CG neurons appeared in the cultures. Neuron-like cells were not found in liver-, notocord- or neural tube-conditioned media if FBS was used. These results are consistent with the hypothesis that the A^+ cells contribute to the formation of embryonic CG neurons.

ONSET AND PATTERNING OF THYROTROPIN RELEASING HORMONE mRNA EXPRESSION IN THE DEVELOPING FROG BRAIN AND RETINA. Y.P. Loh and W.P. Hayes (SPON: E.B. Van Deusen). Laboratory of Developmental Neurobiology, NICHD, Bethesda, MD 20892.

To explore how the initiation of the neuropeptide phenotype is regulated in the vertebrate CNS, the development of thyrotropin releasing hormone (TRH) gene expression was examined in developing Xenopus laevis using *in situ* hybridization. Coronal sections of embryos, as well as of brains and retinae from pre- and post-metamorphic frogs were hybridized with sense and antisense radiolabeled 48-mer oligonucleotides encoding regions of Xenopus TRH mRNA (Richter, K.,et al., EMBO J. 3:617, 1984).

TRH mRNA expressing cells were first detected in discrete regions of the forebrain and hindbrain of the embryonic CNS on developmental day 1.5 (Stage 29/30). This basic pattern of TRH expression was maintained through day 2 (Stage 33/34). Anteriorly, labeling was restricted to a bilaterally paired group of cells in the lateral wall of the diencephalon. Posteriorly, labeling was organized in repeated pairs of laterally positioned clusters in the rhombencephalon. By day 2.5 (Stage 39), the diencephalic labeling was more complex. Each of these bilateral groups, still seen just anterior to the level of the optic stalk, was now extended and bifurcated caudally forming two distinct groups of cells in the dorsal and ventral wall of the infundibulum. The more widely distributed pattern of TRH expressing cells seen in adult frog was found in tadpoles by day 4.5 (Stage 46). This included discrete labeling of retinal cells in the innermost lamina of the inner nuclear layer, indicating they may be amacrine cells.

We are currently investigating whether the adult-like distribution seen by day 4.5 can be accounted for by these two initial groups of TRH expressing cells, or whether the new cells seen in the telencephalon and mesencephalon arise from independent TRH cell groups. (W.P.H. is supported by an Associateship from the National Research Council.)

CLONAL ANALYSIS OF GABAERGIC NEURONS IN FROG EMBRYO SPINAL CORD. S.A. Moody and K.S. Kersey. Department of Anatomy and Cell Biology, University of Virginia, Charlottesville, Va 22908

In the embryonic spinal cord of Xenopus laevis, there are 7 classes of interneurons that express GABA-like immunoreactivity: ascending (**as**), midhindbrain reticulospinal (**mhr**), vestibular commissural (**vc**), rostral hindbrain commissural (**rh**), rostral midbrain (**rm**), optic tract (**ot**) and rostral forebrain (**rf**) (Roberts et al. '87 JCN 261:435). Because Xenopus CNS descends from several embryonic blastomeres(Moody '87 DB 119:560) we tested whether clonal membership is correlated with neurotransmitter phenotype. Single blastomeres of the 16-cell embryo were injected with 10% Texas red-dextran-amine. At late tailbud stages they were fixed, and the entire CNS was processed for indirect immunofluorescence of GABA.

Blastomere V1.1 (see Moody '87 for nomenclature) gives rise to cells in the dorsal spinal cord. None of these were GABAergic. Two specimens had V1.1 progeny in the dorsal part of the rostral forebrain, a few of which were GABAergic. Blastomere V1.2 gives rise to cells in dorsal brain and dorsolateral spinal cord. GABAergic cells in the clone were found sparsely in **rf**, **ot** and **rm**; they were found in great numbers in **mhr** and among the **as** neurons of the spinal cord. Blastomere D1.2 populates dorsolateral brain and ventrolateral spinal cord. Most of the GABAergic neurons of the brain were progeny of this blastomere, but very few GABAergic neurons of the spinal cord descended from it. Blastomere D1.1 gives rise to large regions of the brain and ventral spinal cord. The only GABAergic cells in its clone were occasional cells in the **ot** and ventral forebrain. Thus, GABA expression is not associated with specific blastomeres at this stage. Those that populate lateral regions of the brain and spinal cord produce most of the GABAergic neurons.

352.8

A METHOD FOR DETERMINING EMBRYONIC ORIGINS OF XENOPUS NEUROSECRETORY CELLS. K.M. Conway, NINDS, Bethesda, MD 20892.

The fluorescent dye quinacrine indicates host versus donor origin in chimerae made by grafts between Xenopus laevis and Xenopus borealis frog embryos. Fixatives for use with quinacrine staining (e.g. Carnoy's) impair neuropeptide immunocytochemistry (ICC) used to identify neurosecretory cells. A simple detergent treatment allowed the two protocols to be combined. Brain tissue was immersed in either Carnoy's fix or a paraformaldehyde-picric acid fix used in ICC. A monoclonal antibody (PS-45) which heavily stains mesotocinergic neurons in Xenopus laevis was used in rhodamine labelled ICC. Some slides were then detergent treated (1% Triton-X-100 in phosphate buffered saline (PBS), pH 7.4, overnight). After quinacrine staining, cover slips were mounted with 1:1 glycerol:PBS, pH 4.0. Carnoy's fixed tissue gave strong quinacrine staining, but weak ICC. Tissue fixed for ICC gave strong ICC, but weak quinacrine staining. Detergent treated tissue fixed for ICC gave strong ICC and quinacrine staining with moderate backround. To test this protocol in context, grafts comprising large regions of left anterior neural plate were exchanged between laevis and borealis embryos; these animals were then raised for 4 weeks to swimming tadpole stages (45-47) and processed as described. Individual immunoreactive cells of donor and host origin were identified. This demonstrates the feasibility of future studies using smaller grafts to accurately locate neural plate precursors of neurons with specific peptidergic phenotypes.

352.9

EVIDENCE THAT CELLS EXPRESSING LHRH mRNA IN THE MOUSE ARE DERIVED FROM PROGENITOR CELLS IN THE OLFACTORY PLACODE. S. Wray, P. Grant and H. Gainer, LNC, NINDS, Bethesda, MD 20892

In situ hybridization histochemistry and immunocytochemistry (ICC) were used to study prenatal expression of LHRH cells in the mouse. Cells expressing LHRH mRNA and peptide product were first detected on E11.5 in the olfactory pit (OP). On E12.5, there was a dramatic increase in the number of LHRH cells, with more than 90% located in nasal regions, on 'tracks' extending from the OP to the base of the telencephalon. From E12.5 to E15.5, LHRH cells were detected in a rostral to caudal gradient in forebrain areas. Prior to E12.5, cells expressing LHRH mRNA were not detected in forebrain areas known to contain LHRH cells postnatally. Quantitation of cells expressing LHRH mRNA showed that the number of cells on E12.5 equalled the total number of LHRH cells in postnatal animals. Between E12.5-E15.5, the location of LHRH cells shifted; the number of LHRH cells in the forebrain increased, while the number of LHRH cells in nasal regions decreased. These findings establish that cells first found in the OP and thereafter in forebrain areas produce LHRH mRNA, and confirm the identity of cells detected by ICC. To further examine the ontogeny of the LHRH system, ICC was combined with ^{3}H-thymidine autoradiography to determine when LHRH cells left the mitotic cycle. We show that LHRH neurons exhibit a discrete time of birth, suggesting that they arise as a single neuronal population between E10.0-E11.0. Postnatal LHRH neurons were 'birth-dated' shortly after differentiation of the olfactory placode and before LHRH mRNA was expressed in the OP. These studies support the hypothesis that both nasal and forebrain LHRH cells arise from a discrete group of progenitor cells in the olfactory placode.

FLUORESCENTLY LABELED TISSUES INCLUDING ENDOTHELIUM IN XENOPUS TADPOLES. C.M. Rovainen Dept. Cell Biol. and Physiology, Washington Univ., St. Louis, MO 63110

The goal of this work has been to mark endothelial cells in vivo and to follow their migration, cell divisions, and possible degeneration during angiogenesis in the optic tectum of transparent tadpoles of albino Xenopus laevis. Rhodamine-dextran was injected into single blastomeres, and cell progeny were observed sequentially with epifluorescence and a SIT camera. A variety of cell types and mixtures were labeled, including brain, eye, olfactory sac, cranial ganglia, epidermis, gut, myotomal muscle fibers, extraocular muscles, notochord, and heart. Some clones included circulating fluorescent blood cells and walls of blood vessels. The fluorescent label initially was distributed through the cytoplasm of cells in each clone. Later it was packaged in vesicles. Both forms of label can be followed in case histories of development. These preliminary results indicate that intracellular fluorescent labeling may be a feasible approach for following the behavior of individual endothelial cells during angiogenesis. Supported by USPHS Grant HL41075.

COATED PITS AS A CELLULAR MARKER FOR MUSCLE IN DROSOPHILA WITH THE TEMPERATURE-SENSITIVE MUTATION SHIBIRE. M.R. Hummon and W.J. Costello. Dept. Zool. Biomed. Sci./Col. Osteopathic Med., Ohio University, Athens, OH 45701.

Pupal heat pulse (HP: 30C, 6h) induces abnormal muscle (fused or deleted fibers) in Drosophila bearing the ts mutation shi. In bilateral mosaic flies (+/shi) exposed to pupal HP, each indirect flight muscle (DLM; DVM I; DVM II and III) is normal (+) or exhibits the induced shi phenotype. These mosaic flies can exhibit different phenotypes on a single side, suggesting more than one cell lineage for flight muscle. We tested a phenotype of shi membranes, heat-induced coated pits (CP), for use as a possible cellular marker in the mosaic flies. $In(1)w^{vc}$ (Ring X) females and y w sn^3 shi males were used, to represent genotypes present in mosaic flies. Adults 1-2 days old were exposed to non-permissive temperature (30C) for 20 min., dissected in fix at 30C, and processed for TEM. Identified DLM fibers were scanned (7,000-12,000X) for CP. The perimeter of each fiber is about 500 um and was measured to obtain the number of CP per membrane unit. CP were numerous in shi DLM (12-25/500 um, mean=18.9; 7 fibers from 2 flies); in Ring X DLM, CP were rare (0-2/500 um, mean=0.9; 7 fibers from 2 flies). Thus, the heat-induced occurrence of CP in shi tissue can be an effective marker at the cellular level. Incidence of CP may indicate the genotype of the muscle in mosaics and permit further assessment of cell lineage of DLM and DVM. NIH-NRSA (MRH)

352.12

EXPRESSION OF NEURONAL PHENOTYPE BY THE TE671 CLONAL CELL LINE. H. Anne Ahmad[1,2,*] and Ronald J. Lukas[2] (SPON. D.L. Glanzman). Department of Psychology, Arizona State University, Tempe AZ 85287[1] and Division of Neurobiology, Barrow Neurological Institute, Phoenix AZ 85013[2].

Controversy has evolved regarding the relationship between the TE671 cerebellar medulloblastoma and the RD embryonal rhabdomyosarcoma human clonal cell lines and the expression by the TE671/RD line of glial vs. neuronal character. We have utilized immunocytochemical (IC) and enzyme-linked immunosorbent assay (ELISA) approaches with a variety of monoclonal or monospecific antibodies raised against neuronal or glial proteins to address these issues. By both IC and ELISA criteria, levels of TE671 cellular expression of neuron-specific enolase, neurofilament proteins, and choline acetyltransferase are higher than those for glial fibrillary acid protein and the S-100 antigen, which are labeled at levels marginally above background. Positive IC staining and ELISA results are also observed for TE671 cells labeled with antibodies against vimentin and alpha- and beta-tubulin. Taken together with our other results indicating that TE671 cells adopt a neuronal morphology on treatment with specific drugs, express functional muscarinic and nicotinic receptors, and exhibit specific GABA and choline uptake, the present IC and ELISA results demonstrate that the TE671/RD line expresses at least some characteristics of cells of neuronal lineage.

352.13

EXPRESSION OF GLIAL FIBRILLARY ACIDIC PROTEIN GENE IN IMMATURE OLIGODENDROGLIA IN-VITRO: A CORRELATIVE IMMUNOCYTOCHEMICAL AND IN-SITU HYBRIDIZATION STUDY. B.H. Choi, P. Amodei*, J. Geddes*, M. Suzuki* and R.C. Kim*. University of California at Irvine, Irvine, CA 92717.

In previous studies, we presented evidence to suggest, in the developing human and rodent CNS, that the earliest glial forms within the developing CNS are radially organized; that these cells contain glial fibrillary acidic protein (GFAP); that "transitional" cells possessing the features of both oligodendrocyte (OC) and astrocyte (AS) appear just prior to the onset of myelination; and that these early radially organized glial cells may be the ultimate source of all macroglial cell types including AS, OC and ependymal cells. We have also shown the presence of immature OC that co-express myelin basic protein (MBP) and GFAP in culture. In order to further define this phenomenon, a correlative study was carried out with in-situ hybridization using biotinylated cDNA probe for GFAP (provided by Dr. L. Eng) and single and double immunofluorescent labeling for GFAP, MBP and galactocerebroside (GC) in immature OC (obtained by McCarthy and de Vellis method). The cells that express both AS and OC markers in these cultures with or without addition of serum are identified as early as 5 hours following the isolation of immature OC. Such cells are also found in long term cultures of astrocytes derived from the original mixed glial cell culture maintained in serum containing medium. In-situ hybridization using biotinylated cDNA probe for GFAP demonstrates localization of GFAP gene within the processes and cytoplasms of cells with OC morphology. These data suggest not only a close and dynamic ontogenetic relationship between, but also a common cell lineage for AS and OC.

(Supported in part by NIH grant ES 02928)

NUTRITION AND PRENATAL FACTORS

353.1

PRENATAL DIETARY SUPPLEMENTATION WITH N-3 FATTY ACIDS ACCELERATES EYE-OPENING IN MICE. B.Bulman-Fleming and P.Wainwright. Dept. of Health Studies, Univ. of Waterloo, Waterloo, ON. N2L 3G1.

Evidence from our laboratory suggests that prenatal dietary supplementation with n-3 fatty acids (FA) accelerates sensory development in mice, particularly eye-opening. These results occurred in the context of prenatal ethanol effects, and were therefore accompanied by slight undernutrition. Thus the present study sought to replicate this in a well-fed population and to compare pre- with postnatal supplementation. Pregnant mice were fed either of two liquid diets, each providing 20% of the calories from oil and of these 3% were in the form of n-6 FA. The supplemented group also received 1.8% from n-3 FA. The study consisted of four dietary groups, with all pups fostered at birth. These groups were: (PRE/POST) 1.N3/N3, 2.N3/N6, 3.N6/N6, 4.N6/N3. A fifth group (unfostered) was fed lab chow throughout the study. At day 32 post conception pups were assessed using a standardized battery of tests measuring neurobehavioral development. Prenatal n-3 supplementation resulted in a significant but small acceleration of behavioral development overall; individual tests showed a similar effect on eye-opening. There was no difference in body weight between the n-3 and n-6 groups, but they were heavier than the lab chow group. Despite this, their behavioral development was retarded relative to the lab chow control, with this being less severe in the n-3 group.

353.2

PRENATAL TRYPTOPHAN DIET EFFECT ON RAT DEVELOPMENT FROM WEANING TO ADULT. M.Sakuma, L.M. Hryhorczuk,* Dept. of Biol. Sci., Wayne State Univ., Detroit, MI 48201: Lafayette Clinic, Detroit, MI 48207

The long-lasting effect of tryptophan diet fed during the latter half of pregnancy was investigated by open field behavior of offspring. Pregnant females were placed on a diet containing either 0.03% (F), 0.30% (M) or 3.0% (H) of tryptophan during the second half of pregnancy. Offspring were tested at 3, 6, 10, and 15 weeks for seven items in the open field test. The items included rearing count, rearing latency, corner crouch duration, corner crouch latency, face washing count, face washing latency and defecation. Body weights were also measured. Two-way analysis of variance with repeated measures for diet (F, M, H) and age (3, 6, 10, 15 weeks) revealed that all variables showed an age dependency at $p<0.01$ and only defecation differed with respect to diet ($F=6.515$, $p<0.01$). Defecation has been used as an index of emotionality. Significant diet dependent body weight differences were obtained at 3 weeks ($F=4.256$. $p<0.05$) and 6 weeks ($F=6.231$, $p<0.01$). Although the F diet group recorded the lowest weights and the H diet group the highest weights at 10 and 15 weeks, the differences were not statistically significant. This warrants further investigation with a larger number of animals.

353.3

INOSITOL TRANSPORT IN PC12 CELLS: EFFECTS OF INOSITOL DEPRIVATION. Z.W. Yang, G.A. Paleos, and J.C. Byrd. Developmental Neurobiology Program, University of Pittsburgh School of Medicine, W.P.I.C., Pittsburgh, PA 15213.

Inositol triphosphate (IP_3) is an important second messenger in the mediation of the effects of many growth factors. We have studied the transport of myo-inositol, a precursor of IP_3, in the NGF-responsive cell line PC12. We have found that the PC12 inositol transporter closely resembles the comparable carrier found in non-transformed cells. Specifically, this transporter is saturable; sodium dependent; inhibited by cytochalasin B, phloridzin, and PCMB; and shows a low affinity for D-glucose. PC12 cells survive deprivation of inositol as long as 4 days without showing signs of overt toxicity. However, following this period, there is a marked increase compared to controls in the labeling of cellular membranes following brief exposure to [^{3}H]myo-inositol, indicating a state of intracellular phosphatidylinositol deficiency. Furthermore, the Km of the inositol transporter is decreased from 76 μM to 54 μM, suggesting an ability of these cells to modify the affinity of the inositol transporter during periods of inositol deprivation.

353.4

CHANGES IN CORTICAL EVOKED POTENTIALS FOLLOWING INFANT MALNUTRITION. I.Weiss, A. Barnet*, CHNI, Washington, D.C. J.M.Flinn, R.Holt*, S.Lydick*, George Mason, Fairfax, VA.

Cortical evoked potentials (EPs) were recorded from severely malnourished infants at admission to hospital (group MA), at discharge (group MD), and from age-matched controls (group CA and CD). We report the results of a principal component analysis of the EPs recorded from C_3 and C_4 to patterned flash. Eight factors were identified with eigenvalues > 1. Four rotated factors (1,3,5 and 8) showed significant differences between groups. For factors 1 and 3, the scores of the malnourished infants changed in the same direction as those of the age-matched controls between admission and discharge. E.g., for factor 1 ($F(3,108)=6.93$, $p<.001$) the factor scores significantly increased between admission and discharge: -.477 for MA & +.476 for MD, -.115 for CA and +.348 for CD. In contrast, for factors 5 and 8 the changes in the malnourished group were in the opposite direction from the controls. E.g., for factor 8 ($F(3,108)=4.47$ $p<.05$), the scores were -.072 for MA, -.434 for MD, +.157 for CA and +.544 for CD. MA differed significantly both from MD and CD, which differed significantly from each other. These results show that infant malnutrition appears to impair some aspects of brain development and functioning but not others.

353.5

PRENATAL PROTEIN MALNUTRITION CAUSES INCREASED RESISTANCE TO EXTINCTION OF LEARNED SPATIAL ALTERNATION IN RATS. *J. Tonkiss Ph.D, *J.R. Galler M.D., *R.R. Timm and *R.N. Formica (SPON: O. Resnick, Ph.D). Cntr. Behav. Dev., M921, Boston Univ. School of Med., Boston, MA 02118.

This study formed part of an ongoing project to assess the effects of prenatal protein malnutrition on hippocampal function. Sprague-Dawley rats whose mothers were provided with a low (6%) or adequate (25%) protein diet during pregnancy were fostered at birth to adequately nourished dams, and continued to receive the 25% protein diet after weaning. At 90 days of age, 10 previously undernourished and 12 well-nourished males (each with different biological and foster mothers) were selected for testing of spatial working memory on an elevated T-maze, susceptibility to interference and resistance to extinction. There were no differences between nutritional groups in spatial learning or working memory, and both groups were equally susceptible to the effects of a source of proactive interference. However, rats with histories of prenatal malnutrition required a significantly greater number of days (mean ± SEM:12.2 ± 1.0 versus 9.5 ± 0.8) to eliminate the previously learned response. Although it is clear that complete hippocampal dysfunction did not result from the prenatal treatment, the increased resistance to extinction (often noted in hippocampectomized animals) could indicate one specific dimension of hippocampal dysfunction worthy of further investigation.

LOCOMOTOR ACTIVITY IN SPONTANEOUSLY HYPERTENSIVE RATS (SHR) AND WISTAR KYOTO RATS (WKY) FED LOW PROTEIN DIETS J.T. Earnhardt* and D.J. Mokler (SPON: N. Cross). Dept. Pharmacol., Univ. New England, Biddeford ME 04005.

Protein malnutrition during development alters motor activity and levels of neurotransmitters in the central nervous system. SHR display enhanced motor activity although the effects of changes in dietary protein on this behavior have not been studied. The dams of SHR and WKY were fed a diet of either 8% or 25% casein beginning 7 days postpartum. The 8% casein diet was methionine supplemented and made isocaloric with the 25% casein diet by adjusting carbohydrate. After weaning, animals were fed the diet previously given the respective dams. After six months on the diet, individual animals were placed in plexiglass cages and motor activity was monitored for 30 min. Motor activity in SHR fed 8% casein and housed individually from weaning was higher than 25% SHR, 8% WKY or 25% WKY. Motor activity in SHR and WKY fed 25% casein did not differ. In contrast, 8% casein reduced motor activity in WKY. Clonidine (.03 - 1.0 mg/kg ip) suppressed accommodated motor activity in all groups, although a dose response relationship was not apparent. SHR were more sensitive to the effects of clonidine which were not altered by changes in dietary casein. Thus, motor activity is differentially affected in mature SHR and WKY by reduction of dietary casein. (Supported by NHLB 37738)

PRENATAL PROTEIN MALNUTRITION AFFECTS VIGILANCE STATE MODULATION OF DENTATE RESPONSIVENESS. C.M. Beiswanger*, K. Austin*, J. Bronzino and P.J. Morgane. Worcester Foundation for Experimental Biology, Shrewsbury, Mass. 01545.

The paired-pulse technique was used to assess the effect of prenatal protein malnutrition on vigilance state modulation of responsiveness in the dentate gyrus of adult rats. Pups born to dams on either 25% or 6% casein diet were fostered at birth to females on 25% diet, providing control (25/25) and prenatally malnourished (6/25) groups. Evoked potentials were recorded in the dentate in response to paired stimulus pulses to the perforant path across 4 vigilance states (AW,IW,SWS,REM). The first response (p1) of each pair was used to generate a stimulus-response (S-R) curve. The ratio of the two responses (p2/p1: paired-pulse index or PPI) was used as an indicator of the relative level of inhibitory or facilitatory activity in the dentate. Both 6/25 and 25/25 rats exhibit PPI responses dependent on IPI: early inhibition (20-40 ms), facilitation (40-100 ms) and late inhibition (100-1000 ms). Vigilance state modulation of the PPI is seen in early inhibition in both groups. However, malnutrition abolishes the increase in p1 amplitude in SWS/REM relative to IW/AW seen in 25/25 S-R curves. These results suggest that two systems modulate dentate responsiveness across vigilance states. One affects transmission of signals (S-R curves) and is sensitive to prenatal protein malnutrition. The other affects inhibition/facilitation (PPI), but is not sensitive to prenatal dietary insult. (Support: NIH grants HD-23338 and HD-22539).

EFFECTS OF PRENATAL PROTEIN MALNUTRITION ON KINDLING-INDUCED ENHANCEMENT OF DENTATE GRANULE CELL ACTIVITY. J.D. Bronzino, R.J. Austin-LaFrance, R.J. Franceschini* and P.J. Morgane. Trinity College, Hartford, CT 06106.

Several studies indicate that hippocampal kindling enhances transmission at the level of the perforant path/dentate synapse. Single and paired-pulse stimulations were used to assess the effects of prenatal protein malnutrition on dentate granule cell activity before and after kindling. Animals born to dams fed either a low (6%) or normal (25%) casein diet were fostered at birth to lactating dams of the 25% casein diet. At 90-120 days of age, field potentials evoked by single and paired-pulse stimulation of the perforant path were recorded from the granule cell layer of the dentate gyrus before, during and after kindling. Input/output (I/O) and paired-pulse response measures of EPSP slope, population spike amplitude (PSA) and PSA/slope ratio were analyzed to evaluate the effect of kindling on granule cell response. The prenatal nutritional insult results in a significantly higher degree of synaptic enhancement, as measured by I/O curves, and a significantly higher degree of enhanced granule cell inhibition, as measured by paired-pulse index curves. (Supported by NIH Grant #HD-22539)

EFFECTS OF PROTEIN MALNUTRITION ON THE DENTATE GYRUS IN RATS OF THREE AGE GROUPS. L. Cintra, S. Diaz-Cintra, A. Galvan*, T. Kemper* and P. J. Morgane. Dept. Physiol., Inst. Invest. Biomedicas. UNAM. Mexico D.F. 04510, and Worcester Foundation for Expt. Biology. Shrewsbury, MA 01545.

The hippocampal formation is especially vulnerable to many forms of neuronal insults such as alcohol, heavy metals and various forms of malnutrition. We have studied morphometrically the effects of protein malnutrition (8% casein diet), instituted before mating and continued during gestation and into postnatal life, on the dentate gyrus. Our physiological studies have shown alterations in hippocampal long-term potentiation (Austin et al., 1986) and kindling (Bronzino et al., 1986) produced by protein malnutrition. Using the rapid Golgi method we studied the dentate gyrus in malnourished rats at 30, 90 and 220 days of age. We found a significant reduction in apical dendritic branching in the molecular layer of the dentate gyrus at 90 and 220 days of age as well as a significant reduction in dendritic spines on the outer 2/3 of the apical dendritic tree of dentate granule cells at 30, 90 and 220 days of age. These findings point to a marked effect of protein malnutrition on the molecular layer of the dentate gyrus which may account, in part, for some of the physiological changes we have previously reported following protein malnutrition. QUANTITATIVE STUDY OF DENDRITIC SPINES FROM THE LARGE PYRAMIDAL CORTICAL NEURONS IN SEVERE INFANTILE MALNUTRITION. L. Benitez-Bribiesca*; I. De La Rosa*; R. Freyre* and A. Feria-Velasco (SPON: G. Tapia-Arizmendi). Unidad Inv. Clinica en Enfermedades Oncologicas, I.M.S.S., Mexico, D.F.; Univ. Autonoma de Guadalajara; and Unidad Inv. Biomed. Occte., I.M.S.S., Guadalajara, Jal. MEXICO.

It is known that protein-calorie malnutrition can alter the development of the central nervous system, both in experimental animals and men, provided that it occurs before the brain has completed its full growth. Dendritic spines, the main site of cortical synapsis, are altered in various pathologic conditions, such as Down syndrome and other chromosomal anomalies; likewise those structures are abnormal in senecence and chronic vascular disease. These abnormalities have been linked to the mental deficiency occurring in those conditions. Our objectives were to study the morphology and numerical distribution of spines in the apical dendrite of the V layer-pyramidal cells of the cortex from infants dying of severe malnutrition (SM), 2 to 24 months old and to compare them with a control group of eutrophic infants of similar ages dying of other causes. Material was obtained from fresh autopsies from the pre and retrorolandic areas (PR and RR), as well as occipital cortex (OC); cortical blocks were processed by the rapid impregnation Golgi method. Dendritic spines were counted in 150 µm-thick sections under a light microscope. Apical dendrites were significantly shorter ($p<0.01$) in the SM group. The total number of spines was diminished in the SM group: 33.3% in the PR, 21.7% in the RR and 16% in OC areas in comparison to the control group. Striking anatomical malformations and fusion of dendritic spines were observed. Our results suggest that severe neurological and physiological damage in malnourished infants can be related in part to the deficient synaptic cortical networks and impared brain plasticity that results from abnormal dendritic spine development.

SPINAL TRIGEMINAL PROJECTIONS TO THE MAGNOCELLULAR REGION OF THE MEDIAL GENICULATE NUCLEUS IN RABBITS. P.M. McCabe, J.M. Hitchcock, C.G. Markgraf, M.A. Tucker*, R.W. Winters*, and N. Schneiderman. Dept. of Psychology, University of Miami, Coral Gables, FL 33134.

The magnocellular region of the medial geniculate nucleus (mMGN) has been demonstrated to be important in classically conditioned cardiovascular responses (CRs) to acoustic conditioned stimuli (CS) and shock unconditioned stimuli (US). Lesions of mMGN prevent acquisition and abolish the retention of heart rate CRs. It has been demonstrated that cells in mMGN receive somatosensory as well as auditory input, and therefore may be a site of convergence of CS and US information. In the current paradigm the US consists of periorbital shock, and therefore the US pathway involves trigeminal input. The present study examined the connections from the trigeminal nuclei to mMGN in an attempt to identify the potential US inputs in this paradigm.

New Zealand albino rabbits were injected with either the retrograde fluorescent tracer Fluorogold, or the retrograde/anterograde tracer horseradish peroxidase conjugated with wheat germ agglutinin (HRP-WGA). Injections were given using glass micropipettes (tip o.d. 15-25u) connected to a micro-pressure injection system. Initially, injections (10-30 nl) were placed in mMGN or in nearby control sites. After retrograde labeling was identified in a trigeminal region, HRP-WGA was injected into the labeled region and the anterograde labeling was observed.

Injections were centered in mMGN, but due to spread often included portions of the suprageniculate region, ventral subnucleus of MGN, posterior intralaminar nucleus, and posterior thalamus. Cell body labeling was observed in the contralateral caudal subnucleus of the spinal trigeminal nucleus (ST) about 1-2 mm caudal to obex. These cells were located both in the marginal layer (subnucleus Z) of the caudal subnucleus, and in deeper regions of the same subnucleus. More sparce labeling was also seen in subnuclei interpolaris and oralis of ST. Injections of HRP-WGA into the caudal subnucleus of ST led to anterograde labeling in mMGN, as well as in the ventrobasal thalamus. Currently, studies are being conducted to assess whether this pathway is involved in the relay of US information to mMGN in the classically conditioned heart rate response paradigm. Supported by NS 24874, HL 07426, HL 36588.

354.2

EFFECT OF LESIONS OF THE SPINAL TRIGEMINAL TRACT ON ACQUISITION OF CLASSICALLY CONDITIONED BRADYCARDIA IN THE RABBIT. J.M. Hitchcock, T.L. Reed*, P.M. McCabe, and N. Schneiderman. Dept. of Psychology, University of Miami, Coral Gables, FL, 33124.

The purpose of the present study was to investigate the neural pathway that carries unconditioned stimulus (US) information in the classically conditioned bradycardia response paradigm in the rabbit. Because periorbital shock is used as the US, it was hypothesized that spinal trigeminal (ST) input would be involved.

New Zealand albino rabbits received bilateral electrolytic lesions of the ST tract at the level of the facial nerve or control lesions in surrounding areas. Following recovery from surgery, animals received 30 trials of a tone conditioned stimulus (CS) (560 Hz, 90 dB) paired with the periorbital shock US (0.5 sec, 3 mA). A group of unoperated animals served as pseudoconditioned controls. Comparisons with the pseudoconditioned group demonstrated that the control lesion group exhibited conditioned bradycardia responses (CRs), but the ST tract lesion group did not exhibit CRs. In addition, the ST tract lesion decreased the orienting response (OR) to the first presentation of the tone, and attenuated the initial bradycardiac component of the biphasic unconditioned response (UR).

The present results suggest that the ST tract may be part of the US pathway in this paradigm. Concurrent neuroanatomical studies (McCabe et al., this volume) indicate that the ST has direct projections to the magnocellular region of the medial geniculate nucleus (mMGN), which is part of the CS pathway. Thus, the mMGN may be a site of convergence of CS and US inputs in this paradigm.

Some of the lesion effects in this study may have been due to damage to nearby auditory fibers, so future studies will address this question. Future studies will also investigate the effect of lesions of the caudal subnucleus of the ST, which contains the cells of origin of the projection to the mMGN. These studies may delineate the part of the ST nucleus that carries US information in this paradigm. Supported by NIH grants NS 24874, HL 07426, and HL 36588.

DISRUPTED CLASSICAL EYEBLINK CONDITIONING IN PATIENTS WITH ALZHEIMER'S DISEASE. P.R. Solomon, E. Levine*, T. Bein* and W. W. Pendlebury. Dept. of Psychology, Williams College, Williamstown, MA 01267 and Dept. of Pathology, Univ. of Vermont College of Medicine 05405.

Healthy human subjects ranging in age from 18-85 and patients with Alzheimer's Disease (AD) underwent delay classical conditioning of the eyeblink (EB) response to a tone conditioned stimulus (CS) and a corneal air puff unconditioned stimulus (UCS). In healthy subjects, there was a decline in the percentage of conditioned responses with age that was most pronounced in subjects over age 50. Compared to aged matched controls, AD patients showed a statistically significant further decline. These conditioning deficits could not be attributed to nonassociative factors such as changes in sensitivity to the tone CS or the air puff UCS or to changes in spontaneous blink rate. The results are discussed in terms of using the classically conditioned EB response in humans as a model system for studying age-related deficits in learning and memory.

HIPPOCAMPECTOMY PREVENTS TRACE EYE-BLINK CONDITIONING IN RABBITS. J. R. Moyer, Jr., R. A. Deyo* and J. F. Disterhoft. Dept. of Cell Biology and Anatomy, Northwestern Univ. Med. Sch., Chicago, IL 60611.

Hippocampectomy retards extinction but not acquisition of eye-blink conditioning with a short (300ms) trace interval (Moyer et al., 1988). In the present study, a longer (500ms) trace interval was used to evaluate the effects of hippocampectomy on acquisition of trace eye-blink conditioning.

Young adult male albino rabbits received aspiration lesions of either the hippocampus plus neocortex (n=6), the overlying neocortex only (n=6), or a sham control lesion (n=6). Rabbits were trained (using a trace paradigm employing: a 100ms tone CS, a 500ms trace interval and a 150ms corneal air puff UCS) to a behavioral criterion of 80% CRs or for a maximum of 25 days.

Surgical Condition	Trials to Criterion	Percent CRs 1st day	Percent CRs Last day	Percent SLCRs 1st day	Percent SLCRs Last day
Hippocampals	2000 ± 0	11.9 ± 4.6	22.3 ± 5.27	55.8 ± 13.99	43.3 ± 2.06
Neocorticals	760 ± 140	8.8 ± 2.9	82.7 ± 1.04	22.2 ± 9.4	3.5 ± 1.31
Sham controls	733 ± 112	16.7 ± 5.4	82.7 ± 0.99	27.0 ± 6.78	3.5 ± 1.32

Hippocampectomy resulted in: 1) an inability to acquire the task within the allotted 25 sessions ($F(2,15)=48.997$, $p < .0001$), and 2) a sustained increase in the percentage of "non-adaptive" short-latency CRs (SLCRs) on those trials during which a CR was given. These associative learning deficits occurred in the absence of any significant differences in UCR amplitudes ($F(2,15)=3.395$, n.s.). That is, these were learning rather than non-specific performance deficits. These data suggest that the hippocampus is necessary for establishing the appropriate temporal relationship between the CS and UCS during associative learning.

RESPONSES OF CELLS OF LATERODORSAL AND LATERAL POSTERIOR THALAMUS TO AUDITORY STIMULI BEFORE AND AFTER CONDITIONING OF A PAVLOVIAN EYEBLINK REFLEX. O. Melamed* and C.D. Woody (SPON:M.Jarvik). UCLA Med. Ctr., Los Angeles, CA 90024.

Recordings were made from 586 units of the lateral thalamic nuclei and adjacent regions of cats to determine the response to click CS after conditioning relative to levels in the naive state. The pattern recorded from the laterodorsal and central lateral (intralaminar) nuclei was characterized by increased activity in the period 54-480 ms after the CS with repetitive increases in later periods. The pattern recorded from the lateral posterior and anterior pulvinar nuclei was characterized by increased activity in the period 12-320 ms after the CS. Components of unit activity preceding some components of the CR were found at each area. The blink CRs were produced rapidly by pairing click CS with glabella tap and hypothalamic electrical stimulation (Hirano et al Br Res 1987; 570-10ms ISI). The CR depended on the order and interval of stimulus pairing. We have not yet determined if the changes in unit activity in the above regions are associatively induced, but they appear to support discrimination of a forward paired CS from a backward paired DS of comparable intensity. The magnitude of unit response to click was greater than that to hiss after conditioning. Intracellular recordings from 142 units measured excitability by depolarizing current required to produce spiking: naive 0.84±.44 nA SD, cond. 0.82±.40 nA and resting potentials: naive 55.1±10.5 mV, cond. 55.3±8.8 mV. (Support: NS25510.)

354.6

ANATOMICAL STUDIES OF ANTERIOR AND POSTEROLATERAL THALAMIC REGIONS SUPPORTING CONDITIONING OF A PAVLOVIAN EYEBLINK REFLEX IN CATS. V. Chizhevsky* and C.D. Woody (SPON:W.Wyrwicka). UCLA Med. Ctr., Los Angeles, CA 90024.

Intracellular and extracellular applications of PHA-L (with added current passage) were used to define, anatomically, regions of the thalamus from which unit responses to a click CS were increased after eyeblink conditioning. One area (a) was located anteriorly at the borders of the reticular (R), lateral dorsal (LD), ventroanterior (VA), anteroventral (AV), caudate (Cd) and anterior intralaminar nuclei. Another area (b) included the LD and central lateral (CL) nuclei. A third area (c) was located in the lateral posterior (LP) - anterior pulvinar (Pl) complex.

Within these regions three major types of neurons were identified: 1) medium to large (300-500 um^2) size cells with radially arranged, bushy dendrites; 2) small (150-200 um^2) cells with locally ramifying axons; and 3) various (150-500 um^2) size cells with thick, primary dendrites that gave rise to smaller secondary branches. (Supported by NS25510.)

EXPRESSION OF C-FOS AND PKC IN RAT BRAIN AREAS FOLLOWING SINGLE TRIAL LEARNING. F. Milan*, M.G. Nunzi, A. Negro*, I. Martini*, A. Zanotti* and G. Toffano. Fidia Research Laboratories, 35031 Abano Terme (PD), ITALY

Expression of c-fos proto-oncogene seems to participate in the control of genetic events coupling neuronal activation to information storage. In this study, we investigated c-fos expression in rats after behavioural training in a memory task. Young rats were submitted to the passive avoidance test (PA) and sacrified 1hr after the single learning trial. Sagittal brain sections were processed for in situ hybridization autoradiography of c-fos messenger RNA (mRNA) using a 32P-cDNA probe. In PA animals the hybridization signal was detected in the cerebellum and cortex (frontal and fronto-parietal). C-fos mRNA was not detected in the hippocampus, thus indicating that c-fos expression might be differentially regulated in different areas in relation to behavioural training. In view of the role of protein kinase C (PKC) in mechanisms involved in information transfer and c-fos expression, we further evaluated on the same experimental paradigm the expression of α and β PKC subspecies. While there is no detectable PKCs expression in control rats, both α and β subspecies are expressed in cerebellum and cortex of PA trained animals, their pattern thus overlapping the c-fos expression. Further work is requested to elucidate the biological significance of c-fos expression in memory storage and its relationship with PKCs.

RED NUCLEUS UNIT ACTIVITY DURING TEMPORARY COOLING OF THE CEREBELLAR INTERPOSITUS NUCLEUS IN CLASSICAL CONDITIONING, D.G. Lavond, S.A. Kanzawa*, R.M. Adams* & A.A. Zhang, Department of Psychology, University of Southern California, Los Angeles, CA 90089-1061.

Unilateral lesion of the cerebellar interpositus nucleus (IP) abolishes ipsilateral classical conditioning. The plasticity associated with learning may be localized in the IP or in its afferents. Neural unit recordings of cerebellar afferents may be used to detect surviving activity associated with learning.

In the present study, the IP is temporarily inactivated by cooling using fuel-injected Freon to a probe with a heated shaft and a thermocouple at the tip. This system allows for precise temperature regulation and for long durations of inactivation.

Rabbits were well trained on classical conditioning (108 paired trials per day; the CS is a 1KHz, 85 dB SPL, 350 msec tone coterminating with 2.1 N/cm^2, 100 msec airpuff UCS, and measuring nictitating membrane extension as the CR/UCR). The IP was alternately cooled or allowed to warm to normal temperature while recording from the red nucleus. Results indicate that unit activity and behavior are abolished for the duration of cooling. These results support the observations of Chapman (1988) using local infusion of lidocaine into IP.

SOME PROPERTIES OF TRANSFER OF TRAINING AFTER UNILATERAL CEREBELLAR LESION, S.A. Kanzawa* & D.G. Lavond [SPON: W. McClure], Department of Psychology, University of Southern California, Los Angeles, CA 90089-1061.

Rabbits first trained for classical conditioning on one side then lesioned in the ipsilateral interpositus nucleus show no retention/relearning but quickly learn when switched to contralateral training. Possible explanations are that the memory survives the lesion, that nonspecific memory hastens learning, or that initial learning occurs on both sides.

One group of rabbits was first given unpaired training with CS alone (1 KHz, 85 dB SPL, 348 msec) and UCS alone (2.1 N/cm^2, 98 msec) trials (108/day) for 5 days, lesioned ipsilaterally, then trained with paired trials on the contralateral side. The rabbits took as long or longer to learn than normally, suggesting that nonspecific factors do not account for the savings.

A second group was first given paired conditioning and learned normally, lesioned ipsilaterally, and not retrained ipsilaterally but trained contralaterally instead. There was no evidence of savings.

Savings appears to occur only after specific training after the lesion and does not represent access to a memory that survives the lesion.

ROLE OF THE DORSAL AND VENTRAL COCHLEAR NUCLEI IN THE ACQUISITON AND RETENTION OF CLASSICAL CONDITIONING, A.A. Zhang & D.G. Lavond, Departments of Neurobiology & of Psychology, University of Southern California, Los Angeles, CA 90089-1061.

The purpose of this study was to detect whether the dorsal (DCN) or ventral cochlear nucleus (VCN) differentially conveys the auditory conditioned stimulus (CS) to the cerebellar circuitry known to be essential for classical conditioning of the rabbit nictitating membrane response by making lesions and by monitoring auditory evoked potentials.

In acquisiton groups, we first lesioned either DCN or VCN, and later trained the animals by pairing an auditory CS (352 msec, 85 dB SPL, 40 cycle/sec train of clicks) with an airpuff UCS (100 msec, 2.1 N/cm^2). Lesion of either nucleus alone significantly delays learning.

In retention groups, we first trained the rabbits. Early in training the evoked potentials in both nuclei habituated within each trial; after learning there was less intratrial habituation. We hypothesize this might involve the efferent cochlear bundle. After learning, DCN or VCN were lesioned (with NMDA or electrolytically). Lesions of either nucleus alone does not retard subsequent retraining/relearning.

NEURAL UNIT ACTIVITY IN CEREBELLAR INTERPOSITUS NUCLEUS MODELS CLASSICALLY CONDITIONED EYELID RESPONSES IN THE RAT, R.M. Adams*, A.A. Zhang, & D.G. Lavond (SPON: D. Mitchell). Department of Psychology, University of Southern California, Los Angeles, CA 90089-1061.

In the rabbit, neural unit activity in the cerebellar interpositus nucleus (IP) has been shown to "model" the conditioned nictating membrane response. The present study found that similar activity occurs in the IP of rats during classical eyelid conditioning.

Male hooded rats were prepared with subcutaneous EMG electrodes for recording left eyelid responses and bipolar recording electrodes implanted into the left IP. To help insure proper electrode placement, stimulation current was applied until discrete left eyelid movements were evoked. After one week of recovery, each animal was adapted to the restraining device, then trained to criterion by pairing a white noise CS (350 msec, 85 dB SPL) with a left corneal airpuff UCS (100 msec, 2.1 N/cm^2).

Multiple unit recordings from the left IP revealed the development of activity which paralleled and preceeded the conditioned EMG response. These results suggest that findings regarding the role of the IP in the classical conditioning of rabbits may be generalized to other species.

BILATERAL TRANSFER OF THE RABBIT NICTITATING MEMBRANE RESPONSE UNDER NONASYMPTOTIC UCS SHIFTS. J.C. Greiner*, L.A. Wilson*, and M.M. Patterson. Dept. of Psychology and Coll. of Osteopathic Medicine, Ohio Univ., Athens, OH 45701.

We have examined bilateral conditioned responding (CRs) of the rabbit nictitating membrane reflex to a tone conditioned stimulus (CS) and airpuff unconditioned stimulus (UCS) in a classical conditioning delay procedure. We have found that CRs occur bilaterally, with the level of responding significantly lower in the untrained eye. Also, after conditioning one side to asymptote then moving the UCS to the other eye, the pattern of responding gradually reversed with the now trained eye reaching a high level of CRs and CR frequency in the previously trained eye decreasing (Patterson, Greiner, Hutchins, & Wilson, Neuro Abst., 14:395, 1988; Polenchar, Aluko, Donahue, & Patterson, Neuro Abst., 12:181, 1986). This study determined the pattern of bilateral behavior when the USC was switched prior to asymptotic conditioning. Subjects were given 5 conditioning sessions with the UCS applied to the left eye, 10 sessions with UCS on the right, then 10 sessions with the UCS again on the left. Over the initial 5 sessions the level of CRs for the untrained eye were significantly lower than for the trained eye. After switching the UCS (sessions 6-15), the now trained right eye quickly reached a CR level comparable to initial left eye responding and proceeded to asymptote, while CR percentage dropped dramatically in the left eye. The UCS was then switched to its initial position (sessions 16-25). The CRs for the now trained left eye quickly rose to asymptote while CR level gradually decreased in the untrained eye.

R.F. Thompson and associates have determined the cerebellar dentate/interpositus nuclei to be critical for the formation of the CR (McCormick & Thompson, J. Neurosci., 4:2811, 1984). The present results suggest that learning does not occur independently in both eyes, but that a high degree of communication exists between the dentate/interpositus nuclei of the cerebellar hemispheres.

RECIPROCAL CONNECTIONS BETWEEN RED NUCLEUS AND INTERPOSED CEREBELLAR NUCLEI IN RABBIT REEXAMINED. M.E. Rosenfield* and J.W. Moore. Dept of Psychol, Univ of Mass, Amherst, MA 01003.

Dry WGA-HRP (Sigma L3892) was implanted by pipette into the right cerebellar anterior interpositus nucleus (NIA) of albino rabbits (method of Mori, J., et al, *Brain Res Bull*, 6:19, 1981) and left *in situ* for 43-52 hours before sacrifice with T61. Animals were perfused transcardially (descending aorta clamped) with approximately 2 L of .9% saline followed by 1 L of 10% formalin and then 3 L of 12% sucrose solution at 4 degrees C. Brains were blocked immediately on extraction (saving only the brain stem and cerebellum), placed in 30% sucrose in .1 M phosphate buffer (pH = 7.2), and stored for 24 hours at 4 degrees C for 24 h. Brain stem and cerebellum were embedded in gelatin; frozen sections were cut transversely at 60 μ, mounted on subbed slides, and reacted with tetramethylbenzidine (TMB). In contrast to our previous report (*Soc Neurosci Abstr*, 14:493, 1988), we made large implants of the label into NIA avoiding cerebellar cortex. We observed fiber and terminal labeling of contralateral red nucleus (RN) but virtually no retrograde cell labeling. Retrograde cell labeling was observed in the contralateral dorsal and medial accessory olivary nuclei (cf. Weiss, C., et al, *Soc Neurosci Abstr*, 14:493, 1988). Implantation of the label in cerebellar cortex (e.g., HVI) resulted in retrograde labeling in contralateral RN and inferior olive. These findings extend those of our previous report and also agree with a study of RN-NIA connections in cat by Walberg and Dietrichs (*Brain Res*, 397:73, 1986) which also used the Mori et al procedure of implanting WGA-HRP. They disagree with studies that do not use this technique (e.g., Conde, F., *J Neurosci Meth*, 21:31-43, 1987). The evident absence of a RN-IP projection is relevant for studies of neural circuits underlying classical conditioning of the rabbit nictitating membrane.

PREFERENTIAL INVOLVEMENT OF THE AMYGDALOID COMPLEX IN ONE-TRIAL AVERSIVE COMPARED TO ONE-TRIAL APPETITIVE LEARNING. Larry Cahill and James L. McGaugh, Center for the Neurobiology of Learning and Memory and Dept. Psychobiology, University of California, Irvine.

This study examined the relative involvement of the amygdaloid complex (AC) in aversive and appetitive learning tasks. We attempted to equate the relative difficulty of the two situations by designing tasks for both that could be learned in only one trial. Male Sprague-Dawley rats received either NMDA-induced lesions of the AC or control surgery one week prior to placement on a water deprivation schedule. This schedule reduced and maintained their weight at approximately 85% of normal. The training apparatus was a Y-maze consisting of a darkened start arm, plus one darkened and one illuminated choice arm, with a water spout at the end of the illuminated arm. On each of four successive days, the thirsty rats were placed in the start arm and allowed to search until they found the water spout. The decrease in latency to find the water between the first and second days served as the one-trial appetitive measure. On the third day, footshock was given when the rat licked the drinking spout, and the rat was immediately returned to its home cage. The subsequent increase in drinking latency between days 3 and 4 was used as the one-trial aversive measure. Results from two separate experiments showed that while the AC lesioned rats showed no impairment in the appetitive portion, they were greatly impaired in the aversively motivated task. This direct comparison of performance by the same subjects in both learning situations suggests a preferential involvement of the AC in aversive over appetitive learning.

BILATERAL LESIONS OF THE CENTRAL NUCLEUS OF THE AMYGDALA BLOCK LOUD BACKGROUND NOISE INDUCED STARTLE ENHANCEMENT. S. Campeau* and M. Davis. (SPON: C.A. Sorenson). Dept. of Psychiatry, Yale Univ. Sch. of Med., 34 Park St., New Haven, Ct 06508.

High levels of noise elicit stress-like responses in a variety of species. Lesions of the central nucleus of the amygdala block the ability of various stressors (footshocks, immobilization, loud noise) to alter autonomic, hormonal or behavioral measures of stress. High levels of background noise markedly elevate the amplitude of the startle reflex. It was therefore of interest to examine whether amygdala lesions would block startle facilitation by high levels of background noise. Twenty rats (10 with bilateral lesions of the central nucleus of the amygdala, 5 sham-operated controls, and 5 unoperated controls) were presented with seventy 50-msec startle eliciting air puff stimuli (ISI = 30 sec). After the first 30 stimuli (baseline), an 80-db low frequency background noise was turned on for the rest of the test session. Air puffs rather than noise bursts were used to elicit startle to minimize possible auditory-auditory interactions between background noise and an acoustic startle-eliciting stimulus. Baseline startle response amplitude was comparable across groups, whereas noise enhancement of startle observed in the controls was significantly reduced in amygdala- lesioned animals. These results are consistent with other literature showing that high levels of noise elicit stress-like effects which are dependent upon the central nucleus of the amygdala.

GLUTAMATE IS PRESENT IN MEDIAL GENICULATE BODY NEURONS THAT PROJECT TO LATERAL AMYGDALA AND IN LATERAL AMYGDALA PRESYNAPTIC TERMINALS. C. Farb, J. LeDoux, and T.A. Milner. Div. Neurobiology, Cornell Univ. Med. Coll., NY, NY 10021.

Projections from medial geniculate body (MGB) to lateral amygdala (AL) have been implicated in the classical conditioning of emotional responses to acoustic stimuli. Recent physiological evidence implicates glutamate (Glu) as a transmitter in this pathway. To identify this anatomic substrate, an antibody to hemocyanin-conjugated Glu was localized in the AL using the peroxidase-antiperoxidase method. By light microscopy, Glu-like immunoreactivity (Glu-LI) was in perikarya and varicose processes throughout the AL. By electron microscopy, Glu-LI was in perikarya, dendrites, axons and axon terminals. Terminals with Glu-LI (0.2-1.5 μm) contained numerous small, clear and 1-3 large dense-core vesicles and formed primarily asymmetric junctions on distal (small) dendrites and dendritic spines. To determine the sources of Glu terminals, retrograde transport of WGA-HRP following an injection into the AL was combined with Glu immunocytochemistry. Within the MGB, many cells containing both Glu-LI and retrogradely transported WGA-HRP were present in the medial MGB, posterior intralaminar nucleus, and suprageniculate nucleus. Electron microscopic analysis of the AL following injections of WGA-HRP into the MGB demonstrated that anterogradely labeled terminals were similar in morphology and types of synaptic associations to terminals with Glu-LI. These data suggest that Glu may be the transmitter in the geniculo-amygdala emotional conditioning circuit. (Supported by NIH 18974 and NIMH 38774).

LONG-TERM POTENTIATION (LTP) IN THE LATERAL AMYGDALA (AL) IN RESPONSE TO STIMULATION OF THE MEDIAL GENICULATE BODY (MGB). *C. Clugnet, J.E. LeDoux*, Div. of Neurobiology, Cornell Univ. Med. Coll., NY, NY 10021

Projections from the MGB to AL have been implicated in emotional learning. Recent *in vitro* studies have produced LTP in AL by stimulation of the external capsule. In the present study we examined whether LTP could be produced in AL *in vivo* by stimulation of the MGB. Rats (N=12) were anaesthetized with chloral hydrate (7%, ip) and immobilized with d-Tubocurarine chloride (0.12 mg/kg, iv). Extracellular unit responses were recorded in AL during MGB stimulation. Test pulses were single shocks (500 μsec., 300 to 500 μA, 0.3 Hz). Ten train-stimuli consisting of 30 pulses (bipolar, 2 ms apart, 250 μsec half-width, twice the intensity of the test stimulus) at 400 Hz were delivered at 1 Hz. This was repeated five times, once every 5 min. LTP, measured by extracellular recordings of a population spike, was induced in 6 out of 12 rats. The effect lasted from 20 min. to more than 1 hour. Measures of the maximal amplitude of the evoked population spike (average latency 6 ms) showed increases of 100% to 300% over baseline. In two additional rats, kynurenic acid (0.5 μM, icv), a broad spectrum excitatory amino acid antagonist, suppressed responses to test stimuli for 45-60 min. These studies show that LTP can be induced *in vivo* in lateral amygdala by stimulation of the MGB and that normal transmission in this pathway is mediated by excitatory amino acid receptors. Further studies will examine effects of excitatory amino acid receptor blockade (NMDA and non-NMDA) on LTP. Supported by MH38774 and NYHA.

THE AMYGDALA CENTRAL NUCLEUS AND APPETITIVE PAVLOVIAN CONDITIONING: LESIONS IMPAIR ONE CLASS OF CONDITIONED BEHAVIOR. M. Gallagher, P.W. Graham, and P.C. Holland. Department of Psychology, University of North Carolina, Chapel Hill, NC 27599 and Duke University, Durham, NC 27706.

Rats with bilateral lesions of the amygdala central nucleus (CN) were trained in an appetitive Pavlovian conditioning task. conditioned responses (CRs) that are representative of two classes of behavior were monitored. One type of CR resembled the orienting responses that were elicited by the conditioned stimuli (CSs) prior to pairing with food reinforcement; the other type of CR resembled the behavior elicited by food reinforcement itself. These are referred to as CS-generated and US-generated CRs, respectively. Relative to the control group, the group with CN lesions was impaired in acquisition of CS-generated CRs to both auditory and visual CSs. Orienting responses and habituation to the CSs were, however, comparable for the lesion and control groups. Moreover, the group with CN lesions readily acquired the US-generated CRs. Thus, a specific class of conditioned behavior was impaired by CN damage. Although the effect of CN damage is often characterized as an impairment in fear conditioning, this interpretation cannot account for the present findings. These results, in combination with those of prior investigations, suggest that the CN is part of a neural system which underlies conditioning-dependent potentiation of orienting/alerting behavior.

MEMBRANE COMPOSITION AND CELL SURFACE MACROMOLECULES II

355.1

LOCALIZATION OF THY-1-LIKE IMMUNOREACTIVITY IN THE RAT AND MOUSE TASTE BUD. R. S. Lasher and P. F. Erickson. Depts. of C and S Biology and Medicine, Univ. Colorado Med. Sch., Denver, CO 80262.

Thy-1 is a major cell surface-associated glycoprotein in neurons and some non-neuronal cell types in vertebrates. The objective of this study was to determine whether or not Thy-1 was associated with the sensory cells in mammalian taste buds. Adult rats and Balb/c mice were perfused with 4% paraformaldehyde, and the tongues were sectioned either on a cryotome or vibratome. Sections of rat tongue were incubated with either OX-7, a monoclonal antibody specific for Thy-1.1, or 1,9C, a monoclonal antibody specific for rat Thy-1. Sections of mouse tongue were incubated with a monoclonal anti-Thy-1.2. Binding of primary antibody was visualized using an indirect immunoperoxidase procedure. Controls included omission of the primary antibodies and use of other monoclonals not specific for Thy-1.

In both rats and mice Thy-1-like immunoreactivity was found to be associated with the plasma membranes of cells in taste buds but not of other epithelial cells. It was also associated with nerve fibers within the epithelium and basal region of the taste buds. In addition, intense immunoreactivity was associated with the lamina propria within valate and fungiform papillae and underlying adjacent epithelium which contained taste buds, but it diminished markedly in more lateral regions of lamina propria. Mast cells also were intensely immunoreactive, and often were found in the lamina propria in the region of the taste buds.

As both 1,9C and OX-7 produced the same pattern of immunoreactivity in rats, it is very likely that the results truly reflect the presence of Thy-1 and are not a result of cross-reactivity with the core protein of rat heparan sulfate proteoglycan which shares a single determinant with Thy-1.1 (Greenspan and O'Brien, 1989, *J. Neurogenetics* 5:25). Thus, Thy-1 is associated with cells in both the adult rat and mouse taste bud. This has not been observed for other types of adult mammalian sensory cells, including olfactory epithelium, hair cells, and rods and cones (eg., Terkelsen et al., 1989, *Anat. Embryol.* 179:311). However, it remains to be determined whether (a) Thy-1 is associated with all the cells in a taste bud, (b) it is developmentally regulated, and (c) the Thy-1 associated with the lamina propria underlying the taste buds plays any role either in the development of the papilla or in directing nerve fibers to the site of the papilla during development and regeneration.

355.2

IMMUNOCYTOCHEMICAL LOCALIZATION OF NEURITIC MONOCLONAL ANTIBODY ON THE CELL SURFACE OF CULTURED RAT DORSAL ROOT GANGLIA. G. E. Goode[1], T. Russell[2], and G. H. DeVries[2], Department of Anatomy and Cell Biology, Eastern Virginia Medical School[1], Norfolk, VA 23501, and Department of Biochemistry and Molecular Biophysics, Medical College of Virginia[2], Richmond, Virginia 23298.

The objective of this study is to test several monoclonal antibodies raised against cultured rat dorsal root ganglion cells for their specificity to surface antigens of cultured neurons, cultured Schwann cells and fibroblasts. Two-week cultures of rat dorsal root ganglion cells, one week cultures of Schwann cells, fibroblasts, and mixed cultures of all three were grown, fixed and immunoreacted in twenty-four well plastic dishes and examined at the light and ultrastructural levels. Four of nine neuritic monoclonal antisera were specific for surface antigens on dorsal root ganglia cell bodies, their neurites and appendages. Electron dense reaction produce (DAB) was most concentrated in associated with neurites and their multivesiculated beaded enlargements. Two of the nine antisera reacted with surface antigen on Schwann cells, but not fibroblasts. A neuron specific antibody will be used to quantify the membrane of neuronal origin derived from axolemma membrane fractionations. Supported by NIH grant NS10821 and National Multiple Sclerosis Society grant RG1818.

355.3

ULTRASTRUCTURAL EXAMINATION OF TOR 23 BINDING IN THE RAT CORTEX AND ANTERIOR PITUITARY E.N. Garrett*, J.M. Kuby*, and P.D. Kushner, ALS Res Center, Pacific Presbyterian Medical Center, San Francisco, CA 94115

The monoclonal antibody *Tor* 23 binds the apparent surface of a subset of neurons in the rat CNS (J. Neurosci. 8: 3035, 1988). We have used pre- and post-embedding techniques for TEM examination. Pre-embedding immunoperoxidase localization confirmed that *Tor* 23 binds the external membranous surface of rare somata in the cortex. At the soma surface *Tor* 23 staining is associated with many but not all neighboring structures, including synapses. Other stained structures in the gray matter are synaptic profiles and fine, unmyelinated processes. An interpretation of the pattern of stain around the soma is that *Tor* 23 stains a soma's environment. Interestingly, *Tor* 23 also binds the cytoplasm of a subset of gonadotrophs (Neurosci. Abs. XIV: 442. 1988). Post-embedding immunogold colocalization of *Tor* 23 and luteinizing hormone (LH) revealed that *Tor* 23 localizes to secretory granules that contain LH. This result suggests that like LH, *Tor* 23 antigen of the pituitary may be secreted. One interpretation of the selective binding specificity of *Tor* 23 in the cortex on rare neurons and in the pituitary within secretory granules is that *Tor* 23 antigen is a secreted molecule with a neurocommunicative function. Funded by the ALS and Neuromuscular Research Foundation and the Department of Health Services, State of California.

TOR ANTIBODIES BIND SK-N-SH CELLS P.D. Kushner, D. T. Stephenson, E. N. Garrett*, S. Wright* and K. Eagle*. ALS Res. Center, Pacific Presbyt. Med. Center, San Francisco, CA 94115

An important complement to the investigation of novel molecules is a cell line that expresses these molecules. We are using a collection of monoclonal antibodies (MAbs) made to nerve terminals of the electromotor organ of the Torpedo ray (designated *Tor*) to investigate potentially novel neuronal surface molecules. In the present study we report that the human neuroblastoma cell line, SK-N-SH, binds many *Tor* MAbs. SK-N-SH cultures express two cell phenotypes: a small spiny (neuronal) cell and a larger epitheloid-like (flat) cell. Both cells have some biochemical properties of neurons in the undifferentiated state and can interconvert spontaneously. Conditions of differentiation reduce cell division and induce the neuronal cells to have elaborate processes. Differentiated with DMSO, cultures have no flat cells. Differentiated with retinoic acid (RA), cultures are a mixture of flat cells below and neuronal cells on top. Viewed with scanning electron microscopy, neuronal cells have smooth limiting membranes and long, extended processes that branch at defined points and frequently end in growth cones. In RA treated cultures, the neuronal cells express membrane associated acetylcholin-esterase and bind *Tor* 23, a *Tor* MAb of special interest (J. Neurosci. 8:3035, 1988). In conclusion, differentiated SK-N-SH cultures are a system for in vitro expression of *Tor* antigens. Supported by the ALS Association and the ALS and Neuromuscular Research Foundation (San Francisco).

GLIAL HYALURONATE-BINDING PROTEIN (GHAP) IS BOUND TO HYALURONATE IN VIVO. R. Asher* and A. Bignami. Harvard Medical School and VA Medical Center, Boston, MA 02132.

Glial hyaluronate-binding protein (GHAP) is a CNS-specific glycoprotein of 60 Kd known to bind hyaluronate (HA) in vitro. This latter property formed the basis of its isolation from human white matter (Perides et al., J. Biol. Chem. 264:5981, 1989). Frozen sections of human and dog spinal cord were digested with Streptomyces hyaluronidase in order to determine whether or not GHAP is bound to HA in vivo. Digestion with Streptomyces hyaluronidase prior to conventional staining by indirect immunofluorescence led to a pronounced reduction in the intensity of the staining reaction. Similarly, the protein could be released into the soluble fraction of brain homogenates by hyaluronidase. In these extracts, however, the immunoreactive band was 70 kd rather than 60 kd as purified human GHAP. This band was not detected in identical brain homogenates lacking the enzyme. Also, hyaluronidase digestion had no effect on purified GHAP. In conjunction with immunoelectronmicroscopy showing an extracellular localization of GHAP (Vanderhaeghen et al., in preparation), the finding suggests that a GHAP-HA complex forms the matrix of brain white matter. Supported by NIH grant NS 13034 and the Veterans Administration.

ABSENCE OF BRAIN SPECTRIN(240/235) IN DENDRITES OF MAMMALIAN BRAIN. S.R. Goodman and I.S. Zagon. Dept. Structural and Cellular Biology, Univ. South Alabama, Mobile, AL 36688 and Dept. Anatomy, Penn. State Univ. Coll. Med., Hershey, PA 17033.

The discovery of non-erythroid spectrin by our laboratory has led to the identification of at least 2 isoforms: brain spectrin(240/235) located in neuronal cell bodies and axons, and brain spectrin(240/235E) located in neural cell bodies and dendrites. Recently Ivy et al. (*Synapse* 2:329, 1988) has reported the presence of brain spectrin(240/235) in Purkinje cell dendrites if tissues were fixed in 4% paraformaldehyde. In experiments examining Ivy et al.'s report, we have utilized rat brain perfused with and without 4% paraformaldehyde, and sections stained with brain spectrin(240/235); both peroxidase and rhodamine served to visualize the primary antibody. Our results reveal *no staining of dendrites* in tissues perfused with and without 4% paraformaldehyde, but neuronal cell bodies and axons were immunoreactive in both preparations. These results confirm earlier light (Riederer et al., *J. Cell Biol.* 102:2088, 1986) and electron (Zagon et al., *J. Neurosci.* 6:2977, 1986) microscopic studies demonstrating that brain spectrin(240/235) is a compartment-specific isoform of spectrin which is enriched in axons and cell bodies but is not present in dendrites.

Supported by NIH Grant NS-21246.

BIOCHEMICAL MICROHETEROGENEITY OF Cat-301 AND VC1.1 HIGH MOLECULAR WEIGHT ANTIGENS Sam Zaremba[1] Janice Naegele,[2] Dan Geschwind,[1] Colin Barnstable,[2] and Susan Hockfield[1]. [1]Section of Neuroanatomy and [2]Department of Ophthalmology, Yale University School of Medicine.

Monoclonal antibodies Cat-301 and VC1.1 have previously been shown to recognize surface antigens on subsets of mammalian CNS neurons. A 680 kd chondroitin sulfate proteoglycan is responsible for the surface staining by Cat-301 (Zaremba et al., Neuron 2:1207). Three polypeptide bands, of MW 95-105, 140 and 170 kd, were reported to react with VC1.1 (Arimatsu, et al.,J Neurosc 7:1250). We now report that VC1.1 also recognizes a 700 kd antigen. Experiments indicate that Cat-301 and VC1.1 recognize distinct epitopes on partially overlapping sets of high molecular weight (HMW) molecules: (i) Cat-301 immunoprecipitates contain VC1.1 immunoreactivity (and vice versa); (ii) following precipitation to apparent depletion with Cat-301, VC1.1 immunoreactivity remains (and vice versa). The biochemical diversity in these HMW antigens is consistent with immunocytochemical results. Double label immunocytochemistry demonstrates the presence of three different populations of antibody-positive neurons in various CNS regions: Cat-301$^+$/VC1.1$^+$, Cat-301$^+$/VC1.1$^-$, and Cat-301$^-$/VC1.1$^+$. The Cat-301$^+$/VC1.1$^+$ neurons may carry either a single proteoglycan with both epitopes or independent molecules, each with one or the other epitope. These results raise the possibility that these HMW antigens are members of a family of surface molecules unique to particular neuronal subsets.

355.8

BIOCHEMICAL ANALYSIS OF CORTICAL CELL SURFACE MOLECULES RECOGNIZED BY ANTIBODIES VC1.1 and VC5.1
C. J. Barnstable and J. R. Naegele (SPON. W.H. Miller) Department of Ophthalmology, Yale University School of Medicine, PO Box 3333, New Haven, CT 06510.

The surfaces of subpopulations of CNS neurons are stained by monoclonal antibodies VC1.1 and VC5.1. In cerebral cortex, these correspond to identified subpopulations of GABAergic interneurons. Each antibody recognizes a limited number of different polypeptides. We have now investigated the biochemical nature of these polypeptides.

Deglycosylation of cat cortex membranes with N-glycanase abolished VC1.1 immunoreactivity on Western blots indicating that this epitope is part of an N-linked carbohydrate. Neither the intensity nor the mobility of VC5.1 polypeptides was altered by this treatment.

Species and developmental comparisons of VC1.1 staining on tissue sections and Western blots suggested that the 95-105 kD band recognized by this antibody probably corresponds to a myelin associated molecule such as MAG.

Two other VC1.1 immunoreactive bands with M_r 130-140 kD and 160-170 kD also reacted with a monoclonal antibody against N-CAM polypeptides (5D12). Higher molecular weight VC1.1 immunoreactive bands may include some of the 680 kD chondroitin sulphate proteoglycan also recognized by antibody Cat-301 (see Zaremba et al., this meeting).

Our results demonstrate that specific CNS cell types can create unique cell surface molecular arrays by controlling the carbohydrates expressed on common polypeptide backbones.

355.9

DISTRIBUTION OF PEANUT AGGLUTININ (PNA) BINDING MOLECULES AT DENERVATED NEUROMUSCULAR JUNCTIONS IN FROGS. T.Somasekhar* C.-P.Ko Dept. Biol. Sci., Univ. So. Calif., Los Angeles CA 90089.

PNA selectively binds to glycoconjugate(s) in the extracellular matrix at neuromuscular junctions (NMJs) and myotendinous junctions (MTJs) in the frog. To examine whether innervation plays any role in the distribution of PNA binding molecules, denervated skeletal muscles of the frog (R.pipiens) were double-stained with rhodamine-PNA and FITC-α-Bungarotoxin. Short-term denervation (1-4 wks) does not affect PNA binding at either NMJs or at MTJs. There was no increase in PNA staining at extrajunctional sites of the muscle, even after 5 months of chronic denervation. However, long-term denervation (3-5 months) results in significant loss of PNA staining at NMJs but not at MTJs. Electron microscopy of long-term denervated muscles shows the absence or depletion of HRP-PNA reaction products at NMJs. HRP reaction products are completely absent at NMJs lacking both nerve terminal and Schwann cell but are present at denervated junctions with persisting Schwann cells. Thus, while denervation does not have an immediate effect, Schwann cells may have a role in the long-term maintenance of PNA-binding molecules at neuromuscular junctions.

355.10

A COMPARISON OF TENASCIN AND PEANUT AGGLUTIN- BINDING MOLECULE (PNA-BM) DISTRIBUTIONS IN FROG SKELETAL MUSCLES. C.-P. Ko, T. Somasekhar*, D.B. Folsom*, & C.-M. Chuong[1]. Dept. Biol. Sci., [1] Dept. Pathol., Univ. So. Calif., Los Angeles CA 90089

Tenascin (J1; cytotactin) is an extracellular matrix molecule found at myotendinous junctions (MTJs) and some neuromuscular junctions (NMJs) (see Sanes, 1989, Ann. Rev. Neurosci. 12:491). We have shown that PNA selectively stains NMJs and MTJs in frogs (Ko, 1987, J. Neurocytol. 16:567). To study if PNA-BMs are related to tenascin and to examine the role of tenascin at NMJs, normal and denervated (1-2 mos.) muscles of frog and developing tadpole muscles were double-stained with fluorescently tagged anti-tenascin antibodies and PNA. In normal frog muscles, tenascin stains MTJs well but only faintly stains some NMJs, as compared with intense PNA staining of all MTJs and NMJs. In denervated muscles, more than 50% of NMJs were brightly stained with anti-tenascin; PNA staining was unchanged. The interstitial areas near denervated junctions were also labelled with anti-tenascin, but no PNA staining was seen. In tadpole muscles, both NMJs and MTJs were stained clearly with both anti-tenascin and PNA. Results suggest that tenascin is not identical to PNA-binding molecules in frog muscles. Furthermore, tenascin distribution at NMJs is related to the state of innervation and development.

355.11

THE DEGRADATION RATES OF TWO CLASSES OF ACETYLCHOLINE RECEPTORS DIFFER IN RESPONSE TO REINNERVATION. S.-L. Shyng* and M.M. Salpeter, Neurobiology & Behavior, Cornell University, Ithaca, NY 14853.

This study compares the responses of two classes of junctional acetylcholine receptors (AChRs) to reinnervation. The two classes are: AChRs which are predominantly synthesized before muscle denervation (referred to as original or slow AChRs), and AChRs which are predominantly synthesized after denervation (referred to as new or fast AChRs). It has been shown in the mouse sternomastoid muscle that the degradation half life (t1/2) of the original AChR decreases after denervation from ~8d to ~3d (Levitt & Salpeter, Nature, 291:239, 1981) and reverts back to ~8d after reinnervation (Salpeter et al., J. Cell Biol., 103:1399, 1986). The new AChRs, on the other hand, have a t1/2 of ~1d (Shyng & Salpeter, J. Cell Biol.,108:647, 1989).

The present study investigates the response of the new (or fast) AChRs to reinnervation. Mouse sternomastoid muscles were denervated by nerve crush and the denervation was maintained by recrushing the nerve every second day for 14 days. All junctional AChRs were inactivated with non-radioactive α-bungarotoxin (BGT) 4 days after the first crush. Newly inserted AChRs were labeled with ^{125}I-α-BGT two days after the last crush. Experimental nerves regenerated 3 to 6 days after the last crush while the control nerves were cut and ligated to prevent regeneration. We found that unlike the original AChRs, once the new AChRs have been inserted into the postsynaptic membrane, their degradation rate (t1/2~1d) does not change in response to reinnervation. The control degradation curve also indicates that although the vast majority (>90%) of AChRs synthesized in denervated muscle are fast AChRs having a t1/2 of ~1d, there may be a small component (<10%) that has a t1/2 of ~3-4d and thus may be slow AChRs. We suggest that innervation and denervation may regulate the ratio of original (or slow) and new (or fast) AChRs that are synthesized, and that the structure of these two classes of AChRs determine whether, once in the postsynaptic membrane, they can further respond to the nerve by modifying their degradation rates.

DIFFERENTIAL EXTRACTION OF AXONALLY TRANSPORTED PROTEOGLYCANS, J.S. Elam, Florida State University, Tallahassee, FL 32306

This study was designed to differentially solubilize axonally transported proteoglycans by a sequence of extractions that would infer their relationship to nerve terminal membranes. Groups of 15-20 goldfish were injected in one eye with 100 μCi of $^{35}SO_4$ and contralateral optic tecta removed and pooled 16 h later. Tecta were homogenized in 0.25 M sucrose containing protease inhibitors and 1 mM sodium phosphate pH 7.4. Following centrifugation at 100,000 xg for 1 h, the particulate fraction was sequentially suspended and re-centrifuged in (i) homogenization buffer lacking sucrose (lysis wash), (ii) homogenization buffer containing 1 M NaCl, and (iii) homogenization buffer containing 1% Triton-X100 or homogenization buffer containing 1% Triton X100 - 1 M NaCl. Populations of proteoglycans in each fraction were isolated on DEAE ion exchange columns. Results showed that the distribution of transported proteoglycan $^{35}SO_4$ was: original supernatant 24%, lysis wash 15%, 1 M NaCl wash 12%, Triton wash 7% or Triton-NaCl wash 46%, unsolubilized after triton-NaCl 3%. The solubilization pattern obtained suggests that axonally transported proteoglycans are approximately 39% soluble or loosely attached to membrane (original sup+lysis wash), 12% extrinsic membrane proteins (NaCl wash) 7% integral membrane (Triton wash) and 39% integral membrane with salt perturbable attachments [e.g., to cytoskeleton] (Triton-NaCl minus Triton).

355.13

REGULATION OF GLYCOLIPID SYNTHETIC ENZYMES DURING MYOGENESIS IN VITRO. L.D. Cambron* and K.C. Leskawa* (SPON: J. Porter). Dept. of Anatomical Sciences and Neurobiology, University of Louisville, Louisville, KY 40292

During myoblast differentiation in vitro there is a transient increased synthesis of total neutral glycolipids and/or gangliosides during contact and membrane fusion (Leskawa and Hogan, J. Neurochem. 49S:59B, 1987). Using [^{3}H]-Ser as a precursor, clonal murine myoblasts (E63) showed similar increased synthesis during fusion. To better understand regulatory mechanisms involved, glycosyltransferases were assayed during myogenesis. Certain enzyme activities were maximal during myoblast membrane fusion, including GlcCer synthase (GlcT) and GM3 synthase (SAT-1), which then decreased in myotubes. Others sharply increased at cell contact and then decreased during fusion (LacCer synthase (GalT-2) and $LcOse_3Cer$ synthase (GlcNAcT-1)). In contrast, $GbOse_3Cer$ synthase (GalT-6) gradually increased as myotubes formed. Fusion-defective varients (fu-1), cloned from the same parental line (L8), showed similar changes with two exceptions: the contact-related increase in LacCer synthase was absent and GM3 synthase increased 2 days earlier than that seen with E63 cells. The results support suggestions that LacCer is involved in cell contact and that ganglio series structures are minor components in muscle, and further demonstrate that glycolipid synthesis is under complex regulation during differentiation. Supported by NIH grant NS 21057.

355.14

ANTIBODY AND COMPLEMENT MEDIATED DEMYELINATION OF DORSAL ROOT GANGLION CULTURES REQUIRES TERMINAL COMPLEMENT COMPLEXES. S.MANE* and C.KOSKI* (SPON:G.BERGEY.)UNIVERSITY ofMARYLAND SCHOOL of MEDICINE,Baltimore,MD,21201.

In the present work we examined whether terminal complexes of the complement cascade(TCC) were required for in vitro demyelination of dissociated rodent dorsal root ganglion(DRG)myelinated by rodent Schwann cells,by anti-peripheral myelin antibody(anti PNM Ab) from patients with Guillain Barre' Syndrome(GBS). IgM from an acute phase GBS plasma(anti PNM Ab titre,84U/ml),diluted 10-fold in media containing 50μg/ml ascorbic acid was incubated with sets of comparable myelinated DRG cultures in the presence of 20% normal human serum depleted of complement component C7 (C7D-NHS), C7D-NHS+C7, heat-inactivated C7D-NHS+C7 or C7D-NHS in the absence of IgM anti PNM Ab. Demyelination was quantitated by counting damaged and intact myelin segments in 20 high power fields of gluteraldehyde-fixed,Sudan Black stained cultures. Only treatment of cultures with IgM+C7D-NHS+C7 resulted in maximum damage,52.7%,of myelin segments which was significantly greater than the 12-18%seen with C7D-NHS without C7(to inhibit TCC formation),in the absence of Ab, when heat-inactivated C7D-NHS was used to prevent activation of the early complement cascade, or with the media alone.

In summary, our work suggests that the formation of TCC is required for Ab and complement mediated demyelination of this in vitro system.This may be an important mechanism involved in demyelination seen in GBS.

MONOCLONAL ANTIBODIES DEVELOPED AGAINST MEMBRANE PROTEINS ALTER THE GROWTH OF CULTURED ASTROCYTES. E.E. Geisert, Jr. Department of Cell Biology and Anatomy, Neurobiology Research Center, University of Alabama at Birmingham Medical Center, Birmingham, AL 35294.

In previous studies, a rabbit polyclonal antiserum developed against dissected rat brain white matter was found to alter the growth of cultured neonatal rat astrocytes. There was a dramatic decrease in the mitotic activity of the cells and type 2 astrocytes developed long highly branched processes. To begin defining the antigens responsible for these effects, antibodies were affinity purified from western blots of white matter membrane proteins. Antibodies pulled from proteins ranging in molecular weight from approximately 100 kDa to 160 kDa had similar effects as the original antiserum. These affinity isolated antibodies cross reacted with proteins outside the molecular weight range from which they were isolated. Thus, it was not possible to define a specific antigen responsible for the altered growth of cultured astrocytes using this method. Once the molecular weight range of the antigens was defined, monoclonal antibodies were developed against astrocytic membrane proteins within this molecular weight range. The cell lines resulting from seven fusions were screened for their abilities to bind to living astrocytes and then for their abilities to alter astrocytic growth. This report defines the effects of two of the monoclonal antibodies produced (AMP1 and AMP2). When cultured astrocytes were treated with both of these monoclonal antibodies, the effect was similar to that observed with the original anti-white matter antiserum. On western blots AMP1 stains a band at 120 kDa and AMP2 stains a protein at 190 kDa. Both of these antibodies stain the external surface of cultured astrocytes. Supported by PHS grant NS23613 and the Whitehall Foundation.

EFFECT OF EXOGENOUS FATTY ACIDS ON MUSCARINIC ACETYLCHOLINE RECEPTORS IN THE NEUROBLASTOMA-GLIOMA HYBRID NG108-15 CELL CULTURE. P. RAY* and W. MIDDLETON* (SPON: J.V. WADE). Dept. of Biol., Div. of Exptl. Theraps., Walter Reed Army Institute of Research, Wash. DC 20307-5100.

The clonal neuroblastoma-glioma hybrid NG108-15 cell line was used to investigate changes in ligand binding of muscarinic acetylcholine receptors (mAChRs) due to addition of fatty acids into the growth medium. Levels of mAChRs were monitored by binding of [^{3}H]-quinuclidinyl benzilate ([^{3}H]QNB) in cell homogenate. Culturing NG108-15 cells for 4-5 days in medium containing unusual proportions (40-80 uM) of polyunsaturated fatty acids (arachidonic, linolenic, linoleic) caused a concentration-dependent decrease (40-70%) in total cellular mAChRs. Upon withdrawal of fatty acids from the medium, the concentration of receptors returned to control levels. Treatment of cells with the antilysosomal agent NH_4Cl (5 mM) along with the fatty acids blocked the decrease of mAChRs. We hypothesize that under the experimental conditions the polyunsaturated fatty acids are incorporated into the cell membrane increasing its fluidity and thereby facilitating the transport of mAChRs to their degradation sites in the lysosomes.

THERMOGENIC RESPONSES FOLLOWING ADRENALECTOMY IN GENETICALLY LEAN AND OBESE MICE. Cheryl Chancellor-Freeland*, P. Dubuc* and H. Carlisle. (Spon. H. Carlisle). Dept. of Psychology, University of California, Santa Barbara, CA 93106.

Adrenalectomy reverses obesity in genetically obese mice (ob/ob) presumably by correcting deficient energy expenditure. Recent work, however, suggests that adx alone is not sufficient to restore normal energy expenditure, but that dietary restriction must accompany adx. In the present study, obese-adx, obese-intact and lean-intact mice were maintained on a 2.6g/day diet and were then tested in a gradient layer calorimeter for 2 hrs at 5 C to determine whether heat production (O_2 consumption) as well as heat loss were normal.

Contrary to predictions, results did not indicate improved thermogenesis following adx in obese mice. Moreover, there were no significant differences between groups. A follow-up test, however, indicates that both obese-intact and obese-adx groups show higher levels of heat production in the afternoon (12 noon-4 pm) relative to the morning (7-11:30am). Lean mice, on the other hand, seem to generate heat at a constant level independent of a circadian influence.

356.2

RESPONSE OF THE NEURONS OF THE GLOBUS PALLIDUM TO GASTRIC DISTENTION AND EMPTYING. F. Vázquez-Pereyra* and E. Tirado Casique*. (SPON: J.A. Roig). Dept. of Physiology, School of Medicine, U.N.A.M., Apdo. Postal 70-250, 04510 México.

In a previous work, aphagia and adipsia were observed in cats after surgical implantation of chronic electrodes in the globus pallidum (GP). Other authors have reported deaths caused by aphagia and adipsia secondary to bilateral lesions of the GP in rats. These data suggest that the GP might be involved in the behavior oriented towards food ingestion. To dilucidate if the GP receives information about the degree of gastric distention we performed a series of experiments in 9 cats anesthetized with urethane. The unitary activity of the GP was recorded for control and during distention and emptying of the stomach. The recorded activity was plotted as frequency histograms. Of the 39 recorded units, 23 responded to either or both maneuvers; 74% responded to both, distention and emptying of the stomach, and the other 24% responded only to either one. These results support the suggestion that the GP is involved in the processing of the information generated by the degree of gastric distention.

356.3

EFFECT OF NEUROPEPTIDE Y (NPY) ON FOOD INTAKE IN FASTED RATS AND SITE OF ACTION. R.R. Schick, V. Schusdziarra*, B. Mertens*, Ch. Nussbaumer*, M. Classen*, Dept. of Internal Medicine II, Technical Univ. of Munich, D-8000, F.R.G.

Central administration of NPY induces food intake in satiated animals and this effect is mediated by hypothalamic sites. Little is known, however, about the effect and site of action in fasted animals. To examine this further, rats were fitted with brain cannulae aimed at the lateral ventricle (ICV; N=8), the ventromedial (VMH) and lateral hypothalamus (LH) (N=44). After recovery, 24-hr fasted rats were injected with either NPY (10µg/10µl ICV; 1µg/0.5µl tissue) or saline and food intake (F) was recorded. Results: During ICV saline F was 5.9 ± 0.4 g (0-60 min) and 8.3 ± 0.6 g (0-120 min), which was significantly augmented by ICV NPY to 8.7 ± 0.9 g and 14.4 ± 1.5 g ($p<0.05$). This increase in F was due to a 2-fold increase in the time period spent with feeding. Following intracerebral injection of NPY, in 50 % of the histologically identified LH and VMH sites an increase in F (≥20%) was observed (10/20 LH; 5/11 VMH sites). This was statistically not significant, however. Mean F 0-60 min was 4.6 g vs. 3.9 g (LH) and 6.4 g vs. 5.5 g (VMH). Outside the LH or VMH regions, NPY-induced increase in F was observed only in 2/13 sites. Conclusion: NPY effectively stimulates food intake not only in satiated, but also in fasted rats. While this effect may in part be mediated by VMH and LH sites, brain areas other than these have to be examined in view of the highly potent action of ICV NPY.

356.4

THE EFFECT OF NEUROPEPTIDE Y (NPY) ON INTAKE OF FLAVORED SOLUTIONS. M. Grace, W. Welch, C.J. Billington and A.S. Levine VA Medical Center and the University of Minnesota Minneapolis, MN 55417 (SPON: M. Dysken).

Central administration of NPY induces voracious eating, but only limited drinking. We evaluated the effect of intraventricular (icv) NPY injection (5µg) on intake of sucrose (2%), saccharin (0.2%), saline (0.8%) and HCl (0.1M) solutions compared to intake of tap water. There were significant main effects of flavor [$F_{(4,43)}=3.77$, $p=.01$] and drug [$F_{(1,43)}=8.239$, $p=.006$] and a significant interaction [$F_{(4,43)}=2.76$, $p=.04$] over a 4 hour period.

Solution	*Vehicle (ml)*	*NPY (ml)*
Tap Water	1.5 ± 0.2	2.4 ± 0.6
Sucrose	2.3 ± 1.2	10.9 ± 4.2* $p < 0.05$
Saccharin	3.3 ± 1.5	8.8 ± 3.7
Saline	2.5 ± 0.8	4.6 ± 1.5
HCl	0.6 ± 0.1	0.8 ± 0.1

When food was returned to the cage 4 hours after icv NPY injection there was a main effect of drug [$F_{(1,43)}=17.8$, $p=.0001$], but not of flavor on food intake, although the latter approached significance. Food intake (4-6 hr) was not significantly increased after rats ingested tap water, saccharin or saline; but was increased after sucrose and HCl intake. These data confirm the finding that NPY does not have a major effect on water intake in the absence of food; however, NPY does seem to elevate the imbibition of a 2% sucrose solution in the absence of food. (Supported by VA Medical Research and NIDA 1RO1-DA03999)

356.5

THE EFFECT OF INTRACEREBROVENTRICULAR (ICV) NPY ON FOOD REINFORCED BEHAVIOR. D.C. Jewett*, A.S. Levine, J. Cleary*, D.W. Schall* and T. Thompson*. (SPON: G. Maletta). University of Minnesota and VA Medical Center, Minneapolis, MN 55417.

Central administration of NPY results in voracious eating in satiated rats. In the present study we evaluated the ability of NPY to maintain a high level of responding for food. Six rats were trained to press a lever for 45 mg food pellets. The number of responses required for each food pellet was slowly increased to 40 responses (FR 40). A stable low level of responding was maintained in satiated rats. One administration of vehicle (icv) was followed by five successive days of NPY injections in rats trained under the above schedule. There was a main effect of NPY on responding. ($F=4.1$, $p<.01$, $d.f.=5,25$) across days. NPY significantly increased responding, compared to vehicle (10.00 ± 7.4 responses/4 hr), on all but the first day ($p< .05$). Responding peaked on day three of NPY injection at a mean of 5095 (±1159) responses. We then compared these data to those obtained from rats food deprived to 80% of their free feeding body weight. This level of food deprivation resulted in a pattern of responding over the four hour session that was similar to that observed when NPY was given to satiated rats. However, mean total responses were greater under food deprivation (10,194. ± 1040) than under NPY. These data suggest that NPY is a potent stimulator of food intake under conditions requiring a high response cost for each 45 mg food pellet. Patterns of NPY induced responding for food are similar to those produced under conditions of substantial food deprivation.

356.6

A CRITICAL SITE FOR NEUROPEPTIDE Y-INDUCED EATING LIES IN THE CAUDOLATERAL PARAVENTRICULAR/ PERIFORNICAL REGION OF THE HYPOTHALAMUS. B.G. Stanley, W. Magdalin*, and S.F. Leibowitz. The Rockefeller Univ., New York, NY.

Previous work has shown that neuropeptide Y (NPY) stimulates a marked eating response when injected directly into various hypothalamic areas. However, the most effective site has not yet been ascertained. To clarify this, we tested NPY in a wide range of hypothalamic regions using an extremely small injection volume. In satiated adult male rats with implanted guide cannulas, NPY (78 pmol/10 nl) or artificial CSF vehicle (10 nl) was injected through a 33-gauge needle directly into one of 45 evenly-spaced hypothalamic sites (n=3 to 11 rats/site). The results demonstrate that NPY's effect on eating behavior is site specific, with by far the largest responses obtained along the caudolateral edge of the paraventricular nucleus and medial perifornical region. The average food intake obtained from this region was 12.5±1.9 g in 1 hr and 23.0±3.7 g in 4 hrs. NPY injection into sites bracketing this region, less than 1 mm from the critical area, yielded reduced responsiveness, 30% to 67% lower in magnitude, with even smaller responses at greater distances. This suggests that the receptors activated by NPY to induce eating are centered in the lateral paraventricular/perifornical region of the hypothalamus.

356.7

A STRUCTURE-ACTIVITY ANALYSIS OF NEUROPEPTIDE Y-INDUCED EATING BEHAVIOR. W. Magdalin*, B.G. Stanley, A. Fournier[1] and S.F. Leibowitz. (SPON: N.E. Miller). The Rockefeller Univ., New York, NY and [1]INRS, Blvd. Hymus, Point Claire, Quebec.

Porcine neuropeptide Y (pNPY), a 36 amino acid peptide, stimulates a marked eating response when injected into the paraventricular hypothalamus (PVN). To clarify the amino acid sequence required to obtain this response, we compared the effectiveness of various doses of pNPY, human NPY, hNPY free acid, and several C-terminal pNPY fragments (2-36, 5-36, 16-36 & 25-36). Groups of satiated adult male rats, with indwelling guide cannulas in the PVN, were injected with peptide, in 0.3 μl of artificial CSF, and food intake was measured 1 and 4 hrs later. Consistent with our previous results, pNPY (24-235 pmol) elicited a dose-related eating response. Surprisingly, eliminating the N-terminal tyrosine (fragment 2-36) actually increased the potency 2- to 4-fold, while the 5-36 fragment had only a small effect, and the other fragments were ineffective. Human NPY was about 3-fold less potent than pNPY, and its free acid form was ineffective. These findings suggest that the hypothalamic receptors activated by NPY to induce eating may not be identical to those underlying some of NPY's other effects and that these receptors are sensitive to structural changes in both the C- and N-terminal portions of this peptide.

356.8

CONTINUOUS INSULIN INFUSION INTO LATERAL VENTRICLES OF SHEEP FOR THREE DAYS DID NOT EFFECT FOOD INTAKE. L.A. Foster*, K.N. Ames*, R.S. Emery*(SPON. C. Sisk).Dept. of Anim. Sci. Michigan State Univ. E. Lansing MI 48824

In monogastrics insulin infusion into CSF decreases intake. Our objective was to determine if ruminants respond similarly.

Lateral ventricles were cannulated in 14 sheep. Surgeries (Sx) were done on two sheep at a time. Following Sx both sheep were infused with artificial CSF (ACSF) at the same rate for a minimum of one week via either osmotic mini-pumps (134 ul/day) or autosyringes (.7 -1.7ml/day). At the end of the baseline period, porcine insulin (3-5mU/kg/day) was added to the ACSF of one sheep for three days and the other sheep remained on ACSF. There were no differences for intake means between treated and controls (paired T test; $p<.7$; SED = .3kg/day). Concentrations of insulin in a CSF sample from the cistern magna from: control sheep was .0013mU/ml (sensitivity of assay);a treated sheep was 1.2mU/ml.

INSULIN AND 2-DEOXYGLUCOSE HAVE DIFFERENTIAL EFFECTS ON GASTRIC MOTILITY IN RATS. Robert K. Cato*, Loretta M. Flanagan, Joseph G. Verbalis, Edward M. Stricker. Departments of Behavioral Neuroscience and Medicine, University of Pittsburgh, Pittsburgh, PA 15260.

Pharmacological doses of insulin (3-25 U/kg, sc) elicited feeding and increased gastric motility in rats. In contrast, 2-deoxy-D-glucose (2-DG) had dose-dependent effects on gastric motility; doses of 100 and 200 mg/kg ip, which do not affect food intake, caused pronounced increases in gastric motility, whereas 500 mg/kg 2-DG, which reliably elicits food intake, caused a virtual elimination of gastric motility. Thus, unlike insulin, 2-DG does not produce parallel effects on food intake and gastric motility in rats. Like cholecystokinin (CCK) and LiCl, which also abolish gastric motility in rats, 500 mg/kg 2-DG increased pituitary oxytocin (OT) secretion whereas neither the smaller doses of 2-DG nor insulin-induced hypoglycemia had this effect. Also, pretreatment with 5 mg/kg naloxone, which potentiates the inhibition of gastric motility and the stimulation of OT secretion induced by CCK and LiCl, similarly enhanced both of these effects of 2-DG but had no effects in insulin-treated rats. These results suggest that 2-DG has a dual effect on gastric motility, consisting of an insulin-like excitatory component and a CCK/LiCl-like inhibitory component that appears only at the higher doses and is mediated by the paraventricular nucleus of the hypothalamus.

CIRCADIAN RHYTHMS OF INSULIN SECRETION RATES AND GROWTH HORMONE IN EATING DISORDERS. J. Licinio, K.A. Halmi, P.E. Stokes. Department of Psychiatry, Cornell University Medical Center, White Plains, NY 10605.

Insulin is known to participate in the regulation of eating behavior and body weight in animals. We will present data from 4 eating disorder patients and 2 normal controls studied under the following four protocols: a) analysis of C-peptide and insulin decay curves following bolus injection of those peptides to assess individual distribution parameters of each peptide; b) using C-peptide as a marker of insulin secretion, the parameters obtained in protocol "a" are used in an open two-compartmental mathematical model to estimate insulin kinetics in response to mixed meals. The 24-hour circadian rhythms of pancreatic insulin secretion and insulin systemic distribution are then compared to the simultaneously measured circadian rhythms of growth hormone and cortisol sampled every 15 minutes; c) measurement of insulin kinetics in response to a standard oral glucose load; d) intravenous glucose tolerance test, which will be used to assess insulin sensitivity with the use of Richard Bergman's minimal model. Our acutely-ill normal-weight bulimic patients were more glucose intolerant and had higher insulin secretion rates and higher systemic distribution rates as well as higher number of peaks of growth hormone than recovered bulimics or normal controls.

356.11

HIGH LEVELS OF DIETARY FAT REDUCE FEEDING RESPONSES TO BOTH 2-DEOXY-D-GLUCOSE (2DG) AND MERCAPTOACETATE (MA). J. Taylor* and S. Ritter (SPON: F.Young). Dept. of VCAPP, Washington State University, Pullman, WA 99164-6520.

The level of fat in a rat's maintenance diet appears to alter feeding responses evoked by blockade of either glucose utilization ("glucoprivic feeding") or fatty acid oxidation ("lipoprivic feeding"). It has been suggested that elevation of dietary fat enhances lipoprivic feeding, but attenuates glucoprivic feeding. To understand more fully the relationship of dietary fat to the expression of these metabolic controls of food intake, we systematically examined the effect of dietary fat on feeding responses to 2DG-induced glucoprivation and MA-induced lipoprivation. Adult male rats adapted to one of 3 levels of dietary fat (10%, 40% or 60% of caloric content) for at least 2 wks were tested with 2DG (0, 50, 100, 200 and 400 mg/kg, s.c.) and MA (0, 400, 600 and 800 umol/kg, i.p.). Intake of the maintenance diet was measured hourly for 6 hrs during the light portion of the photoperiod. We found that total calories ingested in response to 2DG was inversely related to dietary fat content. In rats ingesting 60% fat, 2DG did not stimulate feeding significantly at any dose. MA stimulated food intake only in rats ingesting 40% fat but did not stimulate feeding in rats maintained on either the 10% or the 60% fat diets. Thus, high levels of dietary fat appear to suppress both glucoprivic and lipoprivic feeding, but the mechanisms responsible for these effects are not yet understood.

356.12

GLYCEMIC, INSULIN AND FEEDING RESPONSES TO DUODENAL GLUCOSE INFUSION IN THE RABBIT. P.J. Geiselman, L. O'Farrell, D.S. Gray*, A. Acevedo-Cruz*, T. Teruya* and Y. Teruya*. Dept. Psychol and Neurosci. Prgm., UCLA; Div. Diab., USC Sch. Med., Los Angeles, CA 90024.

Rabbits were given duodenal infusions of 0.3M glucose or 0.15M NaCl at a fast (3ml/min) or a slow (1ml/min) rate, and serial samples of blood were collected from jugular cannulae.

Fast duodenal glucose infusion produced a sharp increase in insulin levels followed by a precipitous decline in glycemic levels when food was not presented. When food was present, rabbits increased their food intake and, thus, did not show a decrease in glycemic levels. After slow duodenal glucose infusion, insulin levels showed only a moderate increase, which failed to decrease glycemic levels. When food was present in this condition, rabbits suppressed feeding.

These data are consistent with the hypothesis that hunger can be mediated by an insulin-induced decrease in blood glucose. Whereas, insulin levels that are insufficient to produce a significant reduction in glycemic levels appear to mediate satiety.

OPIOID RECEPTOR SUBTYPE MEDIATION OF HYPERPHAGIA IN RATS FOLLOWING EXPOSURE TO A HIGH FAT DIET . A. K. Islam and R. J. Bodnar, Dept. of Psychology, Queens College, CUNY, Flushing, NY 11367.

Selective antagonists can specify the roles of different opioid receptor subtypes in various feeding models. By comparing the relative efficacies of naloxone (NAL), a short-acting, nonspecific opioid receptor antagonist, and naloxonazine (NAZ), an irreversible μ-1 opioid receptor antagonist, our laboratory has implicated the μ-1 receptor subtype in the opioid modulation of free feeding, deprivation-induced feeding and morphine hyperphagia, but not opioid hyperphagia induced by glucoprivation or agonists of kappa and delta receptor subtypes. The present study evaluated the opioid receptor subtype mediating short-term (2 h) hyperphagia following exposure to a high fat diet (67% Purina mash, 33% Crisco) by comparing the inhibitory effects of NAL (0.1-10mg/kg, IV; 1-5 μg, ICV, 20 min and 24 h pre), NAZ (10 mg/kg, IV, 24 h pre), and ß-funaltrexamine (ß-FNA: 10 μg, ICV, 18 h pre), an irreversible μ receptor antagonist, relative to vehicle injections. Significant dose-dependent inhibitions of high fat diet intake occurred following systemic (68% decrease) and central (51% decrease) NAL injections. While ß-FNA significantly reduced ingestion of the palatable diet by 37%, NAZ (8% increase) failed to alter intake. These data indicate that central μ-2 and non-μ opioid receptor subtypes are involved in the opioid mediation of hyperphagia following exposure to a high fat diet.

356.14

CENTRAL MEDIATION OF TASTE AVERSIONS PRODUCED BY MORPHINE, NALOXONE, LITHIUM, METHSCOPOLAMINE, AND SCOPOLAMINE IN RATS. G. Carre, R.E. Filyer*, V.L. Grant*, G.M. Martin*. Dept. of Psychology, Memorial Univ. of Newfoundland, St. John's, NF, A1B 3X9

Eight experiments studied conditioned taste aversions (CTA's) produced by drugs (apomorphine, lithium chloride, methscopolamine, morphine, naloxone, and scopolamine) administered to the ventricles. Control injections were delivered intraperitoneally (IP) and infused in the cerebellum, with the exception of apomorphine which was only given IP. When infused in the cerebellum, only a high dose of methscopolamine produced a reliable CTA. When administered IP, all drugs induced CTA relative to saline controls. When infused in the fourth ventricle all drugs with the exception of apomorphine produced CTA relative to saline controls. These findings, combined with those from area postrema ablation studies, suggest that the area postrema is one chemosensory site at which lithium chloride and methscopolamine induce CTA. Morphine, naloxone, and scopolamine may also induce CTA at sites neighboring the fourth ventricle. Apomorphine appears to induce CTA at a site distant from the fourth ventricle.

INJECTION OF OPIOID ANTAGONISTS INTO THE PARAVENTRICULAR NUCLEUS : EFFECTS ON DEPRIVATION-INDUCED FEEDING. A.S. Levine, M. Grace*, W. Welch*, C.J. Billington* and P.S. Portoghese. VA Medical Center and University of Minnesota, Minneapolis, MN 55417.

Previously, we and others have demonstrated that PVN injection of opioid agonists increases feeding and PVN injection of naloxone decreases feeding. In the present study we administered opioid antagonists of the kappa, delta and mu receptors into the PVN of 24 hour food deprived male rats. Nor-binaltorphimine (nor-BNI) had a main effect on food deprivation-induced feeding [$F_{(3,67)} = 6.93$, $p = .004$]. Doses of 15 (68.4 ± 6.5%), 10 (76.4 ± 9.2%) and 1 nmol (81 ± 9.9%) nor-BNI significantly decreased food intake compared with vehicle injected controls during the first hour of the study ($100 \pm 2.9\%$, $p < 0.05$). There was no significant main effect of the delta antagonist naltrindole (1 nmol: 108 ± 10.7%) on deprivation-induced feeding (100 ± 10.9%). There was a tendency for the antagonist ß-funaltrexamine (ß-FNA) (10 nmol: 76.8 ± 4.9%, $p = 0.057$) to decrease feeding when injected 24 hours prior to presentation of food. The non-specific receptor antagonist ß-chlornaltrexamine dihydrochloride (ß-CNA) (10 nmol: 48 ± 9.7) potently decreased deprivation-induced feeding (100 ± 14.9, $p = .012$) when injected into the PVN 24 hours prior to administration of food. These data support the concept that the PVN and the kappa opioid receptor play important roles in opioid-induced feeding. (Supported by VA Medical Research and NIDA 1RO1-DA03999)

356.16

CENTRAL INJECTIONS OF MU AND DELTA OPIOID AGONISTS STIMULATE SALINE INTAKE IN NON-DEPRIVED RATS. B.A. Gosnell, D.D. Krahn and M.J. Majchrzak. Dept. of Psychiatry, Univ. of Michigan, Ann Arbor, MI 48109-0116.

Endogenous opioid peptides are thought to play a role in mediating the palatability or rewarding aspects of sweet tastes. There is some evidence, however, which suggests that opioids may also influence the preference for the taste of salt (Bertino et al., Pharmacol. Biochem. Behav. 29:617, 1988; Cooper and Gilbert, Psychopharmacol. 84:362,1984). In the present studies, we measured the effects of central administration of the mu agonist [D-Ala^2,$MePhe^4$, Gly-ol^5]enkephalin (DAGO) and the delta agonist [D-Thr^2]Leucine enkephalin-Thr^6 (DTLET) on the ingestion of salt solutions. In non-deprived rats given a choice of water and 0.6% saline, icv injections of DAGO (1 and 3 nmols) significantly increased the intake of 0.6% saline; mean 2 hr saline intakes were 1.6, 6.6 and 8.5 mls for the 0, 1 and 3 nmol doses, respectively. Baseline water intake was minimal and was unaffected by DAGO. DTLET (1 and 3 nmols) also significantly increased 0.6% saline intake; mean 2 hr intakes were 1.1, 6.2 and 8.3 mls, for the 0, 1 and 3 nmol doses, respectively. In rats given a choice between water and 1.7% saline, DAGO and DTLET stimulated both water and saline intake; total volume ingested (water + 1.7% saline) was equal to or less than the amount ingested when 0.6% saline was available. The effect of naloxone (icv) was measured in rats on a deprivation schedule in which water and 0.6% saline were available for only 2-3 hrs/day. Naloxone (20 and 50 ug) significantly decreased 0.6% saline intake (1 hr intakes were 27.5, 19.5 and 14.8 mls, respectively, for the 0, 20 and 50 ug doses); baseline water intake was low (3-5 mls) and was unaffected by naloxone. These results suggest a role for central mu and delta opioid receptors in mediating the preference for salt solutions.

356.17

LATERAL HYPOTHALAMIC STIMULATION-INDUCED FEEDING THRESHOLDS ARE INCREASED FOLLOWING CHRONIC EXPOSURE TO NALTREXONE. *S. Uysal* and E. E. Coons.* Department of Psychology, New York University, New York, NY 10003.

Several laboratories have demonstrated that chronic opioid receptor antagonism results in increased numbers of brain opioid receptors and supersensitivity to exogenous opiates and endogenous opioids. We expected that subsequent to chronic naltrexone treatment (two 30 mg pellets implanted s.c. for nine days), thresholds for inducing feeding by electrical stimulation of the lateral hypothalamus (LH) would be reduced since a) LH stimulation-induced feeding (SIF) is opioid mediated (Carr & Simon, 1983), b) opiates injected into the ventral tegmental area (VTA) potentiate LH SIF (Jenck et al., 1986), and c) VTA opioid receptors upregulate greatly in response to chronic naltrexone treatment (Tempel et al., 1984).

SIF thresholds were assessed for each animal under the following conditions: 1) baseline, 2) acute naloxone, 3) acute naltrexone (NTX), 4) during chronic NTX treatment, 5) after chronic NTX treatment, and 6) during acute NTX challenge on the first day after NTX pellet removal. Thresholds were determined four times during each feeding test.

Acutely, naloxone and NTX both increased mean SIF thresholds, naloxone being more potent. Within a test session, thresholds progressively increased, as previously demonstrated (Carr et al., 1987). Mean SIF thresholds also were elevated during chronic NTX treatment. However, unlike acute NTX, chronic NTX uniformly elevated thresholds within a test. After removal of NTX pellets, SIF thresholds were elevated uniformly within a test; during acute NTX challenge thresholds progressively increased. Furthermore, the rate at which acute NTX elevated SIF thresholds was increased following chronic NTX treatment. Within 3-4 days of NTX pellet removal mean SIF thresholds returned to baseline levels.

CNS REGIONAL CHANGES IN ^{3}H-DIPRENORPHINE BINDING FOLLOWING ELECTRICALLY ELICITED FEEDING IN THE RAT. E.A. Stein[1], K.D. Carr[2] and E.J. Simon[2]. Depts. of Psychiatry, Medical College of Wisconsin, Milwaukee, WI 53226[1] and NYU Medical Center, New York, NY 10016[2].

Feeding induced by both natural cues, as well as lateral hypothalamic electrical stimulation (ESLH) can be inhibited by opiate antagonists and antibodies to opioid peptides. In contrast, opiate agonists have been reported to increase food intake. The central sites at which opioid peptides modulate feeding and how they play a role in its maintenance is not well understood. To address these issues, we compared regional ^{3}H-Diprenorphine (^{3}H-Dpr) binding in rats a) getting ESLH and allowed to eat, b) ESLH in the absence of food, and c) implanted rats receiving no ESLH. On the final day of testing, ^{3}H-Dpr (0.002 mg/kg) was injected IV following trial 5 of a 10-trial session. Rats were subsequently sacrificed and brains prepared for autoradiography. Since we utilized an *in vivo* procedure, peptide released as a consequence of the behavior will occupy receptors and lead to a decrease in ^{3}H-Dpr binding. Independent of food intake, ESLH caused increases in binding in the frontal cortex, cingulate, bed nucleus of the stria terminalis, medial habenula and zona incerta, and decreases in the claustrum, nucleus accumbens, lateral hypothalamus, ventral tegmentum and caudate. In addition, eating decreased binding in the medial prefrontal cortex and basolateral amygdala and increased in gustatory cortex. Results are discussed in view of the role of opioids in consummatory behavior as well as structures known to be involved in motivated behaviors. ROLE OF PARAVENTRICULAR NUCLEUS MEDIATING OPIATES' ACTION ON POLYDIPSIA: STUDY OF INBRED MICE. I. Nagatomo*, T. Katafuchi* and K. Koizumi. Dept. of Physiology, SUNY Health Science Center at Brooklyn, NY 11203.

We have previously reported that excessive drinking (5-8 times of normal mice) of inbred mice, STR/N, which is not caused by a lack of vasopressin or kidney dysfunction, is related to abnormality in the brain opiate system (1). In the present study effects of direct injections of an opiate antagonist, naltrexone methobromide, to the PVN were found to be more specific than that of the drug given to the lateral ventricle; a much smaller dose was effective in attenuating spontaneous drinking only in STR/N, and even at a higher dose the drug did not affect food and water intake of control mice. In brain slice preparations effects of opiates on activity of PVN neurons were examined. Morphine added to the bathing medium (10^{-6}M) supressed neural activity of 44% of PVN cells tested in STR/N, while in control mice 62% were inhibited. Threshold for the inhibitory action was 10^{-7} to $^{-8}$M for STR/N compared to 10^{-8} to $^{-9}$M in controls. No neuron was excited by the opiate in both strains. Naloxone blocked morphine's action on PVN neurons, but had no direct effect. Dynorphin added to the bathing medium at 10^{-6}M inhibited only ¼ of PVN neurons in polydipsic strain, while ½ of cells were inhibited in controls. Our results indicate that the PVN, rather than the AV3V (1), may be more involved in the primary polydipsia. (Supported by a grant from USPHS NS- 00847). (1) Abst. Soc. Neurosci. 1988 14: 1106.

REGULATION OF AUTONOMIC FUNCTIONS IV

357.1

NEURAL PATHWAYS INVOLVED IN THE CONTROL OF PERIPHERAL ENERGY HOMEOSTASIS. AB Steffens*, B Balkan*, PGM Luiten, and AJW Scheurink*. (SPON: AJ Sipols). Dept of Animal Physiology, University of Groningen, 9750 AA Haren, The Netherlands. Dept of Psychology, Univ of Washington, Seattle WA, 98195 USA.

Areas within the CNS that contribute to the regulation of food intake are also involved in the regulation of blood glucose and plasma FFA levels in resting and exercising rats. Particularly hypothalamic areas such as the ventromedial (VMH), the lateral (LHA) and the paraventricular (PVN) hypothalamus play an important role. The regulation of peripheral glucose and FFA levels is mediated both directly via neural pathways and indirectly via hormones; e.g., glucagon, insulin, epinephrine, norepinephrine, corticosterone, and CCK.

Neuroanatomical data reveal the intrahypothalamic connections and pathways between the hypothalamus and the motor areas of both the sympathetic system (the intermediolateral column of the spinal cord) and the parasympathetic system (the dorsal motor nucleus of the vagus and the nucleus ambiguus in the brain stem).

Physiological data suggest that the hypothalamus can regulate blood glucose, plasma FFA, and insulin independently of each other. For example noradrenergic stimulation of the VMH leads to a concomitant increase of glucose, FFA, and insulin levels into the blood whereas noradrenergic stimulation of the LHA causes an increase in glucose and insulin and a decrease in plasma FFA. Experiments dealing with selective adrenoceptor blockade in distinctive hypothalamic areas of exercising rats, and glucose tolerance tests in pair-fed VMH-lesioned rats, provide additional evidence for the important role of the hypothalamus in the control of peripheral energy homeostasis. (Supported by grants from the Netherlands Organization of Scientific Research).

MELATONIN PROTECTS HAMSTERS AGAINST THE HYPOCLYCEMIC EFFECT OF D-AMPHETAMINE. B.G. Ortega - Corona, N. Esparza -Avalos* and F. Antón-Tay. Unidad de Investigación Biomédica, IMSS, Instituto de Biología, UNAM and Biología de la Reproducción, UNAM, Iztapalapa, MEXICO 06760.

Amphetamine (AMPH) LD_{50} was determined in golden hamster, Cricetus auratus, kept for two weeks previously under standard control conditions. The effect of either a single melatonin dose (1 or 10 mg/Kg 2 ½ hs before experiments or a similar dose given for 3 days previous to the experiment was studied. Glucose plasma levels were enzymatically determined and animal survival rate was assesed 3 hs after AMPH administration. AMPH treated animals showed low levels of plasma glucose (12 $\pm$ 1.2 mg/dl) and a lower survival rate than the melatonin treated ones. Glucose levels in the melatonin treated animals at either 1 or 10 mg/Kg dose and under experimental conditions were 73 $\pm$ 6.6 mg/dl, $p < 0.001$. Our results suggest that dead after a LD_{50} dose of AMPH is at least partially due to hypoglycemia and that melatonin could exert its protective effect by counteracting this lowering of the plasma glucose.

357.3

ONLY THE μ OPIATE RECEPTOR MEDIATES HYPERGLYCEMIA AFTER 3rd VENTRICULAR OPIOID PEPTIDE INFUSIONS IN RATS. M.W. Gunion, M.J. Rosenthal, J.E. Morley, S. Miller, and B. Zib. GRECC, Sepulveda VAMC, Sepulveda, CA 91343.

Three experiments were performed. In all experiments, hypothalamic 3rd ventricle infusions were given through chronic cannulae implanted at least one week prior to testing; blood samples (120 ul) were taken from the tail tip 0, 15, 30, 60, 90, and 120 min postinfusion. In Expt. 1, the agonists DAGO (μ), β-endorphin ($\mu+\epsilon$), DSLET (δ), and dynorphin (k) (0,.3,1,3,10 nmol/rat in 0.9% NaCl+0.1% BSA) were tested for effects on glucose, free fatty acids, and corticosterone. Both DAGO and β-endorphin increased glucose and corticosterone; neither affected free fatty acids. Dynorphin transiently elevated glucose, and caused prolonged increases in free fatty acids and corticosterone. DSLET had absolutely no effect on any measure. In Expt. 2, naloxone (1 mg/kg, sc, 20 min prior to 3rd ventricle infusion) suppression of the effectiveness of DAGO (3 nmol), β-endorphin (10 nmol), and dynorphin (10 nmol) was tested. While the elevations of glucose and corticosterone caused by DAGO and β-endorphin were blocked, there was no alteration of the effects of dynorphin; that is, the dynorphin effects were not mediated by opiate receptors. Expt. 3 tested whether the ϵ receptor mediated the β-endorphin effects. The μ-specific antagonist β-funaltrexamine (20 μg, 3V) was given 24 hr prior to testing with DAGO (3 nmol) or β-endorphin (10 nmol). Both peptides produced significant hyperglycemia in vehicle-pretreated rats, but neither had any discernible effect in rats pretreated with the μ-receptor blocker. In sum, although there may be at least four opiate receptor types in rat brain (μ, ϵ, δ, k), only the μ-receptor mediates hyperglycemia after infusions of opioid peptides into the 3rd ventricle. ELECTROPHYSIOLOGICAL RECORDING FROM NTS NEURONS WHICH RECEIVE AFFERENT INPUT FROM ABDOMINAL CHEMO- AND MECHANORECEPTORS W.B. Laughton and L.A. Campfield Department of Neurobiology and Obesity Research, Hoffmann-La Roche Inc., Nutley, NJ 07110

Extracellular single-unit recordings have been obtained from afferent neurons in the nucleus of the solitary tract (NTS) of chloralose/urethane anesthetized male, Sprague-Dawley rats (350g-450g). Recordings were made through single and multi-barreled glass micropipettes (tip diameter 1-2u). Specific, transient alterations in hepatic-portal glycemia, systemic glucose levels, and intragastric pressure were experimentally induced. NTS neurons were identified which responded either to one of these experimental manipulations, or in some cases, to more than one manipulation. Both increases and decreases in neuronal firing rate were seen (in different neurons) following alterations in these parameters; the two types of responses were seen with approximately equal frequency. These changes in patterns of firing in afferent pathways provide the substrates for central nervous system monitoring of peripheral metabolic state. The integration of these signals by the central nervous system plays an important role in the overall regulation of energy balance.

AREA POSTREMA LESIONS ALTER GLUCAGON RESPONSES TO GLUCOSE LOADS. B.J. Davis, W.Williams and M.L. Mangiapane, Departments of Neurology, Neurobiology and Anatomy, and Pharmacology, University of Rochester School of Medicine and Dentistry, Rochester, NY 14642.

The area postrema (AP) is thought to be part of the autonomic circuitry of caloric homeostasis. Lesions of the AP alter body weight maintenance levels and glucoprivic feeding responses (Contreras, et al, Fed. Proc. 43, 1984). In the present study we assessed the effects of bilateral AP lesions on plasma glucose, insulin and glucagon responses to an oral glucose load (OGL). Young adult male Sprague-Dawley rats were given electrolytic lesions of the AP. Sham lesioned rats served as controls. All rats were tested on day 7 and again on day 25 after surgery. After an overnight fast, rats were given150 mg glucose/100 gm body weight. Blood was withdrawn at 0 minutes (fasting level), and at several time points after OGL. Plasma glucose, insulin and glucagon levels were determined for each time point.

At 7 days following lesions, sham and AP rats showed comparable glucose levels at 0,2, 60 and 120 minutes following OGL. However, at 30 minutes, glucose levels of AP rats were significantly higher than in shams. Likewise, insulin levels were comparable in AP rats and shams at 0,2, 60 and 120 minutes with a higher insulin level at 30 minutes in AP rats. At 7 days, glucagon responses of the two groups differed only at 2 minutes following OGL with AP rats showing significantly lower levels.

At 25 days, AP rats showed fasting hypoglycemia, but glucose and insulin responses were comparable between shams and AP rats at all other time points. In contrast, AP rats showed significantly elevated glucagon levels with respect to shams at all time points following OGL except at 2 minutes. We conclude that removal of the AP alters the endocrinology of glucose homeostasis and that metabolic alterations following AP lesions may be related to altered glucagon responses. Supported by AG05937 and HL32981.

BROWN ADIPOSE TISSUE (BAT) ACTIVATION OF RATS FOLLOWING VENTROMEDIAL HYPOTHALAMIC (VMH) STIMULATION. J.A. Thornhill, I. Halvorson, L. Gregor and M. Desautels. Dept. of Physiology, Univ. of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0.

Interscapular brown adipose tissue (T_{IBAT}), colonic (T_C), surface tail temperatures (T_t), and blood pressure (BP) were monitored in urethane-anesthetized male Sprague-Dawley rats before and after repeated (3) electrical stimulation of the VMH. The VMH of various age-matched, cold-acclimated (C.A., kept at 4°C 3 weeks prior to testing) or warm-acclimated (W.A., kept at 22±1°C) was stimulated (120 μA, 50 Hz, 0.5 msec duration pulses) for 30 sec. Intravenous (iv) propranolol HCl (2.5 mg/kg) was given 10 min prior to the last VMH stimulation. VMH stimulation to the W.A. groups did not significantly increase T_{IBAT}s or T_Cs, compared to pre-injection control values, though T_{IBAT}s were significantly raised in other W.A. rats following iv infusion of norepinephrine HCl (40 μg/ml). C.A. rats showed a significant rise in T_{IBAT}s, above those of T_Cs, following VMH stimulation, effects abolished upon the third VMH stimulation following propranolol administration. GDP binding of isolated BAT mitochondria of C.A. groups was significantly increased from age-matched W.A. animals. Results indicate that C.A. increases the thermogenic capacity of BAT such that VMH stimulation can evoke a significant rise in T_{IBAT} above that of T_C, effects not detected in W.A. rats. Supported by MRC of Canada.

THERMOGENESIS IN BROWN ADIPOSE TISSUE IS MODULATED BY THE RETINOHYPOTHALAMIC SUPRACHIASMATIC COMPLEX. S. Amir, CSBN, Concordia University, Montreal, Canada, H3G 1M8.

The hypothalamic suprachiasmatic nuclei (SCN) regulate several functions concerned with the maintenance of energy balance, including feeding, corticosterone secretion and glucose metabolism. Another mechanism of energy balance regulation that might be under SCN control is heat generation in brown adipose tissue (BAT). The present study shows that stimulation of SCN neurons by microinjection of the excitatory amino acid glutamate (100 mM-1 M, in 0.25 ul), activates interscapular BAT (IBAT) thermogenesis in rats. Similarly, electrical stimulation of the retinohypothalamic projection (RHP) (a 30 sec train of square wave pulses, 50 pulses per sec, pulse duration 0.5 msec, intensity 100-400 uA), which leads to release of glutamate in the SCN, activates IBAT thermogenesis. The effect of RHP stimulation on IBAT activity can be blocked by injecting the excitatory amino acid blocker, kynurenic acid (0.5-2 ug in 0.25 ul) or the NMDA receptor antagonists, gamma-D-glutamylaminomethyl phosphonic acid (0.5-2ug), into the contralateral SCN; injecting the preferential kainate/kuisqualate receptor blocker, gamma-D-glutamylaminomethyl sulphonic acid (0.5-5ug) has no effect. Together, the results show that stimulation of the RHP can activate thermogenesis in BAT and that the signal for such activation involves action of glutamate at NMDA receptors in the SCN.

THERMAL STIMULATION, THERMAL SENSATIONS AND CHANGES IN DIGITAL PULSE VOLUME: A METHOD FOR STUDYING INTEGRATIVE FUNCTIONS OF CNS: I. V. Kojo (SPON: European Neuroscience Association), Dept. of Physiology, Univ. of Helsinki, Helsinki, Finland.

Changes in digital pulse volume (DPV) were measured during thermal stimulation of the glabrous skin of human hand. The aim of the study was to search if those changes are associated with changes in physical stimulus parameters or thermal sensation.

The skin was stimulated with a contact stimulator which allows the subjects to control the temperature during experiments. The subjects were told to increase or decrease the temperature of the stimulator until they feel a thermal sensation and to keep the sensation constant for two minutes by adjusting the stimulus as required. DPV was measured with a plethysmography.

Innoxious warming increased and cooling decreased DPV. However, changes in DPV began before the stimulus temperature began to change. Heat pain caused a decrease in DPV.

With stimuli producing innoxious thermal sensation the DPV changes seem to be dependent on physical temperature parameters. The changes are also associated with the psychological factors (e.g. expectancy) of the subjects. This method allows the study of CNS receptive, integrative and afferent functions by a simple but effective tool.

THE HYPOTHERMIZING EFFECT OF NOREPINEPHRINE (NE) MICRODIALYZED INTO THE PREOPTIC AREA (iPO) OF GUINEA PIGS IS INDEPENDENT OF ENVIRONMENTAL CONDITIONS. N. Quan, C.M. Blatteis, and R.D. Howell.* Dept. of Physiol. Biophys., Univ. of Tennessee, Memphis, TN 38163

NE microinjected iPO produces different thermal effects, depending on the ambient conditions. However, microinjection per se introduces artifacts which may confound the results. As microdialysis obviates these problems, we examined whether the thermal response to NE microdialyzed iPO is also affected by the environment. Previously prepared, conscious guinea pigs were exposed to 24±1, 33±1 or 15±2°C at 8:30 a.m.; other animals were exposed to 24±1°C at 8:30 p.m. in the dark. After their T_{CO} had stabilized, NE was administered (10 ug/ul at 2 ul/min for 3 h). NE induced a fall in T_{CO} under all conditions. It was, however, significantly smaller in the animals in 33 and 15° than in those in 24°C. The latency of the T_{CO} fall and its recovery after perfusion were longer at night than during the day. Thus, the ambient conditions did not affect the direction of the T_{CO} response to NE but modified its magnitude and course. (Supported by NS 22716.)

VOLATILE ANESTHETIC ACTION ON THERMOREGULATORY RESPONSES IN THE NEURAXIS OF CATS. W.T. Schmeling, J.P. Kampine and D.C. Warltier*. Depts of Anesthesiology & Pharmacology, Medical College of Wisconsin, Milwaukee, Wisconsin 53226

Normal thermoregulatory (TR) function is modulated by the preoptic region (POR) of the anterior hypothalamus and at other sites including the spinal cord (SC). Volatile anesthetics disrupt normal TR function and produce post anesthetic "shivering" (SH). The present investigation examined the action of halothane (H) on TR responses produced at the POR and SC of cats. Cats were chronically instrumented with bilateral cannulae in the POR. Double lumen thermodes allowed selective heating (HT) and cooling (CO) of the POR. Electrodes were implanted in hindlimb and forelimb muscles. Animals underwent selective HT and CO thermal challenge of the POR in the awake state, during H and during emergence. Pontine transected cats underwent alternate HT and CO cycles of the spinal cord. HT and CO was performed in the unanesthetized state, at 0.25-2.0% H and during emergence. EMG responses were quantitated and analyzed for power spectral density. HT and CO of the POR in the conscious state resulted in appropriate TR responses, including increased EMG SH activity to CO. H abolished these SH responses. During emergence from H, typical spontaneous SH responses were significantly attenuated by HT of the POR and augmented by CO. CO of the SC produced graded SH like responses. H dose dependently diminished this response. During emergence, CO of the SC induced a SH response similar to controls. The ability of the POR to modulate post anesthetic SH implies that there may be a resetting of the normal gain and an imprecision in the TR responses of the rostral CNS. The attenuation of SH responses at the SC implies a significant blunting action of H on SC TR mechanisms. Spectral analysis of EMG responses during emergence, were similar to the true SH responses to the TR challenge observed in the unanesthetized state, without.evidence of tonic--clonic type activity.

ELECTRICAL PROPERTIES OF NEURONS IN THE GUINEA PIG GALLBLADDER. G M. Mawe. Department of Anatomy and Neurobiology, The University of Vermont, Burlington, VT 05405

Recent studies indicate that the ganglionated plexus of the gallbladder is similar in structure, connections, and transmitter content to the ganglionated plexuses of the small intestine. Given these similarities, and the fact that the gallbladder originates as an evagination of the duodenum, intracellular recording techniques were used to determine the basic membrane properties and action potential characteristics of gallbladder neurons, for comparison with those of neurons in the small intestine.

The mean resting membrane potential of gallbladder neurons, with overshooting spikes, was -50.0 ± 1.0 mV, with values ranging from -40 to -58 mV and the mean input resistance was 75.6 ± 5.4 MΩ (n = 41). These neurons responded with single or multiple fast EPSPs following fiber tract stimulation. No rundown of the fast EPSPs was observed during stimulation at frequencies up to 10 Hz. Depolarizing current pulses (≥ 200 ms) elicited only single or double spikes regardless of the amplitude of the pulse beyond the spike threshold. The stimulus evoked spikes were abolished by TTX (0.5 μM). Spikes reappeared when TEA (20 mM) was added to the TTX-containing solution. The mean duration of afterspike hyperpolarizations (AHP) was 179.9 ± 11.9 ms. The amplitude of the AHP was decreased by 20 mM TEA or 100 μM curare. Anodal break action potentials could be elicited in some of the gallbladder neurons, but only when rather large hyperpolarizing currents pulses (producing 20-30 mV hyperpolarization) were injected into the cells.

Results from this study indicate that the neurons located in the gallbladder represent a class of neurons with properties that differ from those of neurons studied in the small intestine. Supported by NS26995.

NEURAL CONTROL OF MOTILITY IN SUBSEGMENTS OF THE DOG COLON WALL. K.D. Keef*, R.J. Stevens* and S.M. Bowen*. (SPON: J. Peacock) Dept. of Physiol., Univ. of Nevada, Reno, 89557.

The contractile response to enteric nerve stimulation was investigated in subsegments of the colon wall including the outer half of the circular muscle (OHCM) and myenteric plexus; the inner half of the circular muscle (IHCM) and submucosal plexus; the longitudinal muscle (LM) and myenteric plexus; and "bulk" circular muscle (BCM) with both plexus regions removed. All subsegments of the colon with the exception of the BCM exhibited ongoing rhythmic activity although the frequency and pattern of activity varied markedly from layer to layer. Rhythmicity could be induced in the BCM with acetylcholine (10^{-7}M). Tetrodotoxin (5×10^{-7}M) did not abolish rhythmic activity in any subsegment and in the OHCM and IHCM led to enhancement of rhythmic activity suggesting a tonic release of inhibitory transmitter substance. Transmural stimulation (20 Hz, 10 s) of the OHCM or IHCM gave a large initial contraction which was largely eliminated with atropine (5×10^{-7}M) and in the case of the OHCM was followed by an inhibitory phase. Neurally induced inhibition of contraction in the IHCM was revealed in the presence of atropine. Only 1 of 8 BCM preparations contracted with transmural nerve stimulation suggesting that neural innervation is concentrated in those regions near the myenteric and submucosal border. The results indicate that both the basal contractile activity of colonic subsegments and their neural control differs throughout the colon wall.

357.13

HISTOCHEMICAL IDENTIFICATION OF NEURONS INNERVATING BOTH THE JEJUNUM AND ILEUM OF THE RAT. X. Zhang*, R. Fogel* and W. Renehan. (SPON: J. Elkes) Depts. of Medicine and Anatomical Sciences and Neurobiology, University of Louisville School of Medicine, Louisville, KY 40292.

Most mammalian sensory and somatic motor systems are topographically organized. Furthermore, a viscerotopic organization of vagal cells innervating the rat stomach has been suggested. We explored the organization of the innervation of the rat intestine by determining whether individual afferent and efferent neurons innervate both the jejunum and the ileum. Five Sprague Dawley rats were injected with Fast Blue and WGA-HRP. One tracer was injected into the jejunum and the other into the ileum. Five days later the brainstem, prevertebral ganglia (PG), nodose ganglia (NG), selected dorsal root ganglia (DG) and the injection sites were removed. In the brainstem, labeled cells were seen only in the dorsal motor nucleus of the vagus (DMNV). Of these cells, 19.3 ± 0.4 % contained both labels. In contrast, only 2.9 ± 0.5 % of nodose cells were double labeled. In the PG and DG, 8.9 ± 0.4 % and 19.7 ± 0.6 % of the cells were double labeled, respectively. Our results suggest that a substantial percentage of DMNV and DG neurons innervate a large portion of the intestine. In contrast, the afferent information reaching the DMNV via the NG, as well as the sympathetic innervation, is very specific. The significance of this pattern of innervation in the coordination of intestinal function requires further study. VA Merit.

357.14

INNERVATION OF THE PANCREAS BY NEURONS IN THE GUT. A. L. Kirchgessner, and M. D. Gershon, Department of Anatomy and Cell Biology, Columbia Univ. P & S, New York, NY 10032.

Enteric neurons project out of the gut to innervate neurons in prevertebral ganglia and the gallbladder. We therefore investigated whether neurons in the bowel send functional axonal projections to the pancreas. The retrograde tracer, FluoroGold (FG) was injected into the pancreas. In addition, the intercalating fluorochrome DiI, was microinjected into myenteric ganglia. FG labeled neurons in the myenteric, but not the submucosal plexus, of the duodenum (the first 6 cm) and the antrum of the stomach. The density of FG-labeled neurons was higher in the stomach (9.2 ± 0.9/ganglion) than in the duodenum (3.8 ± 0.3/ganglion; $p < 0.001$). No labeling was observed in controls in which inadequate time was allotted for retrograde transport. Myenteric neurons were found in both duodenum and antrum that were doubly labeled by FG and anti-5-HT sera. In addition, thick bundles of 5-HT-immunoreactive nerve trunks ran between the duodenum and the pancreas. Most 5-HT-immunoreactive axons in the pancreas terminated in ganglia, although some fibers were also observed near acini, ducts, vessels, and islet cells. Following injection of DiI into myenteric ganglia, fluorescent fibers were seen to collect into bundles that entered the pancreas at many locations through the intervening connective tissue. Veratridine (10 μM) was perfused through the lumen of duodenal segments to which pancreas was left attached. The cytochrome oxidase (CO) activity of pancreatic ganglion cells was demonstrated histochemically and measured by computer-assisted video microdensitometry. Duodenal veratridine increased pancreatic neuronal CO activity; this effect was antagonized by tetrodotoxin (1.0 μM), hexamethonium (10 μM), and mechanical ablation of the myenteric plexus of the gut. It is concluded that there is a functional entero-pancreatic innervation, that pancreatic ganglia are targets of this innervation (*via* a nicotinic synapse), and that some of the entero-pancreatic fibers are serotonergic. Supported by NIH grants NS 12969 and NS 07062.

BOMBESIN (BB) MICROINJECTED INTO THE PARAVENTRICULAR NUCLEUS (PVN) INHIBITS GASTRIC ACID SECRETION (GAS) STIMULATED BY TRH MICROINJECTED INTO MEDULLARY NUCLEI. H. Yang* and Y. Taché. CURE, West VA Medical Ctr., Dept. of Med. and Brain Res. Inst., UCLA, Los Angeles, CA 90073.

Microinjection of BB into the PVN inhibits GAS stimulated by pylorus ligation or electrical vagal stimulation in the rat (Brain Res. 422:118, 1987;Jpn. J. Pharmacol. 45:129, 1987). In the present study we investigated medullary nuclei and autonomic pathways involved in mediating the inhibitory effect of BB injected into the PVN. Male rats (SD, 220-350 g) fasted for 24h were anesthetized with urethane and implanted with gastric fistula. GAS was measured by flushing the stomach and titrating the flushed perfusate. Microinjections were performed by pressure ejection over 2 min of 50 nl of peptides or vehicle. After 30 min of basal GAS, BB or vehicle was microinjected bilaterally into the PVN (30 pmol/site) and immediatly after the stable TRH analog, RX 77368, was microinjected unilaterally either into the dorsal vagal complex (DVC, right side) or nucleus ambiguus (NA, left side). Basal GAS expressed per 2 h was 21 ± 2 μmol (n=70). Microinjection of BB into the PVN, unlike into the lateral hypothalamus inhibited by 69% the acid response (129 ± 12 μmol/2h) to RX77368 (8 pmol) microinjected into the DVC. Also, BB injected into the PVN, inhibited by 53% the GAS response (120 ± 12 μmol/2h) to intracisternal injection of TRH (550 pmol) and by 100% gastric acid response (73 ± 10 μmol/2h) to RX77368 (8 pmol) microinjected into the NA. The inhibitory effect of bombesin against RX 77368 microinjected into the NA was completely abolished by cervical cord transection. BB in PVN inhibited GAS induced by medullary vagal stimulation through spinal pathways. (supported by NIH DDK-30110).

357.16

ROLE OF GABA IN CONTROL OF GASTRIC MOTILITY IN THE CAT DORSAL VAGAL COMPLEX. C.D. Rossiter*, P.J. Hornby, R.L. White*, J.W. Harmon*, R.A. Gillis* (SPON: L.M. Petrucelli). Depts. of Pharmacology and Surgery, Georgetown University, Washington, D.C. 20007.

Immunocytochemical techniques have demonstrated a remarkable density of GAD immunoreactivity in the dorsal vagal complex, specifically the dorsal motor nucleus of the vagus (DMV) and the medial subnucleus of the tractus solitarius (mNTS). These nuclei are known to influence gastric function since excitation of the DMV and mNTS results in increases and decreases in gastric motility, respectively. Therefore, to evaluate the role of GABA in control gastric motility we microinjected 20-100ng of bicuculline ($GABA_A$ antagonist) into the DMV and mNTS in alpha-chloralose anesthetised cats while monitoring pyloric motility and blood pressure. Microinjection of bicuculline into the DMV (N=7) resulted in statistically non-significant increases in pyloric minute motility index (MMI) of 4.5±1.9. However, microinjection of bicuculline into the mNTS (N=5) evoked a marked increase in pyloric MMI of 11.7±3.7 ($P<0.05$). This occurred with no significant increase in mean blood pressure or heart rate. The increase in pyloric motility was reversed by vagotomy or by microinjection of 50-100ng of muscimol ($GABA_A$ agonist) into the mNTS during the peak response. These data indicate that GABA present in the DMV may have, at most, a minor role in control of gastric motility; however, GABA present in the mNTS exerts a tonic inhibitory effect on neurons controlling excitatory vagal outflow to gastric smooth muscle. TRH INHIBITS THE ACTIVITY OF GASTRIC INFLATION-RELATED NEURONS IN THE SOLITARY NUCLEUS.
R.C. Rogers and M.J. McCann. Dept. Physiology, Ohio State University College of Medicine, Columbus, OH 43210.

Thyrotropin releasing hormone (TRH) has been identified as a potent central regulator of gastrointestinal function. It has been hypothesized that TRH-containing neurons in the central nervous system influence gastric function by modulating the effectiveness of gastric vago-vagal reflexes. To test this hypothesis, we studied the effects of small amounts of TRH (10-100 femtomole in 10 to 100 picoliters) on the firing rate of single neurons in the nucleus of the solitary tract (NST). Of 23 NST neurons responsive to gastric distension (2 ml) 11 or 48% were inhibited by micropressure applications of TRH; none were excited. These results provide evidence that a part of the TRH effect on the regulation of gastric function involves the suppression of NST responses to gastric vagal afferent input from the vagus nerve.

OXYTOCIN (OT) EXCITES GASTRIC DISTENTION-RELATED NEURONS IN THE NUCLEUS TRACTUS SOLITARIUS (NTS). M.J. McCann and R.C. Rogers. Dept. of Physiology, Ohio State University, Columbus, OH 43201.

Previous reports indicate that central OT neurons can influence the vagal control of gastric function. OT neurons from the paraventricular nucleus project to vagal sensory (NTS) and motor nuclei in the brainstem. We determined whether OT could modulate the activity of NTS neurons that were specifically related to gastric function. A triple-barreled glass recording electrode/injection pipette array was used to record single extracellular potentials and eject OT or vehicle solutions. The array was positioned in the medial NTS and gastric-related neurons were identified by inflating the stomach with a balloon. Responsive cells were either excited (ON), or inhibited (OFF) by gastric inflation. When OT (100-300 fm in 100-300 pl) was pressure ejected onto these cells, the following effect on spontaneous activity was found:

	ON	OFF
excite	60%	36%
inhibit	0%	21%
no effect	40%	43%

The predominant effect of OT was excitatory. 82% of the cells responding to OT were excited; ON cells were preferentially stimulated by OT. Thus, OT may influence gastric function by modulating gastric-related sensory neurons in the NTS, which then affect the vagal output to the stomach. (Supported by NS 24530).

TYROSINE MODULATES STRESS GASTRIC ULCERATION IN RATS:
R.Murison*, D.Hellhammer, H.Lehnert. Depts. Physiological Psychology,Univ.Bergen/Norway, University Trier/FRG and Internal Medicine, University Mainz/FRG.
The aim of the present study was to explore whether increasing available tyrosine under a stress exposure would modulate the extent of gastric ulceration developing in response to that stress. Earlier studies have demonstrated that tyrosine supplementation is able to modulate endocrine and neurochemical responses to other stressors.

Food-deprived male rats were subjected to a stress of restraint in room temperature (17.5°C) water for 75 minutes. Experimental animals were injected i. p. with 200 mg/kg tyrosine 30 minutes before the initiation of stress procedures. After removal from the restraint, animals were returned to their home cages for 15 minutes prior to sacrifice. Prior injection with tyrosine at this dose level clearly led to a reduction in the amount of bleeding gastric ulceration when compared to saline-injected rats subjected to the same stressor.

These data provide further evidence for the potential of tyrosine to modulate stress responses and suggest a role for this amino acid in protection against stress pathology, although the mechanism remains undetermined.

THE GASTROINTESTINAL CORRELATES OF MOTION SICKNESS IN THE CAT. I.M. Lang, M. Steensrud*, and S.K. Sarna* Dept. of Surg. & Physiol., Med. Coll. Wisc., Zablocki VAMC, Milw., WI 53295.

The aim of this study was to determine the motor and myoelectric activity of the GI tract associated with motion sickness in the cat. Four cats were preselected for their susceptibility (1 vomit in < 10 min) to motion sickness induced by vertical oscillation (VO) at 0.5 Hz. These cats were chronically instrumented with strain gauge force transducers on the fundus, antrum duodenum, and ileum; bipolar electrodes on the antrum and small intestine; and catheters in the jugular vein and gastric corpus. The effect of VO on GI activity was determined and compared to that activated by $CuSO_4$ (5-10 mg, ig) or UK 14304(1-5 µg/kg, i.v.). In all experiments VO inhibited motor activity of the stomach and upper small intestine within 5 min of onset which lasted until approximately 5 min after VO ended. During some experiments the cats exhibited a short lasting antral dysrhythmia which was accompanied by profuse salivation but no change in GI motor activity. At other times the cats vomited and every vomiting episode was accompanied by a characteristic set of motor and myoelectric events (e.g., the retrograde giant contraction (RGC)) similar to that observed previously in the dog. The RGC activated by VO was not significantly different from that activated by $CuSO_4$ or UK14304. Tachygastria was not observed during VO. Conclusions: 1) Motion-induced vomiting, like other forms of vomiting, is accompanied by a stereotypic set of GI motor and myoelectric events including the RGC. 2) The prodromal signs of vomiting (e.g. salivation), which have been equated with nausea in man, are correlated with gastric dysrhythmias other than tachygastria. Therefore, nausea may not be associated with either tachygastria or the gastrointestinal motor correlates of vomiting.

SYNAPTIC ACTION ON SUBSTANTIA NIGRA COMPACTA NEURONS BY SUBTHALAMIC INPUTS STUDIED BY A SPIKE TRIGGER AVERAGING METHOD. Y. Kang*, Y. Kubota, and S. T. Kitai. (SPON: L.D. Partridge) Dept. Anatomy & Neurobiology, College of Medicine, The University of Tennessee, Memphis, Memphis, TN 38163.

The nature of synaptic inputs from the subthalamic nucleus (STH) to the substantia nigra compacta (SNc) were studied by a spike trigger averaging method in an *in vitro* slice preparation in the rat. In a saggital slice containing both SNc and STH, EPSPs were produced in SNc neurons by activation of STH neurons and by microstimulation. First, extracellular antidromic unitary spikes were recorded from STH neurons following microstimulation (< 5 uA) of a discreet site of SNc to identify the area of STH projection. Subsequently, intracellular potentials were recorded from SNc neurons located in the stimulated site. Glutamate induced or spontaneously firing extracellular spikes recorded from STH neurons were used to trigger a computer which averaged synaptic potentials recorded from SNc neurons. Microstimulation was applied through tungsten microelectrodes (DC resistance of 1-3 MΩ). To exclude the possibility of stimulating passing fibers, microstimulation was also applied to multiple sites in STH and its surrounding areas. Biocytin was injected to identify the morphology and location of recorded SNc neurons, and their transmitter phenotype was examined by TH immunoreactivities. STH spike triggered averaging of SNc intracellular responses clearly indicated that STH inputs exert excitatory synaptic action on SNc neurons. Based on the rise time of STH induced EPSPs, the synaptic site was considered to be located on the proxymal dendrites of SNc neurons. The amplitude and falling phase of both unitary and composite EPSPs were markedly attenuated depending on the holding potential at which A-current was active. These data indicate that STH neurons exert excitatory action on SNc neurons and the theshold for spike generation of SNc neurons by this input can be greatly modified by the state of membrane potential. [Supported by NIH NS 20702 and NS 23886 to STK].

TWO TYPES OF SUBSTANTIA NIGRA COMPACTA NEURONS BASED ON ELECTROPHYSIOLOGICAL MEMBRANE CHARACTERISTICS.
Y. Kubota, Y. Kang*, and S. T. Kitai. Dept. Anatomy & Neurobiology, College of Medicine, The University of Tennessee, Memphis, Memphis, TN 38163.

Electrophysiological membrane properties of dopaminergic (DA) neurons in the substantia nigra compact (SNc) were studied in an *in vitro* slice preparation in the rat. Intracellular potentials were recorded from SNC neurons using conventional techniques. Biocytin was intracellularly injected to study the morphology of the recorded SNc neurons and their TH immunoreactivity for identification of DA neurons. SNc TH positive neurons were classified into two types based on their electrophysiological membrane properties (i.e., Type I and II). Type I neurons were characterized by (1) having a low threshold calcium spike, (2) moderate slow return to base line after the offset of intracellularly applied hyperpolarizing current, and (3) no pronounced IS-SD inflection on the rising phase of fast action potential. Type II neurons, on the other hand, were characterized by (1) having no low threshold calcium spike, (2) a prominent and prolonged slow return to base line after the offset of hyperpolarizing current, and (3) a prominent IS-SD inflection. Ramp-like slow depolarizing potential followed by rapid repolarization can be produced in both Type I and Type II neurons. IS-SD spikes can be triggered in both Type I and II neurons by depolarizing current injection. The amplitude and threshold of the spikes linearly decreased with a hyperpolarization of the membrane potential. However, the range of threshold changes was much greater in Type I neurons. These findings indicate that Type I neurons can change their timing of firing (e.g., from rhythmic firing to bursting mode) much easier than Type II neurons. [Supported by NIH NS 20702 and NS 23886 to STK].

358.3

THE REGULATION OF RHYTHMIC FIRING OF SUBSTANTIA NIGRA COMPACTA (SNc) DOPAMINERGIC NEURONS. S. T. Kitai, Y. Kang*, and Y. Kubota. Dept. Anatomy & Neurobiology, College of Medicine, The University of Tennessee, Memphis, Memphis, TN 38163.

It has been reported that SNc DA neurons can fire in a regular pacemaker like pattern. We have attempted to investigate the underlying electrical membrane factors responsible for regular rhythmic firing of SNc neurons in an *in vitro* slice preparation. Intracellular potentials were recorded from SNc DA neurons using a conventional technique. To identify the morphological and transmitter phenotype of the recorded neurons, biocytin was intracellularly injected and tyrosine hydroxylase immunocytochemistry was performed. All of the recorded DA neurons displayed rhythmic firing and the firing frequency was dependent on the holding potential. A bath application of 4-AP increased its frequency. An addition of TTX in the bath abolished Na spike and revealed the underline pacemaker- like potential (PLP) which was characterized by a slow ramp-like depolarization followed by a rapid repolarization. PLP frequency was also voltage dependent and was activated at holding potentials between -55 to -45 mV. PLP could also be activated following the offset of intracellularly injected hyperpolarizing current pulses. The rate of rise of PLP was related to the intensity of the injected current. Intracellular injection of EGTA blocked the repolarizing phase of PLP, prolonged its time course (< 1 sec), and markedly reduced its frequency. These data suggest that calcium current may be involved in the depolarizing phase of PLP and that PLP is responsible for rhythmic firing of SNc neurons. The threshold of PLP and its rate rise are dependent on the spike after-hyperpolarization, which are influenced by calcium dependent potassium current and A-current. [Supported by NIH NS 20702 and NS 23886 to STK].

ELECTROPHYSIOLOGICAL COMPARISON BETWEEN SNC CELLS OF YOUNG AND AGED WISTAR RATS. Lavín, M. A. and R. Drucker Colín. Instituto de Fisiología Celular, UNAM, Apdo.Postal 70-600, 04510 Mexico, D.F.

There is evidence indicating that some characteristics of substantia nigra compacta (SNC) are altered in aged animals (McGeer et al, Arch. Neurol. 34: 33, 1977).

Young male Wistar rats (3 months old) and aged (18 and 20 months old) were anesthetized with halothane, tracheostomized and fixed to a steretotaxic apparatus. Extracellular activity was recorded using microelectrodes filled with 2% pontamine blue in 0.5 M sodium acetate (12-20 Mohms). 102 SNC cells were recorded in young rats. These cells had a frequency rate of 3.38±2.14 spikes/seg (X± SD) a spike interval of 0.97±0.24 seg and a mean duration of 3.59±1.71 mseg. In 18 months old rats 16 cells were recorded, the frequency rate was 3.47±0.99 spikes/seg, the spike interval of 0.75±0.55 and the mean duration of 2.5±1.02 mseg. In 20 months old rats, 25 cells were recorded and their frequency rate was 1.75±1.31 spikes/seg their spike interval was 1.66±2.06 seg and the mean duration of 3.27±1.28 mseg. The difference in the frequency rate was significant. There was also a significant difference in the frequency distribution pattern between young and old rats since the latter showed more activity than the former. In conclusion there are electrophysiological changes in the aged rats, which may reflect either altered membrane properties or changes in dopaminergic activity.

CORRELATION OF DOPAMINE AGONIST INDUCED GLUCOSE UTILIZATION INCREASES AND INHIBITION OF SUBSTANTIA NIGRA PARS RETICULATA NEURONAL ACTIVITY. J.M. Trugman[1], B.G. Weick[2], J.R. Walters[2], and G.F. Wooten[1].
[1]University of Virginia, Charlottesville, VA. 22908 and [2]NINDS, Bethesda, MD. 20892.

[^{14}C]-2-Deoxyglucose (2-DG) autoradiographic studies of dopamine agonist-induced turning in rats with unilateral 6-hydroxydopamine lesions of the nigrostriatal pathway have shown that D1 agonists (SKF 38393 5.0-25.0 mg/kg) markedly increase glucose utilization in the substantia nigra pars reticulata (SNr) ipsilateral to the lesion whereas D2 agonists (quinpirole 0.1-5.0 mg/kg) do not (J. Neurosci. 7:2927, 1987). In studies using extracellular single unit recording in paralyzed ventilated lesioned rats, SKF 38393 (10 mg/kg) was more effective than quinpirole (1.0 mg/kg) in inhibiting the activity of SNr neurons (Brain Res. 405:234, 1987). We have now studied the effect of SKF 38393 (10 mg/kg) and quinpirole (1.0 mg/kg) on glucose utilization in paralyzed ventilated rats. SKF 38393, but not quinpirole, increased 2-DG uptake in the SNr ipsilateral to the lesion resulting in marked left/right asymmetry (55% increase compared to the contralateral side, $p<0.01$). The results support a positive correlation between increased glucose utilization and inhibition of SNr neuronal activity in this animal model. Since both D1 and D2 selective agonists induce turning, the results do not support a correlation between increased glucose utilization or inhibition of SNr activity and turning behavior. Glucose utilization increases observed in awake behaving rats following D1 stimulation likely represent a primary drug effect and not a consequence of movement or sensory feedback.

NOVEL BRANCHING OF SINGLE DOPAMINERGIC NIGROTECTAL CELLS IN THE RAT. K.J. Campbell, M. Takada and T. Hattori. Dept. of Anatomy, Univ. of Toronto, Toronto, Ontario M5S 1A8, Canada.

Our previous work has reported that single cells in the substantia nigra pars reticulata (SNr) send divergent axon collaterals ipsilaterally to both the striatum and superior colliculus (SC) in the rat. These bifurcating SNr cells, many of which express dopaminergic traits, are located predominantly in the ventrolateral portion of the nucleus at its rostal level. Employing a combination of fluorescent retrograde tracing and immunofluorescence histochemistry for tyrosine hydroxylase, we examined further characteristics of this specific SNr cell population. More than 50% of cells projecting ipsilaterally to both the striatum and SC also issued third collateral branches to the contralateral SC. The vast majority (greater than 85%) of these multi-collateralized cells were dopaminergic. Selective chemical lesions of the medial forebrain bundle with MPTP or 6-hydroxydopamine, did eliminate multi-branched SNr cells under study, whereas similar lesions of the SC failed to induce noticeable degeneration of the cells. This suggests that dopamine may preferentially be transported only towards the striatal terminals of parent SNr cells, while another substance (possibly GABA) only towards their SC counterparts. Supported by the MRC of Canada.

PROJECTIONS OF THE NUCLEUS TEGMENTI PEDUNCULOPONTINUS TO CRANIAL NERVE NUCLEI IN THE RAT. S. Keane and I. Grofova, Dept. of Anat., Mich. State Univ., E. Lansing, MI 48824.

Several lines of evidence have suggested that the basal ganglia (BG) may influence movement through projections to the nucleus tegmenti pedunculopontinus (PPN). Previous studies from our laboratory have demonstrated prominent descending PPN projections to the pontine and medullary reticular nuclei as well as sparse direct projections to the spinal cord. The present study utilizes anterograde transport of the lectin Phaseolus vulgaris (PHA-L) to determine whether the PPN also projects to the motor nuclei of the cranial nerves.

Following large PHA-L injections centered in the PPN, labeled fibers exhibiting preterminal and terminal varicosities were observed bilaterally in the 7, 12, Amb, and occasionally in the Mo5 nuclei. The dorsal nucleus of 10 and the solitary nucleus also contained a moderate number of labeled fibers. The densest terminal plexus, presenting two different distribution patterns, was observed in the 7 nucleus. The first pattern was characterized by prominent concentration of labeled fibers in the contralateral rostromedial 2/3 of the nucleus, and the second by diffuse bilateral distribution with greater ipsilateral density.

These observations support a concept that the PPN is an anatomically and functionally diversified nucleus which may mediate BG influences on motor, autonomic, and sensory functions. (Supported by N.I.H. Grant NS25744).

PUTATIVE KAPPA OPIOID-SENSITIVE NEURONS INCLUDE NIGROTECTAL AND NIGROTHALAMIC CELLS. L.A. Thompson and J.M. Walker. Dept. of Psychology, Brown University, Providence, RI 02912.

Since prodynorphin peptides are virtually isolated from other opioid peptide families in the substantia nigra pars reticulata (SNR), the striatonigral prodynorphinergic projection is a model system for the investigation of opioid peptide function. A group of SNR output neurons that increase their spontaneous firing rate in response to a mechanical pressure stimulus applied to the hindpaw are particularly sensitive to the kappa opiate U50,488. While 67% of these pressure-sensitive cells were inhibited by the iontophoretic application of U50,488, less than 21% of other SNR neurons were affected by this compound. In order to better characterize these neurons, extracellular single unit recordings were carried out in anesthetized rats and the targets of these neurons were determined by antidromic activation. These pressure/kappa-sensitive neurons project to the tectum and to the ventromedial thalamus; some are branched neurons projecting to both structures. These cells comprise approximately 30% of spontaneously active SNR neurons and appear predominantly in the lateral aspect of the SNR. These results suggest that prodynorphin peptides may influence motor responses to sensory inputs through actions on these nigrotectal and nigrothalamic neurons.

358.9

DIFFERENTIAL EXPRESSION OF CCK AND NEUROTENSIN (NT) mRNAS IN THE SUBNUCLEI OF RAT VTA. A. Jayaraman, T. Nishimori, P. Dobnar*, and G.R. Uhl. Dept of Neurol, LSU Sch of Med, New Orleans, LA 70112, ARC/NIDA, Depts of Neurol & Neurosci, Johns Hopkins Sch of Med, Baltimore, MD 21224; and U of Mass Med Sch, Worcester, MA 01605.

Cytoarchitecture and neural connections suggest a structural basis for functional heterogeneity among the subnuclei of VTA. Many of the dopaminergic neurons of VTA also coexpress CCK and NT. To further characterize the neurochemical organization of VTA, we studied the pattern of expression of mRNAs encoding CCK & NT in each of the subnuclei of VTA using quantitative in situ hybridization techniques. Studies using 35-S labeled oligonucleotides with specificity for CCK & NT mRNAs show that they are distinctly distributed in the different nuclei of VTA. CCK mRNA is expressed maximally in parabrachialis pigmentosus (14.2% of neurons), interfascicular (12.9), & rostral linear nuclei (12.6%), and just above background levels in caudal linear (4.1) and paranigral (3.2) nuclei. In contrast, NT mRNA is expressed maximally in caudal linear nucleus (15.6%) and nucleus parabrachialis pigmentosus (12.4%), moderately in rostral linear nucleus, minimally in nucleus paranigralis, and only weakly in interfasicular nucleus.

Our results indicate that the different subnuclei of VTA display surprising differences in their neuropeptide gene expression. These differences could have importance considering the key roles played by these neurons in several functions of the brain, including locomotion and central mechanisms of behavioral reinforcement.

358.10

THE NIGROSTRIATAL PROJECTION SYSTEM IN PIGEONS: AN LM AND EM IMMUNOHISTOCHEMICAL STUDY USING ANTISERA AGAINST TYROSINE HYDROXYLASE. E. Karle, K.D. Anderson, and A. Reiner (SPON: M. Shibata). Dept. of Anatomy and Neurobiology, Univ. of Tennessee, Memphis, TN, 38163

In all amniotic vertebrates studied, the striatum receives a massive dopaminergic input from the substantia nigra. A number of studies have used immunocytochemical techniques with antisera against tyrosine hydroxylase (TH) to characterize the LM and EM features of this input in a variety of mammalian species. Since very little ultrastructural data are available on the nigrostriatal system in nonmammals, we investigated this system in pigeons using anti-TH.

At the LM level, numerous TH+ terminals were observed throughout the striatum. LM comparisons to sections labeled for dopamine beta hydroxylase (which labels noradrenergic terminals) revealed that the vast majority of TH+ terminals in the pigeon striatum were dopaminergic. EM examination revealed that a significant percentage of the synaptic terminals in the striatum were labeled for TH. The TH+ terminals contained numerous densely-packed, round and pleomorphic, medium-sized vesicles, some of which were labeled. TH+ terminals typically made symmetric synapses, primarily with the dendritic shafts of striatal neurons, but also on the dendritic spines of striatal neurons.

These results suggest that there are major similarities in the organization of the nigrostriatal projection system in birds and mammals. Dopaminergic terminals in the striatum in pigeons appear similar in terms of their abundance, morphology, and postsynaptic targets to that previously reported in rats. Supported by NS19620 (A.R.) and Huntington's Disease Society of America (K.D.A.).

358.11

LM AND EM STUDIES OF SUBSTANCE P-CONTAINING TERMINALS ENDING ON NIGRAL NEURONS IN PIGEONS. K.D. Anderson, E. Karle and A. Reiner. Dept. Anatomy and Neurobiology, Univ. of Tennessee, Memphis, TN

In all amniotes studied, a large population of striatonigral projection neurons contains substance P (SP) and is by far the major source of SP+ terminals in the nigra. The ultrastructural features of SP+ terminals in the nigra have been studied in rats and monkeys, but whether features observed in these two mammalian species are typical of those present in other amniotes is unknown. Using immunohistochemical techniques for electron microscopy, we examined SP+ terminals in the substantia nigra in pigeons. SP+ terminals contained densely-packed unlabeled small vesicles, and often also contained several labeled large dense-core vesicles. Reaction product was also present in the cytoplasm of the terminals and surrounding the vesicles. Observed synaptic membrane specializations were of the symmetric type. Dendrites contacted by SP+ terminals were densely lined with terminals, about half of which were SP+. To determine whether SP+ terminals contact the subpopulation of nigral neurons that contain dopamine, we used LM double-label immunohistochemical techniques to simultaneously label dopaminergic nigral neurons (using an antiserum against tyrosine hydroxylase, TH) in combination with labeling of SP+ terminals. SP+ varicosities in close association with large and small TH+ dendrites were abundant. SP+ varicosities in contact with TH+ perikarya were also common but less numerous. These results indicate that in pigeons SP+ striatonigral projection neurons form axodendritic synapses having features similar to those in mammals and suggest that the targets of many of these synapses are dopaminergic nigral neurons. Supported by NS19620 (A.R.) and Huntington's Disease Society of America (K.D.A.)

358.12

TOPOGRAPHY OF STRIONIGRAL PROJECTIONS IN THE NORTH AMERICAN OPOSSUM. O.B. Gbonegun and J.C. Hazlett. Department of Anatomy and Cell Biology, Wayne State University, Detroit, MI 48201.

In a recent retrograde tracing study (Gbonegun and Hazlett, '89), WGA-HRP was used to determine the origin of projections to the opossum substantia nigra. Our findings suggested that the strionigral connections might be topographically organized in the medial-lateral dimension. In order to clarify these data, we injected WGA-HRP in portions of the caudate nucleus or putamen and examined the distribution of strionigral fibers. Labeled fibers resulting from caudate injections ramified in the medial two thirds of the pars reticulata throughout its length, while those observed after putamen injections occupied the lateral half of this subdivision throughout much of its length. Reacted fibers within the pars compacta were sparse following injections in the head and body of the caudate nucleus and absent after placements in the putamen. Little if any orthograde transport was seen among the pars lateralis neurons after any striatal injections. Therefore, as in the rat, the opossum pars reticulata is the primary terminus for striatal projections. These projections exhibit a rudimentary topography in which the fibers from the caudate and putamen overlap in the middle of the pars reticulata but otherwise distribute to medial (from caudate) or lateral (from putamen) aspects of this subdivision.

358.13

SOMATOSENSORY MAPPING AND MICROSTIMULATION OF PRIMATE SUBTHALAMIC NUCLEUS (STN). T. Wichmann*, H. Bergman*, and M.R. DeLong (SPON: L. Fechter). Dept. of Neurology, The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

The STN likely has a role in motor control since it receives topographic input from the pre-central motor fields and projects to the globus pallidus. While lesions of STN result in hemiballismus, the effect of microstimulation on movement is uncertain. In a green monkey, we examined the effects of STN microstimulation, and also mapped neuronal responses to somatosensory examination to characterize the stimulation sites and extend previous studies which suggested a somatotopic organization of STN.

Microelectrode penetrations were made from an oblique anterior approach in the parasagittal plane in a 500 um-grid. Cells responding to deep palpation and movement of individual joints of the contralateral arm were found mainly in anterior dorsal STN, whereas cells responding to similar manipulations of the contralateral leg were found mainly in the central and posterior STN. Cells responsive to orofacial movements were located more laterally. Cells with similar responses to passive stimulation were often clustered along individual penetrations. Most ventral STN cells did not respond to somatosensory examination. These findings provide new evidence for a somatotopic organization of STN.

STN microstimulation (trains of 400 ms; biphasic pulses; 40 uA; 300 us/phase; 400 pulses/s) was carried out during the same penetrations at 200 um intervals. Stimulation within STN did not evoke movements. However, stimulation in and near the lateral internal capsule induced contralateral limb movements. Stimulation of areas above, below and rostral to the STN produced contralateral saccades. The lack of microexcitability sets STN apart from motor cortex and some of its efferent targets such as putamen.

358.14

ELECTRO-PHYSIOLOGICAL STUDIES OF THE CONNECTIONS BETWEEN THE SUBTHALAMIC NUCLEUS (STN) AND GLOBUS PALLIDUS (GP) IN BEHAVING MONKEYS. H. Bergman* and M.R. DeLong. Dept. of Neurology, Johns Hopkins Univ. Sch of Med., Baltimore, MD 21205

Earlier lesion and electrical stimulation studies suggested that the STN projections to GP are inhibitory, while more recent anatomical, physiological and pharmacological studies suggest their excitatory (glutamatergic) nature.

Microelectrode recordings were carried out simultaneously in the STN and both segments of GP in two awake behaving Rhesus monkeys. The STN electrode was used interchangeably for microstimulation and single unit recording. STN-GP connections were studied by observing the responses in GP neurons to microstimulation of the STN, as well as by crosscorrelating the spontaneous activity of GP and STN neurons (usually recorded in the same place where the stimulation was delivered). The internal connectivity of GP was studied by correlating the activity of distant (recorded by two microelectrodes) and neighboring (recorded by one electrode) GP neurons.

Microstimulation (bi-polar single pulse, max amplitude 40 uA) in the STN resulted in short latency (<10 ms) complete inhibition (mean duration 40 ms) of spontaneous activity in 40% of the recorded GP neurons (n= 180). However, none of the neuron-pairs studied showed correlated activity. Neighboring GP neurons yielded a flat correlogram in 80% of cases (n=74), and a short latency inhibition in 20%. No one of the distant GP neuron-pairs (estimated distance between 0.5 to 4 mm) showed correlated activity (n=49).

In conclusion, the inhibitory responses of GP to STN stimulation are more likely not due to activation of the STN projection neurons. Furthermore, the lack of crosscorrelation between STN and GP and the lack of common input to simultaneously recorded GP neurons indicate that GP afferents are highly topographic and specific.

358.15

ORGANIZATION OF VENTRAL STRIATAL EFFERENT PATHWAYS WITH THE DOPAMINERGIC NEURONS OF THE PRIMATE SUBSTANTIA NIGRA. E.L. Lynd*, S.N. Haber (SPON: T. Begenisich). Department of Neurobiology and Anatomy, University of Rochester Medical Center, Rochester, New York, 14642.

We undertook a study to examine the pattern of efferent projections from the ventral striatum to the substantia nigra in relation to the dopamine containing neurons. We also examined the relationship of these striatal terminals with specific nigro-striatal projections.

Injections of tritiated amino acids , PHA-L, and WGA-HRP were placed in various striatal regions including the nucleus accumbens, ventromedial caudate, rostral medial caudate, and ventral putamen. Sections were double stained using an antibody to tyrosine hydroxylase. Results demonstrate that the entire rostral-caudal extent of the substantia nigra receives inputs from these striatal regions. Rostrally the terminal labeling for all ventral striatal injections converges in the medial aspect of the substantia nigra. More caudally labeling extends out laterally. Terminal labeling overlapped with the cell bodies of the dopamine neurons as well as their dendrites. Results indicate that nigral neurons projecting to the striatum receive inputs from a different region of the striatum. For example some dopamine neurons in the medial portion of the substantia nigra project in part to the dorsal caudate and receive some inputs from the ventral striatum. These studies suggest that the connections of the striatum and the substantia nigra are complex with both reciprocal and non- reciprocal pathways.

358.16

VASOACTIVE INTESTINAL PEPTIDE (VIP) INNERVATION OF THE EXTENDED AMYGDALA IN THE RAT: A LIGHT AND ELECTRON MICROSCOPIC IMMUNOCYTOCHEMICAL STUDY. H.T. Chang and Q. Tian*. Department of Anatomy and Neurobiology, The University of Tennessee - Memphis, College of Medicine, 875 Monroe Ave., Memphis, TN 38163.

The concept of the "**Extended Amygdala**" was proposed recently by Alheid and Heimer (Neurosci. 27:1,'88) as an area which includes the centromedial amygdala, the sublenticular part of the substantia innominata, and the bed nucleus of stria terminalis (BNST). A region along the posterior limb of the anterior commissure is also included in the extended amygdala based on its apparent intimate relationship with BNST and the central amygdaloid nucleus, and was earlier identified as the interstitial nucleus of the posterior limb of the anterior commissure by de Olmos ('72). This region, however, is not easily distinguished from the ventral striatum in Nissl preparations, and is referred here as the caudal ventral striatum (VSc). In support of VSc as a part of the extended amygdala, we report here that in contrast to the rest of the ventral striatum, only VSc is densely innervated by vasoactive intestinal peptide immunoreactive (VIP+) axons. The dense plexuses of VIP+ axons in VSc appeared to be continuous with those in BNST. A few VIP+ neurons were also found within these regions. Preliminary electron microscopic analysis revealed that VIP+ boutons formed asymmetrical synapses with mainly dendrites and spines of VSc neurons.

ADRENERGIC INNERVATION OF THE RAT SUBSTANTIA INNOMINATA: A LIGHT AND ELECTRON MICROSCOPIC IMMUNOCYTOCHEMICAL STUDY. H. Kuo and H.T. Chang, Department of Anatomy and Neurobiology, The University of Tennessee - Memphis, College of Medicine, 875 Monroe Ave., Memphis, TN 38163.

Adrenergic and noradrenergic inputs to the rat substantia innominata (SI) were studied by immunocytochemical localization of phenylethanolamine N-methyltransferase (PNMT) and dopamine ß-hydroxylase (DBH), the synthetic enzymes for adrenaline and noradrenaline, respectively, using rabbit antibodies to PNMT and DBH (Eugene Tech International). While many PNMT-like immunoreactive (PNMT+) axons were found in SI, sequential double-labeling experiments indicated that PNMT+ axons were much less numerous than DBH-like immunoreactive (DBH+) axons in SI. In order to ascertain that the PNMT+ axons were adrenergic fibers, double-immunofluorescence labeling experiments were performed using a mouse monoclonal antibody to tyrosine hydroxylase (TH) (Boehringer Mannheim), the synthetic enzyme for dopamine. The result indicated that all PNMT+ axons in SI were also immunoreactive for TH. Preliminary electron microscopic analysis revealed that PNMT+ boutons in SI formed asymmetrical synapses with dendrites of SI neurons.

NON-CHOLINERGIC CORTEX-PROJECTING NEURONS IN THE RAT BASAL FOREBRAIN: A LIGHT AND ELECTRON MICROSCOPIC STUDY. J.A. Whittaker*, K.A. Williams*, H. Kuo, N.G.F. Cooper, S.T. Kitai, and H.T. Chang, (SPON: S.K. Bhattacharya) Department of Anatomy and Neurobiology, The University of Tennessee - Memphis, College of Medicine, 875 Monroe Ave., Memphis, TN 38163.

Previous studies have shown that some of the cortex-projecting neurons in the rat basal forebrain were non-cholinergic. In this study we sought to further characterize their morphology and synaptic relationships. The retrograde tracer Fluoro-Gold was injected into the frontal cortex. Sections containing retrogradely labeled neurons in the substantia innominata (SI), the globus pallidus (GP) and the nucleus basalis (NB) were processed for immunofluorescence reactions using antibodies raised against choline acetyltransferase (ChAT). The results indicated that most of the retrogradely labeled neurons were immunoreactive for ChAT. The few non-cholinergic cortex-projecting neurons were found in GP and SI. Some of these cells appeared smaller, while others were comparable in sizes as the cholinergic cortex-projecting neurons. Work is in progress to examine the ultrastructural morphology and the synaptic relationships of these non-cholinergic retrogradely labeled neurons using an immunoperoxidase reaction with a mouse antibody raised against Fluoro-Gold.

(Supported by USPHS Grants EY02708 to NGFC, NS20702 to STK, NS21003, AG05944, and a grant from the Alzheimer's Disease and Related Disorders Association to HTC.)

IDENTIFICATION OF ZINC-CONTAINING EFFERENTS TO THE NEOSTRIATUM BY RETROGRADE TRANSPORT OF ZINC SELENIDE G.A. Howell, P. Mandava*, M.K. Christensen*, and C.J. Frederickson, Lab for Neurobiology, Univ. Texas/Dallas, Richardson, Texas 75083

Prior denervation studies have indicated that the zinc-containing efferents to the neostriatum originate within the cerebral cortex. In the Present work, Se^{-2} was iontophoresed into the striatum precipitating ZnSe in zinc-containing axonal boutons. The resulting retrograde transport of the reaction product from the labeled boutons was studied to determine the specific cells of origin.

The Se^{-2} was stereotaxically delivered from glass micropipettes (1-2 uA; 100-300 sec; 10-20 Mohm tips) and the rats were sacrificed 24 h later. Cryostat sections (20 um) were developed in Timm silver solution to render the ZnSe visible.

Silver grains were found in the zinc-containing neuropil at the injection sites and in the perikarya and proximal dendrites of cortical neurons located primarily in superficial layers and distributed topographically according to the rostro-caudal placement of the injection. Labeled perikarya were not found in the substantia nigra or medial thalamus, indicating that those efferents to the striatum are not zinc-containing.

TARGETS OF HIPPOCAMPAL AXONS IN NUCLEUS ACCUMBENS (VENTRAL STRIATUM). G. E. Meredith, F. G. Wouterlood, and A. Pattiselanno* Dept. Anatomy and Embryology. Free University Medical School, Amsterdam, THE NETHERLANDS.

Nucleus accumbens (acc) receives an extensive projection from the hippocampus. The neuronal targets of these axons are not known but may include GABAergic or cholinergic neurons. We examined the synaptic relationship between hippocampal terminals and their targets in Acc by combining fornix lesions or iontophoretic injections of *Phaseolus vulgaris*-leucoagglutinin (PHA-L) in the subiculum with immunocytochemistry for glutamate decarboxylase (GAD) or choline acetyltransferase (ChAT).

In dual-labelled light microscopic sections we found GAD- or ChAT-immunoreactive perikarya and dendrites embedded in a web of PHA-L-labelled hippocampal fibers. An electron microscopic examination of over 200 PHA-L-labelled or degenerated terminal boutons revealed that 100% of them form asymmetric synaptic specializations; 96% make contact with spines; and 4% contact dendritic shafts. We never found a labelled or degenerated bouton in contact with a ChAT-immunoreactive element even though they were sometimes juxtaposed. Degenerated boutons did form synapses with GAD-labelled elements, particularly labelled spines. These findings suggest that most hippocampal inputs to nucleus accumbens monosynaptically activate GABAergic neurons but probably have little relationship with cholinergic cells.

THE ORGANIZATION OF THE EFFERENT PROJECTIONS FROM THE PRIMATE VENTRAL PALLIDUM. S.N. Haber*, E. Lynd*, D. Wolfer*, and S. Mitchell+, Department of Neurobiology and Anatomy, University of Rochester School of Medicine, Rochester, NY 14642, and +VA Medical Center, Syracuse, NY.

The ventral pallidum is considered to be the limbic-related portion of the globus pallidus by virtue of its afferent connections with the nucleus accumbens, and its efferent projection to the dorsomedial nucleus of the thalamus. In the rat, the ventral pallidum projects to the subthalamic nucleus, the lateral habenular nucleus and the substantia nigra, the ventral tegmental area, as well as to the dorsomedial nucleus of the thalamus (Haber et al., J.C.N., 235:322). Little is known of the ventral pallidal efferent connections in the monkey. We report here a study of the organization of ventral pallidal efferent connections in the primate to determine whether efferent pathways differ from those observed in the rat.

Injections of 3H amino acids, WGA-HRP, or PHA-L were placed centrally into the ventral pallidum, in the region directly below the anterior commissure. As expected, a dense terminal field is observed in the subthalamic nucleus and the substantia nigra. However only the most medial portion of the subthalamic nucleus receives this innervation, while terminals are not limited to the medial nigra. A densely labeled fiber bundle travels in the stria medularis to terminate in the lateral habenular nucleus. Fibers from these injections also reach the dorsomedial nucleus and the ventral anterior nucleus of the thalamus, the lateral and medial parts of the hypothalamus, and the striatum. Although the regions to which the projections from the primate ventral pallidum do not appear to differ substantially from those of the rat, the density and organization of these projections are significantly different in a number of regions.

ACCUMBENS PROJECTIONS TO DORSAL AND VENTRAL PALLIDUM AND TO THE EXTENDED AMYGDALA IN THE MONKEY USING PHA-L. G.F. Alheid[1], C. Haselton[2], L. Heimer[2,3] 1) Depts. of Behav. Med. and Psychiat., 2) Otolaryn., & 3) Neurosurg., Univ. Virginia, Health Sci. Ctr., Charlottesville, Va. 22908.

We have recently advocated that the nucleus accumbens could be considered a mixed structure with similarities to both the striatum and the extended amygdala. The latter structure includes the centromedial amygdala, the bed nucleus of the stria terminalis (BST) as well as interconnecting cell columns beneath the globus pallidus. To further evaluate this view we have re-examined accumbens projections with the anterograde tracer phaseolus vulgaris leucoagglutinin (PHA-L) in marmoset monkeys.

As previously observed, the accumbens projects to the ventral pallidum but also to the medial tip of the internal pallidal segment. Moreover, terminals appear to form a double layer in the ventral pallidum as is the case for striatal projections to dorsal pallidum. Injections medial, central and caudal in the accumbens resulted in terminal labeling in the extended amygdala with the most extensive terminals from the central or caudal injections in nucleus accumbens. Terminals were observed particularly in subpallidal areas but also in the BST. Additional axons continued caudally along the medial surface of the peduncle entering the substantia nigra at its medial edge. Scattered axons were also observed in the paraventricular nucleus of the thalamus. Supported by USPHS #NS 17743.

DISTRIBUTION AND REGULATION OF TYROSINE HYDROXYLASE (TH) mRNA IN MESENCEPHALIC DOPAMINE (DA) NEURONS, Linda T. Weiss-Wunder and M.-F. Chesselet, Dept. of Pharmacology, Med. Coll. Pennsylvania, Philadelphia, PA 19129.

Subpopulations of mesencephalic DA neurons have different electrophysiological, pharmacological and anatomical characteristics. We have measured the level of mRNA for TH, the rate-limiting enzyme in the synthesis of DA, in subgroups of DA neurons in rats and mice using in situ hybridization histochemistry with an ^{35}S-labelled cRNA probe (D. Chikaraishi). In addition, we have analyzed the changes in levels of of TH mRNA induced by alterations in the activity of DA neurons in the mouse. Levels of mRNA were quantified in emulsion-coated slides using computer-assisted grain analysis. In controls, the mean cellular labelling for TH mRNA was 30% lower in lateral and mid portions of the A9 DA cell group than in medial A9 and A10. In mice treated with fluphenazine-N-mustard (FNM; 4 µmol/kg), an irreversible antagonist of DA D2 receptors, DA turnover was increased in the striatum, but TH mRNA was unchanged in A9 and A10 DA neurons 3, 5, and 8 hours after a single injection of FNM. Striatal DA turnover was still increased after 1 and 2 days, but not 4 and 6 days of FNM (2 injections/day). TH mRNA was decreased in A9 DA neurons after 2 and 4 days of treatment, but unchanged at 4 days in neurons of the A10 group. The results suggest that subpopulations of mesencephalic DA neurons are differentially regulated at the level of TH gene expression and that activation of A9 DA neurons by sustained blockade of DA D2 receptors results in a compensatory decrease in TH mRNA which may participate in the molecular adaptation of DA neurons to chronic neuroleptic treatment. 6-HYDROXYDOPAMINE (6OHDA)-INDUCED CHANGES IN LEVELS OF STRIATAL mRNAs ENCODING SOMATOSTATIN (SOM) AND GLUTAMIC ACID DECARBOXYLASE (GAD) AS DETECTED BY IN SITU HYBRIDIZATION HISTOCHEMISTRY (ISHH). J.J. Soghomonian and M.F. Chesselet. Dept. of Pharmacology, Medical College of Pennsylvania, Philadelphia, PA 19129.

The mRNA for GAD and SOM were visualized on coronal sections of rat neostriatum using ISHH with ^{35}S-labeled cRNA probes (A.J. Tobin and R. Goodman) and radioautography. The nigrostriatal dopamine pathway was lesioned by one injection of 6OHDA (6 µg in 2 µl) in the substantia nigra after desipramine pretreatment. A higher intensity of GAD labeling was observed in striatal neurons on the lesioned as compared to the contralateral side. This marked asymmetry was observed in a large proportion of labeled neurons at three coronal levels of the striatum corresponding to plane A10, A9.5 and A9[1]. Few intensely GAD-positive cells could however be observed in both ipsi- and contralateral striata. ISHH for SOM mRNA revealed densely labeled cells scattered throughout the striatum. Using computerized grain analysis, the mean labeling associated with individual striatal cells was significantly lower on the ipsilateral side of the lesion than the contralateral side, with a maximum difference of 35%. This effect in mRNA content was observed at coronal level A9.5 but not A9[1]. Comparison with sham operated animals, showed that the SOM labeling asymmetry in 6OHDA treated rats was solely related to an increase of mRNA levels in the striatum on the contralateral side of the lesion. These results substantiate a different role of dopamine in the regulation of GAD and SOM mRNA in rat striatum. (Supported by BNS 16841, MH 44894-01 and PMAF fellowship to J.J.S.). NMDA GLUTAMATE RECEPTORS STIMULATE TYROSINE HYDROXYLASE ACTIVITY IN NIGROSTRIATAL DOPAMINE TERMINALS. J.A. Arias-Montaño*, D. Martínez-Fong* and J. Aceves*. (SPON: J. Villarreal). Dept. of Physiology, Biophysics and Neurosciences, CINVESTAV-IPN. Ap. Postal 14-740, 07000 México, D.F.

Glutamate receptors have been demostrated on nigrostriatal dopamine terminals (Roberts, P.F. et al. Brain Res. 235: 83, 1982). Here we have studied the role of glutamate receptors modulating tyrosine hydroxylase (TH) activity in these terminals.

Experiments were performed in striatal slices of the rat brain; TH activity was evaluated determining by HPLC l-Dopa accumulation following Dopa decarboxylase inhibition with NSD-1015 (0.5 mM).

l-Glutamate increased TH activity in a dose-dependent manner (EC_{50} = 3 µM); this effect was blocked by 10 µM 2-amino-5-phosphonovaleric acid, a selective NMDA receptor antagonist. The stimulatory effect was calcium-dependent and tetrodotoxine insensitive.

These results suggest that glutamate stimulates striatal dopamine biosynthesis by activation of NMDA receptors coupled to calcium channels presumably localizated on nigrostriatal dopamine terminals.

359.4

EFFECTS OF DOPAMINE RECEPTOR STIMULATION ON SUBSTANCE P RELEASE IN SUBSTANTIA NIGRA OF RATS. **D. Orosz* and J.P. Bennett, Jr. Departments of Neurology, Psychiatry and Pharmacology, University of Virginia Medical School, Charlottesville, VA. 22908.**

Basal ganglia outflow is mediated by both Substance P- and GABA-utilizing pathways in the striatonigral system. We have monitored release of Sub P into the extracellular fluid (ecf) of rat substantia nigra, utilizing brain microdialysis in rats with unilateral lesions of the ascending nigrostriatal pathway (nsp). Nsp lesions were made with 8 µg of 6-hydroxydopamine injected perinigrally, followed 2 weeks later by implanataion of Carnegie-Medicin dialysis probe holders into the substantia nigra reticulata (snr). Dialysis was performed in awake animals before and after systemic treatment with apomorphine, 1 mg/kg.

Substance P was assayed by a modified RIA with sensitivity of detection of 0.2 fmol. Using ^{3}H-Sub P, we found that the 2 mm Carnegie-Medicin probes had an efficiency of 5-6% transfer of Sub P at 1 µL/min perfusion rate. Basal Sub P ecf levels averaged 0.2 nM in lesioned snr and rose 2-3 fold after apomorphine treatment. No rise in Sub P ecf levels was observed after vehicle injection.

We conclude that the Sub P-utilizing component of the striatonigral pathway is activated by stimulation of supersensitive DA receptors.

DOPAMINE D1 HETERORECEPTORS ON STRIATONIGRAL AXON TERMINALS ARE NOT STIMULATED BY ENDOGENOUS DOPAMINE EITHER TONICALLY OR AFTER AMPHETAMINE: EVIDENCE FROM TERMINAL EXCITABILITY

L.J. Ryan, M. Diana*, S.J. Young* and P.M. Groves, Dept. Psych., Oregon State Univ., Corvallis, OR 97330 and Dept. Psychiat., Univ. California San Diego, La Jolla, CA 92093.

The role of dopamine D1 heteroreceptors on striatonigral axon terminals was investigated in rats. Direct infusion (1 and 10 uM; 300 nL in 5 min) of the direct acting, specific dopamine D1 agonist, R-SKF 38393, into the substantia nigra terminal field of antidromically identified neostriatal projection neurons decreased the electrical excitability of these terminals whereas infusion into nonterminal regions did not. The effect could be at least partially reversed by subsequent infusions of the specific D1 antagonist, R-SCH 23390 (10 uM). In contrast, systemic administration of SCH-23390 (0.3 and 0.6 mg/kg, iv), of the non-specific antagonist, haloperidol (0.2 mg/kg, iv) and of the indirect acting dopamine agonist, amphetamine (1.0 and 5.0 mg/kg, iv) were without effect. Since activation of D1 receptors caused a decrease in excitability, the lack of effect of antagonists indicates that endogenous dopmaine is not tonically activating these receptors. Furthermore, the lack of effect of amphetamine indicates that even high levels of released dopamine in substantia nigra do not affect neostriatal D1 heteroreceptors. Thus it is unlikely that endogenous dopamine modulates neostriatal control of the substantia nigra through these presynaptic terminal D1 heteroreceptors.

359.6

NEURONAL LOCALIZATION OF CANNABINOID RECEPTORS IN THE BASAL GANGLIA.

M. Herkenham, A. B. Lynn*, B. deCosta†*, and E. K. Richfield. Unit on Functional Neuroanatomy, NIMH, and †Laboratory of Medicinal Chemistry, NIDDK, Bethesda, MD 20892.

Cannabinoid receptors have recently been characterized and localized using a potent analog, [^{3}H]CP55,940, in section binding assays. In rat brain the highest densities are in the globus pallidus (GP) and substantia nigra pars reticulata (SNr). Selective lesions of either the striatonigral or nigrostriatal pathway were respectively made by unilateral infusion of ibotinic acid into the striatum or 6-OHDA into the medial forebrain bundle (mfb). After 2 or 4 week survivals, slide-mounted brain sections were incubated with ligands selective for cannabinoid, dopamine D-1 ([^{3}H]SCH-23390) and D-2 ([^{3}H]raclopride) receptors, and the dopamine uptake site ([^{3}H]GBR-12935), and exposed to ^{3}H-sensitive film. Resulting autoradiography showed ibotinate-induced losses of cannabinoid, D-1, and D-2 receptors in the striatum and topographic losses of cannabinoid and D-1 receptors in GP and SNr at both survivals. Four weeks after mfb lesions (which resulted in amphetamine-induced rotations), there was loss of GBR binding in the striatum and substantia nigra pars compacta but no change in cannabinoid receptor binding. The data show that cannabinoid receptors in the basal ganglia are neuronally located and are co-localized with D-1 receptors on striatal projection neurons, including their axons and terminals. Cannabinoid receptors are not localized on dopaminergic nigrostriatal cell bodies or terminals.

DOPAMINERGIC FEEDBACK CONTRIBUTES TO FUNCTIONAL DIFFERENCES BETWEEN TYPE I AND TYPE II STRIATAL NEURONS.

E.S. Nisenbaum, A.A. Grace, and T.W. Berger. *Departments of Behavioral Neuroscience and Psychiatry, University of Pittsburgh, Pittsburgh, PA 15260*

Type I and Type II striatal neurons can be identified based on their paired impulse responses to stimulation of the corticostriatal pathway. We have examined the extent to which dopaminergic (DA) feedback contributes to functional differences between these two striatal cell classes.

Destruction of DA afferents increased the spontaneous activity of both Type I and Type II neurons *in vivo*. Such denervation also increased the range of facilitation displayed by Type I neurons to interstimulus intervals (ISIs) of <50 ms, and decreased the magnitude of inhibition to ISIs of 50-250 ms. In contrast, responses of Type II cells were unaffected.

Using a corticostriatal slice preparation, paired impulse stimulation of cortical afferents produced a facilitation of striatal cell discharge to ISIs of 10-400 ms. DA (10 µM) did not affect the facilitatory responses of *in vitro* neurons to short ISIs. However, in a small percentage of these cells, DA produced a pronounced inhibition to ISIs of 30-480 ms which was similar to that found for Type I neurons *in vivo*. This effect was mediated by activation of D_1 but not D_2 receptors.

Potentiation of GABAergic activity using pregnanolone (5 µM) selectively enhanced short-interval (10-20 ms) inhibition of approximately 50% of the *in vitro* neurons sampled; the paired impulse profiles of these *in vitro* cells parallelled those displayed by Type II neurons *in vivo*. When low doses of DA (5 µM) and pregnanolone (5 µM) were combined, separate populations of neurons displayed either short- or long-interval inhibitory responses. These results define conditions under which Type I- and Type II-like neurons can be identified *in vitro*, and suggest that long ISI inhibition observed *in vivo* is mediated by activation of D_1 receptors. Supported by NS19608, MH00343, MH09717.

CHARACTERIZATION OF LUCIFER YELLOW-LABELED RAT STRIATAL NEURONS IDENTIFIED BY THEIR RESPONSE TO PAIRED PULSE CORTICAL STIMULATION.

S.-P. Onn, T.W. Berger & A.A. Grace *Departments of Behavioral Neuroscience & Psychiatry, Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.*

In vivo intracellular recording and Lucifer yellow staining were used to differentiate the properties of Type I and Type II striatal neurons categorized by their inverse responses to paired pulse stimulation (Nisenbaum et al, J. Neurosci. 8: 4138, 1989). Type I cells exhibited a more variable morphology. The multipolar to fusiform soma (22-35 µm long) gave rise to 2-3 comparatively long and thick primary dendrites, which divided into sparsely spined or heavily spined processes extending distally. The axons arose from the soma and ramified locally, but only axons of densely spinous neurons could be followed for long distances. These neurons had higher rates of spontaneous activity (2.6-17.7 Hz) and fired predominantly in a bursting pattern. In the majority of Type I cells examined, the spikes did not exhibit prominent IS-SD breaks.

Type II neurons were similar in morphology to the medium spiny neurons, with the 14-22 µm long soma giving rise to 3-6 primary dendrites with densely spinous, angular or recursive secondary and tertiary processes. The axon arose from the soma and arborized extensively within the dendritic field, with the main axonal branch extending for long distances. These neurons were silent or slow firing (0-7.4 Hz), with spikes exhibiting prominent IS-SD delays. Most neurons fired individual spikes, but faster firing cells (>3-4 Hz) often fired in bursts. Systemic administration of apomorphine (0.1 mg/Kg i.v.) was observed to facilitate spike firing in Type II neurons in response to frontal cortical stimulation. This could be reversed by the administration of haloperidol (0.1 mg/Kg i.v.). In contrast, apomorphine had no observed effect on the physiology of two Type II neurons that were not firing spikes spontaneously. Supported by USPHS NS19608, NS08288, & MH00343.

359.9

DOPAMINERGIC MODULATION OF STRIATAL SENSORY PROCESSING

T.I.Lidsky, A.M.Cosentino* and S.Banerjee CUNY Med

Sensory processing in the striatum changes during changes in behavior (1). The present study assessed the possible role of dopamine in striatal sensory plasticity. Striatal field potentials were evoked by facial stimulation in urethane anesthetized rats. Dopamine release due to stimulation of the substantia nigra (SN) attenuated striatal sensory responses. Surprisingly, the dopamine receptor blocker Haldol (H) also attenuated sensory responses. Further work suggested that the attenuation is due to increased dopamine release caused by blocking presynaptic receptors. Paradoxically, H reversed the inhibitory effect of the SN: after H, SN stimulation enhanced striatal sensory responses. The latter effect, since it was blocked by picrotoxin, may be due to inhibitory striatonigral feedback triggered by the enhanced dopamine release brought about by SN stimulation in combination with presynaptic receptor blockade.

The present findings indicate that the synaptic effects of dopamine may differ from the functional effects. While dopamine inhibits striatal firing, its effects on striatal processing can be either suppression or facilitation as a function of dopaminergic tone.

ON-LINE MORPHOMETRY OF TYROSINE HYDROXYLASE-IMMUNOREACTIVE AXON TERMINALS IN CAUDATE PUTAMEN AND NUCLEUS ACCUMBENS IN RAT WITH A FOCUS ON SYNAPSES.

D.S. Zahm and J.W. Haycock.[1] Dept. of Anat.& Neurobiol., St. Louis Univ. Sch. of Med., St. Louis, MO 63104 and [1]Dept. of Biochem., LSUMC, New Orleans, LA 70119.

On-line analysis of tyrosine hydroxylase immunoreactive striatal boutons was executed with the EM analogue of a **camera lucida** (Carl Zeiss) supported by morphometric functions of hardware and software dedicated to 3-D reconstruction (Eutectic). We report on a preliminary sample of every fifth of 1,864 intact boutons generated by a "gating" procedure utilizing the x-y traverse controls of the microscope. Boutons were located in dorsolateral (dl, 777) or dorsomedial (dm, 150) caudate-putamen (Cpu) and in rostral (r, 254) or medial (m, 559) accumbens (Acb) or the accumbal "core" (124). Patch and matrix compartments were not distinguished. Skewed-right, monomodal frequency distributions of profile area in CPu and Acb with medians of 2.6 and 2.3 µm^2, respectively, reflected the sums of bimodal plots that contrasted dm vs. dl CPu and m vs. r and core accumbens. Some profiles in CPu (7.3% of 927) and Acb (8.9% of 937) exhibited synaptic appositions which, excepting less than 0.5%, were symmetric and ranged from 0.05 to 3.5 µm in length. Postsynaptic targets of synapses in mAcb were skewed toward dendrite shafts (72%) as opposed to spines (11%). Those in CPu were distributed equally among shafts (43%) and spines (46%) as were those in rAcb and core Acb (41% shafts, 41% spines). Suppported by USPH NIH NS-23805.

359.11

BREAKDOWN OF DOPAMINE D1/D2 RECEPTOR SYNERGISM IS INDEPENDENT OF RECEPTOR DENSITY. G.J. LaHoste, M. Andreini*, L.C. Brunner* and J.F. Marshall. *Department of Psychobiology, University of California, Irvine 92717.*

Recent evidence indicates that in neurologically intact animals dopamine (DA) receptor subtypes act synergistically; i.e., DA receptor-mediated events (either behavioral or electrophysiological) require concomitant stimulation of D1 and D2 receptors to be manifest. Following 6-hydroxydopamine-induced DA denervation or subchronic reserpine treatment, however, there is a breakdown in synergism; D1 and D2 receptors act independently and with greatly increased sensitivity to agonists. We tested the hypothesis that treatments which alter receptor density would modify D1/D2 synergism. Four groups (n = 8) of adult male rats were given daily injections of saline (1.0 ml/kg), SCH 23390 (SCH; 0.5 mg/kg), haloperidol (HAL; 0.5 mg/kg), or both SCH and HAL (0.5 mg/kg each) for 21 days. Seventy-two h after the last drug injection, animals were observed for motor stereotypies in response to stimulation of D1 receptors alone (SKF 38393, 20 mg/kg, 30 min after the D2 antagonist eticlopride, 0.1 mg/kg), D2 receptors alone (quinpirole, 3.0 mg/kg, 30 min after the D1 antagonist SCH 23390, 0.1 mg/kg) or both D1 and D2 receptors (SKF 38393, 20 mg/kg + quinpirole, 3.0 mg/kg). This procedure was repeated at 48 h intervals until all subjects had received each of the test conditions in counterbalanced order. The data from all four groups were virtually identical; subjects displayed a pattern of complete D1/D2 synergism (i.e., stereotypies were observed only after concomitant stimulation of D1 and D2 receptors). By contrast, when independent groups of rats were treated for 5 d with reserpine (1.0 mg/kg/day), stereotypies were observed following stimulation of either D1 or D2 receptors alone, indicating a breakdown in D1/D2 synergism. Since previous receptor binding studies have shown that chronic treatment with SCH or HAL increases D1 or D2 receptor densities, respectively, whereas five days of reserpiine treatment does not alter D1 or D2 receptor binding, the present data indicate that D1/D2 synergism is unrelated to D1 or D2 receptor density.

359.12

STRIOSOMAL AND GRADIENT PATTERN OF DOPAMINE HIGH-AFFINITY AND MONOAMINE SYNAPTIC VESICLE SITES IN THE RABBIT CAUDATE. J.F. Marshall, R. Navarrete* and S.J. O'Dell, Dept. of Psychobiology, Univ. of Calif., Irvine, CA 92717.

The dopaminergic afferents to the neostriatum appear distributed heterogeneously, reflecting the patch-matrix organization of this structure as well as topographic gradients. For example, the tyrosine hydroxylase (TH) immunoreactivity is lower in striosomes of the caudate nucleus (CN) than in surrounding matrix (Graybiel et al, *PNAS 84*:303-7). Yet, it is unclear whether such heterogeneities mark differing densities of dopamine (DA) innervation or populations of DA terminals differing in their characteristics. In rabbit neostriatum we have used film autoradiography to quantify the binding of [^{3}H]mazindol (MAZ), which recognizes the high-affinity catecholamine transporter of DA neurons, and [^{3}H]ketanserin (KET), which labels the monoaminergic synaptic vesicles of this structure, in relation to acetylcholinesterase (AChE) histochemistry and [^{3}H]hemicholinium-3 (HC-3) labeling on adjacent sections. The AChE-poor striosomes of the rabbit CN correspond to [^{3}H]HC-3-poor regions (Rhodes et al, *Br. Res. 412*:400-4). A patchy distribution of both [^{3}H]MAZ and [^{3}H]KET binding was observed in the anterior CN, with circumscribed zones of 20-40% lighter binding of these ligands corresponding with regions sparse in AChE and [^{3}H]HC-3 binding. At the level of the body of the CN, the patchy distribution of [^{3}H]MAZ and [^{3}H]KET binding is less evident, but there is a striking three-fold dorso-ventral decreasing gradient of [^{3}H]MAZ binding, with lowest levels found in nucleus accumbens (NAc). However, [^{3}H]KET binding is almost (75-80%) as high in NAc as in dorsal CN. The lighter binding of both [^{3}H]MAZ and [^{3}H]KET in striosomes, together with the lower TH immunoreactivity of this compartment, suggests a less dense innervation by DA fibers of striosomes than matrix. But we hypothesize that the dorsoventral gradient of [^{3}H]MAZ binding sites may reflect a NAc population of DAergic terminals having a paucity of high-affinity DA transport sites.

ULTRASTRUCTURAL CHANGES IN RAT BRAIN ASSOCIATED WITH NEUROLEPTIC DRUG TREATMENT. C.K. MESHUL, A. JANOWSKY*, D.E. CASEY*, AND R.K. STALLBAUMER*. V.A. MEDICAL CENTER AND DEPTS. OF PATHOLOGY, PSYCHIATRY, AND NEUROLOGY, OREGON HEALTH SCIENCES UNIVERSITY, PORTLAND, OR. 97201.

We have previously shown that treatment with haloperidol (0.5 mg/kg/day, 14 d) causes an increase in the number of synapses containing perforated postsynaptic densities (PSDs) in the caudate but not the nucleus accumbens (Meshul and Casey, 1989). This effect was reversed after discontinuation of the drug. There was no effect on total synapse density. We have now examined the effects of haloperidol (0.5 mg/kg/day, 14 d and 30 d), a dopamine D-2 receptor blocker, SCH 23390 (1 mg/kg/day, 14 d), a D-1 receptor blocker, or clozapine (30 mg/kg/day, 14 d), a weak D-1/D-2 receptor blocker, on the number of perforated PSDs and the total number of synapses in the caudate. One day after treatment, the rats were perfused with fixative and the caudate prepared for electron microscopic analysis. Both haloperidol (14 d) and SCH 23390 (14 d) caused a 40% increase in the number of synapses with perforated PSDs as compared to the controls, while clozapine had no effect. In addition, there was a 30% increase in the number of perforated PSDs following haloperidol treatment for 30 days There was no change in total synapse density following haloperidol or SCH 23390 treatment for 14 days, but clozapine (14 d) and haloperidol (30 d) caused a decrease in the total number of synapses. The lack of perforated PSD change with clozapine may correlate with its low incidence of extrapyramidal side effects. Supported by the V.A.

DEVELOPMENT OF THE STRIATAL PATCH-MATRIX ORGANIZATION FOLLOWING PERINATAL DOPAMINE DEPLETION.

A.M. Snyder-Keller. Wadsworth Center for Laboratories and Research, New York State Dept. Health, Albany, NY 12201

Nigrostriatal dopamine (DA) projections are early markers for the patch/matrix organization of the striatum. During the first postnatal week in the rat, patches of DA fibers overlap with clusters of striatal neurons (Snyder-Keller, Neurosci. Lett. 91: 136 (1988)), projecting back to the substantia nigra (Fishell & van der Kooy, J. Neurosci. 7: 1969 (1987)). In order to determine the influence of DA on the formation of striatal patches, the organization of immunocytochemically-identifiable cell types was examined during development, in normal rats and in rats DA-depleted as infants (0 or 3 days) or in utero (E17). During the first week of life, corresponding patches of DA afferents and substance P (SP)-immunoreactive neurons exist in the dorsal striatum of normal animals. AChE-positive zones found primarily in the lateral striatum also show partial overlap with both SP and DA patches. Injection of 6-HDA into the lateral ventricles of fetal (E17) or infant rats produced a dramatic loss of striatal DA terminals, but did not disrupt the patchy distribution of SP-immunoreactive neurons nor the pattern of AChE staining. The distribution of cells immunoreactive for enkephalin or calcium-binding protein was also not noticeably changed by pre- or postnatal DA depletion. These experiments suggest that the patchy distribution of DA afferents is secondary to the early clustering of striatal neurons forming the patch compartment, and is not necessary for the maintenance of striatal patch/matrix organization. MULTIPLE CHALLENGES WITH APOMORPHINE INCREASE ROTATIONAL BEHAVIOR IN 6-OHDA OR KAINIC ACID LESIONED RATS L.M. Wyatt, A.B. Norman, M. Kulmonpunporn, C.A. Moody*, P.R. Sanberg, and M.N. Lehman. Departments of Anatomy & Cell Biology, Neurology, and Psychiatry, Univ. Cincinnati Coll. Med., Cincinnati, OH 45267

Rotational behavior following injection of the dopamine agonist apomorphine is a commonly used test of nigro-striatal dopamine function in rats. The present study assessed the stability of this measure over time. Male Sprague-Dawley rats either received a unilateral injection of 6-OHDA to the medial forebrain bundle or substantia nigra or kainic acid (KA) lesions to the striatum. After a minimum of 10 days, rats were placed in an open-field arena, allowed to habituate, and then injected with apomorphine (0.1 or 0.25 mg/kg s.c.). The number of complete, tight rotations in either direction was counted visually and expressed as the difference between the two directions. Data were grouped by 5 minute periods. Identical tests were then repeated at intervals of 3-5 days. Preliminary results indicate a significant increase in the total number of rotations between the first and subsequent trials for 6-OHDA rats ($p<.05$) and in both total rotations and peak number of rotations in a 5-minute period for KA lesioned rats ($p<.05$). Latency to the peak number of rotations did not change between trials. Duration of rotational behavior was not significantly increased for either 6-OHDA or KA lesioned rats. This phenomenon indicates a sensitization to the effects of repeated administration of apomorphine and has implications for the use of rotational behavior to quantify drug interactions following surgical interventions with dopaminergic systems. NEURAL MECHANISMS MEDIATING DOPAMINE AGONIST-INDUCED DYSTONIA IN THE PARKINSONIAN MONKEY A.R. Crossman*, I.J. Mitchell* and M.A. Sambrook*. (SPON: Brain Research Association)
Experimental Neurology Group, Dept. of Cell and Structural Biology, University of Manchester, Manchester M13 9PT, England.

Dystonia refers to a class of movement disorders which is characterised by a syndrome of abnormal sustained postures. Relatively little is known about the pathophysiology of dystonia though the basal ganglia have long been implicated in the underlying pathology. This report describes an experiment which investigates the neural mechanisms which mediate experimental dystonia in a novel model of dopamine agonist-induced dystonia in the macaque monkey. This condition was produced by chronic dopamine agonist treatment of an animal with a unilateral parkinsonian syndrome induced by infusion of MPTP into the right carotid artery. The treatment resulted in the appearance of axial and contralateral limb dystonia at peak dose. The 2-deoxyglucose (2-DG) metabolic mapping technique was applied to the animal during the expression of active dystonia. Densitometric analysis of the resultant autoradiographs revealed large asymmetries in 2-DG uptake between the lesioned side of the brain (which gave rise to the dystonic symptoms) and the control side. Increases in optical density on the lesioned side relative to the unlesioned side were seen in the subthalamic nucleus (36.1%), lateral pallidal segment (12.4%), medial pallidal segment (16.7%) and substantia nigra (18.4%) In contrast, large decreases in optical density were seen in the ventral anterior/ventral lateral nuclei of the thalamus (10.6%) and lateral habenula (14.9%) ipsilateral to the lesion. These findings are interpreted as suggesting that dystonia results from over-activity of the projections from the putamen to the medial pallidal segment and from the lateral pallidal segment to the subthalamic nucleus but decreased activity in the subthalamopallidal and pallidothalamic pathways.

NEONATAL DEVELOPMENT OF NIGRAL DOPAMINERGIC NEURON ELECTROPHYSIOLOGY *IN VIVO* J.M. Tepper, F. Trent*, and S. Nakamura, Center for Molecular and Behavioral Neuroscience, Rutgers University, Newark, NJ 07102

Neuroanatomical data indicate that dopaminergic (DA) neurons are among the earliest in the brain to differentiate, migrate, and send axons to neostriatal terminal fields, but data concerning the development of their physiological properties are lacking. Extracellular single unit recordings were obtained from antidromically identified nigrostriatal (NS) DA neurons in urethane-anesthetized rat pups ranging in age from postnatal day (PD) 1 to PD28. NSDA neurons from PD1-3 rats fired spontaneously at low rates (0.96±.1 spikes/s), in an irregular pattern lacking bursts, with long periods of inactivity. Mean firing rates increased over the next week (PD4-6, 1.3±.2; PD7-9, 1.5±.2), and bursts typically consisting of 2 spikes with interspike intervals less than 100 ms were observed, giving rise to bimodal interspike interval histograms. Spontaneous firing rates and patterns reached adult values between the 3rd and 4th postnatal weeks. Spike waveforms were wider in PD1-3 rats (4.95±.7 ms) than in adults (3.36±.1), and often exhibited a delay between the initial segment (IS) and somadendritic (SD) components > 1 ms. In PD1-7 neonates, the IS spike amplitude was often ≥ that of the SD spike.

The mean latency of striatal-evoked antidromic (AD) responses did not change significantly from PD1-3 (15.6±.9 ms) through adulthood (14.6±.6), although the proportion of AD responses that consisted of the full IS-SD spike decreased from PD1-3 (50.3±8%) through maturity (25.3±3%). IS-SD AD responses in neonates showed long delays between the 2 spike components, often > 2 ms. Equivalent proportions of NSDA neurons in neonates and adults displayed multiple, discrete AD latencies, and AD threshold currents did not differ significantly with age, suggesting that NSDA axons can function at least as early as PD1. Intracellular recordings did not reveal striatal-evoked synaptic responses in NSDA neurons although all non-DA nigral neurons responded with IPSPs whose mean onset latency (9.8±.4 ms) did not differ from adults.

Thus, rat NSDA neurons are physiologically competent at least from PD1, although the rate and pattern of spontaneous activity do not mature to adult values before PD21-28. Several physiological indicators suggest that neonatal NSDA neurons exist in a more depolarized state than in the adult rat. This may be due to a combination of immature membrane properties and a relative lack of physiologically functional neostriatal and/or pallidal inhibitory afferents.

3-ACETYLPYRIDINE RESULTS IN DEGENERATION OF BOTH EXTRAPYRAMIDAL AND CEREBELLAR MOTOR SYSTEMS: LOSS OF THE DORSOLATERAL STRIATAL DOPAMINE INNERVATION. A. Y. Deutch, J. Elsworth, D. Rosin, S. Bruce*, M. Goldstein[1], and R. H. Roth. Depts. of Psychiatry and Pharmacology, Yale Univ. School of Medecine, New Haven, CT 06508 and [1]Dept. of Psychiatry, NYU School of Med, NY, NY 10016.

Although 3-acetylpyridine (3-AP) is well known to effect degeneration of the olivocerebellar climbing fiber system, another pyridine, MPTP, effects degeneration of the nigrostriatal dopamine (DA) system; it has only recently been shown that MPTP results in some cerebellar toxicity. We have examined the effects of 3-AP treatment of rats on the nigrostriatal DA system. 3-AP resulted in degeneration of the DA innervation of the dorsolateral striatum (CP), and the emergence of a distinct patchy distribution of surviving tyrosine hydroxylase (TH)-immunoreactive fibers. 3-AP treatment decreased DA content in the dorsolateral but not central CP, and did not alter DA levels in the NAS or PFC. 3-AP treatment also decreased striatal TH activity. *In vitro* studies showed that 3-AP inhibited MAO_B but not MAO_A activity; however, deprenyl pretreatment did not prevent the 3-AP-induced decrease in striatal DA. These data indicate that 3-AP results in degeneration of both extrapyramidal and cerebellar motor systems, and that 3-AP-induced sequelae may serve as a useful animal model of olivopontocerebellar atrophy-associated parkinsonism.

GABAERGIC INTERNEURONS, RATHER THAN SPINY CELL AXON COLLATERALS, ARE RESPONSIBLE FOR THE IPSP RESPONSES TO AFFERENT STIMULATION IN NEOSTRIATAL SPINY NEURONS. C.J. Wilson, H. Kita and Y. Kawaguchi, Dept. of Anat. and Neurobiol., Univ. of Tenn. Sch. Med., Memphis, TN 38163.

Cortical or local stimulation evokes a powerful EPSP followed by less prominent GABAergic IPSP in neostriatal slices, and corresponding response components occur *in vivo*. Because many spiny projection neurons contain GABA, it is usually assumed that the IPSPs arise from recurrent axon collaterals of the spiny neurons. Recently, GABAergic interneurons have been demonstrated in the neostriatum. These offer an alternative explanation for the IPSPs.

We examined the responses of identified spiny neurons to antidromic stimulation in slices and intact rats. Antidromic spike afterpotentials were distinguished from synaptic potentials by preventing the antidromic spike in the recorded cell by collision with a previous spike or application of strong hyperpolarizing current. No IPSPs comparable to those associated with excitatory orthodromic stimulation could be observed under these conditions.

To determine whether orthodromic activation could occur in the absence of action potentials in the spiny neurons, cortical stimulation was applied in a slice with intact connections from a portion of the cerebral cortex. This orthodromic stimulus does not directly activate any neostriatal neurons or their axons. It was adjusted so that it evoked small subthreshold synaptic potentials in spiny neurons, but did not cause any spiny neurons to fire action potentials. Under these conditions we were still able to detect the IPSP.

Thus, excitation of spiny projection neurons is neither necessary nor sufficient for the observation of the GABAergic IPSPs observed in spiny cells. The GABAergic IPSPs must therefore arise from the action of another GABAergic cell type in the neostriatum.

360.2

THE MORPHOLOGY OF PARVALBUMIN IMMUNOREACTIVE NEURONS IN THE RAT NEOSTRIATUM. H. Kita, T. Kosaka, and C. W. Heizmann, Dept. of Anat. & Neurobiol., Univ. of Tenn. Sch. Med., Memphis, TN 38163 USA, Natl. Inst. for Physiol. Sci., Okazaki, 444 Japan, and Inst. for Pharmacol. and Biochem., Univ. of Zurich-Irchel, Zurich, Switzerland.

Studies have indicated that a small population of neurons in the neostriatum contain a Ca-binding protein parvalbumin (PV) and that these neurons are strongly immunoreactive for GABA and glutamate decarboxylase antibodies. We have conducted more detailed light and electron microscopy on the PV-immunoreactive neurons.

Rats were prefused with 4% paraformaldehyde, 0.1% glutaraldehyde, and 0.2% picric acid in 0.12M phosphate buffer. The brains were removed and sectioned on a Vibratome. The brain sections were processed for immunocytochemistry for PV using avidin-biotin-peroxdase method.

Light microscopy revealed that PV-neurons correspond with medium size aspiny neurons described in previous Golgi studies. The medium sized somata were fusiform or polygonal in shape and aspiny dendrites were smooth and cylindrical at the proximal portion but were varicosed at the distal portion. Electron microscopy revealed that the somata of PV-neurons contain a deeply intended nucleus and an intranuclear rod. Many synaptic boutons were found on the proximal and distal dendrites and only a few were on the somata. While a small number of the boutons on the somata and proximal dendrites formed symmetrical synapses, the majority formed asymmetrical synapses. Many PV stained boutons were found on the somata and proximal dendrites of medium spiny neurons which were identified by their morphological features.

The data indicate that immunohistochemistry for parvalbumin selectively stains medium, aspiny, GABAergic interneurons in the neostriatum. The electron microscopy suggested that the neurons are incorporated in a feed-forward inhibitory circuit that they receive excitatory afferent inputs and their outputs are to inhibit neostriatal projection neurons. EVIDENCE THAT THE EXTRASTRIOSOMAL MATRIX OF THE PRIMATE STRIATUM CONTAINS A MOSAIC OF NEURONAL CELL-CLUSTERS PREFERENTIALLY PROJECTING TO THE EXTERNAL AND TO THE INTERNAL PALLIDUM. J.-M. Gimenez-Amaya* and A.M. Graybiel.

Dept. of Brain and Cognitive Sciences, MIT, Cambridge, MA 02139, USA.

In a preceding report (Gimenez-Amaya and Graybiel, Neurosci. Abstr. 14:156) we presented retrograde tracer evidence that striatal neurons projecting to the pallidum in the primate are concentrated in the extrastriosomal matrix of the putamen (P) and caudate nucleus (CN), and that different populations of neurons project to the two pallidal segments (GPe, GPi). We also suggested that neurons projecting to each pallidal segment may aggregate in clusters, some at a distance from the main fields of striatal labeling. In this study we have analyzed this clustering phenomenon, and have investigated the topography of the striatopallidal projection in 41 hemispheres of 24 adult squirrel monkeys in which we placed HRP-WGA as a retrograde tracer in GPe, GPi or both, or HRP-WGA and [35S]methionine as anterograde tracers in CN, P or both. The findings suggest: (1) there is a global, three-dimensional, largely radial topography of the striatopallidal projection, in which the CN as well as the P participates (e.g. anterograde and retrograde evidence suggests a sizable projection from the rostral CN to the rostral GP, especially GPe); (2) there is a highly ordered mosaic of projection-neuron clusters in the extrastriosomal matrix. In fact, no injection in the pallidum, whether in GPe or in GPi, failed to evoke labeling of some cell clusters. For GPi injections (with a lesser fiber-of-passage problem), clustering was a dominant pattern. The relative weakness of labeling of striosomes accounted for some but by no means all of the patchiness. We conclude that clustering of striatopallidal projection neurons may help to account for functional heterogeneity of striatal units studied physiologically and for functional specificity of different striatal output paths. SENSORY AND OCULOMOTOR PROPERTIES OF SINGLE NEURONS IN THE CAUDATE NUCLEUS OF THE ALERT CAT : EVIDENCE FOR REGIONAL ORGANIZATION W.A.Thomas*, C.R. Olson, and E.M. Bowman. Department of Psychology, Princeton University, Princeton, N.J. 08544.

The caudate nucleus of the cat is anatomically heterogeneous. At a gross level, it consists of connectionally distinct sectors: a lateral (L) zone (with input from somesthetic and skeletomotor cortical areas), a dorsomedial (DM) zone, (with input from visual association and oculomotor cortical areas) and a ventromedial (VM) zone (with input from prefrontal and other complex areas). At a fine level, it consists of chemoarchitecturally and connectionally distinct compartments: the striosomes and matrix.

We have searched for signs of functional heterogeneity in the caudate nucleus by recording from 135 neurons in 3 cats trained to execute saccadic eye movements and maintain fixation on visual targets. We have found: (a) that caudate neurons exhibit robust task-related activity in relation to the appearance of the target (32%), the execution of the saccade (10%) and the maintenance of fixation (57%); (b) that neuronal properties vary by subregion, with phasic sensory and saccadic signals most common in the DM zone, tonic fixation-related signals most common in the VM zone, and task-related firing rare in the L zone. We are currently investigating the relation between neuronal physiology and striosomal-matrix organization.

360.5

MORPHOLOGY OF NEURONS IN CELL CLUSTERS IN THE CAUDATO-PUTAMEN AND NUCLEUS ACCUMBENS OF THE RAT. V.B. Domesick, P.A. Paskevich* and H.K. Evans*. Mailman Research Center, Mclean Hospital, Belmont, MA 02178 and Harvard Medical School, Boston, MA.

In the present study, several recently observed differences between cell clusters composed of serially contiguous cells in the caudato-putamen (C-P) and nucleus accumbens (NA) are reported. The arrangement of individual cells in the clusters were visualized by three-dimensional reconstructions (software by John Kinnamon, 1987) from serial one micron sections. Clusters in the C-P frequently include up to 25 neurons, while the number in the nucleus accumbens was often higher, up to 50. The morphology of the neurons was examined in serial semi-thin sections and in ultrathin sections. In the C-P, most cells in a single cluster appear to be of the small-to-medium type with smooth unindented nuclei corresponding to the spiny projection neurons of Graveland and Difiglia (1985). In the NA, small cells with one or two processes form clusters; these clusters are solely composed of neurons with either smooth or indented nuclei. At the ultrastructural level, the profiles of cytoplasmic membranes are typically separated by a 6nm space with intercalated zonulae occludens and wider spaces. In the C-P, these appositions are usually. soma-somatic, while in the NA they also are dendro-somatic. These cell clusters are included within larger neuronal groups which resemble the striatal cellular islands described in the primate by Goldman-Rakic, 1982. (This work is supported by 1R01 MH43018.)

EXPRESSION AND SECOND MESSENGER RESPONSES OF MUSCARINIC RECEPTORS IN PRIMARY CULTURES OF RAT NEOSTRIATUM. K. Nishi*, P.T. Akins, D.J. Surmeier, S.T. Kitai (SPONSOR:William L. Byrne), Dept of Anatomy and Neurobiology, College of Medicine, The University of Tennessee, Memphis, Memphis, TN 38163

One action of acetylcholine in the neostriatum is the inhibition of dopamine-stimulated increases in adenylate cyclase activity. We employed the primary culture model of rat neostriatum to investigate the role of post-synaptic receptors in this action.

Primary neostriatal cultures were established and maintained from embryonic (E17) rat neostriata as previously described (Surmeier et al. Dev. Brain Res., 42:265-282,1988). Binding studies were carried out with 3H-N-methyl-scopolamine (NMS) on intact cultures maintained 3, 7, and 14 days in vitro. The neuronal population was estimated from cell counts and protein was measured for each experiment. The Bmax at 3, 7, and, 14 days was 138±17, 212±68 and 187±43 fmol/mg protein or 1060±55, 2061±420 and 32000±3000 sites/neuron. These results indicate muscarinic receptors rapidly increase in cultured neostriatum.

Previous studies determined that receptors were predominantly of the M1 subtype and linked to phosphoinositide turnover. We tested their linkage to adenylate cyclase. Cultures (12 DIV) were labeled with [3H]adenine and cAMP levels were stimulated with 10 uM forskolin (76%) or 10 uM dopamine (93%) in the presence of 1 mM isobutylmethylxanthine. Carbachol (50 μM) had no effect on these stimulated levels. The results suggest that the M1 receptor expressed by neostriatal neurons does not directly inhibit adenylate cyclase. This work was supported by P.H.S. grants NS 20702 to S.T.K., NS 26473 to S.T.K. and D.J.S.

MUSCARINIC MODULATION OF A TRANSIENT OUTWARD CURRENT IN RAT NEOSTRIATAL NEURONS. P. Akins, D. J. Surmeier and S.T. Kitai, Dept. of Anatomy and Neurobiology, College of Medicine, The University of Tennessee, Memphis, Memphis,TN 38163.

Cholinergic interneurons are important elements in the circuitry of the neostriatum. However, little is known about the modulatory actions of acetylcholine on voltage-dependent conductances in neostriatal neurons. Current-clamp studies (Misgeld et al., Pflugers Arch., 407:482-487, 1986) of striatal neurons have suggested that muscarinic agonists modulate the conductances controlling the duration of the calcium-dependent plateau potential. To quantitatively characterize the specific conductances mediating this effect, we have investigated the actions of muscarinic agonists on ionic currents in rat neostriatal neurons using the whole cell voltage clamp technique.

Neurons were cultured from embryonic rat neostriatum and recorded from as previously described (Surmeier et al., Brain Res., 473: 187-192, 1988). Preliminary experiments have shown that in roughly half of the neurons, bath application of carbachol in the presence of a nicotinic receptor antagonist (mecamylamine) increases the transient outward current evoked by depolarizing test pulses. This transient current exhibited activation and inactivation characteristics similar to the A-current previously described in these neurons. In a smaller percentage of neurons, carbachol application increased the sustained outward currents evoked by depolarization. No consistent effects were observed on holding current at -70 mV or on the outward currents evoked by holding the cell at -40 mV. These results suggest that acetylcholine may depress excitability in neostriatal neurons through enhancement of the A-current. This work was supported by P.H.S. grants NS 20702 to S.T.K., NS 26473 to S.T.K. and D.J.S.

MULTI-CHANNEL RECORDING OF NEURONAL ACTIVITY IN HISTOLOGICALLY DEFINED COMPARTMENTS OF NEOSTRIATUM IN FREELY MOVING RATS. S.F. Sawyer, J.Y. Chang, C.D. Myre and D.J. Woodward, *Dept. of Cell Biology & Anatomy, Univ. Texas Southwestern Medical Center at Dallas, Dallas, TX 75235.*

Anatomical studies have revealed a heterogenous organization in the mammalian neostriatum consisting of a patchwork of spatially congruent neurochemical and hodological compartments ("patches") that are embedded within a more voluminous "matrix". To date, electrophysiological evidence concerning the functional aspects of patch and matrix in awake behaving animals is lacking. We report here our initial electrophysiological findings concerning neurons located in the matrix. Sixteen microwires were implanted in the dorsolateral neostriatum of adult male Long-Evans rats. Subsequently, multi-channel extracellular single unit recordings were obtained from the freely moving animals, including during an auditory-cued treadmill paradigm. Localization of recording sites to patch or matrix was inferred on-line by positive responses (i.e., 5-10 ms latency orthodromic excitation and/or 100-200 ms duration post-stimulus inhibition) to electrical stimulation of prelimbic or motor cortex, respectively. Microlesions of selected recording sites, in conjunction with radiolabeling of histological sections with ^{3}H-Naloxone to label patches, permitted verification of the location of recording sites to either patch or matrix. Neostriatal neurons typically exhibited enhanced spike activity during treadmill-induced locomotion, as previously described (West et al., Soc. Neurosci. Abstr. *13*:979, 1987). These neurons were found to be located in the matrix. Furthermore, many of these units were identified as "Type II" neurons (based on responses to twin pulse cortical stimulation). In contrast, a smaller sample of "Type I" neurons in the matrix did not exhibit pronounced treadmill-related changes in firing rate. The activity of neurons in the patch compartment are currently under investigation to examine the general issue of functional heterogeneity within the neostriatum. *Supported by NIDA grant DA-05352.*

EFFECTS OF PILOCARPINE ON THE DORSAL IMMOBILITY RESPONSE IN THE RAT. G.A. Cottrell, T. Potter*, M.E. Meyer* and C. Van Hartesveldt. Dept. of Psychology, Univ. of Florida, Gainesville, Fl, 32611 U.S.A.

Cholinergic agonists, such as pilocarpine, are known to increase immobility latencies on a number of catalepsy tests in rats. These agents elicit catalepsy when injected into the mesencephalic reticular formation but have no effect when administered alone to the striatum. The effect of pilocarpine on the Dorsal Immobility Response (DIR), a response elicited by grasping a rat by the dorsal skin at the nape of the neck and lifting it off its feet, was tested on male and female Long-Evans rats. All surgery was done a minimum of 2 weeks prior to testing. Guide cannulae were implanted above the anterior dorsal striatum. In Exp. 1, pilocarpine (90 mg/kg, sc) increased bar catalepsy latencies but decreased DIR latencies. Exp. 2 found that pilocarpine, in doses as low as 1.25 mg/kg sc, was effective. This effect appears to be cholinergic since scopolamine (1 mg/kg, sc) pretreatment blocks it. In Exp. 3, the DIR was decreased following bilateral pilocarpine injection (5 ug/0.2 ul/side) into the striatum. Striatal scopolamine (10 ug/0.4 ul/side) pretreatment blocked the effect of pilocarpine on the DIR. Thus DIR is exquisitely sensitive to cholinergic manipulation but the cholinergic control and neural site of action are different for catalepsy and DIR.

DOPAMINE AND CALCIUM BINDING PROTEIN-CONTAINING NEURONS AND FIBERS OF THE NIGROSTRIATAL SYSTEM FOLLOWING ADULT AND NEONATAL 6-OHDA LESIONS. L. M. Grimes, H. Criswell, M. Sar*, W.E. Stumpf, R.A. Mueller, G.R. Breese. Bio. Sci. Res. Center, UNC-Chapel Hill, NC 27599.

Rats treated ICV with 6-OHDA as neonates,but not as adults, exhibit self-injurious behavior (SIB) when given L-DOPA. We compared the destruction of the nigrostriatal dopamine system in adult- and neonatal-lesioned rats. Rats were perfused with 4% paraformaldehyde and 0.2% glutaraldehyde. Serial Vibratome sections (30 μm) were immunostained for tyrosine hydroxylase (TH), 28kD calcium binding protein (CaBP), and for colocalization of both antigens. Radioimmunocytochemistry for TH was performed on 4μm frozen sections in striatum. 30% of TH-containing neurons in ventral tegmental area (VTA) and 10% in substantia nigra pars compacta (SNPC) were preserved in adult-lesioned rats, 10% of VTA cells and none in SNPC were preserved in neonatal-lesioned rats; cells preserved in adult but not neonatal-lesioned rats were in the lateral VTA and dorsal SNPC. In VTA and dorsal SNPC, neurons containing CaBP and TH were destroyed in the same proportions as neurons containing TH alone. Some fibers were preserved in the nucleus accumbens (NA) and olfactory tubercle (OT) of neonatal and adult-lesioned rats; in adult-lesioned rats, some fibers were also preserved in ventral caudate-putamen (CP). These results suggest that neurons in the lateral VTA and medio-dorsal SNPC are the source of fibers which project to the ventral CP and protect against SIB. (Supported by NS-21345 and HD-23042.)

DISTRIBUTION OF THE LIMBIC SYSTEM ASSOCIATED MEMBRANE PROTEIN (LAMP) IN THE CAUDATE NUCLEUS (CN) AND SUBSTANTIA NIGRA (SN) OF THE CAT M.-F. Chesselet, C.Gonzales and P. Levitt. Med. Coll. Pennsylvania, Philadelphia, PA 19129.

LAMP is a cell surface 64-68 kD glycoprotein associated, in the adult, with brain areas innervated by the limbic system. We have analyzed the distribution of LAMP in the basal ganglia of the adult cat using immunoperoxidase staining and a monoclonal antibody. In CN, areas of intense LAMP staining were in register with areas of weak acetylcholinesterase activity (striosomes), which receive inputs from the amygdala and prefrontal cortex. In contrast, the extrastriosomal matrix, which receives afferents from the cingular cortex, A10, A8, and the densocellular zone of A9, was devoid of LAMP labelling. In the SN, an intense labelling for LAMP in the cell sparse zone of the pars compacta contrasted with the absence of immunostaining in areas containing dense clusters of dopaminergic neurons (densocellular zone). The results show that subsets of neurons of the CN and SN share a common antigenic determinant with the limbic system, further revealing a segregation of limbic inputs in the basal ganglia.

ORIGIN OF THE AMYGDALOID PROJECTION TO THE LATERAL SUBSTANTIA NIGRA AND RETRORUBRAL FIELD. C. Gonzales and M.-F. Chesselet. Dept. of Pharmacology, Medical College of PA, Phila. PA 19129

In an attempt to identify the site of origin of the projection of the central nucleus of the amygdala (CeN) to the lateral substantia nigra (SN), small iontophoretic injections of the anterograde tracer PHA-L were made in discrete areas of the CeN. PHA-L was detected immunohistochemically in 30 um thick sections using an antibody to PHA-L (Vector Laboratories) and the avidin-biotin system with diaminobenzidine as the chromogen. In addition, adjacent sections were processed for somatostatin (SOM) immunoreactivity using an antibody (R. Benoit) against SOM 1-12. Only injections of PHA-L into the dorsal and rostral CeN resulted in heavily labeled bouton-like swellings in the lateral SN pars compacta and SN pars lateralis. These injections also gave rise to a dense labeling in an area of the retrorubral field which partially overlaps with the A8 dopaminergic cell group and contains a dense plexus of SOM-positive nerve terminals. Similar labeling was observed after injections rostral, or dorsal and medial to the CeN. These results suggest that the cells of origin of the amygdaloid projection to the lateral SN are located in a restricted area of the CeN but are also present in a region dorsal and rostral to the CeN within the sublenticular substantia innominata (extended amygdala).

MORPHOLOGICAL CHARACTERS OF INTRACELLULAR LABELED SPINY NEURONS IN RAT NEOSTRIATAL GRAFTS. Z.C.Xu, C.J.Wilson and P.C. Emson Department of Anatomy and Neurobiology, School of Medicine, U. T. Memphis. Memphis, TN. and AFRC Institute of Animal Physiology and Genetics Research, Cambridge, U.K.

A cell suspension prepared from 15-18 day embryonic striata was implanted into neostriata of adult rats two days after kainic acid lesion. Intracellular recording *in vivo* was performed 2-6 months after implantation. After recording, neurons were stained by intracellular injection of biocytin.

The somatic sizes of the labeled spiny neurons in the grafts were larger than in normal neostriatum, with cross sectional areas ranging from 112.6-375.6 μm^2 (as opposed to 112-197 in the host neostriatum). The dendritic fields were similar in size and complexity to those of normal neostriatum. Dendrites of graft spiny neurons near the edges of the grafts crossed the boundary , with some dendrites remaining in the graft and some entering the host. The pattern of spines along the dendrites was similar to normal cells (i.e. the first 20 µm from somata had few spines, the peak spine density was between 40-100 µm), but the overall density of spines on graft spiny neurons was lower than the host cells , especially in the center of the grafts.

Axons of the graft spiny neurons branched repeatedly to form a dense network throughout the grafts, and mostly confined to the grafts. A few axon collaterals could be traced a short distance outside the grafts. Electron microscopic analysis revealed synaptic contacts both in the grafts and in the host neostriatum. These synapses in the grafts were similar in structure to those in the hosts. About 40% of the labeled terminals contacted dendrites, with the remainder contacting dendritic spines or spine stalks.

AXONAL PROJECTION PATTERNS OF IENTIFIED NEOSTRIATAL MATRIX SPINY CELLS REVEALED BY INTRACELLULAR INJECTION OF BIOCYTIN IN RATS. Y. Kawaguchi, C.J. Wilson and P.C. Emson. Frontier Research Program, RIKEN, Wako, Japan 351-01, Dept. Anatomy and Neurobiology, Univ. of Tennessee, Memphis, Memphis, TN, and AFRC Institute of Animal Physiology and Genetics Research, Babraham, Cambridge, U.K.

Cytochemical studies have shown that substance-P containing neostriatal spiny neurons project primarily to the substantia nigra (SN) and entopeduncular nucleus (EP), while enkephalin-containing cells project primarily to the globus pallidus (GP). A thorough classification of cells based on their axonal projections is not possible using population labelling techniques, but requires examination of the complete axonal projections of single neurons.

We have found that complete visualization of the axonal projections of single neostriatal neurons can be achieved using intracellular injection of biocytin. Labeled cells were visualized by avidin-biotin-HRP complex with DAB reaction. Neurons residing in the matrix compartments were identified by counterstaining sections containing the injected cells using immuno-histochemistry for calbindin. In the matrix, we have found at least three subtypes of spiny neurons: (1) cells that project only to (GP), (2) cells projecting to GP and SN, (3) to GP, EP and SN. All three kinds of neurons have axonal branches in GP. The shapes and densities of the GP arborizations varied in the three cell types, with the cell projecting only to GP projecting more heavily there than the other two. These results indicate that spiny neurons are more heterogeneous in their efferent projection patterns than previously suspected, and that population studies of efferent projections and peptide content may not reveal the the full range of efferent cell types.

DEVELOPMENTAL EXPRESSION OF CALBINDIN-28KD IN STRIATUM OF POSTNATAL RATS. F.-C. Liu, A.M. Graybiel, P.C. Emson and C. Gerfen. Dept. Brain & Cognitive Sci., MIT, Cambridge, MA 02139, USA; A.F.R.C., Inst. Animal Physiology, Cambridge, UK; NIMH, Bethesda, MD, USA.

Calbindin-28KD-like immunoreactivity (CB-LI) is known to be a marker for medium-sized neurons in the extrastriosomal matrix in mature striatum of rat and other species. Here we sought to learn whether CB is expressed selectively by matrix neurons during development, and whether during development its expression is restricted to medium-sized striatal neurons. CB-LI was studied in sections through the caudoputamen (CP) of P0, P3, P7 and P15 rats. For all but P0 tissue, serial-section comparisons with tyrosine hydroxylase-like immunoreactivity (TH-LI) were made. CB-LI was expressed by two neuronal types in the P0 CP: small-to-medium cells and medium-to-large cells with well-stained dendrites. The smaller cells appeared in patches and lattice-works in a ventral arc stretching from mediocaudal to laterorostral CP, mostly ventral to regions with the darkest TH-positive dopamine (DA) islands. With increasing age, CB-LI invaded a progressively larger ventral zone that by P7 included about half, and by P15 nearly three-quarters, of the CP. The early lattice-pattern filled in so that at P7 and P15 there were only relatively circumscript CB-poor zones in otherwise CB-rich fields. Nearly all DA islands detected ventrally occurred in CB-poor patches. Often these islands were smaller than the CB-poor patches. There were many CB-poor zones for which DA islands could not be detected. The larger CB-positive neurons were mostly in the dorsal CP, where fields of small-to-medium CB-positive neurons were lacking. These larger CB-positive neurons were prominent at P0 but were rare at P7 and P15. We conclude that CB-LI is a marker of medium-sized matrix neurons during postnatal development; that its compartmental expression may occur independently of, and along different gradients from, the DA island system; and that different matrix neurons may express CB-LI at different times. The transient population of larger CB-positive neurons may either migrate out of the striatum, die, or cease expressing the CB antigen. Supported by NSF BNS 8720475.

CYTOCHROME c OXIDASE: A STRIATAL MATRIX MARKER S.J. Augood*, D.E. Lawson* and P.C.Emson MRC Group, AFRC, Institute of Animal Physiology & Genetics Research, Babraham, Cambridge, CB2 4AT.

Cytochrome c oxidase (ferrocytochrome c, oxygen oxidoreductase, E.C 1.9.3.1) is present as a trans-membrane protein of the inner mitochondrial membrane in all eukaryotes and forms part of the cell membrane in some prokaryotes. In this study we have compared the distribution of cytochrome oxidase (CO) activity with the pattern of immunocytochemical staining for the enzyme tyrosine hydroxylase (TH) and the calcium binding protein, calbindin 28K (CaBP), in the adult rat striatum at the light microscopic level.

The heterogeneous distribution of CO activity observed in the rat striatum using immunoperoxidase histochemistry was found to be analogous to the immunocytochemical staining pattern seen for TH and CaBP. Within the rat striatum areas of high TH and CaBP- like immunoreactivity (termed the matrix) corresponded to areas of high CO reaction product. Conversely, areas of low TH and CaBP-like immunoreactivity (termed striosomes or patches) corresponded to areas of low CO reaction product. We therefore propose that in addition to the established markers acetylcholine esterase, TH and CaBP, the enzyme CO may be a useful striatal matrix marker.

LONG TERM SURVIVAL OF FETAL STRIATAL GRAFTS: LOCALIZATION OF CALBINDIN, ENKEPHALIN, NADPH-DIAPHORASE AND GABA. R.C. Roberts and M. DiFiglia. Lab. of Cell. Neurobiology, Mass. Gen. Hosp. East, Charlestown MA 02129.

We examined whether neurons in 16 month fetal striatal grafts retained similar morphological characteristics to those seen in 2 month old grafts. We also compared the morphology and frequency of grafted spiny neurons to adult neostriatal spiny neurons, by localizing immunoreacive (i) calbindin-D28k (CAL), a selective marker of spiny neurons. Grafts from 17 day fetal striata were injected into lesioned caudate in 5 adult rats. After 16 months, the neostriatum was processed for the localization of GABA, CAL, enkephalin (ENK) and NADPH-diaphorase (-d) activity. The frequency of iGABA, iENK and NADPH-d neurons in the 16 month grafts (25±6, 13±4, and 3±3, % of total neurons±SD, respectively) was similar to findings in 2 mo. grafts (Roberts & DiFiglia, 1988), indicating long-term survival of these cell types in the grafts. The density of iCAL neurons in the graft vs the host was 58±8%. The nuclear morphology of grafted iCAL cells was much more varied than in spiny neurons from normal caudate. Although approximately 1/3 of grafted iCAL cells had unindented nuclei, and thus resembled neostriatal spiny neurons, the remaining nuclei were markedly indented, notched or ruffled. This indicates a change in phenotype of many grafted spiny neurons. Supported by NS-08308-02 to RCR and NIH NS-16367 to MD.

ULTRASTRUCTURAL LOCALIZATION OF IMMUNOREACTIVE GAP-43 IN THE ADULT RAT CAUDATE NUCLEUS. M. DiFiglia[1], R.C. Roberts[1] and L.I. Benowitz[2] Lab. of Cell. Neurobiology[1], Mass. General Hosp. East, Charlestown MA 02129 and Mailman Research Ctr[2], McLean Hosp., Belmont MA 02178.

Growth-associated protein (GAP)-43 is a neuron-specific phosphoprotein implicated in neuronal development, regeneration and plasticity. In the adult, the neostriatum is among those brain areas with a high content of GAP-43. GAP-43 immunoreactivity was examined in the adult rat caudate (n=5) using a sheep polyclonal antibody. At the light microscopic level immunoreactive (i) GAP-43 was heavily localized throughout the caudate neuropil, but was absent from neuronal somata. At the ultrastructural level, labeling was most prevalent in unmyelinated axons of small diameter (0.12-0.15um). Reaction product was distributed along fibers in discrete patches about 1 um apart and in preterminal sites from which vesicle-filled boutons arose. Staining was also present in small (0.35um) axon terminals which contained round vesicles and formed asymmetric synapses mostly with thin spines. Labeled terminals resembled cortical afferents. Unexpectedly, iGAP-43 was also occasionally found in the heads of thin dendritic spines that received asymmetric contacts. We speculate that GAP-43 may be important in the remodeling of synapses onto medium spiny neurons in the adult caudate nucleus. Supported by NIH NS-16367 to MD, NS-08308-02 to RCR.

THE MORPHOLOGIC BASIS OF A MEDIAL TO LATERAL GRADIENT IN RAT STRIATAL CHOLINERGIC MARKERS. RE Burke, A Karanas,* N Kenyon*. Dept. Neurology, Columbia Univ., NYC, NY, 10032.
The striatum is organized into both distinctly bounded striosomal compartments and gradients of neuronal markers (Graybiel and Ragsdale, 1983). Several studies have shown that cholinergic (CAT) biochemical markers show an increasing medial to lateral gradient in the rat. The morphologic basis of this gradient is unknown. We therefore studied whether CAT perikarya or fibers, or both, are distributed in such a gradient. CAT perikarya were stained by immunohistochemistry using a monoclonal antibody (B-M) and PAP. The striatum was divided into medial and lateral compartments by a line along the greatest dorso-ventral axis. Stained neurons were counted at 400x in the two compartments in 2 representative sections from each rat. The area of each compartment was determined with an image analyzer and the density (neurons/mm^2) was determined. There was no significant difference between lateral and medial density of neurons either at 3 weeks (Lat x=22.2±2.2; Med x=18.6±1.7, p=0.2, NS; N=8 planes in 4 rats) or at 9 weeks (Lat x=17.5±0.7; Med x=18.6±1.0, p=.5,NS; N=8 planes in 4 rats). However, fiber staining in frozen sections in both 3 week and adult rats, showed an increased density in the lateral compartment, especially dorsally. The increased density was apparent both as number of fibers per field at 1000x, and, at the population level, as increased density of staining. NINDS #1K07NS00746, DMRF, PDF.

BASAL GANGLIA AND THALAMUS VI

361.1

EXPRESSION OF STRIATAL RECEPTORS AND CHANNELS IN RNA-INJECTED XENOPUS OOCYTES. S. Mundamattom*, S. Sealfon* and B. Gillo* (SPON: N. Levin). Dept. of Neurology and Neurobiology. Mt. Sinai Medical School. New York, N.Y. 10029.
The GABAergic neurons of the striatum (STR) play an important role in voluntary movement. We studied the expression of receptors and channels in Xenopus oocytes injected with RNA extracted from rat STR microdissections. Cells were voltage clamped 3-4 days after RNA injection. In STR RNA injected oocytes, responses to ACH (1257±167 nA, n=13), GABA (111±40 nA, n=4), NMDA (24±3 nA, n=20), quisqualate (34±12 nA, n=2), kainate (8±2 nA, n=14), CCK (103±10 nA, n=3), Substance P (233±180 nA, n=3) and neurotensin (95±41 nA, n=3) were recorded. Expression of the voltage-activated Ca current (recorded via Ca-sensitive Cl current, Tout) was increased in STR RNA injected cells. By measuring the high threshold Tout, a cAMP sensitive current, we found augmentation of the response by forskolin (25±3%, n=3) and by SKF38393 (53±29%, n=5) in STR RNA injected cells, indicating expression of STR D1 receptors. This system suggests a way to study the interaction of receptors and channels subserving the striatal contribution to motor control.

361.2

PHOSPHOLIPASE-C AND ENKEPHALIN IN THE NUCLEUS ACCUMBENS. P.Voorn* and C.R.Gerfen. Lab of Cell Biology, NIMH, Bethesda, MD 20892.

Enkephalin (ENK)-immunoreactivity (IR) in the nucleus accumbens (NA) is distributed in a heterogeneous pattern, consisting of areas with heavy, moderate or light immunostaining. This pattern is closely related to the distribution of other markers and thalamic afferents. The question is how the mosaic structure of the NA is related to that of the caudate-putamen (CP). In the present study the distribution of Phospholipase-C isozymes (PLC-II and -III, Rhee, Science, i.p.) was examined in the striatum of young (P5) and adult rats, in relation to that of ENK. A comparison was made between the occurrence of ENK and ENK mRNA in the different areas observed in the IR-pattern of ENK in the NA. The results show that in young animals PLC-II is preferentially localized in the patch compartment of the CP, whereas in adults the distribution of the enzyme is rather homogeneous, although heavy staining in the patches can still be recognized. The distribution of PLC-III in the adult is homogeneous. Medially in the NA of adults, areas heavily immunostained for PLC-II are present, which coincide with the lightly immunostained ENK areas. In turn these areas correspond to the so-called cell clusters. This feature makes PLC-II, together with μ-opiate receptors, a specific marker of the cell cluster "compartment". No correspondence was observed between the previously described heavily stained ENK areas laterally in the NA and the distribution of PLC-II. Combined immunocytochemistry and "in situ" for ENK showed that the lightly immunostained areas medially in the NA are occupied by cells lightly labeled for ENK mRNA, whereas the surrounding, moderately immunostained areas consist of cells expressing higher amounts of mRNA. In conclusion,heavy immunostaining for PLC-II is a shared feature of the patch compartment in the CP (best appreciated during development) and the cell cluster compartment in the NA. Furthermore, in contrast to the CP, where no difference is observed in the distribution of cells expressing ENK mRNA in patch or matrix compartment, the heterogeneous pattern of ENK-IR in the NA is reflected in the distribution of ENK mRNA. On the other hand, in the CP patches are characterized by heavy ENK-immunostaining, whereas the cell clusters in the NA are lightly stained and, in addition, express little ENK mRNA.

361.3

DIFFERENTIAL EFFECTS OF CHRONIC HALOPERIDOL AND CLOZAPINE TREATMENT ON EXPRESSION OF SOMATOSTATIN (SOM) mRNA IN THE STRIATUM, NUCLEUS ACCUMBENS AND FRONTAL CORTEX OF THE RAT. P. SALIN, M. MERCUGLIANO and M.F. CHESSELET, Dept. of Pharmacology, The Medical College of Pennsylvania, Philadelphia PA 19129.

Quantitative in situ hybridization with an ^{35}S-labeled cRNA probe (R. Goodman) was used to measure SOM mRNA levels in adult rat brain. In normal animals, the number of neurons containing SOM mRNA was higher in the nucleus accumbens (NAc) (11.7 ± 0.5 cells/mm^2) than in the striatum (St) (4.5 ± 0.2 cells/mm^2) or the Frontal cortex (FCx) (6.7 ± 0.7 cells/mm^2). In contrast, SOM mRNA per individual neuron was more abundant in the St than in the Nac or the FCx suggesting that SOM mRNA expression in these brain structures is differentially regulated. Chronic administration of haloperidol (1mg/kg for 28 days) induced a marked decreased of SOM mRNA contents in the NAc, FCx and in the medial but not the lateral St. Clozapine treatment (20mg/kg for 28 days) increased SOM mRNA in the NAc, but not in the St and the FCx when compared to normal animals. This difference between the effects of haloperidol and clozapine (an atypical neuroleptic) on SOM mRNA expression suggests that alterations in the activity of striatal somatostatinergic neurons may be critical for the induction of extrapyramidal side effects. (Supported by grants BNS 16841, MH 448934-01 and training grant MH 14654 to M.M.)

361.4

EFFECTS OF CHRONIC NEUROLEPTIC TREATMENT ON THE LEVEL OF GLUTAMIC ACID DECARBOXYLASE (GAD) mRNA IN THE GLOBUS PALLIDUS (GP) OF THE RAT AS REVEALED BY IN SITU HYBRIDIZATION HISTOCHEMISTRY (ISHH). M. Mercugliano,[1] M.F. Chesselet,[1] C. Saller,[2] A. Salama [2], and D. U'Pritchard [2]; Med. Coll. Penn., Philadelphia, PA.[1] and ICI America, Inc., Wilmington, DE.[2]

GABAergic neurons constitute the major output pathways of the basal ganglia and are likely to participate in the overall effects of agents which modify striatal neurotransmission. We have compared the effects of two antipsychotic drugs with different pharmacologic profiles and side effects on the level of GAD mRNA in the efferent neurons of the GP. Rats were treated with either 1 mg/kg/day of haloperidol, 20 mg/kg/day of clozapine, or vehicle for 28 days. After sacrifice by decapitation, brains were frozen, cryostat-cut into 10 µm sections, and stored at -70° C. ISHH was carried out using an ^{35}S cRNA probe (A.J. Tobin) on paraformaldehyde post-fixed sections for 3 1/2 hours at 50° C. The intensity of labeling on emulsion-coated slides was measured using computer-assisted grain analysis (Morphon). In control rats, GAD mRNA levels were similar in the dorsal, ventral, medial, and lateral GP. Sections of the GP in clozapine-treated rats showed an increase in labelling for GAD mRNA (average 42%) in all GP regions when compared to corresponding levels in control rats. No change, or a slight decrease, was seen in GP sections of haloperidol-treated rats. The results show that the level of GAD gene expression in the basal ganglia can be altered by pharmacological treatment and suggest that the atypical neuroleptic clozapine, but not haloperidol, may increase GABAergic output from the GP.

361.5

ULTRASTRUCTURAL EXAMINATION OF ENKEPHALIN AND SUBSTANCE P INPUT TO CHOLINERGIC NEURONS IN THE RAT NEOSTRIATUM. M. Martone*, S. J. Young*, D. M. Armstrong and P.M. Groves, (SPON: J. C. Hansen) University of California, San Diego.

In the present study, we use ultrastructural double-labeling immunocytochemical techniques to examine the interaction of enkephalin and substance P containing terminals with cholinergic perikarya in the rat neostriatum. Previous work from this laboratory has shown that in the cat, cholinergic neurons appear to concentrate within substance P rich- and enkephalin-rich patches in the dorsal-lateral caudate nucleus. While it has been demonstrated previously that cholinergic neurons receive input from substance P containing terminals (Bolam et al, Brain Res. 397, 1986), it is not known whether enkephalin interacts in a similar fashion. Both enkephalin and substance P are found in subpopulations of common spiny striatal neurons.

Adult male Sprague-Dawley rats were perfused transcardially using acrolein as the primary fixative. Vibratome sections were processed immunocytochemically for choline acetyl transferase (ChAT) (antibody provided by L. Hersh) using a silver intensified colloidal gold procedure. Sections were then processed for either enkephalin (mouse monoclonal antibody-Sera Labs) or substance P (rat monoclonal antibody-Sera Labs) using peroxidase as the second label. Following the double-labeling procedure, sections were osmicated and embedded for sequential light and electron microscopy.

Preliminary results suggest that cholinergic neurons receive a sparse enkephalinergic input onto their cell bodies and proximal dendrites. Enkephalin-positive profiles, some containing vesicles, were found apposed to 3 out of the 5 cholinergic neurons examined thus far. On two of these neurons, only one such profile was observed. No synaptic specializations were seen although serial section analysis has not yet been attempted. Enkephalin synapses were seen onto unlabeled perikarya and dendrites which formed symmetrical synaptic specializations. Three cholinergic neurons were examined in sections double-labeled for substance P and ChAT. Two of these neurons received input from substance P terminals: as many as five substance P synapses were observed onto a single longitudinally sectioned dendrite. Substance P staining terminals contained large round or pleomorphic vesicles and formed symmetrical synapses.

This work was supported in part by the Office of Naval Research.

361.6

SPECIFIC BILATERAL ALTERATIONS IN LOCAL CEREBRAL GLUCOSE UTILIZATION FOLLOWING INTRANIGRAL INJECTION OF MUSCIMOL AND SUBSTANCE P. C. Dermon*, M. Tzagrounissakis*, P. Pizarro* and H.E. Savaki Lab. of Physiology, Div.Medicine, Univ. of Crete, 71409 Iraklion, Greece.

The local cerebral glucose utilization (LCGU) of 70 bilateral anatomically discrete brain structures was investigated by means of the autoradiographic ^{14}C-deoxyglucose method, in conscious awake rats, following unilateral intranigral injection of either muscimol or substance P. Intranigral injection of the GABAergic agonist muscimol induced: (1) increased glucose consumption within the substantia nigra with the exception of the intermediate zone in the SN reticulata which remained unaffected, and (2) bilateral effects in basal ganglia and associated thalamo-cortical components with the contralateral structures more active. Intranigral injection of substance P induced: (1) enhanced glucose consumption locally in the SN, and (2) bilateral increases in LCGU within the basal ganglia and associated thalamocortical components. It is suggested that stimulation of the intermediate SN-reticulata zone is required for the activation of the ipsilateral reticularis, motor and intralaminar thalamus.

361.7

DISTRIBUTION OF SOMATOSTATIN IN THE BASAL FOREBRAIN OF THE SQUIRREL MONKEY. C. Desjardins*, A. Sadikot and A. Parent, Lab. of Neurobiol., Fac. of Med., Laval Univ., Québec, Canada.

The distribution of somatostatin (SS)-like immunoreactive fibers was studied in three squirrel monkeys (*Saimiri sciureus*) with polyclonal antibodies (SS 309 and SS 320; R. Benoit). A moderately dense network of SS-positive fibers was observed throughout the striatum in a patch-like organization. The putamen showed a greater density than the caudate. Its fibers were larger and its staining stronger peripherally than centrally. At its medial margin, a well defined limit with the pallidum was observed, the later being almost devoid of SS. The ventral striatum stood out by its very strong reactivity, coupled with a marked heterogeneity conferred by non reactive diagonal band of Broca and islands of Calleja. The accumbens nucleus was moderately stained. The amygdalo-striatal transitional zone surrounding the anterior commissure was strongly reactive. Substantia innominata was weakly stained except for some dense plexuses that appeared in register with the cell clusters of the basal nucleus of Meynert. The nuclei of the amygdala showed a wide range of staining. The central nucleus was lightly reactive while the intercalated and medial nuclei were moderately stained. A dorso-ventral gradient of staining was seen in the ventral lateral portion; the staining in the lateral nucleus was moderate to dense whereas it was very light to light in the basal nucleus. The most intensely stained area of the basal forebrain was the ventromedial portion of the amygdala especially the periamygdaloid cortex and the accessory basal nucleus. These findings will serve as a framework for studies of SS modulation in animal models of neurodegenerative diseases. (Supported by MRC, FRSQ and FCAR)

361.8

IMMUNOHISTOCHEMICAL STUDY OF BASAL GANGLIA IN PARKINSONIAN MONKEYS. B. Lavoie, P.J. Bédard and A. Parent. Lab. of Neurobiol., Fac. of Med., Laval Univ., Québec, Canada.

Antibodies against tyrosine hydroxylase (TH), substance P (SP) and enkephalins (ENK) were used to study basal ganglia of cynomolgus monkeys (*Macaca fascicularis*) in normal and parkinsonian states. Five monkeys were treated with MPTP and kept for periods ranging from 1 to 21 months after the onset of bradykinesia. One untreated animal served as a control. The TH denervation of the striatum followed a pattern strikingly similar to that in parkinsonian patients. Caudal putamen and dorsolateral regions of rostral striatum were most severely affected. Depletions in ventromedial striatum were noted only when TH cell loss in midbrain involved ventral tegmental area. A few long and linear TH-positive fibers were still present in severely depleted striatal areas, whereas the patch/matrix compartmentalization remained intact in less affected striatal areas. In contrast, the pattern of distribution of TH-positive fibers at pallidal level was not significantly altered in parkinsonian monkeys. A remarkably dense plexus a TH fibers occurred in the internal pallidum (GPi) and TH neurons remaining in substantia nigra/ventral tegmental area were distributed according to a pattern similar to that found after retrograde tracer injection in GPi in a previous study. These findings indicate that the nigropallidal dopaminergic projection is selectively spared in parkinsonian monkeys. There was also a significant increase in ENK- and a decrease in SP-immunostaining in striatopallidal neurons in MPTP-treated monkeys. These changes were particularly obvious in animals with relatively short (1 to 3 months) survival periods. (Supported by grants from the MRC, FRSQ and FCAR).

361.9

LOSS OF STRIATAL SOMATOSTATIN NEURONS FOLLOWING PRENATAL METHYLAZOXYMETHANOL. J.M. Radke, K. Semba, A. Jakubovic, H.C. Fibiger and S.R. Vincent. Kinsmen Laboratory of Neurological Research, Dept. of Psychiatry, The Univ. of British Columbia, Vancouver, V6T 1W5, Canada.

In the rat striatum, somatostatin is contained in a population of aspiny interneurons, together with neuropeptide Y, and the enzyme NADPH-diaphorase. During development, these neurons undergo their final mitotic division on gestational days G15-16 (Semba et al., *J. Neurosci.* 8:3937, 1988). Methylazoxymethanol (MAM) kills dividing cells by alkylating nucleic acids, and i.p. injections of MAM into rat dams on G15 produces a marked reduction in telencephalic size of the offspring. In the present study we examined the effect of such treatment on the somatostatin system in the rat striatum. Injection of 25 mg/kg MAM into pregnant rats on G15 had no effect on body weight, but resulted in microencephaly of the offspring, when examined at 6 months of age. This was reflected in reductions in the wet weight and protein concentration of the striatum. The concentrations of dopamine and serotonin were increased in proportion to the reduction in striatal tissue, however, the total amounts of these amines per striatum did not differ from control. In contrast, the striatal concentration of somatostatin was reduced by half, and the total amount of somatostatin in the striatum was reduced by over 60%. This reduction was paralleled by a loss of half the somatostatin neurons in the striatum. Although this MAM treatment had a significant effect on the neurochemical organization of the striatum, opiate receptor autoradiography indicated that there was no effect on the patch-matrix organization of the striatum.

361.10

SYNAPTIC CONNECTIONS OF SUBSTANCE P IMMUNOREACTIVE TERMINALS IN THE MARGINAL DIVISION OF THE STRIATUM IN THE RAT. S.Y. Shu, X. Zhang, X. Bao J.F. McGinty*and G.M. Peterson‡ The Fourth Medical College, Xian, China. *East Carolina University,Greenville,NC 27858.U.S.A.

Based on the cellular morphology, immunohistochemistry and projection pattern, a new subdivision, the marginal division has been found in the striatum of rats(S.Y. Shu et al. 1988). The marginal division is more densely filled with Met-enkephalin-,substance P-(SP), dynorphin B-, neurotensin- and cholestokinin-immunoreactive terminals. Electron microscopic study has shown several types of synapses of SP positive terminals onto neurons in the marginal division. One SP containing terminal was often seen to make synaptic contacts with two dendrites or two spines. Two SP-immunoreactive terminals,or one SP positive terminal and one or more SP negative terminals are sometimes observed to make synaptic contacts with one dendrite of the neuron in the marginal division. It is suggested the possibility that imputs from SP-immunoreactive fibers converge or diverge onto neurons in the marginal division.

BASAL GANGLIA AND THALAMUS VII

PECKING AND ASSOCIATED STEREOTYPED OROFACIAL MOVEMENTS EVOKED BY ELECTRICAL STIMULATION OF THE PIGEON STRIATUM. I.J. Goodman. Departments of Psychology, and Behavioral Medicine & Psychiatry, West Virginia University, Morgantown WV 26506-6040.

Striatal mechanisms of orofacial motor activity in birds were studied, using electrical brain stimulation (ESB) in unanesthetized, awake pigeons with stereotaxically-implanted electrodes. ESB (30 Hz, biphasic waves, 0.1 ms, 0-0.6 mA) evoked repetitive pecking (not feeding) and/or stereotyped non-pecking orofacial movements from histologically confirmed dorsolateral (paleostriatum augmentatum, PA) and rostromedial (parolfactory lobe, LPO and nuc. accumbens, Ac) striatal electrode placements. Birds at 80% of normal body wt. displayed lower peck-evoking thresholds than when at normal wt. ESB-evoked pecking rates tended to be positively related to intensity (current), except when interfering movements were simultaneously evoked. Patterns of stereotyped head movements evoked with ESB were similar to those previously reported in pigeons with systemic or direct substantia nigra injections of a dopamine agonist (apomorphine). Similarities in ESB-evoked stereotyped head movements observed from PA, LPO and Ac sites alone do not rule out a functional differentiation among these avian striatal structures, particularly since other studies have provided some anatomical and physiological findings that suggest differentiation. Further striatal studies are required.

362.2

MOTOR IMPAIRMENTS PRODUCED BY MODULATION OF GABAERGIC AFFERENCES OF THE PALLIDUM IN THE CAT. Amalric M., Schmied A.*, Farin D.*,Dormont J.F.* Lab.de Neurobiol.et Neuroph. du Développement, CNRS UA 1121, Bât.440,UPS 91405, Orsay France.

Striatal outputs towards the pallidum (Globus Pallidus, GP, and Entopedoncular nucleus, EP) are mostly GABAergic. To evaluate their role in motor control, we examined the effects of unilateral local microinjections of muscimol or bicuculline into the GP or the EP on the performances of cats trained to release a lever in a simple Reaction Time (RT) task. Opposite effects of muscimol were observed in the 2 structures. In the GP, muscimol at low doses (5-10 ng) induced an increase in RT, followed by contralateral rotations at higher doses. Conversely, in the EP, 10 ng of muscimol induced a decrease in RT and increased the number of anticipatory trials. Higher doses were followed by an arrest of the performance. After muscimol injection, the force exerted on the lever was lowered in the two structures. Bicuculline (20 to 50 ng) slightly decreased RT's, when injected in the GP but had no effect, when injected in the EP. Impairment of performances following GABA receptor activation in the GP was similar to the blockade of dopamine function in the striatum, suggesting a possible modulation of the dopamine on GABAergic Pallidal output. The decrease of RT observed after the activation of EP GABA receptor could result in the blockade of inhibitory outputs of the EP towards the thalamus and/or the midbrain.

362.3

EFFECTS OF NON-STRIATAL GRAFTS AND POST-LESION DELAY ON REVERSAL OF LOCOMOTOR ABNORMALITIES AFTER INTRASTRIATAL KAINIC ACID LESIONS. M. Giordano, E.M. Zubrycki, A.B.Norman, and P.R. Sanberg Div. of Neuroscience, Dept. Psychiatry, University of Cincinnati Medical Center, Cincinnati, OH 45267-0559.

After bilateral intrastriatal kainic acid lesions (KA) Sprague-Dawley male rats received intrastriatal grafts of striatal ridge, dorsal mesencephalon (tectum), and frontoparietal cortex (E 15-16) seven or thirty days after lesion. Subjects were then evaluated in a variety of motor tasks every 4-6 weeks over a period of six months. A differential trend in results was found for haloperidol-induced catalepsy and amphetamine-induced activity tests for different tissue grafts. With regards to catalepsy both striatal groups (early and late post-lesion) had consistently higher scores than both cortical groups. The lesion-only group showed the highest increase in rearings over sixty minutes after amphetamine (1 mg/kg i.p.). The early tectal and cortical groups showed a qualitatively similar pattern, whereas the striatal groups paralleled the response of the sham group. Gross behavioral abnormalities such as convulsions and hyperreactivity were observed in a variety of animals regardless of graft type. These responses maybe the result of further degeneration induced by the lesion and by possible negative effects of the grafts.
These results support the notion that tissue specificity is important for behavioral recovery.

362.4

KYNURENIC ACID-INDUCED BLOCKADE OF EXCITATORY AMINOACID TRANSMISSION IN THE STRIATUM OF RAT PRODUCES A REGIONALLY SELECTIVE IMPAIRMENT OF FORELIMB REACHING. M. Pisa, S. Anwar* and C.A. Booth*. Dept. of Biomed. Sci., McMaster University, Hamilton, Ont., L8N 3Z5.

This research was part of a project aimed at elucidating the regional behavioral roles of striatal excitatory-aminoacid (EAA) activity. Rats (N=10) with chronic intracerebral implants of guide cannulae were trained in a forelimb reaching task (M. Pisa, Neurosci., 24:453,1988) and tested 30 min after bilateral injections of kynurenic acid, an antagonist of EAA transmission (either 0, 24, 48 or 72 nmoles in .4 ul PBS, pH 7.4), into either the dorsolateral striatum or the ventromedial striatum (nucleus accumbens). Striatal region and dose were between- and within- factors, respectively. Only injections of kynurenic acid in the dorsolateral striatum produced a statistically significant, dose-dependent impairment of reaching performance, a regionally selective effect consistent with the findings of previous lesion studies (Pisa and Schranz, Behav. Neurosci. 102:429,1988). Since the excitatory aminoacid glutamate is a major transmitter at corticostriatal synapses, the present results suggests a critical role of corticostriatal glutamatergic transmission in reaching efficiency. (Supported by the MRC of Canada. M. Pisa is a Research Associate of the Ontario Mental Health Foundation).

ELECTROPHYSIOLOGICAL ACTIONS OF NICOTINE ON ANTERIOR THALAMIC AND NEOSTRIATAL NEURONS IN FREELY MOVING AND TREADMILL LOCOMOTING RATS. D.J.Woodward, J.Y.Chang, S.F.Sawyer and R.-S.Lee, *Dept. of Cell Biol., UT Southwestern Med. Ctr., Dallas,TX 75235.*

The anterior thalamic nuclei (ATN) have the highest density of nicotinic receptors in the brain, and nicotine elicits large changes in metabolic activity in these nuclei. The aim of the present study was to investigate the electrophysiological responses to nicotine of neurons in the ATN. Teflon insulated stainless steel microwires (5-16 of 25-65μm diameter) were implanted in ANT or neostriatum of adult male Long-Evans rats. One week later, of the units that were histologically confirmed to be in the ATN, 69% (22/32) exhibited an increase in firing rate following nicotine with a mean±SEM increase of 139.6±14.7% and 148.4±16.7% following the 20μg/kg and 40μg/kg i.v. doses, respectively. The responses started a few seconds after injection and typically returned to pre-drug levels in 1-2 min. Mecamylamine (1.0mg/kg, i.v.), effectively blocked the response to nicotine. In some experiments, gross behavior was entrained by placing the animals on a treadmill (TM) that cycled off and on. 20μg/kg nicotine (i.v.) given during the TM-induced locomotion resulted in a 60.2±10.5% increase in unit activity. In contrast, 40μg/kg nicotine (i.v.) was infused during the TM-off period, causing a 112.3±21.8% increase in unit activity (similar to freely moving). On the fully TM trained rats, 0.1-0.3mg/kg nicotine (i.p.) caused a prolonged suppression of firing rate during TM on phase. Neurons in neostriatum exhibited altered firing patterns for up to 60 min after 0.3mg/kg (i.p.). Subcutaneous nicotine (0.4mg/kg) elicited equivalent increases in firing rate (123±17.1%) and lasted for 5-8 min. Consistent with receptor binding and metabolic studies, these experiments provide evidence that low doses of nicotine activates ATN neurons and that long term changes in receptor mediated events in ATN and neostriatum may induce the increase of glucose uptake. PHYSIOLOGY OF HUMAN CAUDATE NEURONS: I. BASIC MEMBRANE PROPERTIES AND INTRACELLULAR STAINING. C. Cepeda*, J.P. Walsh, W. Peacock* and N. Buchwald. MRRC, UCLA School of Medicine, Los Angeles, CA 90024.

Our laboratory has studied the physiological properties of neocortical neurons in specimens taken from 16 children suffering from intractable epilepsy in which partial or complete hemispherectomies were made. In 5 of these (ages 8 mo. to 8 yr.) caudate nucleus tissue was also taken for pathological study. A small piece of this tissue was made available to us for in vitro physiological and morphological examinations. In brain slices of this tissue intracellular recordings were made with K^+ acetate electrodes (50-100MΩ). Basic membrane properties were determined in 20 neurons. Resting membrane potentials ranged from -65 to -80mV. Action potentials evoked by depolarizing current pulses usually ranged from 70 to 80mV. Most cells showed rectification when hyperpolarizing current pulses were applied. Spike adaptation to the depolarizing current pulses was not observed. The input resistance of these neurons varied between 13 and 26 MΩ. Excitatory postsynaptic potentials were evoked in all cells by intracaudate stimulation. In addition, 19 cells were injected with Lucifer Yellow. All but one of the cells proved to be medium-sized spiny neurons. Dye-coupling was observed in 2 cases. The action potentials amplitudes and input resistances of these human neurons were similar to those obtained in our laboratory from cat and rat brain slices. These results indicate the viability of caudate brain slices obtained from pathological human specimens and establish the feasibility of performing electrophysiological and morphological examinations of this tissue.

362.7

ELECTROPHYSIOLOGICAL EFFECTS OF NMDA RECEPTOR ACTIVATION IN THE DEVELOPING NEOSTRIATUM OF THE CAT. M. Bertolucci-D'Angio*, S.M. Siviy, M.S. Levine C.D.Hull and N.A. Buchwald. MRRC, UCLA, Los Angeles, CA 90024.

It is believed that excitatory corticostriatal inputs are glutamatergic. There is increasing evidence that these postsynaptic receptors are of the kainate/quisqualate variety. Although n-methyl-d-aspartate (NMDA) receptors do not appear to mediate corticostriatal transmission in adult cats and rats, they may be more important during early stages of development. In this study, an in vitro slice preparation was used to assess the effects of NMDA receptor activation in the developing cat neostriatum. Neostriatal slices (400 μm) were obtained from kittens 16-54 days of age. To demonstrate NMDA contributions to evoked excitatory postsynaptic potentials (EPSPs), Mg^{2+} free Ringers was used as the bathing medium. Bicuculline (10 μM) was added in order to block inhibition mediated by $GABA_A$ receptors. Under these conditions, the amplitude and duration of EPSPs evoked by local stimulation was increased. This enhancement was maximal in kittens under 32 days of age, with local stimulation producing long duration EPSPs with bursts of action potentials. This enhancement was reversibly blocked by AP-5 (10-50 μM), a selective NMDA antagonist. To date we have been unable to evoke this bursting response in older cats. These findings demonstrate that NMDA receptors play a prominent role in early development of the cat neostriatum. Supported by USPHS Grant HD 5958.

362.8

PHYSIOLOGY OF HUMAN CAUDATE NEURONS: 2. EXCITATORY AMINO ACIDS AND DOPAMINE. J.P. Walsh, C. Cepeda*, W. Peacock* and N.A. Buchwald. MRRC, UCLA, Los Angeles, CA 90024

In the course of hemispherectomies designed to alleviate intractable epilepsy in children (ages 8 mo. to 8 years), specimens of caudate nucleus were obtained. Using in vitro slice procedures, intracellular recordings revealed that local extracellular stimulation elicited short duration excitatory post-synaptic potentials (EPSPs) in caudate neurons. The general excitatory amino acid antagonist, kynurenic acid, blocked these EPSPs without effecting cell excitability or input resistance. To investigate the possible activation of post-synaptic NMDA receptors during synaptic excitation, slices were bathed in a solution of Mg^{2+} free Ringers. This solution served to eliminate the Mg^{2+} block of NMDA receptors which occurs in normal medium. Synaptic excitation was examined in isolation by adding bicuculline (10 μM) which blocked GABA mediated inhibition. Bicuculline, by itself, had little effect on EPSPs. Bicuculline in Mg^{2+} free Ringers solution increased the amplitude and duration of EPSPs. Supra-threshold extracellular stimulation of slices bathed in Mg^{2+} free saline elicited long duration depolarizations and bursts of action potentials. This enhancement of synaptic input and bursting was blocked reversibly by the NMDA antagonist AP-5 (1-50 μM). In a separate set of experiments, dopamine (DA) was tested for its ability to modulate synaptic input and cell firing in caudate neurons. Two effects were seen: 1) DA (10-100 μM) decreased the number of action potentials elicited by depolarizing current injection and 2) DA decreased EPSP amplitude in a dose dependent manner. These data demonstrate that, in agreement with results from animal models, human caudate neurons receive synaptic input mediated by excitatory amino acids and that DA decreases the efficacy of this input.

VOLTAGE-CLAMP ANALYSIS OF CALCIUM CURRENTS IN RAT NEOSTRIATAL NEURONS. D. J. Surmeier, J. Bargas and S. T. Kitai, Dept. of Anatomy and Neurobiology, College of Medicine, The University of Tennessee, Memphis, Memphis, TN 38163.

Calcium currents play an important role in regulation of neuronal excitability and integration. Previous current-clamp studies have suggested that only high-voltage activated calcium currents are expressed by rat neostriatal neurons. Using the the whole-cell variant of the patch clamp technique, we have found that these neurons express both low-voltage activated (LVA) and high-voltage activated (HVA) calcium currents.

Neurons from embryonic rat neostriatum were dissected and maintained in vitro as previously described (Surmeier et al., Brain Res. 473: 187-192, 1988). Neurons were maintained in culture for from 7-21 days prior to study. Whole cell currents were recorded using conventional techniques. Calcium currents were recorded in media containing (in mM): 120 TEA-Cl, 10 CaCl2, 6 4-AP, 10 Cs-HEPES, 3 CsCl, 11 glucose, 0.01 TTX (pH=7.3). Patch pipettes contained (in mM): 60 CsF, 60 CsCl, 20 TEA-Cl (or F), 10 EGTA, 10 HEPES, 2 Mg-ATP, 0.2 GTP (pH=7.3).

An LVA transient component of the calcium current was evoked by step depolarizations above -40 mV from negative holding potentials (-100 to -70 mV). The LVA current was blocked by Ni (100 μM) but only slightly affected by Cd (50-100 μM). Step depolarizations above -20 mV evoked a more long-lasting, slowly inactivating inward current. This component of the calcium current was preferentially blocked by Cd (100 μM) and was enhanced by replacing Ca with Ba as the charge carrier.

362.10

SEROTONIN EFFECTS ON RAT STRIATAL NEURONS IN *IN VITRO* SLICE PREPARATION. A. Stefani and S.T. Kitai, (Spon: A. Del Bo) Dept. of Anat. and Neurobiol., College of Medicine, The Univ. of Tenn. Memphis, TN 38163.

Anatomical studies indicated that 5-HT axons originating from the dorsal raphe nucleus terminate on the dendrites of striatal neurons in the rat. Although the 5-HT innervation in the striatum is largely "non-junctional" (Soghomonian et al., Brain Res. 481:67, 1989), previous electrophysiological studies indicated that electrical stimulation of the dorsal raphe nucleus induces excitatory postsynaptic potentials. We have examined the effect of bath application of 5-HT in a striatal slice preparation in the rat. Neostriatal slices (300-350 uM thick) were preincubated for 1-2 hours in oxygenated (95% O_2 -5% CO_2) Krebs Ringer buffer (NACl 124, KCl 5, Mg SO_4 1.3 KH_2 PO_4 1.22, $NAHCO_3$ 25.5, $CaCl_2$ 2.3, glucose 10) then transferred to submerged recording chamber at 35° C. Intracellular recordings were obtained with electrodes (50-70 Mega ohm) filled by 3M Methylsulfate. Serotonin was bath applied by adding freshly prepared stocks to the saline and by switching the perfusion from control saline to drug-containing solution. Complete exchange of the chamber volume took 90-150 seconds. Intracellular recordings were fed into a Neurodata (1R-183) preamplifier, displayed on digital oscilloscope and stored on magnetic tape. Records were obtained from 16 neurons with the RMP ranging from -65 to -80. Intracellularly applied depolarizing pulses evoked repetitive tonic firing with little adaptation. The action potential was triggered from a slow ramp-like depolarizing potential. Fast action potential was followed by after-hyperpolarization. Bath application of 5-HT (20-40 um) produced in 85% of recorded neurons a clear increase in firing rate with an increase in membrane resistance during depolarization current injections. An initial transient small hyperpolarization was produced in 6 out of 16 neurons immediately following 5-HT applications, subsequently these neurons also responded with excitations. (Supported by NIH NS 20702 and NS 23886 to STK).

362.11

LONG-TERM, MULTI-CHANNEL RECORDING OF SINGLE UNITS IN RAT NEOSTRIATUM DURING AN ON-OFF TREADMILL PARADIGM

D.Y. Sanchez, R.-S. Lee, S.F. Sawyer, and D.J. Woodward. *Cell Biology and Anatomy, Univ. Texas Southwestern Medical Center, Dallas, TX 75235.*

Previous studies in this laboratory (West et al., 1987) have demonstrated altered modes of activity in rat neostriatal neurons during a fixed interval, on-off treadmill (TM) exercise paradigm. The response of these neurons changed markedly as the rat learned to anticipate the regular cycle of the TM. The objective of the present study was to quantitatively characterize the response of neurons in the neostriatum to TM exercise, over a period of 2 - 7 weeks. Twenty microwires (25-45 μm diameter) were surgically implanted in the neostriatum of adult, male, Long-Evans rats. Days later, TM-naive rats were induced to walk on a treadmill (30 sec on/ 30 sec off). A tone served as a cue for the onset and offset of TM locomotion. Single unit, multi-channel activity of 2 - 6 neostriatal neurons was recorded extracellularly in each animal. We have found that many neurons increased their firing rate during the TM-on phase of each cycle (TM-on response) while a small percentage of neurons showed increased activity during the rest phase (TM-off response). Additionally, some neurons decreased the "on" or "off" response to the TM cycle within the initial 30 min of the rat's first TM session. In contrast, other units did not change their TM response even after several weeks of daily, single-hour trials. Among the neurons that exhibited decreased response to TM over time, some resumed their original TM response after a 10 to 20 min rest period. These results demonstrate that the time course of changes in TM response is highly variable in rat neostriatal neurons. Clearly, the population of neuronal responses even within a small area of neostriatum is highly heterogeneous. We postulate that the pattern of activity of neostriatal neurons corresponds to attentional, anticipational, or context states which change during long term exposure to a sensory motor task.

362.12

LOCALIZATION OF THE CORPUS STRIATUM SUBREGION RESPONSIBLE FOR A PAW TREADING CHOREA IN THE RAT.

H.C.Cromwell* and K.C.Berridge. The University of Michigan, Department of Psychology, Ann Arbor, MI. 48109.

Human striatal lesions are often accompanied by choreic movement patterns. Previous studies have shown that large striatal lesions in the rat result in a paw treading chorea to oral taste infusions (Berridge et al,1988). This exaggerated paw treading was elicited by a wide range of oral stimuli after such lesions. The response was a large amplitude, long duration forepaw movement that is not produced by intact rats.

In the previous large lesion study, the treading was most pronounced following posterior striatal lesions. To determine whether a crucial subregion exists within the posterior striatum responsible for this pathological behavior, small excitotoxic lesions were made. Microinjections of kainic acid (KA), quisqualic acid (QA), quinolinic acid (QUIN), or ibotenic acid (IBO) were made bilaterally into either the posterior ventromedial striatum (including globus pallidus) or the posterior dorsolateral striatum, or the posterior dorsomedial striatum. Potential treading was elicited by oral infusions of either palatable (eg., sucrose) or unpalatable (eg., quinine and HCL) solutions. Paw treading and other elicited behaviors were scored in a slow motion taste reactivity analysis.

The choreic response was most pronounced after lesions in the ventromedial sector. The dorsomedial group also showed infrequent paw treading. The choreic pattern was not seen following dorsolateral damage. The aversive evaluation of the taste seemed to be an important aspect of the triggering mechanism. The choreic treading was only seen to infusions of unpalatable solutions (e.g., quinine). Thus medial posterior damage to the striatum in the rat appears to specifically potentiate treading as a motor pattern elicited by unpalatable oral stimuli.

MOTOR SYSTEMS: REFLEX FUNCTION I

363.1

PHASE-DEPENDENT HUMAN FLEXOR REFLEX CHANGES DURING CYCLING.

D. A. Brown,* C. G. Kukulka. Graduate Program in Physical Therapy, University of Iowa, Iowa City, IA 52242.

This study examined phase-dependent changes in the Human Flexor Reflex (HFR) during cycling. Human studies have not addressed the problem of demonstrating reflex changes independent of the motoneuron pool excitability level. This study investigated the HFR during cycling while controlling ankle muscle activation. Ten healthy, male subjects were each involved in a set of three experiments. All experiments involved cycling on an ergometer at a set rate and workload. A 333 Hz, 15 ms pulse train of electrical stimulation was randomly delivered to the tibial nerve. First, subjects were stimulated at six hip positions while cycling with normal, phasic ankle muscle activity. Next, under static conditions, the HFR was elicited while controlling either the soleus or tibialis anterior (TA) background EMG at a target level. While cycling, stimulation was applied as the subjects maintained similar levels of background contraction. Responses were analyzed by averaging 5-18 stimulation trials triggered at similar hip angles. Trials with distinctively different M-wave amplitudes and baseline EMG activity were eliminated. Results demonstrated changes in response patterns, latency, and mean response peak areas, during cycling, that persist under conditions of steady background muscle activity. It is concluded that the HFR may be modulated by mechanisms independent of motoneuron pool excitability levels.

363.2

DIFFERENTIAL MODULATION OF CUTANEOUS REFLEXES DURING SLOW RHYTHMIC FINGER MOVEMENTS.

A.M.S. Poon*, I.C. Bruce, P.W.F. Poon* and J.C.C. Hwang. Department of Physiology, University of Hong Kong, Hong Kong.

Cutaneous reflexes were elicited in the first dorsal interosseous muscle by electrical stimulation of the digital nerves at specific points in each cycle of 0.5Hz adduction-abductions of the index finger. Reflex EMG components were compared with control values obtained during tonic contractions. After correcting for the voluntary activity and individual variations in timing, EMG activity relative to background was computed (mV/ms) for each component.

Two separate excitatory-inhibitory sequences, one early and one late (onsets 26 & 58 ms), were recorded. During adduction the amplitudes of all components decreased in parallel with the voluntary EMG. In abduction, while the amplitude of the late excitatory component continued to drop below background as voluntary EMG increased, the values for the early components rose. Around the abduction-adduction transition, the late excitatory component switched to maximum amplitude above background, then once again matched the voluntary EMG during the next adduction.

This "switched" modulation of the late component may reflect a change in motor set during slow rhythmic finger movements.

363.3

THE EFFECT OF NON-PAINFUL CUTANEOUS STIMULI ON HUMAN MOTOR PERFORMANCE.

E. Logigian* and D. Cros* (Spon: J. Donoghue) New England Medical Center and Massachusetts General Hospital, Boston, MA.

We investigated modulation of first dorsal interosseous (FDI) motor performance by cutaneous stimuli adjacent to and remote from this muscle. During tonic, and prior to "ballistic", isometric contraction of FDI, trains of non-painful cutaneous stimuli (stim) were applied over the palmar surface of the second digit (PD) or the lateral aspect of the foot (LF) in 4 normal subjects. Rectified surface electromyographic activity (EMG) and force of FDI were recorded. During tonic contraction, both PD and LF stim evoked a consistent late excitatory EMG response (E2) and a less consistent early response (E1). PD, but not LF stim, evoked a long silent period prior to E2. The respective tonic force profiles were therefore different. PD stim produced a relatively large lapse in force followed by a rebound to baseline, whereas LF stim produced a slight increment in FDI tonic force output. In contrast, the amplitude of "ballistic" force pulses, voluntarily produced after an auditory tone, was enhanced when the tone signal was combined with either PD or LF stim. In summary, there are remote effects of LF stim which are excitatory for both tonic and "ballistic" FDI motor tasks. PD stim is inhibitory for tonic motor tasks, but may be excitatory for "ballistic" tasks.

363.4

REFLEX ACTIVATION OF HUMAN WRIST EXTENSOR MUSCLE MOTOR UNITS BY TENDON VIBRATION.

P. Romaiguère*, J.P. Vedel, and S. Pagni* LNF-U3, CNRS,Marseille cedex 9, France.

As required by the Helsinki declaration all subjects gave their informed consent to the experimental procedure.

Recruitment thresholds of motor units (MU) of the extensor carpi radialis muscles were compared during volontary and reflex isometric contractions characterized by similar force increase velocity. MU recruitment thresholds were strongly decreased during reflex contractions. This effect was explained by the almost selective activation of the extensor carpi radialis muscles by their tendon vibration while during volontary contractions the radialis muscles and their synergist, the extensor carpi ulnaris muscle, contracted with the same intensity. This observation suggests a weak diffusion of the Ia motoneuronal activation from the extensor radialis muscles to the extensor ulnaris muscle.

Analysis of MU reflex activity using "post stimulus time histograms" showed that slow MU were mainly monosynaptically activated by tendon vibration while fast MU were activated both monosynaptically and polysynaptically. Slight superficial cutaneous stimulations induced total inhibition of all MU monosynaptic activation without modifying fast MU polysynaptic activation. This differential effect suggests a presynaptic inhibition of the Ia monosynaptic connection with motoneurons by low threshold cutaneous afferents.

363.5

SUCCESSIVE MUSCLE CONTRACTIONS DECREASE RECRUITMENT FORCE THRESHOLDS IN SINGLE MOTOR UNITS. S Suzuki*, A Hayami*, M Suzuki*, S Watanabe*, and R S Hutton Sch of Human Sci., Waseda University, Japan Women's College of PE, Kinjo Gakuin University, Kyorin University, and Dept. of Psych., University of Washington.

Recruitment force thresholds (FTs) in single motor units (SMUs) are known to decrease as speed of contraction increases (Desmedt, TINS, 3:265, 1980). Preliminary evidence suggests that successive muscle contractions also lower the FT in SMUs (Suzuki, et al., Med. Sci. Sports Exerc., 20:S4, 1988). The purpose of this study was to examine further the latter observation. FTs of 30 biceps brachii SMUs were recorded from 6 male subjects (Ss) using fine wire coiled copper electrodes. Ss rested their upper arm horizontally on a table with their elbow angle at 90 degrees in flexion. With the forearm in supination, Ss gripped a handle attached to a force transducer to generate isometric flexion forces. Visual force feedback was provided by an oscilloscope. The initial mean FT for 30 SMUs was 20.8 N (range 1.8 - 54.5 N). FTs were found to decline from < 10% to 100% over the course of 5 additional successive contractions. The initial mean FT was significantly higher ($p < 0.05$) than the mean FT values observed during the final 3 contractions. SMUs exhibiting lower initial FTs generally showed larger percent decreases in FT over successive contractions. Intermittent muscle stretch (90 degrees of extension) tended to reset the SMU FT toward the initial value. This suggests that the source of greater excitatory current in lowering SMU FTs during successive contractions may reside in contraction-induced potentiation of stretch reflex pathways (Hutton et al., J Physiol. (Lon.), 393:247, 1987).

363.6

MECHANICAL AND REFLEX CONTRIBUTIONS TO JOINT STIFFNESS DURING COCONTRACTION. R.R. Carter, P.E. Crago and M.W. Keith. Depts. of Biomedical Engineering and Orthopaedics, Case Western Reserve Univ., Cleveland, OH 44106.

Cocontraction of antagonists can increase joint stiffness independently of joint torque. We are estimating the magnitudes of the passive, intrinsic active, and reflex contributions to the total response during single muscle contraction and during cocontraction of the flexor and extensor pollices longus in human subjects. The total response at the thumb interphalangeal joint is measured while the subjects exert both a net torque and a level of cocontraction. Subjects are instructed to 'not react' to a sudden joint extension. The passive response is measured with the muscles relaxed completely. Each muscle's intrinsic response is estimated separately during electrical stimulation. The total intrinsic component is calculated as the sum of the separately scaled intrinsic responses of the two antagonists. Scaling parameters are estimated by an ordinary least squares fit of the two normalized intrinsic components to the total active response prior to reflex onset, and are unique since torques subtract but stiffnesses add. The passive and total intrinsic components are then subtracted from the total response, leaving only the net reflex component. Reflex components are then compared during single muscle activation and during cocontraction.

LONG LATENCY MUSCLE RESPONSES FOLLOWING RECURRENT LARYNGEAL NERVE STIMULATION IN HUMANS. C. L. Ludlow, S. G. Yin* and M. Hallett. Speech and Voice Unit, NIDCD and Human Motor Control Section, NINDS, Bldg.10/5N226, Bethesda, MD 20892.

Adductor laryngeal muscle responses occur between 22 and 24 ms following stimulation of the superior laryngeal nerve sensory branch. In this study, long latency muscle responses were found in normal volunteers following recurrent laryngeal nerve (RLN) stimulation. Hooked wire recordings from the right and left thyroarytenoid (TA) and cricothyroid (CT) muscles and surface recordings from the posterior cricoarytenoid were made during quiet respiration, effort closure and sustained vowel. Stimulation needle electrodes were placed in the region of the right RLN at the third tracheal ring. Ten single or triple pulse stimulations were administered at different current levels between threshold and supramaximal direct responses. Triggered averages as well as individual muscle responses were measured from each set of ten stimulations. A late response starting between 50 and 60 ms at an amplitude of between 30 and 50% of maximal activity was consistent in the right TA in 80% of subjects tested. This polyphasic response peaked between 60 and 70 ms and lasted 20 to 30 ms. The amplitude increased with higher levels of muscle activation such as during effort closure and with triple pulse stimulation. In some subjects a simultaneous response was seen in either the contralateral TA or the ipsilateral or contralateral CT. An earlier shorter single low amplitude response between 20 and 30 ms occurred inconsistently in 50% of subjects. This only occurred in the right TA, had a duration of less than 10 ms, was enhanced at lower stimulation levels and during respiratory activation. These characteristics are suggestive of a mechanism analogous to a flexor reflex.

363.8

MODULATION OF THE UNLOADING REFLEX DURING VOLUNTARY MOVEMENT: R.R.Young, A.W.Wiegner and L.Davies*. Spinal Cord Injury Unit. Veterans Administration Medical Center. Boston. MA 02132.

During tonic contraction, muscle spindles provide excitatory input to α-motoneurones via Ia afferent fibres. An abrupt decrease in activity in these fibres produces an unloading reflex. This reflex may be useful in maintaining a desired muscle output against small force perturbations but might be counter-productive during very fast movements. We studied the unloading reflex in the biceps of human subjects during voluntary elbow flexion at various speeds.

Three variants of elbow flexion were examined: slow ramp movement under fine control (peak velocity 29±8 deg/s Mean±SD), intermediate speed movements of the type used for everyday limb placement activities (56±18 deg/s) and rapid ballistic movements (356±28 deg/s). While unloading reflexes were observed throughout slow and intermediate speed movements, the reflex could not be demonstrated during ballistic movements until the target had been attained. This suppression of a monosynaptic reflex during ballistic movements may serve to prevent confounding afferent input from reaching the spinal motoneurone pool.

METHODOLOGIES FOR DIFFERENTIATING BETWEEN "RII" AND "RIII" REFLEX EMG RESPONSES IN HUMANS. R.G. Durkovic and S.G. Nord. Depts. of Physiol. & Anat., SUNY Health Sci. Ctr. and Neurology Service, VAMC, Syracuse, NY 13210.

The "RII" and "RIII" components of sural nerve/biceps reflex EMG responses are customarily defined in terms of latencies from stimulus onset ("RII" 40-80 ms; "RIII" 85-150 ms). However, within/between subject variability can sometimes obscure this distinction. As a consequence, we sought additional criteria to help differentiate these two components.

Because of its effectiveness in enhancing lower-limb reflexes, we tested the effect of the Jendrassik maneuver on the reflex components. Innocuous percutaneous electrical stimulation (200 Hz, 4 pulses) of the sural nerve was presented 1/min while recording EMG activity from the ipsilateral biceps femoris muscle. For most subjects "RII" was enhanced and "RIII" was depressed during the maneuver. Recordings from additional muscles also proved useful in that "RIIs" tended to be restricted to muscles near the site of stimulation, while "RIIIs" were widespread throughout the body, like startle responses. Notably, "RIII" onset latencies exhibited a cephalo-caudal sequence, like startle responses. In contrast to reports of some investigators, painful stimuli were not required for eliciting "RIIIs" in most subjects. Supported by NSF Grant BNS 8808495.

DOES ASYMMETRICAL MODULATION OF SEGMENTAL INPUT ALTER ABDOMINAL EXPIRATORY ACTIVITY (AEA) IN HUMANS? B. Bishop, E. Aurnou*, F. Cerny* and J. Hirsch. SUNY/B. Buffalo, NY 14214.

Feedback from proprioceptors in lungs and abdominal wall is essential for AEA and tilting from supine to headup augments AEA. Does changing from supine to the left lateral decubitus position cause a bilateral modification in AEA? To answer this question, we had subjects (Ss) turn from supine to side-lying, as a way of shifting the visceral stretch on the abdominal wall. We expected such a shift to cause regional changes in AEA. EMGs were recorded bilaterally from the internal and external (EO) oblique abdominal muscles while S, wearing a nose clip and breathing through a mouthpiece, expired against an ETL (i.e. a water column of preset heights), a reliable stimulus for AEA. Thresholds for AEA in the four muscles were lower when left-lying than when supine. Regardless of body position, normalized EMG amplitudes of each muscle increased in concert with each increment in ETL. Only in left EO did a change in AEA correlate with the change in body position: its increase in AEA with each increment in ETL was less in the left-lying than in the supine position. These results suggest that an asymmetrical input from abdominal receptors has but minor effects on AEA.

MYOTATIC REFLEXES IN HEALTHY AGING HUMAN SUBJECTS. BM Myklebust, JB Myklebust. Laboratory of Sensory-Motor Performance, Zablocki VA Medical Center & Medical College of Wisconsin, Milwaukee, WI 53295.

In studies of "healthy" elderly subjects (ages 65 years and older) Albert[1] reports that the patellar tendon jerk reflex time is increased, and the Achilles tendon jerk reflex is diminished or absent in approximately 10% of the population. Whether these changes are a concomitant of "normal aging" is uncertain.

We tested myotatic reflexes of the lower extremities in 30 healthy active subjects, ages 65-75 years, and identified the following: 1] Differences in myotatic reflexes, when compared with normal young adult subjects, were recorded in every subject. 2] Achilles and/or patellar tendon jerk reflexes were absent in 3% and delayed in 55% of the subjects. 3] Responses not previously identified in normal healthy subjects were evoked by tendon tap, including responses of the soleus muscle to tibialis anterior tendon taps (*hyperreflexia*), responses of quadriceps and/or hamstrings muscles to Achilles and/or tibialis anterior tendon taps (*reflex irradiation*) , and *reciprocal excitation* of agonist and antagonist muscles following patellar and Achilles tendon taps. 4] Tap-to-tap variability was identified in onset and amplitude of reflex responses of the agonist and antagonist muscles, as well as in responses from limb muscles at a distance from the tapsite.

Previous work suggests that there is plasticity in the CNS of aging humans.[2] Structural changes have been identified in the motoneuron pool which may affect the quality and precession of performance.[3] Our current studies demonstrate a greater variability in myotatic reflex patterns in healthy aging subjects than has been identified previously. Caution must be exercised when using myotatic reflex changes as diagnostic criteria in aging patients with neurologic disease.

EVIDENCE FOR PROPRIOSPINAL ACTIVITY IN PATIENTS WITH SPINAL CORD INJURY. B. Calancie, J. Difini* M. Traad* and D.R. Ayyar* The Miami Project & Dept. of Neurol. Univ. of Miami, Miami FL 33136

Severe spinal cord injury (SCI) results in a complete motor deficit below the lesion, due to the loss of excitatory input onto spinal motoneurons. Descending inhibitory input is also lost, however. We have observed examples of short latency interconnections between upper and lower extremity muscle groups following peripheral nerve stimulation in quadriplegic patients.

EMG activity was recorded from up to 12 muscles simultaneously. Constant-current electrical stimulation of nerves was applied through hand-held surface probes. Responses were amplified and recorded on digital tape for analysis.

Approximately 30% of the patients examined demonstrated responses in upper extremity muscles to stimulation of both contra- and ipsilateral lower extremity mixed nerves. Response latencies were inversely proportional to current strength. The minimum latency in thenar muscles to tibial nerve stimulation at the knee was typically less than 50 ms, consistent with these responses being mediated by rapidly conducting propriospinal pathways.

THE TONIC STRETCH REFLEX IN SPASTICITY. A.M. Sherwood, T. Bacia*[1], M.R. Dimitrijevic and W.B. McKay*, Baylor Coll. Med., Houston, TX 77030, and [1]Medical Acad. Warsaw.

While both phasic and tonic stretch reflexes are exaggerated in spasticity, the tonic reflex is of greater clinical significance. The tonic reflex can be elicited by passive movement or by muscle spindle vibration. We compared these two methods in 50 (unselected) spinal cord injury subjects, in whom we applied vibration to the achilles and the patellar tendons, and passive movement of the ankle or the hip and knee joints. To elicit the vibration reflex (VR), we used an air-driven motor with an eccentric weight, which provided 100 Hz vibration of 2-3 mm displacement. Surface EMG responses were recorded over quadriceps, hamstrings, tibialis anterior and triceps surae muscles. From 13% of the sites, stimulation elicited a spasm. The tonic response to vibration spread to non-vibrated muscles in 32% of the sites. A much more evident form of irradiation is in the vibration-induced spasm (VIS) response, which occurred 39% of the time. These were typically much larger responses in amplitude, in duration and in number of responding muscles (mean of 5), with 41% of the VIS responses appearing bilaterally. In comparisons with passive movement, vibration elicited a response in fewer muscles, although the number of muscles responding to passive movement and to vibration was positively correlated. We conclude that the VR can be used to assess the tonic stretch reflex in spastic patients.

STRETCHED AND ABERRANT OPPOSING MUSCLE TENDON TAP REFLEX RESPONSES AS INFLUENCED BY MOVEMENT IMPAIRMENT AND TENDON IMPACT FORCE. N.J.LAMBERT and W.P. KROLL* Motor Control Lab, Univ. of Denver, Denver, CO 80208

Patellar tendon tap reflex EMG and peak FORCE response to a minimum (MIN), mid-range (MID) and maximum (MAX) impact force were compared in an able-bodied group (AB,n=12) and a disabled group (DA,n=12) for a stretched (STR) rectus femoris muscle and (NSTR) opposing biceps femoris muscle. DA subjects were spinal cord injured with no voluntary movement (n=3) and impaired movement (n=3) or with cerebral palsy and impaired movement (n=6). STR and NSTR peak to peak EMG, and FORCE responses increased with the 3 conditions of impact force (STR: MIN 43uv,MID 249uv,MAX 506uv, $p<.01$; NSTR: MIN 8uv,MID 58uv,MAX 97uv,$p<.01$; FORCE:MIN 3N,MID 16N,MAX 26N). A greater gain of response to increased impact force is observed for STR than NSTR muscle (difference: STR 463mv, NSTR 89uv,$p<.01$); the EMG signals therefore represent responses of different muscles. STR and NSTR, but not FORCE, responses were greater for DA than AB (difference:STR 275uv,$p<.01$;NSTR 89mv, $p<.01$). STR, NSTR and FORCE responses were greatest for subjects with impaired movement. NSTR response is contrary to reciprocal inhibition.

363.15

THE BILATERAL AMPLITUDE IMBALANCE IN THE JAW-JERK REFLEX. H.W. van der Glas, R. Buchner*, F. Lobbezoo* and F. Bosman. Lab. of Oral Pathophysiology, Univ. of Utrecht, Padualaan 14, 3584 CH Utrecht, The Netherlands.

The bilateral amplitude asymmetry of the jaw-jerk reflex has been studied in the surface EMG of the masseter and the anterior temporal muscles of 20 patients with myogeneous craniomandibular disorders and 20 symptom-free subjects.

Constant transient vertical loads given to a central mandibular point while the subjects maintained 10% MVC of a masseter muscle, caused a displacement up to 0.2 mm with a rise time of 3.5 ms. The resulting reflex amplitude was corrected for the effect of the excitability level of the motor neurons by taking into account the background muscle activity. Furthermore, in 3 subjects, the mandibular displacement was successively controlled for each side at 0.05 mm while the reflex was studied for a range of activity levels (4-20% MVC) of the muscles on the displacement side.

With a constant load, significant bilateral reflex asymmetries occurred in 53-75% of the subjects in both samples. The reflex asymmetry was, in general, not correlated with an asymmetry in the background muscle activity, which might cause an asymmetric muscle stiffness. Hence, the reflex asymmetry is predominantly related to an imbalance in reflex gain. The experiments with a constant displacement, where the effect of muscle stiffness is compensated, also indicate the involvement of a different reflex gain.

Stretch reflex latency changes following repetitive reciprocal and hetero-segmental electrical stimulation in spastic hemiplegic subjects. M.F.Levin and C.W.Y. Chan. School of Physical and Occupational Therapy, McGill University, Montreal, Canada H3G 1Y5.

Repetitive electrical stimulation of the spinal cord reportedly decreases spasticity. In a previous study (Hale & Chan 1986), 30 min of transcutaneous electrical nerve stimulation (TENS) applied segmentally to the low back had no immediate effects on lower limb reflexes in spastic hemiplegics. In the present investigation, we extended the study to include changes in stretch reflex (SR) latencies following longer duration (45 min) of reciprocally and hetero-segmentally applied TENS.

Ten spastic hemiplegics and 7 age-matched normals participated in the study. Spasticity was evaluated by clinical scales and electromyographic measurements consisting of: 1) ratio of maximum H-reflex to M response, 2) inhibition of H-reflex during vibration, and 3) soleus SR at rest. Comparison was made of data obtained before and at 3x20 min intervals after 1) placebo stimulation, and TENS applied: 2) reciprocally to the common peroneal nerve, or 3) hetero-segmentally to the contralateral wrist.

Our findings showed that stretch reflex onset latencies were shorter in hemiplegics (45.4±SD 11.8 msec) than normals (54.6±17.3 msec). Both TENS treatments significantly increased SR latencies when compared to placebo stimulation. The mean percentage change in SR latencies was 90.8±7.7% for placebo compared with 109.8±9.2% for TENS to the leg, and 110.5±4.5% for TENS to the wrist ($p<.005$). This increase in latency was evident for up to 60 min post-TENS. No consistent changes were found in other measures.

These results indicated that TENS may reduce spasticity as shown by increased SR latencies via reciprocal and/or non-segmental mechanism(s).

PRELIMINARY STUDIES ON MODIFICATION OF HYPERACTIVE SPINAL STRETCH REFLEXES IN STROKE PATIENTS. R.L. Segal, P.A. Catlin*, R.Cooke*, L.Johnson*, A.McCallum*, D.Murzin*, K.Rubel* and S.L.Wolf. Human Movement Lab. and Div. Phys. Ther., Dept. Rehab. Med., Emory Univ. Sch. Med., Atlanta, GA 30322.

The biceps brachii spinal stretch reflex(SSR) was downtrained in 6 stroke patients(mean age, 58yrs.; mean time postlesion, 5.3 yrs.). Each subject received two baseline sessions without feedback of SSR amplitude. Subjects were then randomly assigned to one of two sequences: 1)Training (9 sessions with feedback & operant conditioning)-control (9 sessions without feedback & operant conditioning)(TC); 2) Control-training (CT). Baseline, control and training sessions consisted of 250 random stretches which occurred 1-5 secs. after maintaining the elbow joint at 90°±5° and biceps EMG at a level to resist a small extension torque. No sequence effect was found between TC and CT. CT median SSR's drifted below baseline in the control phase, but training had a greater effect. TC median SSR amplitudes reduced from baseline during the training phase more than CT amplitudes dropped during CT control phase, suggesting that downtraining occurred. However, an initial smaller decrease in SSR amplitude independent of training may also occur. Percent changes from baseline were greater during the training phases for both sequences ($p<.007$). The average reduction in amplitude was 40.3%. However, 1 subject was unable to downtrain. These preliminary results support the notion that a hyperactive SSR can be downtrained.

363.18

PRELIMINARY STUDIES ON MODIFICATION OF HUMAN SPINAL STRETCH REFLEXES. S.L. Wolf, M.L. Evatt* and R.L. Segal, Human Movement Lab. Div. of Phys. Ther., Dept. Rehab. Med, Emory Univ. Sch. of Med., Atlanta, GA 30322,

The biceps brachii spinal stretch reflex (SSR) was uptrained (N=4) or downtrained (N=5) in normal human subjects (age range: 25-70 years; median age: 31.5 years). Each subject received two baseline sessions without feedback of SSR amplitude. The median values of these pre-training sessions was used to determine the starting point for 8-9 training sessions when subjects' responses were "shaped" through visual cues that showed each response relative to a criterion level.

Each baseline, training session and a single follow-up evaluation (19.4 days post-training) consisted of 400 random stretches which occurred at 1-5 seconds after maintaining the elbow joint at 90°± 5° and biceps EMG within a "window" approximating 15% of M.V.C. Uptrainers were able to increase SSR amplitudes by 63.7% and downtrainers could reduce SSR amplitude by 21.5% from the median baseline values. Differences between the group's averages of median percent changes across sessions were significant ($p<.002$). In 8 of 9 subjects the follow-up SSR changes remained in the appropriate direction without any visual feedback. These findings compliment data on SSR mutability in monkeys as demonstrated by Wolpaw and support the notion of applying this approach to determine if SSR's can be downtrained in humans with hyper-reflexia.

MOTOR SYSTEMS: REFLEX FUNCTION II

364.1

DO NOCICEPTIVE AFFERENTS BELONG TO THE GROUP OF "FLEXOR REFLEX AFFERENTS" ? E.D. Schomburg, H. Steffens and P.F. Schmidt (SPON: J. Noth). Univ. Inst. of Physiology, D-3400 Göttingen, F.R.Germany

In order to analyze a possible specificity of nociceptive cutaneous afferents in spinal motor control the reflex effects of these afferents (activated by radiant heat) were investigated in high spinal cats in comparison and in combination with the effects from low threshold cutaneous, joint and group II muscle afferents (non-nocicepotive "flexor reflex afferents", FRA).

In many respects the results revealed a wide congruence between the motor effects of nociceptive afferents and non-nociceptive FRA: the synaptic effects in lumbar α-motoneurones were similar; there was a wide convergence onto common segmental interneurones; the sensitivity to depressive actions of enkephalins (δ- or μ-opioid receptor agonists) onto the transmission in the reflex pathways was not fundamentally different for both types of afferents. However, beside the reflex pathways presumably used in common a special excitatory nociceptive pathway from the central foot pad to plantaris and foot extensors was observed. This pathway did not follow the flexor reflex pattern, did not show a convergent action with non-nociceptive FRA and was less effectively depressed by enkephalins than an excitatory nociceptive FRA pathway.

Thus nociceptive cutaneous afferents seem to contribute to spinal motor control generally in a similar way as non-nociceptive FRA, which also may evoke reflex effects via private non-FRA pathways.

Supported by the Deutsche Forschungsgemeinschaft (Scho 37/3-2).

364.2

THE ELECTRICALLY-STIMULATED FLEXOR REFLEX IN PITHED RATS IS A TEST MODEL FOR DIFFERENT CENTRAL RECEPTOR TYPES. T. Skarsfeldt*. (Spon: I. Divac). H. Lundbeck A/S, Ottiliavej 7-9, DK-2500 Copenhagen-Valby, Denmark.

Andén et al. found that DOPA increased the muscle tension (flexor reflex) in the hind limb of pithed rats (Nature 202, 1344, 1964). Recently, I described that the dopaminergic (DA) D-1 agonist SK&F 38393 and the DA D-2 agonist pergolide incerased the flexor reflex elicited by electrical stimulation. This effect could be selectively blocked by DA D-1 and DA D-2 antagonists, respectively (Skarsfeldt, Pharmacology & Toxicology 64, 298, 1989). In a recent report we found that not only DA compounds but also the α_1-adrenoceptor agonist St 587 facilitated the flexor reflex (Skarsfeldt and Hyttel, Eur. J. Pharmacol. 125, 333, 1986). The activity of St 587 was selectively blocked by α_1-adrenoceptor antagonists. Additionally, we have observed that clonidine (an α_2-adrenoceptor antagonist) increased the flexor reflex. We have also reported that the 5-HT_{1A} agonist 8-OHDPAT and the 5-HT_1 agonist TFMPP induced a dose dependent increase of the reflex (Skarsfeldt and Larsen, Eur. J. Pharmacol. 148, 389, 1988). The serotonin precursor l-5-HTP had a similar effect which was attenuated by 5-HT_2 antagonists (manuscript submitted). In conclusion the described flexor reflex model can be used as a test for multiple receptors in the spinal cord of pithed rats.

364.3

EFFECTS OF A NORADRENERGIC BLOCKER ON POLYSYNAPTIC SPINAL REFLEXES IN THE CAT. J.F. Miller, C.J. Heckman, M. Munson* and W.Z Rymer. Dept. of Physiol., Northwestern University, Chicago, IL, 60611.

Dorsal hemisection of the spinal cord in the decerebrate cat alters the recruitment and frequency modulation of motoneurons in a way that is similar to some changes seen in spastic human patients. The monoaminergic fibers in the dorsal lateral funiculus may play a role in these changes. Our preliminary results on the effects of the noradrenergic alpha-2 blocker, yohimbine, on 2 polysynaptic spinal reflexes (sural and crossed extension) are consistent with this possibility.

Results: 1) No changes were observed in tendon vibration or stretch reflexes, which are largely dependent upon the monosynaptic Ia pathway. However, single shocks to the ipsilateral sural nerve produced a small excitatory reflex in medial gastrocnemius (MG), as measured by force and EMG. Yohimbine potentiated this presumably polysynaptic response (120-200% of control). This is contrary to the previous work of Engberg et al. (Acta physiol. scand. 72: 142, 1968), but we used a slightly different decerebrate preparation (pre- instead of mid-collicular). 2) In contrast to the single shock response, sustained stimulation of the sural nerve (100 Hz for 1-2 s) produced a powerful activation of MG that tended to be unaltered or decreased (70-80% of control) by yohimbine. 3) Similar sustained activation of the contralateral tibial nerve generated a powerful crossed extension reflex in MG that was clearly decreased by yohimbine (40-50% of control). These alterations in sustained reflexes are consistent with the potentiating effect of noradrenaline upon long latency flexion and crossed extension reflexes seen in spinalized preparations.

Discussion: The reductions in the sustained reflexes were similar to, but not as large as, those produced by dorsal hemisection (sural: 10-30% of control, contralateral: 5-30%). Thus, loss of noradrenergic input may be responsible for some of the effects of dorsal hemisection. We are presently investigating further monoaminergic agents. Future studies will include direct measurements of the effects of these agents on the recruitment and frequency of single motor units.

364.4

THE RELATIVE ROLES OF MUSCLE SPINDLE AFFERENTS AND MOTONEURON POOL ORGANIZATION IN FORCE DEVELOPMENT DURING RAMP STRETCH. Dj. Boškov* and W. Z. Rymer (Spon. C. J. Heckman). Dept. of Physiol., Northwestern Univ., Chicago, IL 60611.

Sudden loss in stiffness (yield) that occurs when active, areflexive muscle is stretched can be compensated by recruitment of new motor units or, to a lesser extent, by increasing the firing rate of already active units. To explore the behavior of various components of stretch reflex, we measured spindle afferent activity, EMG, reflex and mechanical forces in the soleus muscle of the decerebrate cat, starting at different initial forces and applying different stretch velocities.

The time of yielding (ranging from 40 to 80 msec) increased with the velocity of stretch and with initial force. If the muscle was activated after the onset of stretch, the force developed during stretch was significantly higher than that of the muscle tonically active before the stretch. Reflex force contribution during and after stretch and responses of spindle afferents were virtually independent of initial forces, for the same stretch. However, EMGs had a very pronounced dynamic responses at low initial forces, which became very small even at moderate forces. The initial burst of EMG, which always occurred well in advance of yield (30-70 msec), increased with velocity and initial force.

In order to study the behavior of EMG, a computer model of motoneuron pool was produced, based on the model described by MacGregor and Oliver (Kybernetik 16:53, 1974), with increasing firing thresholds and inputs corresponding to central and muscle spindle afferents. For a particular velocity, spindle afferent input was not changed, and the central input was varied to simulate different initial forces. The simulated EMG (a weighted sum of bipolar waveforms), was quite realistic and included features described above for the real EMG. The initial burst was roughly proportional to a sum of synchronized already recruited and newly recruited units. Little new recruitment occurred during stretch, except at very low central drive.

These results suggest that the spindle afferents serve only as simple transducers signalling the disturbance to the motoneurones which are, therefore, responsible for computing a corrective signal, depending on the combination of central and spindle afferent inputs. Although this computation appears to be very crude, it seems suitable to mechanical properties of muscle units and apparently follows the size principle. Predictive reflex action, based on computation of corrective signal from disturbance signal is consistent with the principle of feedforward control.

DIFFERENCES IN FLEXION REFLEX IN DECEREBRATE VS. SPINAL CATS. J.A. McMillan, W.A. Yuhas* and L.L. Morgan.*. Dept. of Biol. and WAMI Program, State University, Bozeman, MT 59717

Excitability of the flexion reflex (FR) is known to be greater in spinal than in decerebrate (DCER) cats. We report here that such differences are more complex than has been previously considered.

Excitability of the FR, evoked by stimulating the left tibial nerve at the ankle and monitored by recording isometric tension from the left semitendinosus, was tested in DCER cats. The thoracic spinal cord was then cut and the same tests were repeated.

In the DCER preparation, the FR was evoked by A-delta fibers at 10 Hz but required input over C fibers at 1 Hz. In the spinal preparation a brisk FR was evoked by A-delta's at 1 Hz; no increase in the reflex was seen after adding C's to the volley. Furthermore, there was no long-latency (>350 msec) response and no prolonged central summation when stimulating C's at 0.5 Hz; both are commonly seen in the DCER preparation.

These results suggest that descending influences which suppress the FR in the DCER preparation affect inputs over A-delta and C fibers differentially. This has implications for our understanding of motor organization and for using the FR as a model of pain perception. (Supported by NSF BNS 86-19148 and NIH RR08218-06)

ALTERED REFLEX ORGANIZATION UNDERLYING CLASP-KNIFE RESPONSES IN CHRONIC SPINAL CATS. T.R. Nichols and T.C. Cope. Dept. of Physiology, Emory Univ., Atlanta, GA 30322, and Dept. of Physiology and Biophysics, Hahnemann Univ., Philadelphia, PA 19102-1192 (TCC).

A striking symptom which follows spinal transection is the clasp-knife response, a flexion-like reflex evoked by muscle stretch (Rymer,W.Z. & Cleland,C.L., Soc. Neurosci. Abstr., 9:529, 1983). We studied clasp-knife responses in chronic spinal cats (T13X, 1-4 weeks) using stretch-evoked reflexes among soleus (S), gastrocnemius (G) and tibialis anterior (TA) muscles in decerebrated preparations. Stretch of G, S or TA produced powerful inhibition in S, prolonged excitation of TA and modest inhibition of G. The inhibition of S and G due to stretch of S was superseded by the tonic stretch reflex and synergistic excitation, respectively, at higher forces in S. The strength of the inhibition increased with length of S. These properties indicate that clasp-knife is due to a mechanism different from the inhibition from G to S regularly observed in control decerebrates (Nichols, T.R., J. Physiol., 410:463, 1989), and that soleus, a pure extensor, is affected preferentially. The clasp-knife pattern contrasts sharply with the absence of autogenic inhibition and poverty of heterogenic reflexes in long-term (11 mo.) lesioned animals (Cope,T.C.,& Nichols,T.R., Soc. Neurosci. Abstr., 14:795, 1988).

RECOVERY OF SPINAL CORD EXCITABILITY FOLLOWING EXPOSURE TO A HYPEROSMOTIC SOLUTION. D.A. Lake. Dept Physical Therapy, Northeastern University, Boston, MA 02115.

Spinal cords of Rana Pipens were isolated and superfused with a modified glucose-Ringer's solution (NaCl, 100 mM; KCl, 2.5 mM; Na2HPO4, 2.5 mM; NaH2PO4, 0.45 mM; CaCl2, 1.9 mM; NaHCO3, 12 mM; and glucose, 2.8 mM) aerated with a 95% O2 and CO2 gas mixture (pH 7.4). The tenth dorsal root (DR 10) was stimulated supramaximally (1-5 mA) using 0.1 ms duration pulses delivered at 0.2 Hz with a bipolar hook electrode. The reflex responses were recorded using bipolar electrodes from the tenth ventral root (VR 10) and passsed through a preamplifier with the low frequency filter set at 10 Hz and the high frequency filter at 30 Hz. Measurements were taken from averages of 16 recorded potentials. The control medium was replaced by the control medium with varying concentrations of the non-electrolyte mannitol (25, 50, 75 and 100 mM). After 30 minutes of exposure to the hyperosmotic medium, the control medium was reintroduced for 60 minutes to measure recovery. All of the hyperosmotic solutions decreased both the amplitude and area of the evoked potentials. Progressive increases in osmolarity progressively decreased the evoked potentials. The decrease in the evoked potential occurred within the first 5 minutes of exposure to the hyperosmotic medium. There was no further significant decrease in the evoked potential over the next 25 minutes. There was a recovery of the evoked potentials after the reintroduction of the control medium. However, the evoked potentials did not return to control levels even after 60 minutes of exposure to the control medium.

364.8

THE EFFECT OF RECURRENT INHIBITION ON SHORT-TERM SYNCHRONIZATION OF MOTONEURONS DURING FICTIVE LOCOMOTION. M.L. McCurdy and T.M. Hamm Div. of Neurobiology, Barrow Neurological Insitute, Phoenix, AZ 85013.

The effect of recurrent inhibition on synchronization of motoneuron discharge was examined during fictive locomotion produced in paralyzed, decerebrate cats by stimulation of the mesencephalic locomotor region. Spike trains of single motor axons recorded with glass microelectrodes were used to collect spike-triggered averages of rectified neurograms, providing a quantifiable estimate of synchronization between the single motor axons and the motor axon populations in several hindlimb muscle nerves. Preliminary results showed short-term synchronization between motoneurons supplying anterior biceps femoris, medial gastrocnemius and lateral gastrocnemius-soleus. Synchronization was decreased (5 of 6 cases), or unchanged, by intravenous administration of mecamylamine given to reduce recurrent inhibition, indicating that recurrent inhibition has a synchronizing effect on motoneuron discharge during fictive locomotion. This finding contrasts with the effects of recurrent inhibition during reflex activity (Adam et al., Biol. Cybern. 29: 229, 1978; Buahin and Rymer, Soc. Neurosci. Abstr. 10: 329, 1984), suggesting that the action of recurrent inhibition on motoneuron synchronization may differ in reflex and centrally generated motor activities.

POST-TETANIC EFFECTS ON MONOSYNAPTIC REFLEXES, DORSAL ROOT REFLEXES AND DORSAL ROOT POTENTIALS IN KITTENS. P. Bawa Kinesiology, Simon Fraser University, Burnaby, B.C., Canada, V5A 1S6.

Tetanic stimulation of muscle afferents results in post-tetanic potentiation (PTP) of monosynaptic reflexes (MSRs) in adult cats. Similar stimulation in new born kittens results in post-tetanic depression (PTD). Percent PTP increases and PTD decreases gradually with age of the animal (Bawa, Canad. J. Physiol., Pharm., 65:328-336, 1986).

Concomitantly recorded dorsal root reflexes (DRRs) and dorsal root potentials (DRPs) exhibited similar pattern of PTP and PTD when muscle nerves were stimulated to elicit these responses i.e. predominantly PTD of DRRs and DRPs in kittens and PTP in adult cats. However, when cutaneous nerves were stimulated to elicit DRRs and DRPs, PTP was rarely observed at any age. Both in kittens and adults PTD of DRRs and DRPs was observed.

The mechanisms underlying these differential post-tetanic effects of muscle and cutaneous nerves could be due to differences in 1) depletion of transmitter, 2) extracellular K^+ accumulation and 3) transmission failure at cutaneous and muscle afferent terminals.

COMPARISON OF RECRUITMENT ORDER BETWEEN PAIRS OF MOTOR UNITS IN THE CAT MEDIAL GASTROCNEMIUS MUSCLE. B.R. Botterman and K.E. Tansey. Dept. of Cell Biol., UT Southwestern Med. Ctr., Dallas, TX 75235.

The order in which motor units are recruited is found to be highly correlated with motoneuron size, as judged by the conduction velocity (CV) of its axon, and with several properties of its muscle unit, such as its contractile strength and fatigability. Among fast twitch (type F) units, it has been shown by others that in the cat plantaris muscle tetanic tension is a better predictor of recruitment order than CV. Therefore, we wished to confirm this finding in another large, hindlimb muscle containing a high proportion of type F units.

Direct comparisons of recruitment order were made in pairs of type-identified medial gastrocnemius (MG) motor units by recording from and stimulating their axons in the MG nerve. Motor units were recruited by monosynaptic reflexes evoked by stimulation of the L_7+S_1 dorsal roots in decerebrate, unanesthetized animals spinalized at C_1. Of the 74 units studied, 77% were recruited by either a single stimulus (n=37) or by a single stimulus following facilitation of the reflex by a 500-pps conditioning train. Of the 17 units not recruited, all but two were type FF units. In 41 of 44 pairs studied, the least forceful unit had the lower threshold for recruitment (1/2 for S-S pairs, 18/18 for S-F pairs, 22/24 for F-F pairs). For the two exceptions in the F-F group, the lower threshold unit was the more fatigue resistant in both pairs and had a slower CV in one pair. In the one S-S pair in which the more forceful slow twitch unit (type S) was recruited first, unit tensions differed by 1 g. Among S-F and F-F pairs, in only 1 pair did the unit with the greater resistance to fatigue have the higher threshold for recruitment. By contrast, the lowest threshold unit had the slowest conducting axon in only 8/15 cases for F-F pairs and 0/2 cases for S-S pairs. However, the correlation between functional threshold and CV was much better for S-F pairs (16/17). In 8 pairs, the CVs were indistinguishable between units.

The present work confirms the findings of others that the relative tension and fatigability of a unit is a better predictor of a unit's threshold for recruitment than its conduction velocity, especially among type F units. NIH grant NS17863.

365.1

A SLICE PREPARATION OF THE VERTEBRATE SPINAL CORD FOR NETWORK AND SINGLE CELL STUDIES. Evelyne Sernagor* and Michael O'Donovan (Spon: J.McIntosh) Lab. of Neural Control, NINDS, NIH, Bethesda, MD, 20892.

We have developed a slice preparation of the embryonic 12-14 day old chick spinal cord for studies of network function and single cell membrane properties. Slices (200-750 μM thick) were cut from the spinal cord using scissors with fine (50 μM) blades. Slices could be made in which roots and individual muscle nerves were preserved intact. Individual motoneurons could be easily visualized in these slices using a microscope equipped with Hoffman optics.

The slices contain a substantial amount of functional synaptic circuitry. Dorsal root stimulation produces synaptic potentials in motoneurons closely resembling those recorded in the hemisected spinal cord. In addition, some components of the circuitry underlying motor activity persist in thicker slices because bath application of the excitatory amino acid NMDA produces rhythmic motor activity similar to that recorded in the intact cord. Further studies are in progress to establish whether or not the phasing of flexor and extensor motor activity is normal in the slices.

On some occasions it has been possible to obtain whole-cell patch clamp recordings from motoneurons in slices which had been subjected to a mild enzymatic treatment. Preliminary results indicate that motoneuron input impedances are in the range of 0.3 to 0.6 Gohm and action potential amplitudes > 80 mV. A prominent feature of the motoneurons' electrical behavior is a potent anodal break response appearing at -40 pAmp and which can produce repetitive firing with larger currents. This preparation should be useful for studying the development of intrinsic neuronal properties and the formation of synaptic connections in the spinal cord.

365.2

THE DEVELOPMENT OF RECURRENT MOTONEURONAL CONNECTIONS IN THE SPINAL CORD OF THE CHICK EMBRYO. Michael O'Donovan. Lab. of Neural Control, NINDS, NIH, Bethesda, MD, 20892.

The development of recurrent motoneuronal connections was studied in the *in-vitro* lumbosacral cord of stage 30-38 chick embryos. Motoneuron axons were activated by ventral root (VR) stimulation and recurrent responses recorded either from the adjacent ventral root (all ages) or intracellularly from motoneurons (stage 36-38 embryos) using K citrate or KCL electrodes. VR stimulation produced depolarizing synaptic potentials in motoneurons, which were largest using KCL electrodes, often had multiple components and fatigued rapidly during repetitive stimulation. Following antidromic stimulation of motoneurons the latency of the intracellular potential averaged 10 ms (minimum 5.5 ms). This latency is compatible with a disynaptic pathway because the preparation is at room temperature and afferent evoked monosynaptic potentials have a latency of 5 ms. In the majority of experiments the recurrent VR potentials were reversibly abolished by bath application of curare (10 μM) or strychnine (100 μM). Surprisingly, the potentials were also blocked by the GABAergic antagonists, picrotoxin and bicuculline (100μM).

These results suggest that the recurrent potentials may be mediated by inhibitory interneurons similar to mammalian Renshaw cells. The early appearance of this pathway during development (stage 30-32) reveals that motoneurons have neuronal *and* peripheral synaptic targets during the cell death period, raising the possibility that both targets may influence motoneuron survival.

365.3

AN INTERSEGMENTAL SPINAL CORD REFLEX IN GUINEA PIG. A. R. Blight. Center for Paralysis Reseach, Purdue University, West Lafayette, IN 47907.

The cutaneous trunci muscle reflex was studied in guinea pigs, using electromyography, motion analysis, selective lesions, retrograde HRP and microscopy. As in the rat (Theriault, A., and Diamond, J., *J. Neurophysiol.* 60: 46-462, 1988) the muscle covers much of the trunk as a subdermal sheet. The dorsal half of the muscle contracts locally in response to tactile or electrical stimulation of the skin. The reflex consists of a brief twitch centered 1-2 cm rostral of the stimulus, and the receptive field includes much of the thoracic and lumbar dorsal surface. Sensory input is carried by segmental cutaneous nerves, the receptive fields of which form overlapping strips on either side of, and perpendicular to the midline. The lateral thoracic nerves from the brachial plexus innervate the muscle on each side. Motoneurons are in the lower cervical ventral horn (C7-T1). The ascending limb of the reflex involves projections in the ventral half of the thoracic lateral funiculus. These axons convey information primarily from ipsilateral skin, together with a limited input from contralateral skin, which crosses at segmental levels. Electromyographic responses to skin stimulation are 15-30 msec bursts at latencies of 15 - 20 msec. The reflex does not readily habituate or fatigue at stimulus frequencies below 10 Hz, and it persists under light pentobarbital anesthesia. This combination of characteristics makes the reflex useful for a variety of physiological and pathophysiological studies of spinal cord function. Currently, it is being used to monitor conduction in traumatically injured spinal cord, allowing repeated measurements in unanesthetized or lightly sedated animals.

365.4

EFFECT OF QUANTITY OF ACTION POTENTIALS ON MOTONEURON OXIDATIVE CAPACITY G. R. Chalmers, R. R. Roy, and V. R. Edgerton. Dept. of Kinesiology and Brain Research Institute. UCLA, Los Angeles, CA 90024.

Two models were used to examine the effects of 6 months of reduced action potential (AP) activity on motoneuron (MN) oxidative capacity. Model 1: 9 female cats were spinalized (SP, T12-T13), to reduce electrical activity in the MNs of the lumbar cord. Based on EMG activity of selected hindlimb muscles, MN AP activity was reduced by approximately 30% (Alaimo et al., *J. Appl. Physiol.* 56:1608, 1984). The hindlimb muscles of 5 of the 9 SP cats were trained (weight support) 30 min/day, 5 days/week. Model 2: 9 female cats were spinal isolated (SI) i.e., complete spinal cord transection at T12-T13 and at L7-S1 and all dorsal roots between transection sites severed. EMG indicated that the generation of APs in MNs in the lumbar cord was virtually eliminated (Roy et al., *Soc. Neurosci. Abstr.* 14:948,1988). The right leg in each cat received cyclic passive stretching for 30 min/day, 5 days/week. Nine normal cats served as control (C). Succinate dehydrogenase (SDH) activity, an aerobic marker enzyme, of MNs in the lumbosacral enlargement was measured using quantitative histochemistry (Chalmers and Edgerton *J. Histochem.* Cytochem, In Press). The results were similar in the exercised and non-exercised limbs, thus these data were pooled. There were no significant differences in MN SDH activity (mean ±SD, n) among the C (0.0148 ±0.0035 OD/min, 1057), SP (0.0135 ±0.0025 OD/min, 1144), and SI (0.0137 ±0.0027 OD/min, 1107) groups. Soma size was determined for MNs in which there was a visible nucleus. There were no significant differences in soma area among the C (4035 ±535 μm^2, 437), SP (4279 ±520 μm^2, 447) and SI (3985 ±516 μm^2, 356) groups. These data indicate that the soma size and SDH activity of lumbar MNs are unaffected by a marked reduction in the number of generated APs for up to 6 months, suggesting that AP activity may not be a major determinant of MN oxidative capacity. *Supported in part by NIH Grant NS16333.*

LOCOMOTION INDUCED BY ELECTRICAL STIMULATION OF THE MAMMALIAN SPINAL CORD. E. Garcia-Rill, Y. Atsuta* and R.D. Skinner, Department of Anatomy, University of Arkansas for Medical Sciences, Little Rock, AR 72205

Electrical and chemical activation of the medioventral medulla (MED), the main descending projection target of the mesencephalic locomotor region (MLR), induces locomotion in decerebrate cats and rats. In the present study, an attempt was made to induce locomotion by activating the descending projection sites of the MED, the cervical and lumbar spinal cord, using electrical stimulation. Adult cats (n=23) and rats (n=8) were anesthetized with halothane and decerebrated at a precollicular level. Stimulation was applied epidurally and subdurally. In 6 cats, a transection was made at the T6 level of the spinal cord and the lumbar enlargement stimulated. Repetitive stimulation of the cervical (C4-T1) as well as lumbar (L3-S1) cord epidurally or subdurally induced low threshold, actual and fictive locomotion as long as long duration, low frequency stimuli were used. Stimulation of the surface of the cord was found to be effective when applied to the dorsal columns or to the dorsal root entry zone. Stimulation of the lumbar enlargement induced locomotion in spinalized animals beginning about 4 hrs after transection. EMGs and neurograms during induced actual and fictive locomotion showed a normal-type locomotor pattern and was changed to a trot and gallop by increasing stimulus intensity. These results suggest that spinal stepping generators can be activated in a controlled manner by local electrical stimulation of the spinal cord in the decerebrate and spinalized mammal. Supported by USPHS grant NS20246 (Patent Pending).

365.6

RECRUITMENT ORDER AND DISCHARGE PATTERNS AMONG PAIRS OF MOTOR UNITS EVOKED BY BRAINSTEM STIMULATION. K.E. Tansey and B.R. Botterman. Dept. of Cell Biol., UT Southwestern Med. Ctr., Dallas, TX 75235.

The progressive recruitment of motor units and the subsequent modulation of their discharge rates are the two primary processes involved in the gradation of muscle force. To begin to assess the significance of rate modulation in the control of muscle force, pairs (n=24) of medial gastrocnemius (MG) motor units (n=46) were recorded from the MG nerve during their activation by stimulation in and below the mesencephalic locomotor region in high decerebrate cats. Graded contractions of up to 2 kg, lasting for up to 30 s, were evoked in MG. Motor-unit type (S,FR,FF), axonal conduction velocity (CV) and maximum tetanic tension (P_o) were determined for pairs of units and correlated with their recruitment order and discharge properties.

In 1 S-S, 10 S-F and 13 F-F pairs, recruitment proceeded by motor-unit type (S>FR>FF: 24/24 pairs), and by increasing P_o (21/23 pairs) and CV (7/10 pairs) when differences within pairs could be reliably measured. In 8 pairs, both units were recruited and their discharge patterns were analyzed. In most pairs (7/8), the motor unit recruited first discharged at a lower mean rate. The range of mean firing rates for evoked activity lasting 0.5-10 s was 11-24 pps for 5 S units, 32-51 pps for 3 FR units, and 36-58 pps for 8 FF units. These 16 units discharged with brief intervals (2.3-15.9 ms), either at the beginning of (initial doublet, n=4), or elsewhere in their discharge. Brainstem stimulation evoked a widely varying response in these units. In some cases, changes in unit discharge rate closely followed changes in muscle force, while at other times rate appeared to plateau as muscle force continued to rise. Pairs containing units of similar type and recruitment threshold often discharged with similar patterns.

This data confirms other work showing that motor-unit recruitment proceeds by increasing P_o and CV. In addition, the discharge rates of recruited units display varying degrees of modulation and generally fall on the steep portion of frequency-tension curves for similar type units. (NIH grant NS1783)

365.7

STUDY OF MOTONEURONAL ADAPTATION AND MOTOR-UNIT FATIGUE BY EXTRACELLULAR ACTIVATION OF SINGLE MOTONEURONS. J.M. Spielmann, G.A. Robinson, Y. Laouris, R.M. Reinking and D.G. Stuart. Dept. of Physiology, Univ. of Arizona, Tucson, AZ 85724.

Motoneuronal adaptation refers to the slowing of discharge rate during sustained or repetitive activation at a constant stimulus strength. Beyond the work of Kernell and Monster (Exp. Brain Res., 46:191 and 197, 1982) little is known about the nature of such adaptation and its relation to functional muscle unit properties and Henneman's size principle. While a few relationships were reported by these workers, many expected correlations were not. Technical difficulties inherent in intracellular work may have confounded their results. We have begun experiments to test for associations between motoneuron adaptation and muscle unit mechanical properties, including fatigability. We expect to resolve some of the previous problems by stimulating single cat motoneurons with extracellularly applied current (Gustafsson and Jankowska, J. Physiol. (Lond.), 258:33, 1976) rather than using the traditional intracellular approach. Individual medial gastrocnemius motoneurons were stimulated with a microelectrode positioned near the motoneuron to ensure a low threshold of activation. Muscle units were characterized by twitch contraction time, peak force, and sag. Each motoneuron was stimulated with sustained current for up to 4 min. After a short rest, the same cell was stimulated with repetitively applied current (600 ms @ 1/s), again for up to 4 min. Motoneuronal responses to sustained stimulation showed a rapid early adaptation followed by a more slowly developing late adaptation (cf. Kernell and Monster, 1982). Repetitive stimulation revealed intra-train adaptations in the majority of cases. In addition, inter-train adaptations were marked by a progressive decline in both firing rate and the number of discharges per train. These results support our "extracellular" approach in the study of motoneuronal adaptation. Supported by USPHS grants NS 07309, HL 07249, NS 25077, NS 08363, RR 05675.

SINGLE-UNIT RECORDING OF LUMBAR LAMINA IX NEURONS IN SPINAL CORD SLICES FROM ADULT RATS. L.-M. Kow and D.W. Pfaff. The Rockefeller University, New York, NY 10021.

Slices (400-500u) of lumbar cord were prepared from rats (b.wt. 120 to 414g), with a Vibratome and with artificial cerebrospinal fluid that contained sucrose in place of NaCl (Aghajanian and Rasmusson, 1989). Single-unit activity was recorded from medial and lateral lamina IX under visual guidance. Bipolar stimulating electrodes were placed at ventral rootlet exit in attempts to activate motoneurons antidromically.

A total of 108 units were recorded in 21 experiments. When applied between repeated serotonin infusions, TRH could modulate the excitatory action of serotonin (15/24 units), even when TRH had no effect by itself. At rest, the proportion of active neurons was higher ($p<.01$) among medial (40/49) than lateral neurons (16/35). More medial than lateral cells fired with regular interspike intervals. More lateral than medial neurons responded to electrical stimulation or transmitters. Thus, medial neurons (where motoneurons innervating lordosis-relevant epaxial muscles are located) and the lateral cell group (which contains limb motoneurons) appeared to behave differently both at rest and upon stimulation.

365.9

RHYTHMICAL MOTOR ACTIVITY IN NEO-NATAL RAT; COMPARISON BETWEEN INTACT ANIMAL AND IN VITRO PREPARATION. J.R. Cazalets*, P. Grillner*, I. Menard*, J. Crémieux*, F. Clarac. Lab. Neurosciences Fonctionnelles (LNF2) 31 chemin J. Aiguier, BP71 13402 Marseille CEDEX 9, FRANCE.

Swimming behavior in the neo-natal rat was compared with locomotor-like activity induced in vitro. The swimming behavior was studied by electromyographic recordings of the four limbs. From day 1 to day 20 the swimming frequency increased from 1 to 5 Hz. The isolated preparation was a brain stem-spinal cord preparation from new born rats (0-6 days). The activity was recorded on ventral roots and hind limb muscles. Bath application of 5-HT (10^{-5}M) and norepinephrine (NE, 10^{-5}M) elicited rhythmical bursting activity (5 to 8 Hz). The temporal characteristics (phase relation and burst duration of either antagonistic or agonistic muscles) recorded in vitro, were directly comparable to those recorded in vivo. Occasionally 5-HT also elicited a pattern consisting of a slow modulation (between .5 and .2 Hz and alternating on right and left lumbar segments) of the high frequency rhythm. Rhythmic patterns were also obtained by bath application of 5-HT and NE when lumbar segments were isolated from the rest of the spinal cord.

365.10

ELECTROPHYSIOLOGICAL ASSESSMENT OF DESCENDING MOTOR PATHWAYS FOLLOWING SPINAL CORD INJURY IN RAT. J.H.Kim, J.S Cheon, Y.G. Park*, R. Prado, and W.J.Levy. Dept. of Neurological Surgery, Univ. of Miami, Sch. of Med., Miami,FL 33136.

Following partial spinal cord injury in the adult cat, the resultant motor deficit can be predicted by monitoring the motor evoked potential(MEP). However, the adult rat with complete transection of the corticospinal tract, the major component conducting the MEP, still recovers hindlimb locomotion within 2-3 weeks. The objective of this study is to electrophysiologically assess the substrate of the recovery of locomotor function after partial spinal cord injury in rat. The evoked potentials were monitored epidurally at T6 and L1 during electrical stimulation of red nuclei(RN; magnocellular division), lateral vestibular nuclei(LVN) and gigantocellular reticular nuclei (RetN). Varying degree of spinal cord injuries were photochemically induced at T8 level of cord in rat(Prado et al., J. Neurosurg.,67:745). The evoked potentials were monitored 1-4 weeks postlesion. The evoked potentials were analyzed as the amplitude ratio between the first peak recorded on the lumbar and thoracic cord (L/T ratio). Upon increasing stimulus intensity, the L/T ratio of LVN evoked potential(LVEP) and RNEP increased to 3 times the value obtained at threshold, but L/T ratio of the RetN evoked potential (RetEP) declined gradually with increased stimulus intensity. Unlike LVEP and RNEP, the L/T ratio of RetEP increased after partial section of dorsal cord. The L/T ratio of the RetEP returned to normal 3 weeks after partial spinal cord injury which was coincide with the recovery of motor function of the hindlimbs.

NON-DEPENDENCE OF PSP'S FROM SURAL NERVE ON ITS PERIPHERAL INNERVATION. H Nishimura & JB Munson. Depts of Neurosurg & Neurosci, Univ of FL Coll of Med, Gainesville, FL 32610.

Stimulation of caudal cutaneous sural (CCS: commonly "sural") or of lateral cutaneous sural (LCS) nerve in pentobarbital-anesthetized cats each elicits PSP's of characteristic EPSP/IPSP configuration in triceps surae motoneurons (TS MN's). We showed that cross-connection (x-conn) of CCS to medial gastrocnemius (MG) nerve did not alter these PSP's (Soc Neurosci Abstr 14: 696, 1988). To extend this result we investigated the ability of similar targets (cutaneous-cutaneous) to sustain or alter input organization in the spinal cord. CCS and LCS nerves were cut and x-conned distally. 1-2 years later, exchange of innervation territory was confirmed by recording each nerve's activity in response to skin stimulation. Intracellular recording from TS MN's showed that stimulation of the distal portion of the CCS nerve (x-conned proximally with LCS nerve) gave PSP complexes appropriate for normal LCS nerve. Stimulation of distal LCS gave the analogous result. Thus CCS-LCS x-conn, like CCS-MG x-conn, did not respecify the input organization of the LCS or CCS nerve in the spinal cord. We further tested target-dependence of CCS synaptic function by axotomizing and capping CCS. After 1-2 years, electrical stimulation of CCS (lacking evident peripheral innervation) elicited apparently normal PSP's in TS MN's. Thus CCS afferents may differ from large muscle afferents in not requiring peripheral innervation to sustain synaptic efficacy in TS MN's. Support: NS15913.

Concordant depolarizing responses produced by locus coeruleus stimulation and norepinephrine in individual spinal motoneurons. S.J. Fung, D. Manzoni*, J.Y.H. Chan, and C.D. Barnes. Dept. of VCAPP, Washington State Univ., Pullman, WA 99164, USA.

Locus coeruleus (LC) stimulation (Fung and Barnes, Brain Res., 402:230, 1987) and norepinephrine (NE) (Fung, White and Barnes, Soc. Neurosci. Abstr., 14:214, 1988) have been shown independently to cause depolarization in spinal motoneurons of cats. The present study was undertaken to compare the membrane response, recordable from the same cell, due to these two causes when applied individually and in combination. In decerebrate cats, stable recordings from motoneurons with antidromic spikes above 60 mV were used in this analysis. Parallel depolarizing changes were evident, within the same cell, following tetanic LC stimulation (4-54 pulses at 500 Hz, 15-50 uA) and iontophoretically applied NE (50-80 nA, 60-90 sec). The NE-induced depolarization was typified by a slow time course, whereas the LC-induced EPSP was briefer in duration, with weak ensuing IPSP in some cells. Both LC stimulation and NE relieved the partial block of the antidromic activation. Upon interaction the LC-induced EPSP summated with the NE-induced depolarization, resulting in motoneuron discharge. H^+ application was without effect on the motoneuron excitability. These data reveal that LC stimulation produced EPSP is mimicked in part at least by the NE application in lumbar motoneurons of cats. Supported by NIH grant NS 24388.

MULTISITE OPTICAL RECORDING OF NEURON ACTIVITY IN ORGANOTYPIC SPINAL CORD SLICE CULTURES OF THE RAT. M.G. Rioult* and H.-R. Lüscher (SPON. M. Wiesendanger). Dept. of Physiology, University of Bern, CH-3012 Bern, Switzerland.

Optical recordings were used to study the electrical activity of different populations of neurons in an organotypic coculture of embryonic rat spinal cord (SC), dorsal root ganglia (DRG) and skeletal muscle. In this culture system functioning synaptic contacts involved in the spinal reflex arc have been shown to exist by conventional electrophysiological technique (Spenger et al. Neurosci. Abstr. 1989).

The cultures, grown for 14 days in vitro, were stained with the fluorescent voltage-sensitive styryl dye RH-237 at concentrations of 5 - 15 µM for 30 min. Changes in fluorescence intensity were recorded by a 12 x 12 element photodiode (PD) array mounted in the image plane of an inverted microscope in epifluorescent configuration. 20x, 0.8 n.a. and 40x, 1.3 n.a. glycerin immersion objectives were used giving a spatial resolution of 28 x 28 µm and 14 x 14 µm respectively. A 100-W mercury lamp was used as a light source. The signal from each PD could be sampled at a maximum rate of 3.3 kHz for 300 msec.

Large DRG cells (diameter approx. 40 µm) were impaled by microelectrodes and stimulated with depolarizing current pulses. The intracellular electrical signal and the fluorescence signals were recorded simultaneously. Action potentials as well as subthreshold depolarizations could be resolved in the optical recordings from the PDs covering the cell body of the stimulated neuron without signal averaging. Extracellular focal stimulation of "dorsal roots" evoked fast as well as slow optical signals recorded from the ventral part of the SC. These signals may arise from synaptic excitation of the motoneurons.

Optical recording in combination with organotypic slice cultures of SC may provide a promising tool for studying local neuronal circuits in the spinal cord. (Supported by SNF No 3.265-0.85)

MORPHOLOGICAL AND PHYSIOLOGICAL EVIDENCE FOR A FUNCTIONAL SPINAL REFLEX ARC IN AN ORGANOTYPIC COCULTURE SYSTEM. C. Spenger*, J. Streit*, U.F. Braschler* and H.-R. Lüscher (SPON: J. Allum), Department of Physiology, University of Bern, CH-3012 Bern, Switzerland

To investigate the spinal reflex arc in vitro, an organotypic coculture of embryonic dorsal root ganglion (DRG), spinal cord (SC) and skeletal muscle (SM) was developed using a modified roller tube technique. Evidence for the differentiation of functioning synaptic contacts involved in the spinal reflex arc in this culture system is presented. HRP filling of DRG cells usually revealed 3 stem dendrites (1-7), one of which was T shaped in about half of the cases. Its peripheral branch extended towards the skeletal muscle explants, and its central branch extended into the ventral region of the SC. Synaptic boutons of HRP filled DRG cells on AChE counterstained motoneurons were seen. Motoneurons were identified by their shape (5.8 ± 1.0 stem dendrites, minor diameter = 22.6 ± 4.9 µm, major diameter = 37.3 ± 10.1 µm, ± S.D. n = 72), location, by AChE staining and by retrograde tracing with HRP or rhodamine beads applied onto the coexplanted skeletal muscle. Skeletal muscle regenerated and formed regularly striated fibres. Neuromuscular contacts were revealed as AChE positive motor endplates, singly or in clusters. Extracellular focal stimulation of DRG cells evoked EPSPs in the motoneurons and action potentials followed by contractions in the muscle fibres, with latencies of 23 and 35 ms respectively (22 °C). The EPSP's had a mean amplitude of 15 ± 5mV (S.D. n=20) and evoked action potentials in 75% of the cases. The EPSP's were blocked by Cd (0.5mM) and kynurenic acid (1mM), showing that they were mediated by glutamate. Pancuronium bromide blocked muscle contractions evoked by stimulation of DRG cells or motoneurons, and in higher doses, spontaneously occurring contractions. This suggests that innervated muscle fibres with differentiated endplates coexisted with undifferentiated hypersensitive fibres. Supported by S.N.F. (Grant No 3.265-0.85)

DIFFERENTIAL INHIBITION OF BACLOFEN ON MONOSYNAPTIC RESPONSES OF MOTONEURONS PRODUCED BY Ia AND DESCENDING FIBERS IN THE CAT SPINAL CORD. P. Rudomín, I. Jiménez and M. Enríquez*. Dept. Physiol. CINVESTAV, México, D.F.

Recent studies in humans with spinal cord trauma (Exper. Neurol. 103: 165, 1989) show that intrathecal baclofen reduces mono- and polysynaptic reflexes and spasticity without greatly affecting voluntary movements. This could be due to a low density, or absence, of GABA-B receptors in the intraspinal terminals of descending fibers, in contrast with Ia fibers. We used cats anesthetized with chloralose (70 mg/kg), paralyzed and artificially respired. The right spinal cord was hemisected at low thoracic level and the left lumbosacral spinal roots sectioned. Intravenous injection of 1.5-2 mg/kg of baclofen markedly depressed (4.7-14% of control), and in some cases abolished, the monosynaptic responses of Ia fibers intracellularly recorded from motoneurons or electrotonically recorded from ventral roots with the sucrose gap technique, as well as the monosynaptic extracellular field potentials recorded in the motor nucleus. The monosynaptic responses produced by stimulation of descending fibers in the ipsilateral ventromedial fasciculus were on the other hand more resistant to baclofen than Ia monosynaptic responses and were depressed to 36-64% of control. They persisted after additional injections of baclofen (up to 3.5 mg/kg), which completely supressed Ia monosynaptic responses. Experiments in progress are aimed to disclose the origin of the descending fibers producing baclofen-sensitive and baclofen-resistant monosynaptic responses in motoneurons. Partly supported by grants NIH NS 09196 and CONACyT PCEXCNA-041739. Baclofen was a gift of CIBA-GEIGY CO.

EFFECTS OF SELECTIVE STIMULATION OF NUCLEUS RAPHE MAGNUS AND ADJACENT RETICULAR FORMATION ON THE INTRA-SPINAL EXCITABILITY OF Ia AND Ib MUSCLE AFFERENTS. I. Jiménez, J. Quevedo, J.R. Eguibar & P. Rudomín CINVESTAV and ICUAP, México, 07000.

Studies of the effects of raphe-spinal fibers on the effectiveness of afferent fibers are limited to cutaneous afferents. We now report the effects of selective stimulation of raphe- and reticulo-spinal pathways on group I muscle fibers. In cats with right hemisection at T13, single pulses (20-100 uA) applied to the nucleus raphe magnus (NRM; 4 mm rostral to obex, midline, 5-6 mm depth) produced negative cord dorsum potentials (CDP) with latency of 5.4±0.5 ms, lasting 45.4±10 ms (n=14). Stimulation of the adjacent reticular formation (RF; 4 mm rostral to obex, 2 mm lat, at 4 mm depth) produced instead a positive CDP with latency of 2.4±0.2 ms, lasting 7.4±4 ms (n=14). Section of the ipsi- dorso-lateral fasciculus abolished the NRM but not the RF responses. Analysis of field potentials showed that NRM fibers end dorsally (0.6-1.8 mm depth) whereas RF fibers synapse with ventrally located neurons (2.8-3.8 mm). Trains (16-18 pulses, 300 Hz, 20-50 uA) applied to NRM and RF reduced the intraspinal threshold of single PBSt Ib afferent fibers to 82.1±15.4% and 79.8±13.6% of control (n=7). The resting threshold of single Ia fibers (n=15) was unchanged by NRM and RF stimulation, which however inhibited the PAD produced by group I PBSt volleys. In two cats the monosynaptic PAD of Ia fibers produced by intraspinal microstimulation was inhibited by RF but not by NRM stimulation. It is suggested that, although raphe- and reticulo-spinal fibers have similar spinal actions, they act on different interneurons along the pathways mediating PAD of Ia and Ib fibers. PGO-RELATED HYPERPOLARIZING POTENTIALS IN LUMBAR MOTONEURONS ARE MEDIATED BY AN INHIBITORY AMINO ACID. F. López*, F.R. Morales, P.J. Soja and M.H. Chase. *Depts. of Physiology and Anatomy, and the Brain Research Institute, UCLA School of Medicine. Los Angeles, CA 90024.*

Inhibitory postsynaptic potentials occur in lumbar motoneurons immediately following the occurrence of pontogeniculooccipital (PGO) waves during active sleep (AS) (*Sleep Res., 18:* 20, 1989). During AS motoneurons also receive a sustained barrage of inhibitory postsynaptic potentials (AS-IPSPs) (*Exp. Neurol., 98:* 418-435, 1987) that are blocked by strychnine (*J. Neurosci., 9:* 743-751, 1989). The present study was undertaken to examine the neurotransmitter control of the PGO-related potentials and to determine whether they are mediated by the neurotransmitter that is responsible for the active sleep-specific IPSPs. In three chronic cats that were implanted for intracellular recording of lumbar motoneurons during sleep and wakefulness, strychnine (15 mM, pH 6.5) was applied juxtacellularly by microiontophoresis using currents of 100 to 200 nA. The intracellular recording electrodes were filled with K-citrate and had resistances of 5 to 15MΩ. PGO waves were recorded from the contralateral lateral geniculate nucleus (LGN) with bipolar electrodes. The membrane potential of lumbar motoneurons was averaged preceding and following PGO activity using specially designed computer software. Prior to the administration of strychnine, the PGO-related IPSP exhibited the following characteristics (which are expressed in terms of their means): latency (measured from the foot of the PGO wave to the initiation of the averaged IPSP), 26 ± 3.7 ms; latency-to-peak, 47.8 ± 3.1 ms; half-width, 25.03 ± 2.9 ms; amplitude, 1.3 ± 0.2 mV; duration, 48.9 ± 11.5 ms. These values are similar to those previously reported for IPSPs following ipsilateral primary PGO waves (*Sleep Res. op cit.*). After the microiontophoretic juxtacellular application of strychnine, the IPSPs were either no longer present in the averaged motoneuron membrane potential, or there were very small hyperpolarizing shifts that were difficult to distinguish from the background noise. These results indicate that the previously described PGO-related IPSPs are mediated by an inhibitory amino acid, presumably glycine, as are the AS-IPSPs. Supported by grant NS 23426.

LUMBAR MOTONEURON BASIC PROPERTIES DURING THE ATONIA OF ACTIVE SLEEP ARE STRYCHNINE-SENSITIVE.

P.J. Soja, F. López*, F.R. Morales and M.H. Chase. *Departments of Physiology and Anatomy and the Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.*

Recently, we reported that the spontaneously occurring IPSPs which inhibit lumbar motoneurons during the atonia of active sleep (AS) are mediated principally by glycine because they are abolished by strychnine, but not by picrotoxin or bicuculline (*J. Neurosci.* 9: 743-751, 1989). In the present study, we further explored the role of glycine in mediating the inhibitory shunt that occurs in these cells during AS. Accordingly, certain basic electrical properties of lumbar motoneurons were determined during quiet sleep (QS) and AS prior to and in conjunction with the microiontophoretic administration of strychnine. Under control drug-free conditions, lumbar motoneuron excitability decreased during AS when compared to preceding episodes of QS, as indicated by a 91.7% mean increase in rheobase (R_h), a 40.9% decrease in input resistance (R_{in}) and a 52.8% decrease in membrane time constant (τ_m) (all $P<0.001$, paired Student's t-test). Following sustained juxtacellular microiontophoretic applications of strychnine, the dramatic changes in these basic properties that occur during AS were suppressed. Motoneuron R_h increased by only 14.3% from QS to AS ($P>0.05$); R_{in} and τ_m were decreased by 11.4% ($P>0.05$) and 20.8% ($P<0.05$), respectively. In addition, in control paired experiments performed during QS, strychnine did not exert any changes in R_h, R_{in} or τ_m ($P>0.05$). Spontaneous IPSP activity normally present during AS (*ibid.*), and IPSPs evoked during QS by low-threshold peripheral nerve stimulation, were either abolished or markedly reduced following juxtacellular strychnine. These results suggest that the decreased motoneuron excitability which occurs during the atonia of AS is due to an enhanced inhibitory synaptic drive that is generated at motoneuronal somata and proximal dendrites. This synaptic drive is mediated primarily by a strychnine-sensitive inhibitory amino acid, such as glycine. Supported by grants NS23426, MH43362 and MH43862 (PJS).

THE ROLE OF THE NUCLEUS RETICULARIS GIGANTOCELLULARIS (NRGC) IN THE CONTROL OF MOTONEURONS AS REVEALED BY POPULATION POTENTIAL ANALYSIS WITH THE SUCROSE GAP TECHNIQUE. J. Yamuy*, I. Jiménez*, F.R. Morales, P. Rudomín and M.H. Chase. *Departments of Physiology and Anatomy, and the Brain Research Institute, University of California, Los Angeles and Centro de Investigación y de Estudios Avanzados del IPN, Mexico, D.F. and D. de Fisiología, Facultad de Medicina, Montevideo, Uruguay.*

The sucrose gap technique was utilized to record the postsynaptic population potentials of spinal cord motoneurons in five cats following stimulation of the medullary NRGc. The preparation was the precollicular decerebrate cat in which NRGc stimulation was performed prior to and after the induction of atonia by the intrapontine administration of carbachol (0.25–1.0 µl, 16 mg/ml). Following stimulation of either the ipsi- or contralateral NRGc (1–4 pulses, 400 Hz, 0.8 ms pulse duration, ≤10 µA), an early depolarizing (i.e., positive) potential was observed whose amplitude varied according to the intensity of stimulation and number of pulses applied. After the intrapontine microinjection of carbachol (L1.3, P2, H-5.5), the depolarizing potential decreased in amplitude and, in addition, NRGc stimulation evoked a longer latency hyperpolarizing (i.e., negative) potential at a time-to-peak of 40 to 54 ms. At the higher levels of current and 4 pulses, hyperpolarizing potentials of 152 to 229 µV were observed. Their duration, measured at their half-width, was between 16 and 25 ms. Because the hyperpolarizing potential was induced specifically during the atonia elicited by carbachol injection, and because it exhibited a latency following NRGc stimulation similar to the IPSP evoked in the chronic preparation during AS (*Br. Res., 386:* 237-244, 1986), we suggest that both potentials are produced by the activation of the same inhibitory pathway. In addition to the data presented in this report, the present experiment demonstrates the usefulness of the sucrose gap technique in studying state-dependent patterns of motor control that are exerted by supraspinal systems. Supported by grants MH43362, NS23426 and by NS09196.

SOMATIC SHUNTS IN NECK MOTONEURONS OF THE CAT. P.K. Rose and P. Brennan*, Department of Physiology, Queen's University, Canada, K7L 3N6.

Recent studies of the electrotonic structure of spinal motoneurons have concluded that specific membrane resistivity (R_m) is not uniform. Instead, R_m of the somatic region (R_{ms}) is lower than R_m of the dendritic tree (R_{md}). A low R_{ms} may be a consequence of damage caused by electrode penetration. If so, the observation that these neurons have "healthy" membrane potentials is surprising since damage caused by electrode penetration should lead to a sharp depolarization. In the present experiments, we have examined the possibility that electrode damage may provide a route for Ca to enter motoneurons, activate calcium dependent K (K(Ca)) channels and cause a hyperpolarization that masks the depolarization due to damage. Two populations of neck motoneurons were studied. In one group, K (Ca) channels were inactivated by intracellular injection of EGTA. Each group of motoneurons had similar electrotonic characteristics. Furthermore, the relationship between the ratio R_{md}/R_{ms} and the resting membrane potential was the same for both populations of motoneurons. These results indicate that activation of K (Ca) channels do not mask the effects of damage caused by electrode penetration. Thus, regional differences in R_m must be attributed to factors other than damage, for example, local tonic synaptic activity. (Supported by MRC)

ELECTRORETINOGRAM B-WAVE AND SLOW PIII COMPONENTS ARE PRODUCED BY MÜLLER CELL RESPONSES TO RETINAL POTASSIUM. R. Wen and B. Oakley II, University of Illinois, Urbana, IL 61801

We tested the hypotheses that light-evoked changes in K^+_o lead to changes in Müller cell membrane voltage, which in turn generate the ERG b-wave and slow PIII currents. Using *B. marinus* isolated retinas and K^+-selective microelectrodes with fine tips, we recorded a light-evoked decrease in K^+_o in the receptor layer and a distinct, light-evoked increase in K^+_o near the OPL; this "distal" K^+ increase was found over <20 µm depth, had a max. amplitude of >0.2 mM, and could not have been an electrical artifact, due to the small field potential at this depth. We also recorded the ERG and the light-evoked responses of rods and Müller cells. Superfusion with 200 µM Ba^{2+} increased the amplitude of rod photoresponses and the light-evoked decrease in K^+_o, but nearly abolished the Müller cell hyperpolarization and slow PIII. 200 µM Ba^{2+} attenuated both the Müller cell depolarization and the b-wave by ~50%, *but this treatment had no effect upon the distal K^+ increase*; under other conditions (*eg* low pH_o), all 3 of these responses varied in unison. Since Ba^{2+} reduces K^+ conductance of Müller cells *in situ* (Newman, 1985), these results are very strong support of the K^+/Müller cell hypotheses of the origin of the ERG b-wave and slow PIII components; the light-evoked changes in K^+_o still are present during superfusion with Ba^{2+}, but the K^+_o-evoked Müller cell responses (and thus the ERG components) are decreased in amplitude, since their K^+ conductance is reduced. Our experiments have demonstrated that K^+-mediated changes in Müller cell membrane voltage are a direct step in the sequence of events leading to the generation of the ERG b-wave and slow PIII components. Supported by EY04364.

WASH-OUT OF GLUTAMATE RESPONSES IN RETINAL DEPOLARIZING BIPOLAR CELLS. S. Nawy and C.E. Jahr. Vollum Institute, Oregon Health Sciences University, Portland OR 97201.

We have investigated the actions of glutamate and several of its analogs on depolarizing bipolar cells (DBCs) under whole-cell voltage clamp using the tiger salamander retinal slice preparation. Drugs were applied with a multi-barreled perfusion system which rapidly exchanged solutions around the slice. Synaptic transmission was blocked by adding 2 µM strychine, 100 µM picrotoxin and 1 mM cobalt to all of the barrels. Glutamate (1 mM) decreased the membrane conductance and evoked outward currents of 10-60 pA in DBCs that were held at -50 mV. Although L-2-amino-4-phosphonobutyrate (APB) (50 µM) mimicked the action of glutamate, neither quisqualate (5 µM) nor kainate (50 µM) elicited any outward current at concentrations that produced large responses in hyperpolarizing bipolar cells. Both glutamate and APB responses washed-out. The rate of wash-out following break-in varied from cell to cell. The time to half-decay ranged from 3 to 24 minutes. Loss of the glutamate response was associated with a decrease in membrane conductance in 10 of 13 cells. The magnitude of the decrease was equal to or greater than that produced by glutamate. We propose that wash-out of the glutamate response is due to the loss of a second messenger(s) which is required to maintain glutamate channels in an open state. As this substance is dialyzed out of the cell, the number of open channels that are available to be closed by glutamate is reduced, and the glutamate current decreases.

TRANSMITTER SENSITIVITIES, RECEPTOR DISTRIBUTION AND CONDUCTANCE MECHANISMS OF MAMALIAN RETINAL NEURONS. J.E.G. Downing*, M. Kaneda*, A. Kaneko and S. Suzuki* National Institute for Physiological Sciences, Okazaki 444, Japan.

To discover the molecular bases for the receptive field properties of retinal output, we characterized the ionic conductances of cells contained within the inner retina. Using enzyme digestion (papain) and mechanical dissociation we separated the complete range of cell types from cat, rabbit and mouse. Cells retaining high degree of morphological differentiation were consistently prepared. Morphologies of bipolar cells can easily be discriminated. Ganglion cells (GC) were identified by retrograde labelling with DiI injected into the superior colliculus, and/or FITC-dextran into the lateral geniculate nucleus (LGN), 3 days before enucleation. Soma size and projection pattern were used to further categorize GC subclasses. Amacrine cells (AC) were identified by their multipolar form, lack of retrograde label and the use of AC-specific fluorescent markers (*eg.* DAPI).

Bipolar cells obtained from the mouse responded to both glycine and GABA. Both glycine-induced currents and GABA-induced currents were almost entirely carried by Cl ions. Since the chloride equilibrium potential in intact cells is assumed to be -55 mV, these transmitter substances are thought to generate hyperpolarizing responses in cells maintained at their resting potential (-45mV). The sensitivity to both glycine and GABA was the highest at the axon terminal bulb, the structure on which amacrine cells make feedback synapses. Pharmacological study revealed that glycine and GABA worked on separate receptor molecules.

POTASSIUM (K) AND CALCIUM (Ca^{++}) CURRENTS (I) IN RETINAL HORIZONTAL CELLS (HC) OF WHITE BASS (Roccus chrysops) J.M. Sullivan* and E.M. Lasater (SPON: J.W. WOODBURY). Depts of Physiol. and Ophthalmol., Univ. of Utah, Salt Lake City, Utah, 84108

I_K's and I_{Ca}'s were isolated, using TTX and either cobalt (I_K's) or 22mM Ca^{++}/4AP (I_{Ca}'s) and studied using whole-cell patch-clamp in enzymatically and mechanically dissociated HCs maintained for 1 to 7 days in culture. I_K's were studied primarily in HC subtypes H1, H2 and H4. They have an inwardly rectifying I_K which activated at membrane potentials below -70mV, and a delayed rectifier which activated above -30mV and was unaffected by up to 50mM TEA. H2's and H4's possess a transient A-type I_K which activated above -40mV in H2's (809±371 pA max at around +70mV), and above -30mV in H4's (380±271 pA max at around +70mV). I_A was fully inactivated at -10mV holding potential and reversibly blocked by 2.5mM 4AP. I_A was small in H1's. I_{Ca}'s were investigated in H2's and H4's which exhibited transient (TR) and sustained (S) currents. I_{Ca}TR was activated above -50mV, while I_{Ca}S was activated above -10mV. Both I_{Ca}'s are fully and reversibly blocked by 10mM cobalt. Supported by EY 05972.

366.5

IONIC CURRENTS OF SOLITARY HORIZONTAL CELLS ISOLATED FROM TURTLE RETINA. A. G. Golard* and P. Witkovsky (SPON: S. Stone). Dept. of Ophthalmology, NYU Medical Center, New York, NY 10016.

Horizontal cell bodies (HCB) and axon terminals (HCAT) were isolated from retinas of the turtle Pseudemys scripta elegans. The cells were maintained in Leibovitz (L-15) medium for 2-4 days. Whole cell patch recordings were obtained in a standard manner.

An anomalous rectifier was present in the HCB and the HCAT. It activates below E_K, its magnitude depends on the K gradient, and its activation kinetics depend on voltage in a complex way.

A transient inward current was also present in both the HCB and the HCAT. This current was blocked by 5uM TTX and is thus presumably carried by sodium.

In addition we found an A current in the HCAT, but not in the HCB. This current shows typical voltage dependent activation and inactivation. However its temporal characteristics are unusual: after being expressed, a long (typically 2 min) pulse interval is needed for full recovery. This current is blocked by 5mM 4-AP and or 20uM Capsaicin.

A small sustained inward current was observed in the HCAT when [Ca]out=20mM. This current was blocked by Co and enhanced by Bay-K 8644. It activated above -30mV and reached a peak near 0mV. These characteristics suggest it is an L-type calcium current.

Supported by Grant EY03570 to PW and Core Grant EY01842.

366.6

UNITARY CONDUCTANCE AND MODULATION OF GAP JUNCTION CHANNELS IN WHITE PERCH HORIZONTAL CELLS. D.G. McMahon, A.G. Knapp, and J.E. Dowling, The Biological Laboratories, Harvard University, Cambridge, MA. 02138.

Dopamine modulates electrical synaptic transmission between teleost retinal horizontal cells. Based on noise analysis we have previously reported that dopamine alters the open probability of junctional channels (SNS Abstr., 14, 161). We have now examined the effects of dopamine on single channel gating events in pairs of voltage-clamped white perch (Roccus americana) horizontal cells.

Dissociation, culture, and recording methods were as previously described. In poorly coupled cells, unitary junctional events were evident as equal and opposite changes in the two clamp circuits. Events were recorded from 18 pairs, 11 with standard solutions and 7 with Cs^+-substituted pipette solutions. The standard solution group; 4 uncoupled with dopamine, 4 with octanol, and 3 untreated pairs, all had unitary conductances of 50-60 pS (mean=54.4 pS ±9.6 SD), while the Cs^+ group (4 dopamine-treated, 3 untreated) had events of 30 pS (mean=30.9 pS ±5.7). Comparison of the duration of junctional channel openings at maximum uncoupling to open durations during onset or recovery from dopamine revealed that dopamine acts by reducing the duration of junctional events (mean at max uncoupling= 7.5 ms vs 15.2 ms for partial uncoupling, 7 pairs). Thus dopamine apparently alters the open time of cell-to-cell channels.

ON Ca AND Na REGULATION IN RETINAL HORIZONTAL CELLS: Na-Ca EXCHANGE, Na-K ATPase, AND INTERNAL Ca STORES. S.Yasui*. (SPON: M. Tachibana). Kyushu Inst. of Tech., Iizuka, 820 Japan.

This study is concerned with Ca^{2+} and Na^+ homeostasis in horizontal cells (HCs) which are second-order retinal neurons. Whole-cell voltage-clamp experiments were made using patch pipettes on solitary HCs isolated from the goldfish eye. HCs were pre-treated with L-glutamate for > 1 hr. Right after the GΩ-seal was ruptured under current-clamp mode, V_m was ≃ 0 mV; the HCs had been kept depolarized about that much. The unit was then immediately put under whole-cell voltage-clamp at the preceding V_m value. The cobalt test revealed the voltage-gated Ca^{2+} influx (I_{Ca}) whose rate exceeded as much as 1 μM/sec: g_{Ca} of HCs does not completely inactivate with time. But, I_{Ca} was absent when Na^+ was replaced by Li^+ in the external medium. I_{Ca} was also abolished when the depolarization-inducing pretreatment was done with a high-K and low-Na Ringer. Furthermore, the switch from normal to Na-free caused the current to shift slowly outward before arriving at the same plateau as attained by cobalt application. These results suggest that Na-Ca exchanger operates to compensate for I_{Ca}, and that blocking it ultimately eliminates I_{Ca} due to Ca-dependent Ca-channel innactivation. Caffeine application induced an outward-going phasic change in current, indicating the presence of Ca stores. Their storage capacity is probably quite high; Ca^{2+} of sevaral mM (cytosolic equivalent) was found to flow into single units before Ca-channel inactivation was completed during block of the Na-Ca exchange. An ouabain experiment showed that Na-K ATPase is present, presumably to balance synaptic and non-synaptic Na-influx including the exchange component.

NETWORK MODELS OF THE HORIZONTAL CELL LAYER IN FISH RETINA. R. L. Winslow*, S. Ma*. (SPON: R. Purple). Dept. of Physiol., University of Minnesota, Minneapolis, MN 55455.

Experimental and modeling studies of horizontal cell response properties in intact retina provide evidence that these cells respond in an approximately linear fashion to a variety of stimuli. In contrast, studies of horizontal cells isolated from fish retina demonstrate the existence of five different voltage-dependent macroscopic membrane currents, including a spike generating Ca^{++} current. We are attempting to understand the physiological basis of differences in isolated cell versus network properties through the use of computer models. We have previously shown that two factors tend to linearize responses of horizontal cells in the intact retina: a) the inward Ca^{++} must be partially inactivated at rest; b) tonic synaptic input from photoreceptors in backgrounds of dark prevents bistable, or spiking behavior (Winslow, J. Neurophysiol., in press). We extend these analyses to address the role played by gap junctional coupling between neighboring horizontal cells in determining network properties. Newtons iteration coupled with conjugate-gradient descent methods are used to compute steady-state responses of large scale networks of horizontal cells, each with a full complement of voltage dependent channels, to arbitrary spatial patterns of synaptic input. Coupling conductances (G_s) two orders of magnitude smaller than that known to exist between pairs of cultured horizontal cells (Lasater and Dowling, PNAS, 82: 3025, 1985) provide a current shunt sufficiently large to block bistable behavior in the network. G_s values in the physiologically observed range yield a network input resistance of 15-30$M\Omega$, and highly linear network I-V curves. The predicted network space constant and dc transfer function are in close agreement with physiological data. Gap junctional coupling between neighboring horizontal cells is therefore a powerful factor acting to linearize properties of the horizontal cell network (supported by The Whitaker Foundation, and NIH #PO1NS17763-07).

366.9

MODELLING OF ELECTRICAL PROPERTIES OF VARICOSE DENDRITES IN RETINAL RADIATE AMACRINE CELLS. G.M.Ratto* and C.Usai* (SPON: G.Maguire) Ist. di Neurofisiologia, Pisa and I.C.B., Genova, Italy.

Radiate amacrine cells display a star-like morphology with long, unbranched dendrites. These processes are very thin (0.1 - 0.3 um) and are interlaced with many large varicosities (about 2 um in diameter).

We simulated the effects of the presence of varicosities on the passive spread and on the size of the postsynaptic potential (PSP) generated by a stationary change of conductance at the synaptic site. Input resistance (R_i) and electrotonic attenuation (A_V) have been computed for a thin cylindrical dendrite, on which a variable number of varicosities has been positionated randomly.

Varicosities reduced R_i for an injected current and increased A_V. The smaller R_i widens the linear range of the PSP-conductance relationship, helping impedance matching with other elements of the network and reducing the effect of synaptic noise. Due to the higher attenuation, a localized conductance change affects a shorter portion of the dendrite, thus increasing the number of local micro-circuits present on a single cell.

NMA: AN INTERACTIVE GRAPHICS APPLICATION FOR GENERATING AND MANIPULATING COMPARTMENTAL MODELS.
M. Tiller*, R. L. Winslow*, R. F. Miller. (SPON: C. Terzuolo). Dept. of Physiol., University of Minnesota, Minneapolis, MN 55455.

NMA, for Neural Modeling Application, is an application which overcomes bottlenecks inherent in the development and execution of large-scale compartmental models of single neurons with voltage-dependent membrane. NMA reads data files generated by a Eutectics Neuronal Reconstruction System (Capowski, J. Neurosci. Meth., 8: 353, 1983) containing information on the length, diameter, and branching pattern of neuronal dendritic trees. Given passive membrane parameters, NMA uses the morphological data to automatically partition the dendritic tree into a number of cylindrical segments of arbitrary electrotonic length. A Schol plot of the dendritic tree is then displayed on a SUN-4 workstation. Users may alter membrane parameters at either the single compartment, branch, primary dendrite, or whole neuron level by selecting a neuron structure using the graphics terminal mouse, and then modifying the structure's parameter list in a pop-up menu. Compartmentalization of the dendritic tree and the displayed Schol plot are immediately updated to reflect parameter changes. Voltage-dependent channels may be inserted at any structural level of the model by clicking on icons representing various channel templates. These presently include templates for synaptic conductances, a delayed rectifier K^+ current, a Na^+ current, a Ca^{++} modulated K^+ current, and a Ca^{++} current. Once a model is specified, NMA automatically generates a simulation program which can be executed by SABER, a general purpose electrical circuit simulation package developed by Analogy Inc. SABER has proven to be a powerful tool for executing compartmental models with non-linear membrane (Flach et al., Soc. Neurosci. Abstr., 13(1): 159, 1987). SABER output can be displayed and manipulated using PITool (Analogy, Inc.) or by passing SABER data structures to S. (NIH Grant PO1NS17763-07).

GABA-ACTIVATED CURRENTS IN RAT RETINAL GANGLION CELLS. M.L. Veruki* and H.H. Yeh, Program in Neuroscience and Dept. Neurobiology and Anatomy, Univ. Rochester School of Medicine, Rochester, NY 14642.

Gamma-aminobutyric acid (GABA) is a major inhibitory transmitter in the vertebrate retina. In the inner retina, GABA has been reported to affect third order neurons by both $GABA_A$ and $GABA_B$ receptor-mediated mechanisms. Here, we examined GABA-activated currents (I_{GABA}) in freshly dissociated rat retinal ganglion cells. A major goal was to determine whether GABA activated in these cells a conductance which involved one or more ionic species and which could be attributed to the activation of $GABA_A$ or $GABA_B$ receptors, or both.

Freshly dissociated ganglion cells were identified by fluorescent retrograde tracers (rhodamine-labeled microbeads or fast blue). GABA agonists and antagonists were applied by pressure and the resulting current was recorded under whole-cell voltage clamp. All ganglion cells recorded thus far (n=58) responded to GABA (0.1-10 uM). In a few cases, differential sensitivity to GABA between the soma and processes could be demonstrated. The response was typically monophasic, hyperpolarizing, and associated with a conductance increase. Prolonged or successive brief applications caused a rapid partial fading of I_{GABA}. The reversal potential for I_{GABA} shifted with varying pipet $[Cl^-]$ in a manner which approximated that predicted from the Nernst equation for Cl^-. Muscimol (5 uM) induced a current which mimicked I_{GABA}. Picrotoxin and bicuculline (200 uM) blocked I_{GABA}. Baclofen (up to 200 uM), in the presence or absence of bicuculline, produced no apparent conductance change (15 cells).

Thus, under our recording conditions, our data to date suggest that the I_{GABA} in rat retinal ganglion cells appears to be predominantly, if not exclusively, a Cl^- current due to $GABA_A$ receptor activation. However, the possibility cannot be excluded that a bicuculline-insensitive, baclofen-activated current exists in the extreme distal dendrites which may have been lost in the dissociation procedure.

A SLOWLY INACTIVATING K^+ CURRENT IN POSTNATAL RAT RETINAL GANGLION CELLS. Nikolaus J. Sucher and Stuart A. Lipton, Dept. of Neurology, Children's Hospital & Harvard Medical Schl, Boston, MA.

K currents in rat retinal ganglion cells have been separated into components resembling I_A, I_K, and $I_{K(Ca)}$ (Lipton & Tauck, *J. Physiol.* 385:361, 1987). Recently, slowly inactivating K currents with distinct biophysical and pharmacologic properties have been described in rat hippocampal cells (I_D; Storm, *Nature* 336:379, 1988) and ganglion cells from tiger salamander retina (I_B; Lukasiewicz & Werblin, *J. Neurosci.* 8:4471, 1988). Here we characterize a slowly inactivating K current not previously described in mammalian retinal ganglion cells. Postnatal ganglion cells (P4-9) were fluorescently labeled *in situ*, dissociated from the retina, and maintained in culture. K currents were recorded using whole-cell recording with patch electrodes containing a KCl-saline. The slowly decaying K current was pharmacologically isolated by suppressing I_{Na} with 1μM TTX, I_A with 5 mM 4-AP, I_K with 20 mM TEA and I_{Ca} and $I_{K(Ca)}$ with 3 mM Co, all added to the bath. The slowly decaying K current was activated from -80 mV by steps positive to –40 mV and was present in 90% of all ganglion cells tested (n = 39). The mean amplitude at 10 mV was 327 ± 222 pA (mean ± S.D.). The current activated in less than10 ms and inactivated with a time constant of about 130 ms at 23°C. Inactivation was voltage dependent, almost complete at 0 mV, and half-maximal at -55 mV. The current was blocked by internal Cs and TEA or by external 1 mM Ba, but not by 250 μM Cd, 3 mM Co, 5 mM 4-AP, or 20 mM TEA. The tail currents reversed at –84.6 ± 2.6 mV (n = 5; r = 0.98; 140 mM K inside, 5.8 mM K outside, equimolar Cl, 35°C). Comparison of this current with I_D and I_B, both of which have been implicated in regulating firing patterns, show that its properties resemble more closely those of I_B in amphibian retina than those of I_D in rat hippocampus. It may thus be important for specific aspects of information processing in the retina.

CRYOPRESERVATION OF POSTNATAL GANGLION CELLS FROM RAT RETINA: PERSISTENCE OF VOLTAGE- AND LIGAND-GATED IONIC CURRENTS. Paul Sforza*, Nikolaus J. Sucher, Toni P.O. Cheng*, and Stuart A. Lipton (SPON: H. Blume). Dept. of Neurology, Children's Hospital & Harvard Med. School, Boston, MA. 02115.

Despite heightened interest in cryopreservation of central nervous system tissue, little is known about its effects on the electrophysiology of neurons. Therefore, we used the patch-clamp technique to study retinal ganglion cells cryopreserved from 1 week-old rats. Following dissociation, retinal cell suspensions containing fluorescently labeled ganglion cells were frozen in 8% DMSO and stored at –80°C for up to 45 days prior to culture. The cryopreserved cells appeared morphologically normal, grew processes, and cleaved fluorescein from fluorescein diacetate, indicating their viability. The cells maintained resting potentials of –60 mV and fired action potentials upon depolarization. Under voltage-clamp, depolarizing pulses activated Na+-, K+- and Ca++-currents. K+-currents were separated into I_A, I_K, $I_{K(Ca)}$, and a slowly decaying I_B (Sucher & Lipton, these abstracts). GABA (20 μM) and glycine (100 μM) activated chloride selective currents that were blocked by bicuculline (10 μM) and strychnine (5 μM), respectively. Glutamate (100 μM), NMDA (200 μM), kainate (125 μM), and ACh (20 μM) activated cation selective currents. The NMDA response was blocked by APV (100 μM), the kainate induced current by CNQX (10 μM), and the ACh evoked current by hexamethonium (20 μM). Comparison of fresh and cryopreserved cells showed that the pharmacological and biophysical properties of these voltage- and ligand-activated ionic currents were largely unaffected by cryopreservation. Hence, this method may help reduce the number of research animals used in a series of experiments by allowing collection of a large number of neurons from a single animal to be used at later times.

EFFECTS OF NOREPINEPHRINE ON GANGLION CELLS AND THE ERG IN THE RABBIT RETINA. Ethan D. Cohen and Robert F. Miller, Dept. Physiol. Univ. of Minn., Minneapolis, MN 55455

We examined the effects of norepinephrine (NE) and other adrenergic agonists and antagonists on ganglion cells in the rabbit retina using extracellular recording in a superfused eyecup preparation. Bath application of NE at low concentrations (1-10μM) produced an increase in the spontaneous activity of all types of ganglion cells studied. Sustained cells were more sensitive to low doses of NE than transient cells. At concentrations above 15 μM, NE was inhibitory to on-sustained cells. We were unable to block the excitatory actions of NE with the β receptor antagonists timolol, propranolol, or the α antagonist phentolamine. The adrenergic agonists phenylephrine and UK-14304-18 had little effect on rabbit ganglion cells. Isoproterenol produced only a weak excitation while only epinephrine duplicated the excitatory effects of NE. We examined the possibility NE was acting through a dopamine receptor. Neither D-1 nor D-2 dopamine agonists SKF38393 or LY171555 were able to completely mimic the effects of NE. However, we were able to completely block the excitation of NE on off-center ganglion cells with the D1 antagonist SCH23390. We conclude that NE appears to be acting as a mixed agonist at dopamine receptors. NE also induced changes in the standing potential and suppressed the C wave of the ERG. These latter actions were blocked by prazosin, suggesting these effects are mediated by α_1 adrenergic receptors. (Supported by EY03014)

REPETITIVE SPIKING IN GANGLION CELLS OF THE TIGER SALAMANDER RETINA. P.A. Coleman, J.F. Fohlmeister and R.F. Miller. Univ. of Minnesota, MN 55455.

The individual contributions of the intrinsic, membrane currents to ganglion cell spike entrainment was assessed with a computer model based on the descriptions of Lukasiewicz & Werblin (J. Neurosci., 1988) and Lipton & Tauck (J. Physiol., 1987). The five ionic currents considered were: 1) Na^+, 2) Ca^{2+}, 3) non-inactivating K^+ [delayed rectifier], 4) fast-inactivating K^+ [A type], and 5) Ca^{2+} mediated K^+.

The model was compared with physiological data obtained from whole cell recordings of ganglion cells in the intact tiger salamander retina-eyecup preparation. A close correspondence between the model and physiological data was observed for both the waveform of individual impulses and the relationship between spike frequency and intracellular polarization. In addition, pharmacological manipulations of ionic currents were compared with the simulated absence of one or more ionic channels. To date, the close correspondence between model and experimentally obtained data suggests that the functional roles for each of the ionic currents can be understood under a wide variety of conditions. This research was supported by EY03014 and EY07376 to RFM.

IMPULSE INITIATION IN RETINAL GANGLION CELLS. P.N. Steinmetz*, J.F. Fohlmeister and R.F. Miller Dept. of Physiology, Univ. of Minn. Mpls. MN 55455

The axons of mudpuppy retinal ganglion cells narrow to a diameter approaching 0.1 μm for a length of 50 to 110 μm, beginning some 10-15 μm from the soma. In contrast, the initial segment and more distal axon are about 1 μm in diameter. In a companion abstract (Coleman, Fohlmeister and Miller,1989), we have analyzed the contributions of 5 different ionic channels to the control of impulse initiation and frequency, by comparing simulated and physiological data. In this study we have used compartmental models to evaluate the function of the thin axonal segments in regulating impulse firing behavior. The neuron included some portion of dendrite, the soma and axon which was compartmentalized into 5 μm segments for numerical integration of the kinetic equations. The density of each channel subtype was altered from compartment to compartment to explore the interaction of asymmetric geometry and non-uniform ion channel distribution. The results of these simulations were constrained by physiological observations which suggest that impulse initiation probably occurs at the initial segment and subsequently activates somatic and axonal spikes within the thin segment. The functional advantages of this arrangement are evaluated in terms of impulse synchronization and reduced shunting by the axon provided by the thin segment. (Supported by NEI grant R01EY07376).

SYNAPTIC INPUT TO A PHYSIOLOGICALLY IDENTIFIED X-CELL IN THE CAT RETINA. A.J. Weber, M.A. McCall, and L.R. Stanford. Department of Comparative Biosciences and the Waisman Center, University of Wisconsin, Madison, WI 53706.

Intracellular injection of horseradish peroxidase (HRP) was used to label a retinal X-cell recorded in an in vivo preparation. This cell, located 4.5° from the area centralis, showed linear spatial summation, and responded tonically to a visual stimulus of standing contrast. After histochemical processing, the cell was embedded in resin, drawn at 1000X, and sectioned tangential to the retinal surface. Approximately 85% of the dendritic arbor of this cell was then reconstructed from photographic montages (23,000x) of alternate serial thin sections. Amacrine and bipolar cell inputs were identified according to the criteria established by Kolb ('79; J. Neurocytol. 8:295). The dendritic field of this "ON-center" X-cell (soma= 360um^2) was approximately 52um in diameter and was confined to sublamina b of the inner plexiform layer (IPL). This cell was found to receive approximately the same number of synaptic contacts from bipolar (60) and amacrine cells (82). Few contacts (5 from bipolar cells) were found on the primary dendrite. Most of the bipolar cell input was found on 2° and 3° dendrites; the majority of the amacrine cell input was onto 2°, 3°, and also 4° dendrites. Both types of input also could be found on more distal dendrites. Although amacrine and bipolar cell inputs were distributed evenly over much of the dendritic field, we did find that the proportion of amacrine cell input increased on dendritic processes that approached the border between sublaminae a and b of the IPL.

The data from this X-cell will be compared with data from Y- and W-retinal ganglion cells in order to determine whether the relative contributions of amacrine and bipolar cell inputs contribute to the physiological differences seen among different classes of retinal ganglion cells. Equally important is the possibility that retinal ganglion cells with very different morphological features, but common physiological characteristics, share similar patterns of synaptic input. Supported by NIH grants EY 04977 and EY 05869.

COMPARISON OF CAT RETINAL GANGLION CELL RESPONSES TO LIGHT STIMULI AND EYEBALL DEFORMATION AFTER INJECTION OF APB AND MUSCIMOL. A.W. Przybyszewski, H.T. Chung*, O.-J. Grüsser and M. Hagner*. Dept. of Physiol., Freie Universität Berlin, Arnimallee 22, 1000 Berlin 33, (West) Germany.

We compared the effects of APB (2-amino-4-phosphonobutyric acid) and GABA-agonists: MU (muscimol) and IBO (ibotenic acid - metabolized into MU) injected (0.5-3 mg pro eye) into the vitreous body on ganglion cell activity evoked by diffuse short (10 ms) or longer (1 s) light stimuli or eyeball deformation. The experiments were performed in pentobarbital anaesthetized cats.

After APB, IBO and MU injection, light-induced responses in on-ganglion cells were strongly reduced in a very similar manner. In contrast, off-ganglion cell light-evoked activity changed only slightly after APB and completly disappeared after GABA-agonists. With all substances, an excitation phase was observed in most ganglion cells. During the excitation phase induced by APB, ganglion cell responses to eyeball deformation were at first reduced, later disappeared completely and significantly faster than the responses to light. In contrast, after MU and IBO injection, responses to eyeball deformation were abolished simultaneously with the reduction in light responses.

We assume that eyeball deformation affects primarily horizontal cell activity and it could be a useful method to determine in which part of the retina APB, IBO or MU interact with synaptic transmission.

Supported in part by a grant of the DFG (Gr 161).

TEMPORAL RESPONSE CHARACTERISTICS OF CAT RETINAL GANGLION CELLS. M.H. Rowe. Department of Zoology, College of Arts and Sciences & Basic Science Unit, College of Osteopathic Medicine, Ohio University, Athens, OH 45701.

A method is described which allows a relatively quick and accurate assessment of the temporal frequency characteristics of retinal neurons. The method is similar to one widely used in the analysis of electronic systems, and is based on the response of a linear, time invariant system to a temporal impulse containing a wide range of frequencies at equal amplitudes. However, instead of an impulse, the stimulus is presented in the form of a temporal 'step', by flashing a grating on for a fixed duration. The response to this step is then differentiated and subjected to Fourier analysis which yields information about the spectrum of temporal frequencies contained in the response. When compared to the actual responses of X- and Y-cells to sinusoidal gratings which either drift or alternate over a range of temporal frequencies (see also Frishman, et al., J. Gen. Physiol., 89: 599-628, 1986), the method yields a function which fits these data points very well. Thus, it can be applied confidently in situations where data collection time is at a premium, such as recording from W-cells or intracellular recording from non-spiking retinal interneurons. Supported by grants EY06013 and EY08038 from the National Eye Institute.

TEMPORAL ALIASING IN OPTIC NERVE FIBERS

Michael A. Crognale* and Gerald H. Jacobs (SPON: Loy Lytle), University of California at Santa Barbara, Santa Barbara, CA 93106

Investigations of neuronal temporal response properties have often utilized trains of regularly repeating stimuli. Attempts to relate the neuronal activity to behavioral observations have typically focused upon the response of the cell at the frequency of stimulation. The response of single optic nerve fibers to temporally modulated stimuli (square wave: 5,10,20,30,40 and 50 Hz) were recorded from the ground squirrel (Spermophilus beecheyi). The stimuli were positioned so as to completely cover the receptive field of the cell. Under these conditions, most ganglion cells produced a phase-locked response to modulation frequencies as high as 50 Hz. This was true for both spectrally opponent cells and spectrally non-opponent cells. At these high frequencies, many cells also produced large modulated responses at half of the stimulus frequency, in addition to the response at the stimulus frequency. The relative amplitudes of these components were dependent on stimulus frequency. As stimulus intensity was increased, the response of the cell at the stimulus frequency increased relative to the response at half of the stimulus frequency. For most cells, there was a range of intensities for which the response at half the stimulus frequency was large while the response at the stimulus frequency could not be detected. These results suggest that behavioral threshold detection and supra-threshold resolution of rapidly modulated stimuli may be mediated by responses from neurons that individually fail to produce a response at the stimulus frequency.

WHITE NOISE ANALYSIS OF RABBIT GANGLION CELL LIGHT RESPONSES. S.C. Mangel, H.M. Sakai* and K-I. Naka. Department of Ophthalmology, University of Alabama School of Medicine, Birmingham, AL 35294.

To characterize the light responses of ganglion cells in the rabbit retina using white noise analysis, we cross-correlated the ganglion cell spike discharges (transformed into unitary pulses) against the analog light input white noise. Sakuranaga et al.(1987) have shown that first and second order kernels from ganglion cell spike trains are proportional to those from intracellular ganglion cell recordings. Because amacrine amd bipolar cells produce kernels of characteristic signature, presynaptic inputs to a given ganglion cell can be inferred by observing the kernel waveforms or signatures.

Ganglion cell light responses evoked by white noise-modulating a full field LED stimulus around a mean luminance were more bandpassed than those evoked by flashing stimuli. At the light levels used, brisk sustained and transient ganglion cells produced well-defined first order but not second order kernels. Large field unit ganglion cells, however, displayed a prominent second order nonlinearity, suggestive of an input from transient on-off amacrine cells. Direction-sensitive cells were specifically tuned to a full field stimulus modulation rate of 20 Hz.

SYNAPTIC INTERACTIONS OF RETINAL DIRECTIONAL GANGLION CELLS. C. Brandon, Department of Cell Biology and Anatomy, Chicago Medical School, North Chicago, IL

In the rabbit retina, ON-center directionally selective ganglion cells (ON-DS GC's) project to nuclei of the accessory optic system; their directional selectivity appears to be generated by GABAergic neurons and modified by cholinergic input.

To study these synaptic interactions, Nuclear Yellow (NY) was injected into the rabbit medial terminal nucleus. Retrogradely labeled GC's were impaled and filled with Lucifer, then studied by immunocytochemical localization of choline acetyltransferase or glutamate decarboxylase, or serial-section EM.

Dendrites of presumed ON-DS GC's branched at an inner plexiform depth of 70%, precisely overlapping cholinergic IPL sublamina b, and occupying the zone between the two most proximal GABAergic strata. In general, there was not more than one or two microns separating these three strata, an arrangement that would permit extensive synaptic interaction among them. ON-DS GC dendrites received synaptic input 1) from many small, clustered amacrine processes that were probably cholinergic; 2) from bipolar cell axon terminals; and 3) from larger amacrine processes with a very low electron density; this last type may be the source of GABAergic input onto the ON-DS GC. It appeared that there was a segregation of synaptic input onto a given ON-DS dendrite, such that clusters of presumed cholinergic terminals, and the larger, pale amacrine processes, impinged on different regions of that dendrite. Such spatial segregation may underlie synaptic mechanisms of directionality.

COMPUTER SIMULATION OF RETINAL MOTION DETECTION. F.H. Eeckman, M.E. Colvin* and T.S. Axelrod*. Lawrence Livermore Natl. Laboratory, Livermore, CA 94550.

We present a three-dimensional simulation of the motion detection circuitry in the vertebrate retina. The model consists of five layers of cells in a closely packed hexagonal array. All cells are modeled as single compartment, leaky-integrator neurons. The following features of retinal organization are present in the model:

1) Coupling and overlap between the receptor-elements. The range of coupling can be changed interactively.
2) Nonlinear gain and thresholding is present in all layers.
3) Difference-of-gaussians type receptive fields.
4) Transient calculation is independent from directional selectivity.
5) Directionally selective inhibition using shunting interactions.
6) Convergence. The ratio of convergence can be changed interactively.
7) Feedback between the inner and the outer retina. The feedback controls the gain in the outer retina and is driven by the amount of inhibition present at the ganglion cell level.

The network presented here is capable of detecting small moving targets against a noisy background. The model performs well down to a corrected signal-to-noise ratio of 2.6.

CHEMICAL SENSES: OLFACTORY PATHWAYS AND PROCESSING

367.1

RAT OLFACTORY BULB GLOMERULI STAIN NON-UNIFORMLY WITH CYTOCHROME OXIDASE AND ACID PHOSPHATASE: POSSIBLE CAUSES AND IMPLICATIONS. C. Weinberg and E. Meisami. Physiology Dept., Univ. of Illinois, Urbana, IL, 61801.

The glomeruli (GL) of the rat olfactory bulb show a marked staining for cytochrome oxidase and acid phosphatase, marker enzymes for mitochondria and lysosomes respectively. Careful comparison of the staining patterns for these two enzymes in serially sectioned bulbs reveals that across the GL layer, the various GL do not stain uniformly, some staining more intensely than others. This non-uniformity is evident even within a particular GL. Based on the assumption that cytochrome oxidase staining indicates neural activity whereas acid phosphatase indicates neural degeneration/turn-over, we have analyzed the patterns of staining for these two enzymes, in 40 um adjacent frontal sections, which are then compared quantitatively. The results indicate that the GL staining darkly for cytochrome oxidase tend to stain lightly for acid phosphatase and vice versa. Also, even within a GL, cytochrome oxidase positive areas tend to be acid phosphatase negative and vice versa. The results imply that in the adult rat, various olfactory GL show differential patterns of activity and degeneration and that this spatial variation in activity may be present even within the same GL. We will also report the effects of olfactory nerve transection and chemical deafferentation on these staining patterns.

367.2

LECTIN LABELING OF RAT OLFACTORY BULB GLOMERULI M.J. RIGGOTT and J.W. SCOTT (Department of Anatomy and Cell Biology, Emory University School of Medicine, Atlanta, GA 30322)

Functional subclasses of sensory neurons can be identified by the carbohydrates they express (Dodd et al, 1984, Nature 311:469). We examined the carbohydrate composition of olfactory bulb glomeruli. The lectins Ulex europaeus 1 (UEA1), and Soybean agglutinin (SBA) bind specifically to subsets of olfactory bulb glomeruli in the adult rat. Individual glomeruli are uniformly labeled, and lightly and darkly labeled glomeruli can be found next to each other. The most densely labeled glomeruli are found in the ventrolateral regions of the main olfactory bulb. Lectin binding was blocked with competing sugars and indicates that UEA1 recognizes fucose and SBA binds to galactose and N-acetylgalactosamine in main bulb glomeruli. It appears that the lectin binds to the afferent components of the glomeruli because denervation severely reduces UEA1 binding and, in partially denervated glomeruli, the remaining afferent fibers continue to bind UEA1. The heterogeneous binding of the lectins UEA1 and SBA indicates that subclasses of receptor cell afferent terminals can be identified by the carbohydrates they express.

CAUDAL-ROSTRAL GRADIENTS OF SYNAPTOGENESIS IN THE NEONATAL RAT OLFACTORY BULB. C.A. Greer, C.K. Kaliszewski* and H.A. Cameron*. Sections of Neurosurgery & Neuroanatomy, Yale University School of Medicine, New Haven, CT 06510.

Local circuits in the olfactory bulb (OB) external plexiform layer (EPL) consist almost exculsively of reciprocal dendrodendritic synapses between interneurons, granule cells, and the output neurons, mitral and tufted (M/T) cells. Prior evidence suggests that M/T cell systems may be parallel circuits that are segregated within sublamina of the EPL. Light microscopy of afferent and efferent projections as well as 2DG studies have suggested that caudal portions of the OB mature first, perhaps in response to early functional requirements. To investigate these issues further we studied gradients of local circuit synaptogenesis in rostral and caudal divisions of the EPL. Rats at 0, 4, 8, 16 and 32 days postnatal were processed for 100 kV transmission electron microscopy. Montages of micrographs, passing radially through the EPL sublaminae, were used to classify dendrodendritic synapses as either Gray type I or type II. The total number of synapses increased by a factor of 4 between 0 and 32 days postnatal. Gray type I synapses led the Gray type II synapses by a ratio of approximately 2:1 throughout development, although this may reflect the difficulty in identifying Gray type II's in single sections. The results showed clear topographic gradients in the appearance of synapses. The caudal OB was most precocious, leading the rostral OB in density of synapses/um^2 by approximately 4 days. Similarly, the superficial EPL led the deep EPL by approximately 2 days. The data, in showing that local circuits in the caudal region are more precocious in their development, support the hypothesis that the caudal regions of the OB mature on an earlier timecourse than the remainder of the OB.

367.4

THE GEOMETRY AND CONNECTIVITY OF DENDRODENDRITIC MICROCIRCUITS IN THE OLFACTORY BULB. T.B. Woolf[1], G.M. Shepherd[1] and C.A. Greer[1,2]. Sections of Neuroanatomy[1] and Neurosurgery[2], Yale Univ. Sch. Med., New Haven, CT 06510.

The external plexiform layer (EPL) of the olfactory bulb (OB) contains reciprocal dendrodendritic synapses between granule cell spines (G_{sp}) and mitral or tufted (M/T) dendrites. The extent to which these circuits may contribute to a divergence or convergence of information within the EPL is not well understood. Moreover, computational modeling has been limited due to the lack of morphometric data on the geometry of these circuits. To address these issues we initiated ultrastructural studies of the EPL in which serial sections were used to reconstruct the 3-dimensional geometry of dendritic processes and their connections. Sixty-six G_{sp}'s have been reconstructed in full and 14 M/T dendritic processes reconstructed to depths of 2 um. The volume of G_{sp} heads was highly variable ranging from 0.03 - 1.6 um^3. Similarly, the G_{sp} head surface area varied from 0.32 - 8.3 um^2. G_{sp} necks were less variable with volume ranging from 0.03 - 0.34 um^3 and surface area from 0.31 - 2.0 um^2. Most of the M/T profiles reconstructed established reciprocal synaptic connections with G_{sp}'s; the density of synaptic connections ranged between 0.5 - 6 per linear um of M/T dendrite. Moreover, in a volume of 530 um^3 the great majority of G_{sp}'s connected to individual M/T dendrites were from different granule cell dendrites, supporting the concept of divergence within EPL microcircuits. In addition, the morphometric results are providing a basis for biophysical computational models in which the functional implications of divergence in local circuit connectivity can be examined.

367.5

EVIDENCE FOR CA++ INFLUX INVOLVEMENT IN THE LONG-LASTING DEPOLARIZATION OF MITRAL/TUFTED CELL DENDRITES IN THE SALAMANDER OLFACTORY BULB. A.R. CINELLI* K. A. HAMILTON and J.S. KAUER. Neuroscience Program and Dept. of Neurosurgery. Tufts Medical School-New England Medical Center, Boston, MA. 02111.

Optical recording methods using several different voltage-sensitive dyes have revealed relatively long-lasting depolarizations in the external plexiform layer of the olfactory bulb after both electrical and odor stimulation. In the present study, real-time video imaging at 30 frames/sec, of calcium-sensitive dyes injected into single mitral/tufted cells has permitted observation of changes in dendritic and somatic Ca++ levels after electrical stimulation of the input and output pathways of the bulb. Orthodromic stimulation elicits long-lasting signals with complex, non-uniform spatial and temporal distributions. Antidromic stimulation showed similar patterns of activity, although generally with faster time courses. These observations are correlated with intracellular electrode recordings and voltage-sensitive dye images from the same cells and agree with the hypothesis that the late depolarization in mitral/tufted dendrites seen with voltage-sensitive dyes are Ca++ related.

Supported by PHS Grants NS-20003, NS-22035 and the Department of Neurosurgery, Tufts-New England Medical Center.

367.6

MEMBRANE CONDUCTANCE CHANGES DURING ODOR-INDUCED POTENTIALS IN RAT OLFACTORY BULB NEURONS. D.P. Wellis and J.W. Scott. Dept. Anatomy and Cell Biol., Emory Univ. Sch. of Med., Atlanta, GA 30322.

Intracellular recordings show that the generation of odor responses in olfactory bulb (OB) neurons involves the differential activation of both excitatory and inhibitory synaptic inputs (Wellis et al., in press; Hamilton and Kauer, in press). As a step toward understanding the biophysical processes underlying odor-induced membrane potential changes, we measured membrane conductance during odor stimulation in rat OB mitral/tufted cells. Odor-induced hyperpolarizations were associated with increases in membrane conductance relative to average resting conductance during spontaneous activity. For example, long-duration, odor-induced IPSPs correlated with a 20 to 65% increase in somal membrane conductance in 5 cells. Granule cells, GABAergic interneurons of the OB, mediate similar long-duration hyperpolarizations and increases in Cl conductance in mitral cells following electrical stimulation of the olfactory tract or nerve. Odor-induced depolarizations, on the other hand, increased (50% and 55% in 2 cells) and decreased (20%, 35%, and 80% in 3 cells) membrane conductance, suggesting that different synaptic mechanisms can depolarize an output neuron. Removal of granule cell-mediated tonic inhibition, for example, could result in a decrease of membrane Cl permeability and depolarization. In addition to the changes measured within a single sniff period, slow decreases in conductance occur across a series of sniffs, suggesting that activation of longer paths of circuitry within the bulb also determine mitral/tufted cell responses to odor.

Supported by NIH NS-12400.

367.7

ODOR RECOGNITION AFTER REMOVAL OF A BULBAR AREA IDENTIFIED WITH 2-DG. X. M. Lu and B. M. Slotnick. The American University, Washington, D.C. 20016.

A reliable focus of 2-DG activity occurs in the dorsomedial olfactory bulb of rats exposed to propionic acid (PA) vapor but removal of the area has no effect on detection of PA (Slotnick et al., Brain Res, 417:343, 1986). To test for odor recognition, rats were trained using operant conditioning for the concept 'respond if the odor is not propionic acid' (e.g. responses to any odor except PA are reinforced). Surgery was performed when rats reliably responded to the initial presentation of novel odors (60 odors tested). In postoperative tests conducted under extinction controls, rats with lesions of the lateral bulb or of the PA focal area had perfect or near perfect performance on this task. Further, there were no differences among groups in discrimination between PA and acetic acid or between mixtures of these odors. Thus, the 2-DG identified bulbar area is not essential for detection, recognition, or discrimination of propionic acid. Supported by NSF grant BNS-8319872 to B.M.S.

PHASE GRADIENTS AND SPATIAL AMPLITUDES OF OLFACTORY EEG SEGMENTS ARE FROZEN AT STATE TRANSITIONS DRIVEN BY RECEPTOR INPUT TO BULB. Walter J Freeman, Univ. California, Berkeley

Measurement of multiple EEG traces recorded simultaneously from 64 sites on the olfactory bulb, nucleus or cortex shows that neurons in each structure generate essentially the same time series in all parts over its surface, though differing between the three parts. With each inhalation there recurs a state transition between the low-level interburst chaotic state and a high-amplitude oscillatory state or burst. The spatial patterns of phase and amplitude modulation reflect a learned attractor, which is accessed through a basin that is defined by an odor CS. The correlation dimension of the burst state appears to be lower than that of the basal interburst state. Both appear to be chaotic, but the burst state has one or more sharp peaks in its spectra, and it may conform reproducibly to learned spatial patterns, whereas EEGs between bursts display 1/f spectra and no reproducible patterns. One interpretation is that a bifurcation occurs with each inhalation from chaos to a learned limit cycle state. A more plausible interpretation is that a stable chaotic attractor characterizes the waking dynamics in both the interburst and burst states, that learning modifies the shape of this attractor, and that odorant recognition is based on the forced relocation to one part of this attractor under impress of an odorant, which places the system in the basin of the appropriate subsection of the attractor. If so, odor perception is not due to bifurcation but to stimuli constraining the system into one wing of a global attractor.

TOPOGRAPHICAL PROJECTION FROM VOMERONASAL ORGAN TO ACCESSORY OLFACTORY BULB. MARY WISGIRDA* & MICHAEL MEREDITH (SPON: P. BORRONI). FLORIDA STATE UNIVERSITY, TALLAHASSEE, FL.

The vomeronasal organ (VNO) is an accessory chemosensory structure found in most terrestrial vertebrates which is involved in reproductive behaviors in many species, including the male hamster. It is an elongated tubelike structure which lies long the base of the nasal septum. Receptor cell axons form 3 nerve bundles which terminate in the accessory olfactory bulb (AOB). Horseradish peroxidase (HRP) was injected into one of these nerve bundles in separate series of hamsters to trace the connections from anterior, central and posterior sets of receptors into the AOB. The HRP was transported retrogradely to the receptor cell bodies and anterogradely to their terminals in the AOB. Frozen sections of the AOB and VNO were processed using TMB histochemistry and examined for HRP reaction product (RP). Anterior nerve injections labeled cells only in the anterior portion of the VNO. Posterior nerve injections labeled cells only in the posterior end of the VNO. Density of RP in 3 areas of each AOB section was determined with computer assisted image analysis. Each nerve had labeled terminals throughout the glomerular layer of the AOB, but their distribution varied significantly. Injection of the most posterior (ventral) nerve produced a much greater density of RP in the ventral than in the dorsal half of the AOB with little variation medio-laterally. In contrast, anterior nerve injections had significantly more RP laterally than medially in the AOB in addition to a ventro-dorsal gradient. These results suggest a degree of topographic organization to this projection which is more complex than a simple point to point connection.

OLFACTORY BULB CONNECTIVITY IN A GYMNOTOID FISH, WITH SPECIAL REFERENCE TO TELENCEPHALIC, LOCUS COERULEUS AND RAPHE INPUTS. E. Sas and L. Maler. Dept. of Anatomy, University of Ottawa, Ottawa, Ontario, Canada K1H 8M5.

The connectivity of the olfactory bulb (OB) of Apteronotus leptorhynchus, was investigated following wheat germ agglutinin-conjugated horseradish peroxidase injections within the OB. Most bulbopetal cells receive reciprocal connections from the OB, with the exceptions of: 1) telencephalic cells at the border of area dorsalis medialis pars dorsalis/area dorsalis centralis, area dorsalis lateralis pars posterior and caudal area dorsalis centralis, 2) nucleus raphe centralis, 3) locus coeruleus. The OB projects bilaterally, with a major ipsilateral component via a medial and lateral olfactory striae. The olfactory target areas are: 1) Telencephalic areas: ventralis pars ventralis, medial olfactory terminal field (between areas ventralis partes ventralis and dorsalis) areas ventralis centralis, ventralis supracommissuralis, ventralis intermedia, dorsalis lateralis pars ventralis, dorsalis posterior and nucleus taenia. 2) Diencephalon: habenula, thalamus, N. preopticus periventricularis posterior and N. tuberis posterior. Distribution of NAergic, serotonergic, substance P and somatostatin fibers in the OB will be discussed as well as the topography of area dorsalis centralis cells projecting to the OB, optic tectum and torus semicircularis.

HYPOTHALAMIC EFFERENTS TO THE RAT OLFACTORY BULB REVEALED BY AN IMPROVED CHOLERA TOXIN B-HORSERADISH PEROXIDASE (CTB-HRP) CONJUGATE. P.M. Young* & F. Mullin*, School of Psychology, Lancashire Polytechnic, Preston, PR1 2TQ. U.K.

The use of periodate to oxidize the carbohydrate shell of HRP produces a high level of coupling leaving little unreacted CTB after conjugation, and no need for further purification. CTB-HRP produced by this technique is an exceptionally sensitive anterograde and retrograde neuronal tracer and it was used to investigate the bi-directional communications of the main and accessory olfactory bulbs. 100 nl injections of CTB-HRP were stereotaxically placed into the required component of the olfactory bulb, 24-72 hours later the animals were sacrificed and 80μm frozen sections were processed using tetramethyl benzidene as the chromogen. Forty two definable brain nuclei contained retrogradely labelled neurones, and twelve of these were in the hypothalamus. These mostly unique findings, demonstrate the sensitivity of CTB-HRP conjugate as a neuronal tracer. The labelled cells in so many parts of the hypothalamus provide a morphological basis for the direct centrifugal pathways required to explain a body of electrophysiological data. Given the significance of the olfactory sense in the rat, it is not too surprising to find direct reciprocal connections with those parts of the brain functioning in the maintenance of internal homeostasis, reproduction and reinforcement.(SPON: BRA)

DiI LABELED, NERVUS TERMINALIS AFFERENTS DISTRIBUTE TO MANY BRAIN REGIONS IN *XENOPUS LAEVIS*. E.F. Perkins* and G.D. Burd. Depts. of Molecular and Cellular Biology and Anatomy, University of Arizona, Tucson, AZ 85721.

In many vertebrates, three types of afferent fibers project from the nasal mucosa to the CNS via the olfactory nerve--axons of the olfactory receptor cells, the vomeronasal receptor cells, and the terminal nerve (nervus terminalis, NT). Using dil (0.1% dil, 90% EtOH, 10% DMSO), we labeled all three fiber systems in *Xenopus laevis* tadpoles and young frogs (stages 43-66) by placing the dye solution into the nasal capsules of paraformaldehyde-fixed animals. After 14 days, bright staining was observed in the olfactory nerve, vomeronasal nerve, and the nerve and glomerular layers of the main and accessory olfactory bulbs (MOB,AOB). We also observed a loose bundle of fibers that projected beyond the glomerular layer. These fibers, which are presumed to be part of the NT, projected caudally through the medial MOB, medial pallium, and septum. At this point in the pathway, individual axons projected into piriform cortex. The fiber bundle then divided with many axons crossing to the contralateral side through the anterior commissure while the majority continued to project caudally on ipsilateral side of the brain. A small group of the contralateral fibers coursed rostrally into the OB and terminated at the edge of the glomerular layer. The other group of the contralateral fibers projected caudally and traveled either along the lateral surface of the diencephalon or along the midline through the preoptic area. The termination of both the ipsilateral and contralateral fibers that project caudally beyond the preoptic area could not be determined. Others have shown that NT fibers are immunoreactive for luteinizing hormone releasing hormone (LHRH). In our study, adult frogs contained LHRH-like immunoreactivity in many of the same regions that were labeled with the dil. Support: NIH-NINCDS #NS25596.

THE AFFERENT CONNECTIONS OF THE MAIN OLFACTORY BULB (MOB) IN THE ARMADILLO (CHAETOPHRACTUS VELLEROSUS). A RETROGRADE TRACING STUDY WITH HRP, FLUORESCENT TRACERS AND SODIUM SELENITE. J.S. de Olmos*, H. Ferreyra-Moyano, C. Beltramino*, E. Barragan* and D. Scapellato*. Inst. Inv. Med., M. y M. Ferreyra, C.C. 389, 5000 Cordoba, Argentina.

The afferent connections of the MOB of the armadillo were examined by injecting horseradish peroxidase (HRP), fluorescent tracers (FT) and sodium selenite (NAS) into this structure, either by microelectrophoresis, hydraulic pressure or implantation of solid pellets. Twenty four to forty eight hours after unilateral injections of HRP or FT to the MOB, tracer-labeled perikarya appeared in the following telencephalic structures on the ipsilateral side: all portions of the anterior olfactory nucleus (AON), except its external part (AONe) the lateral transition field (LT), the piriform cortex (PIR), the nucleus of the horizontal (HDB) and vertical (VDB) limbs of DBB and the nucleus of the lateral olfactory tract (LOT).Labeled cells were also seen in the dorsal and medial transition fields, the ventral and intermediate precommissural hippocampus,ventral preorbital cortex (PRO), the sublenticular substantia innominata, the anterior amygdaloid area, the posterolateral cortical amygdaloid nucleus (PLCO) and the amygdalo-piriform transition area and in the lateral entorhinal cortex. In the contralateral side, labeled neurons were found in all parts of AON with heavy labeling of AONe. Labeled cells were also found in the ventral PRO, LT, and in LOT whereas fewer neurons were also found in the frontal PIR. In the diencephalon and brain stem tracer labeled neurons were observed in the dorsal, perifornical, mamillo-infundibular and lateral hypothalamic areas as well as in locus coeruleus and the dorsal and medial rapne nuclei. When NAS was used as a retrograde tracer for showing zinc-rich bulbopetal projections, this marker was detected only in the paleo and periallocortical formations listed above and in PLCO and LOT. No selenite-labeled neurons could be identified in HDB, VDB or any of the diencephalic and tegmental cell groups labeled with HRP or FT

ANATOMY OF THE MITRAL/TUFTED CELLS OF THE ACCESSORY OLFACTORY BULB IN THE ADULT RAT. S. Takami* and P.P.C. Graziadei. Dept. Biol. Sci., Florida State Univ., Tallahassee, FL 32306-3050.

The output neurons of the accessory olfactory bulb (AOB) have been recognized by HRP retrograde labeling injected into the medial amygdaloid nucleus. Their soma is located in two layers, the glomerular and the external plexiform layers (GL) and (EPL). Here we report on the morphology of the output neurons whose soma is located in the EPL. A rapid Golgi method was used and the neurons studied in serial sections of the AOB. These neurons have soma of 10-25 microns in diameter and apical long dendrites branching in the GL. The neurons can be classified according to the number of their apical dendrites; the larger have as many as 4 dendrites and the smaller only 1. The dendrites expand into the glomerular domain either by tufts or by loop-like, previously unreported, baskets. Not only each dendritic arbolization of the same neuron terminates in different glomeruli, but also each tuft or basket occupies either a relatively small volume of each glomerulus or most of the glomerular volume. Thus each glomerulus may be composed of many compartments provided by different dendrites from different neurons. This arrangement is likely to have some significance in the coding mechanism of the vomeronasal system. Supported by grant NIH NS 20699 to PPCG.

TUFTED CELLS OF THE INTRA- AND INTERBULBAR ASSOCIATIONAL PATHWAYS ARE IMMUNOPOSITIVE FOR CHOLECYSTOKININ OCTAPEPTIDE. T. Jang, T.A. Schoenfeld, R.M. Kream*, and F. Macrides. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545, Tufts University Schools of Medicine, Boston, MA 02111.

Previous studies have shown that two distinct populations of tufted cells in the main olfactory bulb (MOB) of hamsters participate in topographically organized associational pathways. One population mediates point-to-point interconnections between the left and right sides of each MOB. The axons of tufted cells in this intrabulbar pathway travel in the internal plexiform layer (IPL) and terminate in this layer. The other population of tufted cells projects to the superficial plexiform layer of pars externa (pE) of the anterior olfactory nucleus. The neurons of pE in turn project topographically via the anterior commissure to the contralateral MOB. This interbulbar pathway interconnects homotopic longitudinal strips in the left and right MOBs. The somata of both populations are distributed in regions of the external plexiform layer (EPL) that contain substance P (SP), tyrosine hydroxylase (TH) or cholecystokinin octapeptide (CCK) immunopositive tufted cells. Combined retrograde and immunohistochemical analyses, using punctate injections of rhodamine impregnated latex microspheres and the avidin-biotin complex (ABC) or indirect (fluorescein) immunofluorescence procedure, were conducted to assess possible correspondences between these connectionally versus immunohistochemically defined populations of tufted cells. Both populations of associational tufted cells were found to contain CCK-like immunoreactivity. The projections of the SP and TH positive tufted cells appear to be predominantly intrabulbar and restricted to the same side of the MOB as the parent somata. The ultrastructural features of the CCK positive somata and dendrites in the superficial layers and processes in the IPL were examined with a modification of the ABC method followed by conventional electron microscopic procedures. The CCK positive tufted cells receive axo-dendritic peripheral input in the glomeruli and make both pre- and postsynaptic dendro-dendritic contacts in the EPL and interglomerular regions. Their apparent axon terminals in the IPL synapse on immunonegative dendrites. The CCK-like immunoreactivity in terminals is associated predominantly with highly granulated or dense core vesicles.

EFFECTS OF NMDA AND NON-NMDA RECEPTOR ANTAGONISTS ON SYNAPTIC TRANSMISSION IN PIRIFORM CORTEX. J. Larson*, M.W. Jung, and G. Lynch. CNLM, Univ. of Calif., Irvine, CA 92717

Study of the pharmacology of synaptic transmission in piriform cortex has been hampered by a lack of potent and selective antagonists for excitatory amino acid receptors. Here we report effects of the non-NMDA antagonist, DNQX, and the NMDA antagonist, D-AP5, on excitatory transmission in this region.

Slices of rat piriform cortex cut perpendicular to the cortical surface were maintained in vitro. Population EPSPs were recorded in response to lateral olfactory tract (LOT) stimulation or activation of associational (ASSN) fibers.

DNQX (20 uM) completely abolished EPSPs generated by LOT or ASSN inputs. At less than 0.1 uM, DNQX was ineffective and 20 uM was sufficient to completely block either response. The dose-response curves for antagonism of both LOT and ASSN responses were similar with a half-maximal effect at about 2-5 uM. D-AP5 (50 uM) had very little effect on LOT or ASSN responses in medium containing 2.5 mM Mg. Perfusion of Mg-free medium caused a small increase in the peak amplitude of both responses as well as a large prolongation of the decay of EPSPs. D-AP5 reduced the late component of the response with little effect on the increase in EPSP amplitude. In Mg-free medium, application of 20 uM DNQX did not abolish either synaptic response; however, the time course of the remaining EPSP was much slower than the typical response. These responses most likely represent EPSPs mediated solely by NMDA receptors.

These results indicate that low frequency transmission at LOT and ASSN synapses are mediated by non-NMDA (quisqualate/kainate) receptors. However, NMDA receptors in both systems are activated by transmitter release in the absence of extracellular Mg. Recent data (Jung, et al., this meeting) also indicate that NMDA receptors participate in induction of LTP at these synapses. (Supported by ONR #N00014-89-J-1255.)

DO NMDA RECEPTORS PARTICIPATE IN NORMAL SYNAPTIC TRANSMISSION IN THE PIRIFORM CORTEX? D. K. Patneau and J. S. Stripling. Department of Psychology, University of Arkansas, Fayetteville, AR 72701.

Although the role of excitatory amino acids (EAA) in synaptic transmission in the piriform cortex (PC) slice has been extensively investigated, the effects of EAA antagonists on PC function in vivo have not previously been explored. This study examined the role of NMDA receptors in PC synaptic transmission utilizing the non-competitive NMDA antagonist ketamine and evoked potential techniques in male Long-Evans rats with chronically implanted electrodes.

The effects of a sub-anesthetic dose of ketamine administered by slow i.v. infusion on the PC potential evoked by olfactory bulb stimulation was monitored continuously during and at 5 and 15 min following ketamine administration. Analysis primarily focused on distinguishing between ketamine's effects on the monosynaptic component of the population EPSP, reflecting activation of PC pyramidal cells via the lateral olfactory tract (LOT) and the disynaptic component, reflecting activation via the PC association fiber system.

Ketamine had relatively specific effects on the disynaptic component of the population EPSP, reducing its amplitude by over 60%. Other effects included a small, but significant, decrease in the monosynaptic component of the population EPSP. These findings are consistent with the interpretation that NMDA receptors in the PC are primarily found at association fiber synapses, but the possibility that ketamine's effects on the disynaptic EPSP were due to decreased cell excitability could not be excluded.

AFFERENT AND ASSOCIATION FIBER DIFFERENCES IN SHORT-TERM POTENTIATION IN RAT PIRIFORM CORTEX. M.E. Hasselmo and J.M. Bower, Div. of Biology 216-76, Caltech, Pasadena, CA, 91125.

For several years, we have been developing a structurally based model of the piriform cortex as a self-organizing associative network for the classification of olfactory stimuli (Wilson and Bower, 1988, Neural information processing systems, D. Anderson, ed. AIP Press, N.Y., pp. 114-126). We have used this model to explore the possible functional relationships between the afferent input to the cortex and the extensive system of intrinsic association fiber connections. The computer modeling suggests interesting associative properties result if the excitatory synapses associated with these two fiber systems have different forms of modification in response to persistent activity .

To test this possibility, intracellular recordings of 46 pyramidal cells in 25 rat brain slices were made using standard procedures. Afferent and association fiber systems were differentially stimulated with electrodes placed in layer 1a or layer 1b respectively. To quantify synapse modifiability, the height of PSPs to paired pulse stimulation (100ms interval) was averaged over a 50 second period before and after a set of 10 stimulus trains (10 pulses each, 20 Hz).

The results indicate that synapses associated with these two fiber systems are influenced differently by trains of stimuli. Specifically, while long-term changes in synaptic strength appeared in very few cells, short-term potentiation characteristics differed significantly on a paired t-test ($T=5.5$, $df=23$, $p<.00001$). Over the 50 second post-train period, Layer 1b showed an average potentiation of 23.2% in the first pulse of the stimulus pairs, while layer 1a showed an average response depression of 10.9%. Layer 1b potentiation decayed with an average time constant of 72 msecs and was decreased by the NMDA receptor antagonist 2-amino-5-phosphonovaleric acid.

APV DEPENDENT INDUCTION OF LONG TERM POTENTIATION IN PIRIFORM (OLFACTORY) CORTEX SLICES. E.D.Kanter and L.B.Haberly. Neurosci. Training Prog. and Dept. of Anatomy, Univ. of Wisc., Madison, WI 53706.

Several groups have reported that 1sec duration, 100Hz shock trains that induce a robust long-term potentiation (LTP) in hippocampus, induce only a brief post-tetanic potentiation of monosynaptic EPSPs in piriform (olfactory) cortex in vivo and in vitro. However, Roman et al (Br. Res. 418:221) recently reported that LTP of afferent fiber responses in piriform cortex can be induced by brief (4 shock) 100 Hz bursts repeated at the theta frequency when animals are trained to respond to this stimulation. We report here that this theta-pattern stimulation paradigm induces LTP in both afferent and association fiber systems in slices of piriform cortex maintained in vitro.

Extracellular field potentials were recorded in layer Ia (afferent fiber layer) and layer Ib (association fiber layer) of slices of rat piriform cortex cut perpendicular to the surface. Stimulus trains and test pulses were delivered through tungsten microelectrodes placed under direct vision in either layer Ia or layer Ib. Trains for induction of LTP consisted of 10 bursts of 4 pulses at 100Hz delivered at 160ms intervals.

Theta-pattern stimulation induced increases in strength of EPSPs evoked by afferent fiber stimulation by up to 30% (typically 10-20%) and EPSPs evoked by association fiber stimulation by up to 35% (typically 20-30%). The 2 pathways could be independently potentiated in the same slice. Potentiation of the afferent fiber response typically decayed at a slow rate (time constant much greater than 1h); potentiation of the association fiber response decayed at a faster rate (typical time constant of 30m to 1h). Addition of 30μm DL-2-amino-5-phosphonovalerate (APV) to the bath blocked induction of LTP in both pathways. LTP could be induced after washout of the APV. Supported by grant NS 19865 to LBH.

INDUCTION OF SELECTIVE LONG-TERM POTENTIATION IN THE PIRIFORM CORTEX REQUIRES AN INCUBATION PERIOD. J. S. Stripling and D. K. Patneau. Dept. of Psychology, University of Arkansas, Fayetteville, AR 72701.

Repeated high-frequency stimulation that directly activates association fibers in the piriform cortex (PC) selectively potentiates late components of potentials evoked in the PC (Soc. Neurosci. Abstr. 14: 1189, 1988). In previous research we have seen potentiation appear in the PC only after two or more sessions of high-frequency stimulation spaced 24 hr apart. This could be due either to an incubation period necessary for the establishment of potentiation, or to a requirement for more stimulation than is provided by 1 stimulation treatment.

To address this issue, male Long-Evans rats received repeated high-frequency stimulation of PC association fibers in 4 sessions separated by intervals of 1, 4, or 24 hr. Animals receiving stimulation at 24-hr intervals exhibited significant potentiation 5 min and 24 hr after the last stimulation. Animals receiving stimulation at 4-hr intervals showed potentiation only 5 min after the last stimulation, and animals in the 1-hr group showed no significant potentiation at either time. These results suggest that the mechanisms underlying the induction of potentiation in the PC require several hours to be established, and that additional stimulation during this time does not substantially accelerate the process. (Supported by NSF Grant BNS 85-19700.)

CHEMICAL SENSES: GUSTATORY PATHWAYS

368.1

IN VITRO RECORDING FROM SLICES OF THE VAGAL GUSTATORY LOBE OF GOLDFISH. T.E. Finger & T.V. Dunwiddie. Dept. Cell. & Struct. Biology and Dept. Pharmacology, U. Colo. Med. Sch., Denver, CO 80262.

The vagal lobe of goldfish is a laminated evagination of the midmedulla which contains the reflex circuitry required to carry out intraoral food sorting (Finger; *Brain, Behav. Evol. 1988*). Primary gustatory afferents course through the deep fiber layer to terminate in superficial layers while motoneurons innervating the orobranchial apparatus lie in the deep layers. The vagal lobe was removed from cold-anaesthetized goldfish and sliced on a tissue-chopper at 500 μm and placed in artificial CSF. The tissue slices then were placed in a slice recording chamber and permitted to recover for at least 30 minutes prior to recording. A bipolar stimulating electrode was used to stimulate small fascicles in the primary afferent fiber layer; a glass pipette recording electrode was positioned under visual control at different loci in the vagal lobe. Clear evoked population responses were observed at restricted locations in the vagal lobe at 4 msec following stimulation. This negative-going response was recorded in layers 6-8 -- the principal layers of termination of the primary sensory fibers. The maximal response was recordable only for a distance of 0.5 - 0.7 mm across the surface of the lobe confirming anatomical results showing that each fascicle of primary afferent fibers ramifies only within a limited expanse of the lobe. Further, the waveform of the response was labile being sensitive to both the interstimulus interval and voltage applied to the stimulating electrodes. In addition, this response disappeared upon removal of calcium from the bathing solution and reappeared following the reintroduction of calcium. Thus this negative wave appears to reflect synaptic currents and not simply the incoming volley in the primary afferent fibers. Future studies will explore the neurotransmitters involved in the transmission of the primary gustatory inputs.

368.2

CONVERGENCE OF GASTRIC AND GUSTATORY INPUTS IN THE MEDULLA OF THE CHANNEL CATFISH, *ICTALURUS PUNCTATUS*. J.S. Kanwal and T.E. Finger, Dept. of Cellular & Structural Biology, Univ. of Colorado Sch. Med., Denver, CO 80262.

Coelomic (general) visceral inputs ascend through the CNS in parallel to those of the gustatory system. Behavioral and physiological data suggest that gustatory and gastrointestinal inputs may, however, interact at one or more sites within the brain. While "downstream" reflex-type pathways exist for the gustatory modulation of vagal motor output, a locus in catfish where gastric and gustatory inputs converge is unknown.

Electrophysiological recordings were obtained from ventral medullary regions in the vicinity of the facial motor nucleus. HRP-filled, glass microelectrodes (impedance < 1 megohm) were utilized to record in catfish in which stimulating electrodes had been implanted in the stomach. Once the recording electrode encountered neurons responsive to taste and/or tactile stimulation, the stomach was stimulated electrically. If the neurons responded both to gustatory and to electrical stimulation, the recording site was marked with an iontophoretic injection of HRP. Single unit analysis indicated the presence of at least two types of neurons which responded both to chemical stimulation of the oral cavity and to electrical stimulation of the stomach. One neuron type exhibited a spontaneously rhythmic pattern of activity (average firing rate of approx. 10 spikes/s), while the other had a relatively low rate of spontaneous activity (approx. 1 spike/s). Subsequent anatomical analysis confirmed that the gastrogustatory convergence site is situated in the dorsolateral reticular formation at the level of the facial motor nucleus. Several small (≈30 μm) and a few large (≈70 μm) neurons were labeled at the recording site.

ELECTRON MICROSCOPIC OBSERVATIONS OF GLOSSOPHARYNGEAL AFFERENT TERMINALS IN THE HAMSTER SOLITARY NUCLEUS. S. K. Brining, M. N. Lehman, and D. V. Smith. Depts. Anat. & Cell Biol., Otolaryngol. & Maxillofac. Surg., Univ. Cincinnati Coll. Med., Cincinnati, OH 45267.

Light microscopic investigations in several species show rostrocaudally overlapping terminal fields within the nucleus of the solitary tract (NTS) from gustatory fibers in cranial nerves VII, IX and X. In the present study, afferent terminals of the IXth nerve within the NTS were examined with electron microscopy (EM). Crystalline HRP (Sigma Type VI) was placed in the region of the petrosal ganglion of the IXth nerve. After a 2-day survival, hamsters were perfused with 1% paraformaldehyde, 1.25% glutaraldehyde and the brains removed and processed for HRP histochemistry using DAB as the chromagen. Periganglionic placement of HRP resulted in dense labeling of afferent fibers and terminal boutons within the NTS, clearly observable at the light microscopic level. At the EM level, HRP-labeled myelinated and unmyelinated axonal processes were observed in the vicinity of the NTS. Labeled *en passant* and terminal boutons contained small, round, clear vesicles (20 - 40 nm diam) and formed asymmetrical synapses onto small, unlabeled dendritic processes within the NTS. Labelled terminal boutons often had a scalloped appearance due to indentation by surrounding, unlabeled processes. Occasionally, both labeled and unlabeled terminals were found synapsing upon the same dendrite. We are currently in the process of quantifying these observations so that comparisons can be made with the morphology of VIIth nerve afferent terminals (Whitehead, M. C., *J. Comp. Neurol. 244*: 72, 1986). Supported by NS23524 to D.V.S.

368.4

INTRINSIC CHARACTERISTICS OF GUSTATORY NEURONS IN RAT SOLITARY NUCLEUS. R.M. Bradley and R.D. Sweazey. Sch. Dent., Univ. Michigan, Ann Arbor, MI 48109.

To investigate the intrinsic membrane properties of second order gustatory neurons in the nucleus of the solitary tract (NTS), we are using an in vitro slice preparation of the rat brainstem.

Intracellular recordings have been made from 25 NTS neurons. These neurons had stable resting potentials, from -37 to -70 mV ($\bar{x}$ = 52.5 ± 8.7 SD), membrane resistances of at least 50 megohms, and little or no spontaneous activity. Mean membrane resistance was 81.6 ± 28.5 megohms and membrane time constants were 9 msec or less. Action potential amplitudes ranged from 38 to 80 mV ($\bar{x}$ = 60.6 ± 12.9) and spike duration was usually 2 msec or less. Most neurons also exhibited a hyperpolarization after each action potential. These hyperpolarizations ranged from 1 to 16 mV ($\bar{x}$ = 5.5 ± 4.7). Based on responses to an intracellular injection of 0.5 nA, 100 msec depolarizing current pulse, the neurons could be separated into two groups. The first group, which contained most of the neurons, responded with a burst of 4-5 action potentials, whereas the second group exhibited a burst of 12-14 action potentials. These results represent the first intracellular recordings from rostral NTS. Compared to non-gustatory neurons located in caudal NTS, neurons in gustatory NTS are less spontaneously active, are not intrinsically rhythmic and exhibit fewer action potentials to a depolarizing current pulse.

Supported by N.I.H. Grant NS21764.

368.5

Morphology of NTS Cells in Sodium Deprived and 'Recovered' Rats. C. Tessitore King* and David L. Hill. Dept. Psychology, Univ.Virginia, Charlottesville, VA

Sodium deprivation instituted early in prenatal development produces suppressed responses of the chorda tympani nerve (CT) to lingual applications of NaCl. Taste responses of rats fed a sodium replete diet for at least 15 days after deprivation 'recover' to control levels. HRP experiments have revealed that CT terminal fields in deprived rats are the same size as that of controls; however, a rearrangement of the field within the NTS occurs. In 'recovered' rats, the terminal field area is 3x that of controls and the deprivation-induced pattern of innervation persists. Golgi-Cox filled cells from control, deprived and 'recovered' rats were examined. Preliminary data suggest that no differences in soma area or in the number of 1^o dendrites are apparent in any cell type across experimental groups. Fusiform cells of deprived rats show an increase in length of 1^o dendrites, number and length of 2^o dendrites and an increase in the percentage of cells possessing 3^o dendrites. Similar changes were found in multipolar cells of deprived rats except no changes were seen in 1^o dendrites. Ovoid cells were similar in deprived and control rats. In most cases, cell morphology in 'recovered' rats is intermediate to that of control and deprived rats. These results indicate that sodium deprivation and 'recovery' differentially affect the morphology of taste responsive cells in the NTS.

368.6

ORGANIZATION OF TASTE-RESPONSIVE ACTIVITY IN THE PARABRACHIAL NUCLEUS IN THE GOLDEN HAMSTER. C.B. HALSELL and M.E. FRANK (SPON: M. McPheeters) Center for Neurological Sciences/Dept. of BioStructure & Function, UCONN Health Center, Farmington CT. 06032.

The parabrachial nucleus (PBN) is the obligatory third-order relay for the ascending gustatory system in rodents. Only part of the PBN, the pontine taste area (PTA), is responsive to taste stimuli. Although PTA physiology has been examined in hamsters, its location has not been correlated with PBN anatomy. Multi-unit taste-responsive activity was mapped in the PBN and recording sites marked by iontophoretically deposited horseradish peroxidase (HRP). Taste stimuli (0.03 M NaCl, 0.1 M KCl, 0.1 M sucrose and a mixture) were applied to the anterior tongue. The PBN is composed of six subdivisions based on cytoarchitectural criteria and cytochrome oxidase activity. The PTA for the anterior tongue is located within only two of these subdivisions, the medial and ventral-lateral. HRP injections into the rostral pole of the nucleus of the solitary tract preferentially labels the PTA. Connections between the PTA and a physiologically defined gustatory cortical area are being examined. These results suggest that there is a well-defined area of gustatory function in the PBN and provide information required for tract-tracing studies aimed at establishing gustatory, as distinct from visceral, pathways. NIH Grant #NS16993

368.7

PARABRACHIAL NEURAL ACTIVITY DURING LICKING OF SAPID STIMULI BY RATS. H. Nishijo* and R. Norgren Dept. of Behavioral Science, College of Medicine, The Pennsylvania State University, Hershey, PA 17033.

Previously we reported pontine taste responses in behaving rats (Neurosci. Abst.14: 473.4, 1988). In the present study pontine gustatory neural responses were compared when rats ingested fluids by licking or by infusion via an intraoral cannula. Tongue movements were monitored from genioglossus EMG electrodes and tongue contact by a lickometer. A total of 51 single neurons was recorded from the parabrachial nuclei of 3 rats. Of these, 39 neurons were tested during both licking and intraoral infusion of sapid stimuli. When compared with distilled water, 35 responded differentially to one or more of the 4 sapid chemicals. The remainder responded equivalently to both water and taste stimuli. Of the taste neurons, 10 responded best to sucrose (0.3M), 24 to NaCl (0.1M), and 1 to citric acid (0.01M). The best-stimulus categories remained the same regardless of the route of fluid delivery. The side-band responsiveness of some neurons, however, did vary as a function of the method of ingestion. When the rats were licking stimuli, 9 taste neurons responded significantly to only one sapid chemical, but were more broadly tuned during intraoral infusions. Conversely, 3 taste neurons that responded specifically during intraoral infusions were not specific when the animal licked the same stimuli. These results suggest that a taste neuron's best-stimulus category is characteristic, but that second order responses are more variable. Supported by PHS grants NS 20397 and MH 00653.

368.8

CODING OF AMINO ACIDS IN THE GUSTATORY CORTEX OF THE ALERT CYNOMOLGUS MONKEY. T.R. Scott, C.R. Plata-Salaman and V.L. Smith*. Dept. Psychol., Univ. Delaware, Newark DE 19716.

We have completed analyses of gustatory quality and intensity coding in the cortex of the alert monkey based on responses to an array of basic taste stimuli (Plata-Salaman, Scott and Smith, SNA, 1989; Scott and Smith, SNA, 1988). The present study extends this line of research to include stimuli of greater molecular complexity and biological relevance: the amino acids. Chemicals were deionized water, fruit juice, the four prototypical taste stimuli (glucose, NaCl, HCl, quinine) and 16 amino acids selected for their nutritional significance and for the availability of published psychophysical data on their perceived qualities.

Response profiles to the stimulus array were determined for 54 gustatory neurons. The mean spontaneous rate of these cells was 2.4 spikes/s; the mean breadth-of-tuning coefficient was 0.71. Amino acids most effective in activating cortical taste neurons were MSG, PRO and GLY. The least effective stimuli were TYR, THR, PHE and TRP. An analysis of taste quality indicated that the clearest distinction was between sweet and non-sweet stimuli. Among non-sweet chemicals, amino acids were either insipid (allied with water) or sour-bitter (related to HCl and quinine). These findings conform well with electrophysiological results from the peripheral taste nerves of rats and with human psychophysical data.

INTENSITY CODING IN THE GUSTATORY CORTEX OF THE ALERT CYNOMOLGUS MONKEY. C.R. Plata-Salaman, T.R. Scott and V.L. Smith*. Dept. Psychol., Univ. Delaware, Newark, DE 19716.

Single neuron responses to taste stimuli in the primary gustatory cortex of two alert cynomolgus monkeys were analyzed. Chemicals were deionized water, fruit juice and several concentrations of the four prototypical taste stimuli: 10^{-3} to 1.0 M glucose, 10^{-3} to 1.0 M NaCl, 10^{-4} to $3X10^{-2}$ M HCl and 10^{-5} to $3X10^{-3}$ M quinine HCl. Responses could be recorded from a cortical area that extended 4.5 mm A-P, 3.0 mm M-L and 6.0 mm D-V. Taste-responsive neurons constituted 3.7% of the cells tested. Intensity-response functions were determined for 62 gustatory neurons. Thresholds were, glucose: 10^{-1} M, NaCl: 10^{-2} M, HCl: 10^{-3} and quinine: 10^{-4} M. These are similar to psychophysical thresholds determined in humans. Mean discharge rate was a direct function of stimulus concentration for glucose, NaCl and quinine. Other characteristics of cortical taste neurons were: 1) breadth of responsiveness: this was moderate compared to taste cells at other relays. The mean breadth-of-tuning coefficient was 0.65. 2) Topographic organization: there was no clear evidence for a topographic distribution of response either by stimulus quality or intensity. 3) Neuron types: an analysis of response profiles permitted most taste cells to be assigned to a small number of groups, each statistically independent but within which the constituent neurons were not identical. The monkey appears to provide an appropriate neural model for human intensity perception.

CLINICAL AND PATHOLOGICAL CORRELATES OF LOCUS COERULEUS PATHOLOGY IN PARKINSON'S DISEASE AND HUNTINGTON'S DISEASE. R.M. Zweig*, C.A. Ross, J.C. Hedreen, C. Peyser*, J.E. Cardillo*, M. Cohen*, S.E. Folstein*, and D.L. Price (SPON: P.J. Whitehouse). University of Nevada, Johns Hopkins, and Case Western Reserve Schools of Medicine.

Numbers of neurons at selected anatomical levels of the locus coeruleus (LC) were counted in 11 patients with idiopathic Parkinson's disease (PD) without concurrent Alzheimer's disease (AD), 16 patients with Huntington's disease (HD), and age-matched controls. In PD, counts at rostral, middle, and caudal levels were 47%, 37%, and 32% of control values, respectively. Unlike results from AD patients, level-to-level differences were not significant. Neuronal counts in PD correlated negatively with age ($p<.05$ rostrally). Individuals with dementia (determined from blinded chart reviews) had significantly fewer neurons at all levels than those without ($p<.02$). In HD, neuronal counts were similar to controls; however, patients with severe dementia (prospective mini mental state scores <3) had significantly fewer neurons than patients with mild or no dementia (scores >15) at rostral and middle levels ($p<.02$). Rostral LC counts also correlated negatively with impairment of voluntary motor function (scored prospectively) and neostriatal atrophy (macroscopic scoring) in HD patients ($p<.05$). Our findings may reflect relationships between dementia and involvement of the LC or of other structures in which severity of pathology correlates with LC pathology.

369.2

MEMORY DYSFUNCTION AS A CONSEQUENCE OF HYPERTENSION AND HIGH CHOLESTEROL DIET IN THE MONKEY M.B. Moss, T. Kemper*, D.L. Rosene, and W. Hollander*. Boston University School of Medicine, Boston, MA 02118.

As part of the development of a primate model of cerebrovascular disease, the behavioral and neuropathological effects of hypertension, alone or in combination with a hypercholesterolemic diet, were studied in the cynomolgous monkey. An assessment of visual recognition memory using the delayed non-matching to sample task (DNMS) was performed in monkeys that received either coarctation of the thoracic aorta alone (HYP), or in combination with maintenance on an atherogenic diet (HYP + ATH) for 12 months prior to testing. Post-treatment performance on the DNMS task was compared to that of operated contol animals maintained on an atherogenic diet (ATH) and operated control animals maintained on a normal diet (OC) for the same pretesting period. Monkeys with HYP + ATH were significantly impaired as a group in the acquisition of the DNMS task. In contrast, monkeys in the ATH group were unimpaired on the task. Though not impaired as a group, individual monkeys with HYP alone obtained elevated scores relative to monkeys in either the OC or ATH groups. Initial histological assessment revealed multifocal neuropathologies in monkeys in the HYP+ATH and HYP groups, including perivascular hemorrhage, mineral deposits, demyelination and ischemic infarction. The data suggest that hypertension and a high cholesterol diet can act synergistically to produce both CNS damage and impaired higher cortical function. (Supported by Grant HL13262)

369.3

DEFICITS IN PROCEDURAL LEARNING IN AN ANIMAL MODEL OF HUNTINGTON'S DISEASE. J. E. Kelsey and M. M. Sault*. Dept. Psychology, Bates College, Lewiston, ME 04240.

Several reports suggest that patients with Huntington's Disease (HD) are deficient in acquiring skill tasks that require procedural learning. It has also been argued that injection of the neurotoxin, quinolinic acid (QA), into the striatum of rats can reproduce the major histological and neurochemical changes observed in HD. The intent of this study was to determine if QA injections produce deficits in procedural learning. In Experiment 1, ten rats injected with 150 nm QA on each side of the striatum were initially deficient in finding a visible platform in a Morris water tank from a single starting position. Indicating that this deficit was not simply the reflection of a motor deficit that caused them to swim more slowly, Experiment 2 demonstrated that these rats were also deficient in acquiring a position habit in a Y maze. Three rats injected bilaterally with 75 nm were not deficient in either task, indicating that the effects were dose dependent. Thus, this study indicates that a neurotoxin that produces the major histological and neurochemical features of HD also produces one of the major behavioral symptoms, a deficit in procedural learning.

369.4

COGNITIVE DEFICITS IN MOTOR NEURON DISEASE. O.L. Lopez, F.J. Huff and A.J. Martinez. Univ. of Pittsburgh School of Medicin, Pittsburgh, PA 15213

We reviewed the clinical and neuropathological features of a 63 year old man with Motor Neuron Disease (MND) with progressive dementia and without parkinsonism. A battery of neuropsychological tests revealed that language, attention, orientation, visual scanning and problem solving were the cognitive areas affected. Neuropathological examination showed moderate astrocytosis and neuronal loss in the frontotemporal cortex, chiefly in the frontal lobes. Spongiform changes were seen in the upper layers of the temporal cortex. Minimal neuronal loss and astrocytosis were observed in the parietal and occipital lobes, caudate nuclei, putamen, thalamus and substantia nigra. Degenerative changes were seen in the corticospinal tract, spinal anterior horns and hypoglossal and vagus nuclei. This case offers evidence that cortical lesions associated with MND may produce dementia, not always clinically distinguishable from other cortical dementias, and with neuropsychological deficits maily in functions related to the frontal lobe.

369.5

NEUROMUSCULAR FATIGUE IN MULTIPLE SCLEROSIS PATIENTS. C. L. Rice*, F. Furbush*, T. Vollmer*, C. K. Thomas, and B. Bigland-Ritchie. John B. Pierce Foundation & Neurology Dept., Yale University, New Haven, CT 06519.

For MS patients, fatigue is the major symptom limiting physical performance. Contributing factors are being studied by methods used in normal subjects (Bigland-Ritchie et al, J. Appl. Physiol. 61:421, 1986). Preliminary results from one patient showed near normal strength in one leg for maximum voluntary quadriceps contractions (MVC), with complete twitch occlusion. For the other leg, the MVC force was reduced by about 50%, always with large superimposed twitches; but MVC force, calculated by extrapolation, was nearly normal. For both muscles, twitch contraction times and MVC motor unit (MU) firing rates were slow (83 ± 5ms & 14 ± 2Hz) compared to controls (71 ± 7ms & 24 ± 6Hz). Endurance times for repeated 50% MVCs were longer (10-12 min.) than normal (4-5 min.) and twitch occlusion, during brief test MVCs, showed little further decline. Similar results were seen in another less severely affected patient. Since objective signs of abnormal neuromuscular fatigue were absent, and the normal pain and stiffness after exhaustive exercise were not felt, these patients' symptoms may be mainly due to impaired sensory function. Slow muscle properties may result from chronic low frequency MU firing rates due to the limited capacity of demyelinated fibers to carry high rates (Bostock & Grafe, J. Physiol. 365:239, 1985).

KINEMATIC ANALYSIS OF STEREOTYPIC FACIAL MOVEMENTS IN TARDIVE DYSKINESIA. R. E. A. van Emmerik*, R. L. Sprague* and K. M. Newell. Department of Kinesiology, University of Illinois at Urbana-Champaign, Urbana, IL 61801.

A method has been developed to digitize the space-time properties of abnormal stereotypic movements from videotape so that one may analyze the movement dynamics of stereotypic behaviors, such as abnormal lip and jaw movements. These data are presented graphically in representations of different dynamical control spaces to help understand the dynamical properties of stereotypic movements. This orientation provides a more sensitive measurement for the assessment of movement disorders and the basis for a physical account of the dynamics of tardive dyskinesia. Our preliminary data on lip, tongue and jaw motions of patients with tardive dyskinesia suggest: (1) that on drug withdrawal, the space-time characteristics of lip, tongue and jaw movements are highly coupled; and (2) that on re-instatement of psychotropic medication, this highly constrained behavior is not present, although it can be induced in the presence of a secondary task. It appears that tardive dyskinetic movements are consequences of a high degree of constraint imposed on the highly flexible motor apparatus limiting it to a few degrees of freedom that oscillate in a stable mode. Reinstatement of a psychotropic medication releases the ban on the motor apparatus and generates more independently controlled and adaptive behavior.

COGNITIVE DEFICITS IN NONINSULIN DEPENDENT DIABETICS. W. Lichty, Psychology Dept., Washington Univ., St. Louis, MO 63130

Cognitive performance was studied in 178 individuals ages 40-69y: 60 diabetics with NIDDM (noninsulin dependent diabetes) and 118 nondiabetics matched for age ($\underline{M}$=55y) and education ($\underline{M}$=13y). The cognitive tasks evaluated immediate memory (verbal span), long-term memory (paired-associates learning), reasoning (analogies), speed of processing (digit symbol substitution), perceptual identification (number comparison), and frequency coding. Diabetics were significantly impaired on measures of long-term memory, speed of processing, and perceptual identification, with the most severe deficit being on the memory task (M_D=19%, M_{ND}=32%). Performance of diabetics and nondiabetics was equivalent on measures of frequency coding, immediate memory, and reasoning. When the influence of cardiovascular problems was considered in additional analyses, none of the initial findings changed, thus cardiovascular problems do not account for the cognitive decline. Performance scores did not correlate with any diabetic variables such as glycemia, glycemic control, and disease duration. Although diabetics with NIDDM show task-specific, nonglobal cognitive alterations, the cause of the deficits remains to be elucidated. The possibility that CNS deterioration is involved needs to be investigated.

369.8

DIABETIC NEURONAL DISTROPHY OF THE GUT. A.M.Di Giulio, B.Tenconi*, R.La Croix*, P.Mantegazza*, F.Cattabeni& and A.Gorio&. Dept. of Medical Pharmacology, School of Medicine, Via Vanvitelli 32, & Inst. of Pharmacol. Sciences, School of Pharmacy, Via Balzaretti 9, Milano.

Experimental and clinical reports show that diabetes mellitus is associated to functional impairments of the nervous system affecting electrical conduction parameters as well as synaptic transduction mechanisms (see Abbracchio et al., same abstract volume). In the gut of diabetic animals the changes are gradual and develop much more slowly than in the motor and sensory peripheral nerves. 14 weeks following the induction of experimental diabetes noradrenaline hyperinnervates the duodenum, while in the jejunum and large intestine the amine levels appear significantly decreased. Also vasoactive intestinal polypeptide hyperinnervates the small intestine, while the levels of two intrinsic peptides, met-enkephalin and substance P, are markedly reduced throughout the small and large intestine. Serotonin does not appear to be affected in the gut of diabetic animals. The complex alterations involving the neuronal network innervating the gut might be responsible of the gastrointestinal dysfunctions present in the vast majority of diabetic patients.

369.9

RELATIONSHIP OF INSULIN-LIKE GROWTH FACTOR I GENE EXPRESSION TO DIABETIC NEUROPATHY. D.N. Ishii, D.M. Guertin*, G. Huitt* and L.R. Whalen* Physiology Dept., and Anatomy and Neurobiology Dept., Colorado State University, Ft. Collins, CO 80523.

Our previous studies indicate that insulin and insulin-like growth factors (IGFs) may act in concert to support neurite growth and survival in sensory and sympathetic neurons, which are cell populations afflicted in diabetic neuropathy. A decline in insulin activity alone may be insufficient to precipitate neuropathy. The hypothesis that IGF-I gene expression is reduced was tested in streptozotocin diabetic rats. IGF-I mRNA content was sharply decreased relative to total and poly(A)$^+$ RNA in diabetic liver and adrenal glands, whereas histone and tubulin mRNA content were not. The loss in IGF-I mRNAs in spinal cord after 1 and 2 weeks correlated with the early onset of conduction velocity deficits seen in spinal cord and peripheral nerves. Streptozotocin toxicity was not involved because insulin infusion opposed the decline in IGF-I mRNAs. These results support the interpretation that abnormal IGF-I gene expression may contribute to the syndrome of diabetic neuropathy. (Supported by NIH grant RO1 NS24327).

ALTERATIONS OF CENTRAL NERVOUS SYSTEM G-PROTEINS IN EXPERIMENTAL DIABETES. M.P. Abbracchio*, F. Cattabeni, M. Di Luca*, A.M. Di Giulio^, B. Tenconi*^ and A. Gorio (SPON.: M. Motta) Inst. Pharmacol. Sci., Sch. of Pharm., and ^Dept. Med. Pharmacol., Sch. of Med., Univ. of Milano, 20133 Italy.

A single alloxan injection to rats causes the development of experimental diabetes within a week. Besides the relatively well characterized peripheral neuropathy, both experimental and clinical data suggest that signal transduction mechanisms might also be altered in the CNS of diabetics. We have previously shown that in the c. striatum of alloxan-treated rats Gs-mediated processes (dopamine stimulation of membrane adenylate cyclase) are increased, whereas Gi/Go activity (measured as bromocriptine inhibition of adenylate cyclase) is significantly reduced.

In this study, the Gi/Go subpopulation of G-proteins was directly evaluated in several brain areas, including the retina, of diabetic rats by means of pertussis toxin induced ADP-ribosylation. ^{32}P-ADP ribose incorporation into retinal Gi/Go proteins was dramatically reduced; less marked decreases were also observed in the cortex, hippocampus and hypothalamus of diabetic rats. All together, these results suggest either a reduced expression or post-translational structural modifications of Gi/Go proteins in the CNS of diabetics; moreover retinal changes likely preceed similar brain alterations and might represent the earliest sign of diabetic encephalopathy.

369.11

AN ELECTRON MICROSCOPIC STUDY OF THE GRACILE NUCLEUS IN ALLOXAN-INDUCED DIABETIC RATS. S.S.W. Tay, & W.C. Wong, Department of Anatomy, National University of Singapore, Kent Ridge, Singapore 0511.

Alloxan-induced diabetic rats showed drastic changes in the gracile nucleus. At 3-7 days post-diabetes, both electron dense and electron lucent types of degenerating axons, axon terminals and dendrites were present. Degenerating axon terminals contained swollen mitochondria and clustered small spherical agranular vesicles. Degenerating dendrites contained swollen mitochondria, dilated rER, small vacuoles and randomized ribosomes. Some synaptic glomeruli formed by axon terminals and dendrites were also affected. Neuronal cell bodies appeared normal. At 3-6 months, degenerating neuronal cell bodies contained multigranular bodies, neurofilaments, tubulovesicular elements and swollen mitochondria. Macrophages and glial cells were actively removing degenerating neural elements. At 9-12 months, numerous freshly degenerating axons, axon terminals and dendrites were found. Several degenerating neuronal cell bodies were highly vacuolated and filled with amorphous materials. There appeared to be some neuronal cell death at later time intervals. It is concluded that alloxan-induced diabetes has a drastic and prolonged effect on the gracile nucleus.

369.12

BULBOSPINAL AXONAL DAMAGE PRECEDES HINDLIMB PARALYSIS IN RATS WITH EXPERIMENTAL ALLERGIC ENCEPHALOMYELITIS (EAE). G. Samathanam*, M. Wessendorf, R.M. Bowker and S.R. White. Dept. of VCAPP, Washington State University, Pullman, WA 99164-6520 and Dept. of Cell Biol. and Neuroanat., University of Minnesota, Minneapolis, MN 55455.

The autoimmune disease, EAE, is generally characterized as an inflammatory and demyelinating disease with relative sparing of axons. However, recent studies have noted that extensive damage to bulbospinal monoamine- and peptide-containing axons accompanies the hindlimb paralysis stage of EAE in Lewis rats. The present study investigated the time course of development of this axonal damage.

Male Lewis rats, inoculated for EAE, were selected for analysis at each of four stages in the development of clinical signs of disease: weight loss, flaccid tail, partial paralysis and complete hindlimb paralysis. Longitudinal spinal cord sections from rats in each group were stained with serotonin, tyrosine hydroxylase or pre-pro-$TRH_{160-169}$ antisera. By the flaccid tail stage of disease, multiple foci of markedly distorted, swollen axons were found that were positive for serotonin-, catecholamine- or pre-pro-$TRH_{160-169}$ like immunoreactivity. A few distorted axons were also found in sections from rats in the weight loss stage of EAE. We conclude that bulbospinal axonal damage precedes the most severe clinical signs of EAE and may contribute to the severity of clinical signs. (Supported by NS 24388).

PRESERVATION OF MOTOR NERVE FUNCTION DURING EARLY DEGENERATION BY PRETREATMENT WITH THE 21-AMINOSTEROID U74006F. P.A. Yonkers* and E.D. Hall (SPON: P. Ho). CNS Diseases Research, The Upjohn Co., Kalamazoo, MI 49001.

The effects of 5 days of pretreatment with the lipid peroxidation inhibitor U74006F have been examined on the rate of functional degeneration of cat soleus motor nerve terminals after axon section. Female cats were dosed for 5 days with either 6.0, 10.0 or 35.0 mg/kg of U74006F p.o. twice daily followed by unilateral sciatic nerve section at the hip level on day 5. On day 7, the bilateral in vivo soleus nerve muscle prep. was set up to assess the neuromuscular functional status of the 48 hr. degenerating soleus nerve terminals in comparison to the contralateral non-sectioned preparation. In untreated cats, the ratio of the nerve-evoked (0.4 Hz) contractile tension of the 48 hr. nerve-sectioned to that of the contralateral non-sectioned was only 52±8%. U74006F pretreatment produced a dose-related improvement with the 10.0 dose having the best effect; the ratio was 86±5% ($p<0.01$ vs. untreated). The maintenance of tetanic tension during a 10 sec period of 100 Hz nerve stimulation was also improved by the 10.0 dose from only 54.0±5.2% in untreated animals to 72.2±5.7 ($p<0.02$). These results show a preservation of motor nerve function during early degeneration by the anti-oxidant U74006F which suggests a role for lipid peroxidation in the anterograde degeneration process.

369.14

SPINAL CORD PROTEIN IN BOVINE CEREBROSPINAL FLUID RISES IN EXPERIMENTAL ALLERGIC ENCEPHALITIS. C.F. MacPherson and L. Maxie*. Dept. of Psychiatry, Univ. of Western Ontario, London, Ont. N6G 2K3, and Univ. of Guelph, Guelph, Ont.

The anti-encephalitogenic spinal cord protein (SCP) is a normal component of bovine and human cerebrospinal fluids (CSF) and sera. (Soc. Neurosci. Abstr. 1987 13, 1686). The CSF-SCP rose in some animals that developed experimental allergic encephalitis (EAE). To ascertain 1) if the elevated SCP levels in EAE could be confirmed, and 2) if the CSF-SCP/serum-SCP ratio might be useful to monitor human demyelinating diseases, EAE was induced in three Holstein heifers with two i.c. injections of 250 mg of bovine spinal cord in complete Freund's adjuvant. Cisternal CSF was obtained every 4th day and serum every 2nd day. SCP was measured by a competitive inhibition enzyme immunoassay (EIA) using a rabbit anti-BSCP antiserum and purified BSCP. The three heifers developed severe EAE from 7 to 11 days after the 2nd injection of BSC. The average CSF total protein (TP) was elevated twofold after signs of EAE appeared. The average CSF-SCP level before EAE developed was 47 ng/mL. After EAE developed, CSP rose to 108 ng/mL in one animal. The average serum-SCP was unchanged at 645 ng/mL.

369.15

EXTENSIVE ECTOPIC DENDRITE GROWTH IS FOUND ON CORTICAL PYRAMIDAL NEURONS IN A RECENTLY DISCOVERED PUTATIVE MODEL OF TYPE C NIEMANN-PICK DISEASE IN THE CAT. **A.C. Lowenthal* and S.U. Walkley (SPON: P. Model). Dept. Neuroscience, Albert Einstein College of Medicine, Bronx, NY**

A variety of neuronal storage diseases in man and animals have been found to be characterized by ectopic dendritic sprouting. Systematic studies evaluating newly discovered models of these diseases are being pursued as a means to determine if a common metabolic defect underlies this phenomenon. Golgi staining was performed on cerebral cortex of a 10-week old kitten with a partial sphingomyelinase deficiency, and elevated levels of cholesterol, glucosyl- and lactosylceramide, sphingomyelin, and GM2 and GM3 gangliosides identical to that observed in human Niemann-Pick disease type C (D.A. Wenger, et al., unpubl.). Golgi-impregnated pyramidal cells displayed widespread and prolific growth of axon hillock neurites (dendrites), ectopic somatic spine-like processes, and rarely, spiny meganeurites. Nonpyramidal cells were normal-appearing or possessed aspiny meganeurites. The degree of ectopic neurite growth on pyramidal neurons appeared to exceed that seen in all other storage diseases in cats at this age. (NS18804)

369.16

CEREBRAL CORTEX CULTURES FROM POSTNATAL GM2 GANGLIOSIDOSIS CATS. K. Dobrenis*, J. Becker* and M.C. Rattazzi* (SPON: J. Arezzo). Dept. of Pediatrics, North Shore Univ. Hosp. - Cornell Univ. Med. Coll., Manhasset,NY 11030

In order to test enzyme and gene replacement strategies for neurodegenerative lysosomal storage disorders and investigate pathogenetic mechanisms in Tay-Sachs and Sandhoff disease, we have developed methods for culturing cerebral cortex from 2-3 day cats with genetic GM2 gangliosidosis.

Tissue is digested in hyperosmotic solution with trypsin, hyaluronidase, chondroitinase ABC and DNase I, mechanically dissociated, and centrifuged through 4% BSA. Cells are plated on polylysine + collagen in a defined medium (neurons), plus low serum (mixed cell types), or on non-coated vessels in basal medium with high serum (astrocytes). GM2 ganglioside (GM2) storage was detectable by immunofluorescence by 4 days in vitro (DIV) in marker-identified neurons and astrocytes, as well as other cell types. At 120 DIV, GM2 was present in neuronal perikarya and processes, and in meganeurite-like structures, as seen in vivo. Initial observations on astrocytes suggest alterations in growth patterns and neuritogenic properties.

This is the first time GM2 gangliosidosis neurons have been maintained in long-term culture. Our findings indicate these cultures will be useful in our studies and suggest that astroglial abnormalities may be present in GM2 gangliosidosis. Supported by NS21404-04.

PHORBOL ESTER RECEPTORS IN CEREBRAL CORTEX OF CATS WITH GM1 GANGLIOSIDOSIS. G. Shanker and H. Baker*. Dept. of Comparative Medicine, Bowman Gray School of Medicine, Winston-Salem, NC 27103.

GM1 Gangliosidosis is an inherited disease of lysosomal metabolism which is characterized clinically by severe, progressive neurological dysfunction. Lysosphingolipids inhibit protein kinase C suggesting a possible pathogenetic role in these neurological diseases. We measured Phorbol ester binding in cerebral cortex of cats with GM1 gangliosidosis (mutant) compared with age and sex matched normal siblings. Cerebral cortex homogenates were prepared and the binding of [^{3}H] phorbol-12,13-dibutyrate was assayed by the method of Raizada, et al (Neurochemical Res, 13, 51, 1988.) Binding was found to be highly specific as well as time and concentration dependent in both normal and mutant brain, but binding was greater in mutants. Sphingosine inhibited binding to approximately the same extent in normal and mutant brain. Quantitation of binding sites and affinity are in progress. Supported by NIH grant NS 10967.

NEW EXPERIMENTAL THERAPEUTIC APPROACHES IN HEPATIC ENCEPHALOPATHY INDUCED IN RATS BY GALACTOSAMINE. M.Baraldi, P.Zanoli*,^M.L.Zeneroli*,"R.A.Fano*,"R.Fante*,"G.P.Trenti ni*.Chair of Pharmacology and Pharmacognosy, Sch. of Pharm., ^III Dep. of Medicine and "Morbid Anatomy, Sch. of Med., Modena University, Italy.

Hepatic encephalopathy (HE) seems to be the result of an imbalance between an increased inhibitory and a decreased excitatory neurotransmission since GABA-a receptor complex undergoes to a denervation supersensitivity phenomenon. This finding together with the described supersensitivity to sedatives administration of patients with HE prompted us to use benzodiazepine antagonists which counteract temporarelly HE both in animals and men. Degenerative processes have been described in glia and neurons of animals and man with HE. Peripheral toxins such as ammonia could interfere in synthesis and release of metabolic and neuronal pool of glutamate and GABA. Herein we report that there is an increase of glutamate binding sites in brain areas of rats in mild stage of HE galactosamine-induced while in the severe stage there is a decrease. Thought that excitatory aminoacids might play a functional role in the hyperexcitability present in the early stage of HE and a neurotoxic effect we infused intracerebrally the isosteric antagonist of glutamate receptors APH to rats with HE. This infusion however precipitated the rats in severe stage of coma. By the contrary the use of allosteric modulator GM1 associated with NGF seems to counteract the symptoms of HE.

DEGENERATIVE DISEASE: OTHER II

NIGRAL DOPAMINE TYPE 1 RECEPTORS ARE REDUCED IN HUNTINGTON'S DISEASE. F. Filloux, M.V. Wagster, S. Folstein, J. Hedreen, T. Dawson, J. Wamsley (SPON: T. Cook) Dept. Psychiat., Univ. Utah Sch. Med., SLC, UT 84132 and Neuropath. Lab and Dept. Neurol., Johns Hopkins Univ. Sch. Med., Baltimore, MD 21205.

Intrastriatal injection of quinolinic acid has been proposed as an animal model of Huntington's disease (HD). Such neurotoxic lesions of the caudate-putamen result in marked dopamine type 1 (D1) receptor losses in the injected nucleus as well as in the ipsilateral substantia nigra reticulata. In vitro receptor autoradiography was employed with post-mortem human brain to determine whether HD results in a similar loss of nigral D1 receptors. 14 micron, slide-mounted tissue sections of SNR from 7 patients dying of HD and from 6 non-neurological-diseased controls were incubated with [^{3}H]SCH 23390 in the presence of 5 μM serotonin to label D1 dopamine receptors and with [^{3}H]forskolin to label adenylate cyclase. Autoradiograms were quantitated by computerized microdensitometry. Nigral [^{3}H]SCH 23390 binding in HD brains was reduced to 29% of control values (3.79 fmoles/mg tissue in HD brains compared with 12.93 fmoles/mg tissue in controls, $p<0.001$). There was also a moderate correlation ($r=0.78$, $p<0.001$) between [^{3}H]SCH 23390 and [^{3}H]forskolin binding. The results support the interpretation that, in the human as in the rat, neuronal degeneration in caudate and putamen is accompanied by loss of presynaptic nigral D1 receptors, and at these D1 receptors are linked to adenylate cyclase.

370.2

ALTERNATION OR CHANGE IN SOMATOSTATIN AND CHOLINE ACETYL-TRANSFERASE IN RAT BRAIN FOLLOWING QUINOLINIC ACID ADMINISTRATION INTO EACH LATERAL VENTRICLE. H. Kaneda*, Z. Susel*, O. Shirakawa*, T.N. Chase, C.A. Tamminga, (SPON. M.D. Johnson). Maryland Psychiatric Research Center, University of Maryland, Baltimore, MD 21228; NINDS, NIH, Bethesda, MD.

Central neurodegeneration, with a pattern characteristic of Huntington's chorea or Alzheimer's disease, may result from heightened levels of endogenous quinolinic acid (QA). In attempt to link elevated CNS QA with one of the neurodegenerative diseases, we have analyzed SRIF content and CAT activity after QA administration to rats in vivo using a subchronic intraventricular infusion. Eighty ug QA was administered into each lateral ventricle for 14 days. The QA infusion resulted in a significant reduction in CAT activity in the striatum (4.2 $\pm$ 0.27 moles/min/ugprot (QA) VS 5.2 $\pm$ 0.16, $p<0.05$). Subchronic QA administration followed by 2 or 4 weeks of withdrawal did not produce any significant CAT reduction. A reduction in SRIF content was not present in any of the regions. We also studied 2-deoxy-glucose utilization using the same QA administration technique. Alternations in glucose utilization will be reported. These results provide little evidence that low dose infusions of QA produces prolonged neurotoxicity. Moreover, they suggest intraventricular QA produces CAT lesions and SRIF sparing, as has been previously found with intratissue injections, reminiscent of postmortem pathology in Huntington's, not Alzheimer's disease.

370.3

THE EFFECTS OF STRIATAL QUINOLINIC ACID LESIONS AND FETAL STRIATAL TRANSPLANTS ON NADPH-DIAPHORASE AND METABOLIC ACTIVITY. M.E. Ragozzino, E.M. Zubrycki, S.Y. Lu, A.B. Norman, M.T. Shipley and P.R. Sanberg, Div. Neurosci., Depts. Psychiat. and Anat., Univ. of Cinti. Col. Med.,Cinti.,OH 45267.

It was reported that striatal quinolinic acid (QA) lesions produced similar neurochemical changes seen in Huntington's disease, with sparing of somatostatin, neuropeptide Y and NADPH-diaphorase (NADPH-d) neurons (Beal et al., Nature 321:168-171, 1986). Other investigators were unable to demonstrate selective sparing of these neurons (Davies and Roberts., Nature 327:326-328, 1987). The present study investigated NADPH-d sparing and metabolic activity in long-term striatal QA lesions and fetal striatal transplants.

Rats received bilateral injections of 150 nmol of QA into each striata. One month following lesion, transplant animals were injected with 4 ul of Day 17 fetal striatal tissue. Eight months later, alternate striatal sections were examined by Nissl staining, cytochrome oxidase (CO) for determining metabolic activity, and NADPH-d histochemistry.

CO staining was absent in the striatum of animals receiving QA lesions. These areas of diminished CO activity corresponded to areas of neuronal loss. NADPH-d neurons were seen only in areas where metabolic activity resembled normal striatum. The transplants exhibited normal CO staining even when surrounded by areas lacking CO activity. NADPH-d neurons were present in the transplant.

These results do not support a long-term sparing of NADPH-d neurons ater QA lesions as suggested by other investigators. However, they do demonstrate that striatal transplants do contain NADPH-d neurons and are metabolically active over the long-term.

CHRONIC INJECTION OF L-PYROGLUTAMATE INTO RAT STRIATUM SELECTIVELY SPARES ASPINY II NEURONS: NEUROPATHOLOGY SIMILAR TO HUNTINGTON'S DISEASE. G.K. Rieke and J. Semenya*. Dept. of Anatomical Sciences, Meharry Med.College, Nashville, TN 37208.

The neurotoxic hypothesis for Huntington's disease (HD) suggests that endogenous compounds may produce the neuropathology in HD. Recent studies of postmortem HD brains revealed a selective sparing of NADPH diaphorase positive, somatostatin-like immunoreactive aspiny neurons in the striatum. Individual toxins with possible etiological roles in HD would be expected to produce similar lesions in the striatum of rats receiving intracerebral injections of the toxin. Since HD is a long onset progressive disease and neurons are thought to be exposed over time to elevated tissue levels of the toxin(s), the neurotoxic amino acid L-pyroglutamate (L-PGA) was injected into the striatum through an implanted cannula coupled to an Alzet mini-osmotic pump. The pumps were loaded with one of three concentrations of L-PGA: 10.5, 17.6 or 45.8 mg/ml, buffered to pH=7.1 (3-13x amount of L-PGA/gr wet weight rat forebrain). Histological examination of the striatum revealed that the peripheral spongiose region of the lesion contained dis-persed NADPH diaphorase positive, somatostatin-like immunoreactive neurons. Morphologically these cells are the aspiny II neurons with a large soma, several dendrites and an asymmetrically positioned nucleus. L-pyroglutamate, like quinolinic acid, is another endogenous neurotoxin with an etiological potential in HD. The potential role of L-PGA in HD in specific families is strengthened by occurrence of increased amounts of L-PGA in the plasma of family members with HD and some of their offspring "at-risk". The potential role of L-PGA in HD needs to be more thoroughly examined. Supported by Grant No. NSF BNS-8710184 and NIH MBRS 2S06RR08037.

370.5

QUINOLINIC ACID INCREASES SOMATOSTATIN mRNA AND PEPTIDE LEVELS IN CULTURED RAT CORTICAL NEURONS. S.C. Patel*, D.N. Papachristou* and Y.C. Patel* (SPON: H.H. Zingg). Fraser Labs, McGill University, Montreal, Quebec and Newington VAMC, CT.

Striatal atrophy in Huntington's disease (HD) is characterized by selective preservation of a subclass of neurons colocalizing NADPH-diaphorase, somatostatin (SS) and neuropeptide Y (NPY) which show 3-5 fold increases in immunoreactive SS (SS LI) and NPY content. Since quinolinic acid (QUIN) is produced in excess in HD striatum, and since experimental QUIN lesions show neuronal loss with sparing of NADPH-d/SS/NPY neurons, the excitotoxin has been implicated in the pathogenesis of HD. In the present study we determined whether QUIN (a NMDA receptor agonist) stimulates SS gene transcription in cultured cortical cells (which are rich in NADPH-d/SS/NPY neurons). Cultures of dispersed fetal rat cortical cells were exposed to QUIN (1 mM) (with or without the NMDA antagonist 2-APV, 0.5 mM) and glutamate (GLU, 0.5 mM). Cells were extracted for determination of SS LI (by RIA) and SS mRNA (by Northern analysis with a cRNA probe).

	SS-LI (% of Control)	SS mRNA (% of Control)
QUIN	165 ± 8*	254 ± 12*
2-APV	89 ± 6	105 ± 11
QUIN + 2-APV	81 ± 5	122 ± 18
GLU	113 ± 6	117 ± 15

Compared to control, QUIN induced significant (*$p < 0.01$) 1.6 and 2.5 fold increases in SS LI and SS mRNA accumulation respectively which were abolished by 2-APV. By contrast, GLU was without effect on SS LI and SS mRNA. These results demonstrate a QUIN-induced selective NMDA receptor-mediated stimulation of SS gene transcription and SS biosynthesis in vitro, and suggest a similar mechanism for the augmented striatal SS LI in HD.

370.6

CELLULAR COMPOSITION OF STRIATAL PATCH AND MATRIX COMPARTMENTS IN HUNTINGTON'S DISEASE. R.J. Ferrante, N.W. Kowall, E.P. Richardson, Jr.* Mass. General Hospital, Boston, MA

We have previously demonstrated that the patch-matrix pattern, a normal feature of striatal architecture, persists in Huntington's disease (HD) striatum. The pattern is altered, however, in that the matrix zone is significantly reduced in area, while the total area of the patches is unchanged as compared to contols. In addition we have found that there is a relative preservation of immunoreactive CCK terminal fibers in patches and a reduction in matrix cytochrome oxidase activity in HD. Using combined enzyme (NADPH-d and acetylcholinesterase) and routine (cresyl violet and hematoxylin) staining to identify patch and matrix and cell types, we examined the total cell density and numbers of neurons (N), astrocytes (A), and oligodendrocytes (O) within a 0.25 mm2 area in striatal patch and matrix compartments of 6 HD brains (grade 3) and 6 age-matched controls. The dorso-ventral extent of the caudate nucleus (CN) of stained sections was divided into 4 equal areas. Patch and matrix cell counts were made in each area. In the control striatum, the total number of patch and matrix cells (patch=133±12; matrix= 140±9) and their component percentages (patch N=64%, A=15%, O=21%; matrix N=69%, A= 13%, O=18%) were not significantly different. There were no dorso-ventral differences. In HD there were no significant differences between the total cell numbers and individual cell percentages within each of the four areas defined. There was, however, a marked ventro-dorsal gradient of neuronal loss (67%) and astrocyte (280%) and oligodendrocyte (200%) increase. The vulnerability of striatal neurons in HD is not dependent upon their placement within or out of patch and matrix compartments.

370.7

TRANSFORMING GROWTH FACTOR (TGF) I IMMUNOCYTOCHEMISTRY OF HUNTINGTON'S DISEASE STRIATUM. K. Harrington*, A.C.McKee and N.W.Kowall (SPON: B. A. Eckstein). Neurology Service, Mass. General Hospital, Boston MA 02114.

Transforming growth factors are polypeptides that induce the phenotypic transformation of normal cell lines. TGF I (or alpha) shares structural features with epidermal growth factor and is expressed during early fetal development. Recently, cells synthesizing TGF I mRNA have been localized in adult mouse striatum and immunoreactive fibers have been found in rodent globus pallidus. We examined the distribution of TGF I in human striatum using a commercial antibody against TGF I (Peninsula) and standard immunoperoxidase procedures. In normal striatum TGF I is distributed in a patchy pattern surrounded by a matrix of lower intensity staining which is more prominent dorsally. Individual immunoreactive neurons are not resolved. A dense plexus of terminal staining is seen in the external segment of the globus pallidus. In Huntington's disease striatum the patch-matrix pattern is lost and dystrophic subependymal fibers are seen. Rarely, single medium sized neurons are visualized. The terminal staining pattern persists in the globus pallidus. The pattern of TGF I immunostaining strongly resembles that of enkephalin. The functional significance of TGF I in the striatopallidal enkephalinergic projection system is unknown but our findings confirm that this system degenerates in Huntington's disease.

370.8

SELECTIVE SPARING OF NEUROPEPTIDE-Y NEURONS IN HUNTINGTON'S DISEASE CEREBRAL CORTEX. M. Cudkowicz* and N.W. Kowall (SPON: C.E. Poletti). Neurology Service, Mass. General Hosp., Boston MA 02114.

It is well established that neuropeptide Y (NPY) concentrations are elevated in the basal ganglia and cerebral cortex of Huntington's disease (HD) patients. We recently showed that NPY local circuit neurons are preserved while non-phosphorylated neurofilament (SMI 32) pyramidal projection neurons are depleted in the cingulate gyrus and superior frontal cortex.To determine whether similar histological changes occur in other regions of the cerebral cortex, we examined the distribution of NPY neurons and SMI 32 neurons in the occipital cortex of 13 HD and 6 age matched control brains. Adjacent cortical sections stained with cresyl violet were normal. We quantitated the number of NPY and SMI 32 reactive neurons per cortical transverse (neurons/mm) and found no significant difference between the number of NPY neurons in the HD and control brains (unpaired t-test). The mean number of NPY neurons in the occipital cortex of control brains was 35.95 ± 1.81/mm compared to 38.03 ± 2.43/mm in HD. In contrast, the number of SMI 32 immunoreactive neurons was significantly reduced in the occipital cortex in HD. The mean number of SMI 32 positive neurons fell from 27.33 ± 1.93/mm to 19.50 ± 2.20/mm (p=.04). Our findings show that NPY immunoreactive local circuit neurons are spared in HD occipital cortex while SMI 32 pyramidal projection neurons are depleted. The resistance of NPY neurons to degeneration in HD cortex supports the possibility that an glutamate-like excitotoxin is responsible for the pathogenesis of neuronal degeneration in HD.

370.9

DEGENERATIVE AND REGENERATIVE CHANGES ARE FOUND IN HUNTINGTON'S DISEASE STRIATUM WITH NEUROFILAMENT AND NEURAL CELL ADHESION MOLECULE (NCAM) HISTOCHEMISTRY. N.W.Kowall and A.C. McKee, Neurology Service and Dept. Neuropathology, Mass. General Hospital, Boston MA 02114.

Golgi studies have shown dendritic degeneration and regeneration in Huntington's disease (HD) striatum. We used histochemical markers of somatodendritic (non-phosphorylated neurofilament antibody, SMI 32) and axonal (phosphorylated antibody, SMI 31) compartments and axonal growth cones (NCAM, courtesy of Dr. K.S. Kosik) to further investigate this phenomena. SMI 32 labelled many medium sized neurons scattered throughout the normal striatum. In HD the density of SMI 32 positive neurons decreased dramatically and remaining neurons showed dendritic proliferation, tortuosity and fragmentation most pronounced in the subependymal zone. Dendritic spines and growth cone-like filopodia, not apparent normally, were evident. SMI 31 labelled thin, uniform fibers in normal striatum which increased in density in HD and became more coarse, shorter and fragmented. NCAM immunoreactivity in normal striatum was more dense in the striatal matrix compartment. In HD striatum, many short thread-like processes were seen most prominently in the subependymal zone. Our findings show that neurons and axonal fibers degenerate in HD in conjunction with aberrant proliferation of both dendrites and axons.

CYTOPATHOLOGICAL FEATURES,UBIQUITIN,AND HEAT-SHOCK PROTEINS IN AMYOTROPHIC LATERAL SLEROSIS P.N.Leigh,O.Garofalo,P.G.E.Kennedy*,G.B.Clements*, J.Martin,M.Swash,and B.H.Anderton.Departments of Neurology and Neuroscience,Institute of Psychiatry, and Department of Neurology,The London Hospital,London;and*Department of Neurology,Institute of Neurological Sciences,Glasgow,U.K.(SPON: BRA)

Antibodies to ubiquitin detect characteristic neuronal inclusions in vulnerable neurons in ALS. The aims of this study were(1)to clarify the relationship between ubiquitin-immunoreactive(Ub-IR) inclusions and inclusions identified by conventional stains,and (2) to investigate the localisation of other heat shock proteins (HSPs) in damaged anterior horn cells in ALS.Serial sections from ALS and control cases were labelled with affinity-purified ubiquitin antibody,monoclonal antibodies to HSPs, or stained by haematoxylin and eosin.Ub-IR inclusions were associated with a wide range of cytological abnormalities,such as loss of Nissl substance(but not true chromatolysis),small 1-4μm eosinophilic inclusions(Bunina bodies),and large eosinophilic inclusions(Lewy-like bodies)as well as ill-defined vacuolar areas. HSP antibodies did not label neuronal inclusions in ALS.We conclude that Ub-IR inclusions reflect abnormal protein breakdown in damaged neurons.

370.11

INCREASED NUMBERS OF ALZ-50 REACTIVE NEURONS MAY PRECEDE SENILE PLAQUE (SP) FORMATION IN DOWN'S SYNDROME (DS).
D. Larry Sparks and John C. Hunsaker, III* Sanders-Brown Center on Aging, Depts. of Pathology and Neurology, Univ. KY Med. Center; and Kentucky Medical Examiner's Program, Lexington KY 40536.

In contrast to SIDS infants (Sparks et al., A.A. Forensic Sci., 1989), no more ALZ-50 reactive neurons are found in Down's infants than control infants (Wolozin et al. PNAS, 1988). We have studied 10 controls: 3 between 10 and 15 mos. of age; 4 between 5 and 27 yrs; and 3 subjects between 5 and 27 yrs dying after being in coma. 3 DS patients between 1 and 25 yrs of age were investigated. Sections of parahippocampal gyrus were processed with ALZ-50 antibody; adjacent tissue was stained by the Bielschowsky method.

ALZ-50 reactive neuron density was similar in control and Down's infants, each absent Bielschowsky positive pathology. No ALZ-50 or Bielschowsky positive features were observed in either the control group or in the coma cases. ALZ-50 reactive neurons were found without SP in a 19 yr old DS patient. Abundant ALZ-50 positive neurons were found with diffuse form SP in a 25 yr old DS patient. The data indicate the presence of ALZ-50 reactive neurons may antedate SP formation in Down's syndrome.

370.12

ABSENCE OF AMYLOID IN NEURITIC PLAQUES IN YOUNG CASES OF DOWN'S SYNDROME. R.C. Switzer III, S.K. Campbell* and A.P. Osmand*+. R.H. Cole Neuroscience Lab., Depts. of Pathology and Medicine+, Univ. of Tennessee Med. Ctr., Knoxville, TN 37920.

The cortical neuritic plaques that characterize and are diagnostic of Alzheimer's Disease (AD) are also found in virtually all cases of Down's Syndrome (DS) that are 35 years of age or older. Inexplicably, few cases of DS in their 20s have been examined neuropathologically. It is in this age range of DS that we find evidence that contradicts the commonly held conception that the pathological changes of the neurites in neuritic plaques are accompanied by the presence of amyloid. Using a highly sensitive silver stain (Soc. Neurosci. Abstr., 13(1): 678), as well as standard Thioflavin-S (TS) and Congo red (CR) staining techniques on freeze-cut sections, we examined two DS cases ages 21 and 24 yrs. and compared them with 17 and 59 yr old DS cases. No plaques were found in the 17 yr old with any method. In the 21 and 24 yr old cases, argyrophilic plaques were abundant, but no plaques were revealed by the TS or CR methods. In the 59 yr old case, plaques were readily demonstrated by each method, and appeared indistinguishable from those seen in AD. In AD cases, careful comparison of adjacent sections revealed that fewer plaques stained with TS than with silver. These results indicate that advanced neuritic plaque formation can occur in the absence of detectable amyloid. If a plaque is less of a neurophysiologic perturbation without amyloid, then strategies to prevent amyloid deposition could be of value in the treatment of both AD and DS.

370.13

TREATMENT OF BRAIN TUMORS BY CHLORAMBUCIL-TERTIARY BUTYL ESTER (TBC). N.H. Greig*, S. Genka*, H.U. Shetty*, T.T. Soncrant, V. John*, I. Lieberburg*, and S.I. Rapoport. (SPON: C.R. Lake) Laboratory of Neurosciences, NIA, NIH, Bethesda, MD 20892, and Athena Neurosciences, Inc., S. San Francisco, CA 94080

We have developed a lipophilic derivative, TBC, of the widely used anticancer alkylating drug chlorambucil for the treatment of brain tumors. TBC reaches and maintains high concentrations in brain and possesses intrinsic alkylating activity. Following its i.v. administration to rats, TBC (13 mg/kg) achieves a brain/plasma concentration versus time ratio of approximately 30. This compares favorably with a ratio of 0.02 for chlorambucil. Pharmacokinetic studies have demonstrated that TBC remains primarily unaltered in brain, and is metabolized to chlorambucil and phenylacetic mustard systemically. In vitro studies indicate that the rate of metabolism is species-dependent. Additionally, TBC has demonstrated significant anticancer activity against intracerebral implants of Walker 256 carcinosarcoma tumor in rats. Median survival time was increased to 175% of controls, which is significantly greater than that achieved after chlorambucil. Further, quantitation of brain tumor size has demonstrated that TBC causes in excess of 90% inhibition of intracerebral tumor growth. Preclinical pharmacology is presently being undertaken to develop the agent for clinical testing.

370.14

HYDROXYL RADICAL ADDUCTS OF DOPAMINE ARE POTENT INHIBITORS OF ARYLSULFATASE-C. T.A. CAWLEY, JR and T.J. SHICKLEY, Dept. of Pharmacology and Toxicology, Philadelphia College of Pharmacy and Science, Philadelphia, PA. 19104

It has been previously shown that dopamine (DA) is subject to attack by hydroxyl radicals to form a mixture of three possible ring-monohydroxylated products. The products: 2-hydroxydopamine (2OHDA), 5-hydroxydopamine (5OHDA) and 6-hydroxydopamine (6OHDA) are formed in a ratio of 3:2:1.

Arylsulfatases (EC 3.1.6.1) occur in nature in three distinct forms: A/B and C (ARS-C). The deficiency or absence of one or more of the arylsulfatases results in metachromatic leukodystrophy (MLD), a progressive demyelinating disease. In one form of MLD a schizophreniform behavior has been observed.

This laboratory has reported that DA as well as the DA agonist, apomorphine inhibit ARS-C (Soc. Neurosci. Abstr. (14)2 p.1075, 1988). In the present study we examine the effects of three ring-monohydroxylated adducts of DA on ARS-C activity to determine the potential role of free-radicals on inhibition of arylsulfatases.

Partially purified ARS-C (Sigma, S-1629) activity was assayed spectrophotometrically using p-nitrophenyl sulfate (p-NPS) as substrate by measuring enzymatically liberated p-nitrophenol. Inhibition was analyzed by varying DA-adduct concentration in the presence of fixed concentrations of p-NPS.

Analysis of inhibition revealed the following K_i(app): 6OHDA=10uM, 2OHDA=25uM, 5OHDA=55uM and DA=350uM. Kinetic studies disclosed the inhibition for all compounds to fit a model for simple competitive inhibition.

These results suggest a potential role of free-radicals in the generation of inhibitors of arylsulfatases which may have relevance in the heterogeneity of schizophrenia and other neuro-degenerative disorders.

(Supported by USPHS Grant NS-26040 to TJS)

HUMAN AND EXPERIMENTAL NEUROAXONAL DYSTROPHY: PRESENCE OF UBIQUITIN IN DYSTROPHIC AXONS. E. Cochran*, A. Patton*, B. Bacci*, T. Mizutani*, L. Autilio-Gambetti, and P. Gambetti. Division of Neuropathology, Case Western Reserve University, Cleveland, OH 44106.

Ubiquitin, a protein involved in intracellular proteolysis, has recently been demonstrated in a variety of non-membrane bound filamentous cytoplasmic inclusions such as neurofibrillary tangles, Pick bodies, and Lewy bodies. We now report the presence of ubiquitin in dystrophic axons of a case of infantile neuroaxonal dystrophy (IND) as well as of rats intoxicated with p-bromophenylacetylurea (BPAU), which induces the formation of dystrophic axons in the central nervous system following chronic intraperitoneal injection. Immunohistochemistry of the case of IND with antiserum to ubiquitin showed specific and intense staining of numerous dystrophic axons in the nucleus cuneatus, nucleus of the spinal trigeminal nerve, tractus solitarius and dorsal motor nucleus of the vagus nerve. In the BPAU-intoxicated rats, the dystrophic axons present in the nuclei and fasciculi cuneatus and gracilis, nucleus and tract of spinal trigeminal nerve and nucleus dorsalis of Clarke were also immunostained with antiserum to ubiquitin. Immunoelectron microscopy performed in both conditions confirmed that ubiquitin is present in various structures contained within the dystrophic axons as well as in axons and dendrites that appear normal. The presence of ubiquitin in axons and dendrites suggests that the ubiquitin system is active not only in the neuronal cell body but also in its processes.

IMMUNOCYTOCHEMICAL DEMONSTRATION OF ANTIOXIDANT ENZYMES IN THE NERVOUS SYSTEM
F. J. Denaro, UCSD Med Ct, San Diego Ca. and J. S. Schneider, Hahnemann Univ. Phil., Pa

The superoxide anion and other reactive intermediaries, pose a constant threat to biological systems. Extensive biochemical evidence demonstrates that all aerobic organisms contain enzymes which protect the cells against such destructive agents. Crucial to such a protection system are the enzymes Superoxide Dismutase (SOD), Catalase (Cat), and Glutathione Peroxidase (GPX). However, biochemistry can only give a partial picture of the variation in cellular enzyme concentration. Anatomical relationships cannot be revealed by that approach. Yet, such information is key to our understanding of oxidative stress in the CNS. Immunocytochemical evidence is now accumulating on the cellular distribution of these enzymes. Immunocytochemistry has shown a considerable variation in the distribution and concentration of these enzymes among cell types. This fact, together with the other biological importance of these enzymes suggests a possible new cell classification.

370.17

THE RELATIVE INCIDENCE OF ECTOPIC DENDRITE GROWTH ON CORTICAL PYRAMIDAL CELLS VARIES WIDELY IN DIFFERENT NEURONAL STORAGE DISEASES AND MAY BE CORRELATED WITH THE PRESENCE OF GM2 AND/OR GM3 GANGLIOSIDES. S.U. Walkley. Dept. Neuroscience, Rose F. Kennedy Center, Albert Einstein College of Medicine, Bronx, NY 10461

An explanation for the occurrence of the ectopic dendritogenesis which characterizes certain neurons in neuronal storage diseases remains unknown. The availability of a large variety of these diseases in a single species (cat) has allowed for comparative studies on the incidence of neurite growth relative to known biochemical defects. Golgi studies of cortical pyramidal neurons in 7 types of storage disease (GM1 and GM2 gangliosidosis, Niemann-Pick disease types A and C, mucopolysaccharidosis type I, and inherited and swainsonine-induced α-mannosidosis) were evaluated for evidence of ectopic dendritogenesis. At end-stage disease, GM2 gangliosidosis cats revealed the greatest incidence of neurite growth and NPD type A the least. The single case of NPD type C available for study demonstrated the most significant early growth of neurites. A metabolic defect common to all of these diseases appears to be the accumulation of GM2 and GM3 gangliosides. (Supported by NS18804)

SEPARATION, CHARACTERIZATION & QUANTITATION OF CHOLINESTERASE ISOZYMES IN RAT PLASMA. A. Korenovsky*, H. Laev and S. Mahadik (SPON: M. Stanley). Div. Neurosci. NYS Psychiat. Inst., Depts Psychiat, and Biochem & Mol Biophys, P & S, Columbia U., NY, NY 10032.

Plasma cholinesterase (ChE) consists of over 15 isozymes. Reported studies have determined only 2 types of ChE activities (pseudo- and true-) by conventional assay. Levels of individual ChE isozymes can be more useful as markers for cholinergic dysfunction.

Eleven ChE isozymes were detected on slab gel by their activity with either acetylthiocholine (AcTCh) or naphthyl acetate (NA) as substrates. Enzymatic product formed by each isozyme was quantitated by densitometric scanning. Isozymes 3 & 11 (1 being the slowest to migrate) hydrolyzed AcTCh more than NA and were inhibited by BW284C51. Isozymes 1, 2 & 9 hydrolyzed NA more than AcTCh and were inhibited by IsoOMPA. Other minor isozymes showed similar activities with both substrates and were inhibited by IsoOMPA. Isozymes 3 & 11 hydrolyzed NA more (62 & 38% respectively) in presence than in absence of IsoOMPA. The densitometric area of enzymatic product formed by each isozyme was linear with increasing levels of plasma (10-60ul). Using known amounts of standard ChE (horse ChE, Sigma) each isozyme activity was determined. Levels of isozymes remained stable with repeated bleeding but varied (up to 100%) among animals. Quantitative slab gel electrophoresis procedures are applicable for determining changes in individual ChE isozymes.

370.19

HUMAN BRAIN TUMORS HAVE ALTERED PHORBOL ESTER BINDING CAPACITY. F. Battaini, A. Leggio*, S. Govoni*~, L. Frattola*~, I. Apollonio*~, C. Ferrarese~, R. Piolti*~ and M. Trabucchi*. II Univ. of Rome, Dept. Exp. Med. and Bioch. Sci., Chair Toxicol; ~ Univ. of Bari, Dept. of Pharmacobiology; ~ Dept. of Neurology, S. Gerardo Hospital, Monza, Italy.

Increasing evidence points to the involvement of protein Kinase C (PKC) in tumor cell growth; cells with an umbalanced expression of PKC show in vitro altered growth and in vivo tumorigenicity. We have studied PKC expression by means of the binding of 3H-phorbol 12,13 dibutyrate (3H-PdBu) in human brain normal tissue taken from patients operated on for aneurysma and in tumors removed during surgery for cerebral neoplasia. Normal white matter has less than 50% 3H-PBu binding capacity in comparison to gray matter (59.4 versus 136.4 pmoles/mg prot). Glioblastoma and astrocytoma have a lower 3H-PdBu binding capacity (27.9 and 21.1 pmoles/mg protein respectively) in comparison to normal white matter. Tumors of non glial origin, such as meningioma and neurilemmoma, have even less availability of binding sites (12.8 and 11.4 pmol/mg prot). Metastatic specimens have the lowest binding capacity (8.7 pmol/mg prot). No significant modification was observed in all specimens in 3H-PdBu affinity parameters being all in the 10-20 nM range. The data indicate the possibility of an unbalance of the regulatory domain of PKC in brain tumors with possible influence on the catalytic enzymatic function. Moreover considering that PKC exert a negative control on Epidermal Growth Factor receptors (EGFR), our observation may be related to previously reported data on EGFR overexpression in brain tumors.
The results support the importance and the involvement of PKC in the process of malignant brain cell transformation.

DEGENERATIVE DISEASE: PARKINSON'S III

TIME-SERIES ANALYSES OF PARKINSONIAN RESTING TREMOR. C.J. Hunker*, G.E. MacLeod*, and J.H. Abbs (SPON: R. Sufit) Speech and Motor Control Labs, Waisman Center, Univ. Wisconsin, Madison, WI 53705

Hunker & Abbs (1983, 1988) observed uniform average resting tremor frequencies in the lip, jaw, tongue, and finger. However, cross-correlations yielded insignificant coefficients. It was proposed that the CNS may have a somatotopically organized pacemaker commonly activated but independently effecting parkinsonian tremor. From this prospective, the stochastic properties of resting tremor recorded simultaneously from the index fingers and the lower lip of seven subjects were examined. Frequency histograms showed identical, dominant frequencies at each recording site in the same subject, with remaining values densely distributed around this central frequency. The distribution pattern was different for each body part denoting the subtle independent fluctuations in tremor period; the auto- and cross-correlations documented the overall constancy of the tremor frequency as well as the independent shifts in period, respectively. The peak-to-peak amplitudes varied considerably across structures. For some sites, the amplitudes were concentrated around a structure-specific central value, while for others the amplitude distribution decreased monotonically. A tremor amplitude trend analysis at each site indicated that adjacent observations were not independent; rather, there were structure-specific amplitude sequences of variable duration.

Parkinsonian resting tremor is a narrow band, randomly ordered phenomena. While the dominant frequency is invariant across structures, the tremor period independently fluctuates at each site. The peak-to-peak amplitude of the tremor waveform is unrelated across structures as are the modulated amplitude sequences. Resting tremor appears to be a continuous process variably adjusted by an underlying second process. These results support a hypothesized somatotopically organized tremor pacemaker, a related but independently functioning source for each tremorous structure. (NIH Grants NS-13274, HD-03352)

371.2

QUANTIFICATION OF POSTURAL STABILITY IN PARKINSON'S DISEASE. S. Glatt*, J. Wash*, S. Cho*, M. Melnick, R. Dubinsky*, J. Redford* and W. Koller. Center on Aging, University of Kansas Med Ctr., Kansas City, KS 66103

Assessment of efficacy of dopaminergic agonists in Parkinson's disease (PD) are dependent on subjective evaluation. While therapy results in decreased bradykinesia and improved gait, the effect of dopaminergics on postural stability is unclear. We have developed a quantitative method to measure postural stability using a force platform (AMTI, Newton, MA) which can measure forces in three orthogonal planes and movements about these axes to calculate position of the center of pressure (CP). The area traversed by CP during quiet standing was measured in 11 young control subjects (YNS) (age 26.1 ± 3.4 yrs), 7 elderly controls (ENS) (age 62.0 ± 6.3) and 35 patients with PD for 15 seconds. Patients were stratified according to Hoehn and Yahr stage. There were 14 patients in stage 1 (PT 1) (age 68.3 ± 10.2), 12 in stage 2 (PT 2) (age G5.2 ± 7.1) and 9 in stage 3 (PT 3) (age 68.0 ± 11.4). Mean area measurements in cm^2 were YNS 1.280 ± .46, ENS 1.62 ± .394, PTI 1.603 ± .307 PT2 2.356 ± .931, and PT3 4.239 ± .967. Significant differences were seen between PT3 and YNS, ENS and PT1. The data from this pilot study suggest that this method can be used to quantify postural stability in PD and that instability increases with disease severity.

371.3

PRIMING METHOD AND REACTION TIME IN PARKINSON'S DISEASE. F. Viallet, M. Borg, E. Legallet and E. Trouche. LNF 3, CNRS, 13402 Marseille Cedex 9, France.

The priming method consists of introducing a probabilistic bias between two possible stimulus-triggered motor responses : one (frequent) stimulus (75 % of the trials) induced the so-called "primed response", whereas the other (rare) stimulus (25 % of the trials) triggered a non primed response. This procedure was adapted here to a pointing task. A luminous stimulus constituting the target could be placed in either the "primed" (75 %) or the "non-primed" position (25 %), the choice being between two possible trajectories with different amplitudes (large vs small) which were successively and alternately primed. Eleven parkinsonians undergoing therapy were compared with ten age-matched controls. In general, the RTs were significantly longer in the patients. In normal subjects, the RTs of non-primed responses were significantly and constantly longer than those of the primed ones. In parkinsonians, the same pattern was observed with some differences depending on the series : the priming effect increased in the RTs preceding the large trajectory, whereas it decreased in the RTs preceding the small one. These data suggest that the cognitive processes detecting a probabilistic bias in a choice RT task seem to be partly preserved, depending on the amplitude of the forthcoming movement.

DIFFERING TIME COURSES OF DOPAMINERGIC STIMULATION AND CLINICAL EFFECTS IN PARKINSONISM. S.T. Gancher*, W.R. Woodward, J.G. Nutt, B. Boucher* Dept. Neurol. & Biochem., Oregon Health Sciences University, Portland, OR 97201

The pharmacological basis of the acute response to dopaminergic stimulation in parkinsonism is not completely understood. While it is generally assumed that the clinical response reflects concurrent dopaminergic stimulation, it is also possible that receptor activation initiates events that outlast receptor occupancy. To distinguish between these two possibilities, we administered ineffective and effective doses of the dopamine agonist, apomorphine, to parkinsonian patients and monitored clinical responses and plasma drug levels. The response to an effective dose was divided into a suprathreshold phase, the period while plasma drug levels exceeded peak ineffective levels, and a persistence phase, the period after plasma drug levels had fallen below peak ineffective levels. Greater than 75% of the response occurred during the persistence phase. Since apomorphine rapidly diffuses into brain and is not stored, we conclude that the clinical effects are triggered by but do not require continued receptor stimulation. MODULATION OF THE STRETCH REFLEX DURING SINUSOIDAL TRACKING IN PARKINSONISM. M. Johnson*, A. Kipnis*, M. Lee*, T.J. Ebner (SPON: D. Knopman). Depts. Neurosurgery and Neurology, Univ. of MN, EMPI, Mpls., MN 55455.

Disordered sequencing of reflex activity during reciprocating volitional wrist movement was hypothesized to underlie bradykinesia. For 14 Parkinson's and 10 age matched normal subjects, a visually tracked sinusoidal wrist movement was perturbed with a torque transient at 0,90,180,270°. Reflex EMG, volitional EMG, and deflections were recorded. Indices reflecting the ratio of EMG magnitude during phases of tracking produced by homonymous muscle shortening (assisting movement) and lengthening (braking movement) were derived for the volitional and reflex EMG. Indices of reflex and volitional EMG coactivation were also computed. A decrease in extensor reflex assistive/braking (A/B) ratio was found in the Parkinson group (T-test, $p < 0.015$). The parkinsonian patients demonstrate primary defects in reflex modulation in extensors (n=8), flexors (n=3), or both (n=3). The assumption that flexor or extensor reflex defects contribute to bradykinesia is supported by an A/B index comparison ($p < 0.001$). Volitional EMG modulation and coactivation indices show no significant differences between groups. Shift of reflex activity into braking phases without a corresponding shift in volitional EMG occurs in parkinsonism, contributing to symptomatic bradykinesia.

371.6

MOTOR LEARNING IN PARKINSONIAN PRIMATES. C.L. Ojakangas, T.J. Ebner. Depts. Neurosurgery and Physiology, Neuroscience Grad. Prog., Univ. of MN, Mpls., MN 55455.

We have studied the motor learning strategies in primates performing visually guided two-dimensional arm movements. The animals placed a cursor using a manipulandum in target boxes under control conditions and when the relationship between hand and cursor (gain) was varied. As we showed previously, when adapting to a novel gain normal primates gradually scale velocity to the new distance the hand must travel to place the cursor in the target and the time to peak velocity remains constant. In primates receiving a unilateral internal carotid injection of MPTP, velocity profiles were frequently not bell-shaped, even after adaptation. Maximum velocities decreased in relation to normal for all gains ($p < .025$), but did not vary proportionately with distance. Total movement duration increased for all conditions ($p < .001$) as did reaction times for most conditions. Time until peak velocity was not held constant when the animal was subjected to a new gain. Results indicate that the parkinsonian primates utilize a different motor learning strategy than normal primates. A fundamental deficit is seen in scaling velocity to movement distance during the initial phase of movement. Instead, the strategy involves slower velocities and a prolonged deceleration phase during which visual feedback control is available. Supported by NSF/BNS-8707572 and NIH/NS-18338.

KAINIC ACID LESIONS IN THE PONTINE TEGMENTUM CAUSE DISTANT LESIONS OF THE SUBSTANIA NIGRA THAT ARE ATTENUATED BY MK-801. M. Mintz, B.J. Knowlton and A.J. Annala. Dept. of Psychology, Univ. of Southern California, Los Angeles, CA 90089.

In 8 rats lesions in the left pontine reticular formation were made by injection of 1.5 nmol/ul kainic acid. Three of these rats were treated with 5mg/kg MK-801 (MK), an NMDA receptor antagonist, 1/2 hr before injection. All rats that did not receive MK showed twisted posture to the left noted from the time of recovery from anesthetic after injection. After 3 weeks, the rats were sacrificed, their brains fixed, sectioned through the pons and midbrain, and stained with cresyl violet. Areas of sections of left and right substania nigra (SN) were computed for each rat by 2 observers, one unbiased, with good correlation between them. The region of cell loss and gliosis at the injection site was confined to the pontine reticular formation, 1-2 mm caudal to SN. Among rats not receiving MK, the left SN was significantly smaller than the right (correlated t-test, $t=4.742$, $df=4$, $p<.01$). The rats receiving MK did not show a significant difference between left and right($t=.063$, $df=2$). The left-right differences were significantly lower for the MK group ($t=3.396$, $df=6$, $p<.02$). These results suggest that SN cell death in Parkinsonism could be related to the NMDA receptor.

RELATIONSHIP BETWEEN SEVERITY OF SYMPTOMS OF PARKINSON PATIENTS AND CONCENTRATIONS OF *pros*-METHYLIMIDAZOLEACETIC ACID IN LUMBAR CSF. J. P. Green, G. D. Prell, J. K. Khandelwal*, and R. S. Burns* (SPON: J. Thornborough) Dept. Pharmacology, Mount Sinai School of Medicine, CUNY, New York, NY 10029 and Section on Experimental Therapeutics, NIMH, Bethesda, MD 20205

Patients who met clinical criteria for Parkinson's disease (57.9±9.3 SD years old; n=13) and healthy controls (63.3±4.0 SD years old; n=9) gave informed consent for participation in the study. Severity of Parkinson symptoms of all patients was rated by a single observer using the Columbia University Rating Scale (CURS) and the Hoehn-Yahr Rating Scale (HYRS). Many patients had not received L-DOPA in the past; all but one had been drug-free for at least six months. All subjects were on a diet low in monoamines; they were fasted and recumbent from midnight until 9 am when lumbar punctures were performed. Aliquots (14-17th ml) were collected and immediately frozen. Concentrations of *pros*-methylimidazoleacetic acid (p-MIAA) were measured by gas chromatography-mass spectrometry. There was a strong positive correlation between scores on the CURS and levels of p-MIAA in CSF from all patients together (Spearman's $\rho = 0.749$, $p < 0.005$) and males and females analyzed separately. There was a significant correlation ($\rho = 0.67$, $p < 0.02$) between scores rated on CURS and HYRS. However, mean (±SEM) levels of p-MIAA (pmol/ml) from controls (61.1±10.9) and patients with Parkinson's disease (50.6±7.2) were not significantly different ($t=0.8$, $p > 0.1$). The data suggest that levels of p-MIAA, while not pathognomonic of Parkinson's disease, may be associated with the severity of its symptoms. Since levels of p-MIAA in brain are raised by administration of *pros*-methylhistidine (p-MeHis) (J. Neurochem. 52: 561, 1989), a normal component of diet, it is possible that increased p-MIAA in CSF is reflective of p-MeHis or another substance derived from diet. Alternatively, it may reflect aberrant metabolism of an endogenous substance such as free p-MeHis or its conjugate, anserine. [Supported by NIMH grant 31805.]

LEWY BODIES AND EXTRAPERIKARYAL OVOID BODIES IN STRIATONIGRAL DEGENERATION AND PARKINSON'S DISEASE.
T. Yamada*, H. Akiyama*, S. Itagaki* and P.L. McGeer.
(SPON: J.G. Sinclair). Kinsmen Lab. of Neurol. Res., Univ. British Columbia, 2255 Wesbrook Mall, Vancouver, B.C., V6T 1W5, Canada.

Striatonigral degeneration (SND) often produces symptoms indistinguishable from parkinsonism (PD) although the pathology is much more widespread, especially in the striatum. We describe similar pathological features in the substantia nigra (SN) in a case of SND and several cases of PD. In common with PD cases, the SND case showed loss of melanin containing cells. HLA-DR positive reactive microglia were plentiful in the SN in both conditions. Lewy bodies in melanin-containing neurons were also a common finding. These stained positively for tyrosine hydroxylase (TH) and microtubule associated proteins (MAPs). In addition, a previously undescribed pathological entity was found in both conditions. Ovoid structures, up to 7.5 µm in diameter and up to 15 µm in length, were scattered in the neuropil. These bodies are difficult to see by conventional histological methods, lack nuclei but also stained positively for TH and MAPs. They would therefore appear to be swollen neurites, at least some of which are associated with catecholamine neurons. Both types of abnormal bodies stained positively with antibodies to several components of the complement system, indicating they were undergoing degeneration.

THE ROLE OF S-ADENOSYL-METHIONINE IN CHRONIC L-DOPA ADMINISTRATION. B. Crowell,Jr.; R. Benson* and C.G. Charlton. Dept. of Physiology, Meharry Medical College, Nashville, TN 37208.

When injected in the brain S-adenosyl-methionine (SAM) caused Parkinson's Disease (PD)-like symptoms. This suggests that excesses of SAM-dependent methylation may be involved in PD and that the success of l-dopa therapy in PD may be due to the ability of l-dopa to deplete SAM. This will concomitantly increase the synthesis of SAM. It follows that the lack of efficacy from prolonged l-dopa therapy may be due to an increase in the activity of methionine-adenosyl transferase (MAT), the enzyme that synthesizes SAM from methionine and ATP. We tested this hypothesis by administering l-dopa and studying its effects on MAT in the liver and the brain of rats and on the SAM-induced motor abnormalities. Rats were chronically treated with 100mg/kg or 500mg/kg of l-dopa or with saline before sacrificed for enzymatic assay or challenged with SAM.

The results showed that about 73% and 53% of the activity of MAT was in the insoluble fraction of the brain and liver, respectively. L-dopa increased the activity of MAT in the brain by 32% in the 100mg/kg and 37% in the 500mg/kg as compared to the saline treated rats. No significant changes occurred in the liver. As contrast to acute l-dopa (Charlton and Way, 1978) the chronic l-dopa did not significantly alter the SAM-induced motor abnormalities. The decreased efficacy of chronic l-dopa in PD may be explained by an increased MAT activity, which will increase SAM. SAM will react with l-dopa to produce 3-O-methyldopa. This may further explain the high plasma levels of 3-O-methyldopa observed in l-dopa treated PD patients, especially those exhibiting the on-off phenomenon. If the effects of l-dopa in PD is due to its ability to reduce SAM then chronic l-dopa will offset its own effects and this explains why chronic l-dopa did not antagonize the effects of SAM.

EXCESSIVE BIOLOGICAL METHYLATION IN THE BRAIN: A POSSIBLE CAUSE OF PARKINSON'S DISEASE. C.G.Charlton, Dept. of Physiology, Meharry Medical College, Nashville, TN 37208.

Nigrostriatal degeneration, depletion of tyrosine hydroxylase (TH), dopamine, other biogenic amines and melanin are related to the symptoms of tremors, hypokinesia, rigidity and motor freezing in Parkinson's disease (PD). An increase in methylation can cause parallel changes in those biochemicals and can produce cell-damaging metabolites. Therefore, the methyl donor S-adenosyl-methionine (SAM), the limiting factor in methylation, may be involved in the genesis of PD. To test this hypothesis the effects of SAM on motor functions, neuronal degeneration and on TH were studied in the rat. The rats were cannulated for lateral ventricular injection.

SAM caused tremors, hypokinesia, rigidity, motor freezing and abnormal posture and reflexes. Tremors occurred at rest and mainly in the snout and extremities. The rats made attempts before movements were achieved and when propped remained motionless for an extended period. SAM caused damage to the caudate nucleus, septum and hippocampus and a reduction in size of and degeneration in the substantia nigra (SN). These aberrations were accompanied by a reduction in the immunoreactivity and disruption in the cellular compartments for TH in the SN.

The motor abnormalities caused by SAM are physiologically identical to those occurring in PD. The specific degeneration in the SN and the depletion of TH, the synthesis enzyme for dopamine, also parallel the neurological findings in PD. This study and other evidence showed that excesses of SAM-dependent biological methylation in the brain can cause the cascade of reactions that may result in PD and probably other degenerative neurological disorders, depending on the sensitivity of the cellular and molecular substrates for methylation.

ENKEPHALIN AND NEUROPEPTIDE Y ARE DECREASED IN ADRENAL MEDULLA OF PARKINSONIAN PATIENTS. S.L. Stoddard, J.E. Ahlskog*, D. Lucas*, D. Roddy* and S.W. Carmichael. Dept. of Anatomy, Indiana U. Sch. of Medicine, Fort Wayne, IN 46805 and Depts. of Neurology and Anatomy and GI Hormone Research Lab, Mayo Clinic, Rochester, MN 55905.

Adrenal medullary catecholamines have previously been shown to be significantly decreased both in autopsy specimens from parkinsonian individuals and in tissue collected from Parkinson's disease patients who have undergone autologous transplantation of the adrenal medulla to the caudate nucleus (Stoddard et al. *Exp. Neurol. 104*:22-27 and *104*:in press, 1989). To determine the extent of this diminished secretory capability, we measured levels of several neuropeptides in adrenal medullary tissue collected at autopsy from control (N=38) and parkinsonian (N=8) populations. [Met]enkephalin (ENK) and neuropeptide Y (NPY) were measured by radioimmunoassay. Levels of ENK were significantly less ($p=0.016$) in the parkinsonian group ($x \pm SEM = 3597 \pm 690$ ng/gm tissue) than in the control population (9754 ± 1547 ng/gm). Levels of NPY were also notably lower in the parkinsonian group, although the difference did not reach significance (2540 ± 1015 vs. $11,359 \pm 5231$ ng/gm, respectively; $p=0.068$). These results suggest that the adrenal medullary dysfunction associated with Parkinson's disease is not limited to catecholamine content alone, but also includes decreased content, and perhaps secretion, of neuropeptides.

HUMAN NEUROMELANIN: FINE CHEMICAL STRUCTURE AND CHARACTERIZATION. A Vescovi*, L Zecca*, P Traldi**, G Malanca, C Goi**, E A Parati. Neurol Inst C Besta, Milan *CNR, Milan *CNR, Padova. "Forensic pathology , Milan, Italy.

A crucial role of neuromelanin (NM) in Parkinson's disease (PD) ethiopatogenesis has been proposed In fact previous papers clearly report non covalent binding between neuromelanin and several pharmacological active molecules including both the parkinson-mimetic toxins 1-methyl-4-phenylpyridinium ion and Manganese

However, little is known about biosinthesis and chemical structure of neuromelanin and about its putative phisiological functions We report here a study on neuromelanin, performed by electron impact-mass spectrometry studies. By pyrolising NM in the ion source, the main pyrolisis products were identified by their exact masses as pyrrole, alkylcatechols, alkylphenols, 5 OH-indole, 1,4-benzothiazine; the same compounds are observed with natural and sinthetic 5-S-cysteynildopa derived pheomelanins

This comparative analisis is the first step in understanding the chemical composition of neuromelanin and in turn to clarify its biosinthetic pathway and its role in PD ethiopatogenesis

CSF FROM PARKINSON'S DISEASE PATIENTS IS CYTOTOXIC TO VENTRAL MESENCEPHALIC CULTURES AND THE SUBSTANTIA NIGRA OF THE RAT. P.M. Carvey, L.C. Kao, E.S. Lo*, H.L. Klawans*, A. Dahlstrom (1), and A. McRae (1).
Rush University, Chicago, IL, 60612; (1) U. Goteborg, Goteborg, Sweden.

The CSF of Parkinson's disease (PD) patients contains an antibody (Ab) which immunocytochemically reacts with the substantia nigra (SN) of the rat. We have previously reported that the Ab disappears in 8/9 patients exhibiting clinical improvement following adrenal medulla-to-brain transplantation. This might suggest that the Ab participates in the PD process. We examined this hypothesis in ventral mesencephalic cultures as well as in vivo.

The CSF from 3 transplant patients was incubated for 7 days with rat ventral mesencephalic cultures. Immunopositive CSF, taken at the time of transplantation, was overtly cytotoxic to the cultures resulting in a significant diminution of anti-DA immunoreactivity. In contrast, immunonegative CSF taken from the same patients 6-12 months following surgery was without effect. In a second experiment, immunopositive CSF taken from a patient with idiopathic PD or immunonegative CSF taken from a non-parkinsonian patient, was loaded into Alzet minipumps and infused for 14 days (5 ul/hr) into the rat SN (n=4 in each group). Both samples were immunoabsorbed in whole rat blood prior to infusion. Animals infused with immunopositive CSF exhibited cotraversive posturing after 5 days and ipsilateral amphetamine-induced rotations on both the 7th and 14th day of infusion. Immunonegative CSF was without effect. Although the data must be considered preliminary, it may suggest that the immunologic response to nigral degeneration in PD patients may contribute to progression of the disease and further, that the moderate improvement observed in transplant patients may result from loss of this secondary autoimmune component as a result of adrenal medulla-to-brain transplantation.

371.15

THE CSF OF PARKINSON'S DISEASE PATIENTS CONTAINS AN ANTIBODY WHICH IMMUNOCYTOCHEMICALLY REACTS WITH THE SUBSTANTIA NIGRA OF THE RAT. L.C. Kao, A. McRae (1), R.D. Penn, A. Dahlstrom (1), H.L. Klawans*, and P.M. Carvey.
Rush U.,Chicago, IL, 60612; (1) U. Goteborg, Sweden.

Although the CNS is historically considered an immunologically privileged region, many investigators have reported that neurodegenerative disorders are associated with the production of antibodies directed against the CNS. We therefore examined the CSF of Parkinson's disease (PD) patients for antibodies reacting with the substantia nigra (SN).

CSF (diluted 1:1 with tris buffer) was incubated overnight with 10 micron sections of rat SN, as well as other CNS regions, which had been perfusion fixed with allyl alcohol in a cocydylate buffer. An avidin-biotin-peroxidase reaction was employed to visualize immunocytochemical reactivity of the CSF against the CNS. Thus far, 131 patient samples with a variety of neurologic and non-neurologic diagnoses have been examined. 42 of 53 PD patients (79%) have been blindly identified from within the 131 patient series using this technique. Cell bodies are predominantly marked although processes are occasionally observed to react. Postive immunocytochemical reactivity was observed in the SN and VTA, and to a lesser extent, in the retrorubral area and striatum. 3 of 4 (75%) symptomatic MPTP patients were also immunopositive. In addition, 6 non-parkinsonian patients with movement disorders potentially involving the SN, were also immunopositive. In contrast, the CSF 68 patients with a variety of other neurologic disorders, as well as patients undergoing routine myelography were immunonegative. Taken together, this data suggests the degeneration of the SN, whatever its cause, is secondarily associated with the production of an antibody directed against DA rich regions of the brain, and further, that evaluation of this antibody may be useful as a marker for nigral degeneration.

371.16

COGNITIVE IMPAIRMENT IN PARKINSON'S DISEASE: WIDESPREAD AMYLOID PLAQUES IN THE CEREBRAL CORTEX AND CIRCUMSCRIBED NEUROFIBRILLARY CHANGES IN THE ENTORHINAL REGION. H. Braak and E.Braak. Dept. Anatomy, J.W.Goethe University, Frankfurt, Fed. Rep. Germany.

Sensitive silver methods for amyloid and neurofibrillary changes were employed to examine the cortical pathology in Parkinson's disease. Amyloid plaques were found in varying densities in most areas of the cerebral cortex while neuritic plaques were rare or absent. Neither the Ammon's horn nor the neocortex revealed a sufficiently large number of tangles to permit diagnosis of Alzheimer's disease. An abundance of tangles was found only in layer II of the entorhinal cortex. This layer gives rise to the perforant path and via this bundle information from isocortical association areas is transmitted to the hippocampal formation. The affection of layer II consequently isolates the hippocampal formation. In conclusion the impairment of cognitive functions frequently seen in patients afflicted with Parkinson's disease might possibly be associated with the wide spread deposition of amyloid plaques and the severe pathological alteration of layer II of the entorhinal cortex. (Supported by the DFG).

371.17

TYROSINE HYDROXYLASE mRNA EXPRESSION IN THE SURVIVING NIGRAL DOPAMINE NEURONS IN PARKINSON'S DISEASE. F. Javoy-Agid*, E.C. Hirsch, S. Dumas*(1), J. Mallet*(1), and Y. Agid* (SPON: A. Prochiantz). U289 INSERM - Hôpital Salpêtrière - 75013 PARIS - (1) CNRS UPR11 - 91190 GIF S/YVETTE - France

Parkinson's disease (PD) is associated with a massive dopamine (DA) cell death in the substantia nigra resulting in a severe striatal DA denervation. Though an increased striatal DA turnover is observed in the surviving neurons, continuous progression of DA nerve cell death occurs in the course of the disease.

This study was undertaken to see whether the remaining nigral cells were still functionnal. Tyrosine hydroxylase (TH) messenger RNA (mRNA) was detected by in situ hybridization histochemistry using a 35-S-labelled cDNA probe complementary to TH mRNA. The level of expression of TH mRNA in TH-immunostained neurons was determined by estimating the density of grains (detected by nuclear emulsion autoradiography) over a neuron, using the computer assisted system from BIOCOM (France).

In PD, not only did the number of cells expressing TH mRNA decrease dramatically, but the cellular level of TH mRNA was markedly reduced when compared to controls. The data are compatible with immunocytochemical observations and suggest a reduced TH content in surviving cells.

EXCITATORY AMINO ACIDS: ANATOMY AND PHYSIOLOGY II

372.1

DEMONSTRATION OF PUTATIVE GLUTAMATERGIC/ASPARTATERGIC ASSOCIATIONAL CONNECTIONS IN THE OLFACTORY CORTEX OF THE RAT. L.E. White*, K.M. Carnes, & J.L. Price. Department of Anatomy & Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

Studies of excitatory phenomena (e.g. long term potentiation, seizure discharges) in the olfactory cortex suggest that excitatory amino acids play a central role in these processes. In the present study, small injections of a combined solution of ^{3}H-D-aspartate (^{3}H-D-Asp) and wheat germ agglutinin-horseradish peroxidase (WGA-HRP) were placed in the anterior piriform cortex in order to identify presumptive glutamatergic and/or aspartatergic (Glu/Asp) inputs to this region.

The findings suggest that associational projections in the olfactory cortex are Glu/Asp, with the exception of the fibers from the tenia tecta. Neurons retrogradely labeled by ^{3}H-D-Asp were primarily found in the anterior olfactory nucleus, the surrounding anterior piriform cortex, the posterior pirform cortex, the endopiriform nucleus, the anterior cortical amygdaloid nucleus, the periamygdaloid cortex, and the entorhinal cortex. In addition, small numbers of labeled cells were seen in the olfactory bulb, the agranular insular cortex, the claustrum, the magnocellular basal forebrain, the nucleus of the lateral olfactory tract, and the midline nuclear complex of the thalamus.

Fewer neurons were retrogradely labeled by ^{3}H-D-Asp than by WGA-HRP in all of the regions except the posterior piriform cortex, the endopiriform nucleus, and the midline nuclear complex of the thalamus. Except for an occasional cell, neurons in the tenia tecta, the raphe nuclei, and the locus coeruleus were labeled by WGA-HRP but not by ^{3}H-D-Asp. (Supported by NIH NS09518 and ADRC AG05681.)

372.2

ASPARTATE-LIKE IMMUNOREACTIVITY IN CELL BODIES AND TERMINALS OF PRIMARY AFFERENTS. S. De Biasi, D.J. Tracey and A. Rustioni, Cell Biol. & Anat., Univ. North Carolina, Chapel Hill NC 27599.

Glutamate (glu) and aspartate (asp) may act as excitatory transmitters within the central nervous system. We have previously demonstrated glu-like immunoreactivity in central terminals and cell bodies of primary afferents; we present evidence here that aspartate may also be a transmitter in primary afferents, using an antibody raised against asp.

For pre-embedding EM-ICC, rats were perfused with 4% carbodiimide, and 50 µm sections taken from the superficial laminae of the dorsal horn were treated with primary antibody (1:10K) which was visualised using the ABC technique. For post-embedding EM-ICC, rats were perfused with 2.5% glutaraldehyde and 0.5% paraformaldehyde, and thin sections treated with primary antibody (1:5K) which was visualised using colloidal immuno-gold particles. Electron microscopy revealed labelled terminals, including some with scalloped borders characteristic of primary afferents, indicating the presence of aspartate-like immunoreactivity.

In further experiments, rats were perfused with 4% carbodiimide followed by 4% paraformaldehyde. Cryostat sections of dorsal root ganglia were treated with primary antibody against asp (1:5K), visualised using the ABC technique. Light microscopy showed that many of the small cell bodies (20-30 µm diameter) were intensely stained. Comparison of these sections with adjacent sections treated with anti-glu showed that in most small cells, asp and glu were co-localised. Pre-absorption of the aspartate antibody with free asp blocked staining in a dose-dependent manner, while pre-absorption with glu, NAAG, and NMDA did not affect staining of primary afferent cell bodies. These data support the hypothesis that some primary afferents release aspartate as a neurotransmitter.

372.3

SPINOCERVICAL TRACT TERMINALS ARE ENRICHED IN GLUTAMATE-LIKE IMMUNOREACTIVITY: AN ANTEROGRADE TRANSPORT - QUANTITATIVE IMMUNOGOLD STUDY IN THE CAT. J. Broman*, J. Westman* and O.P. Ottersen. Department of Human Anatomy, Uppsala University, S-751 23 Uppsala, Sweden (J.B., J.W.), and Anatomical Institute, Karl Johans Gate 47, N-0162 Oslo 1, Norway (O.P.O).

The present study was undertaken to investigate the possibility that glutamate may be a neurotransmitter in the lateral cervical nucleus (LCN), and special interest was focused on spinocervical tract (SCT) terminals. To identify such terminals, WGA-HRP was injected into the spinal cord of cats. After 3-5 days survival the animals were perfused and the upper part of the spinal cord was removed. Vibratome section containing the LCN were processed with tetramethylbenzidine and H_2O_2 and embedded in Durcupan. Ultrathin sections were then cut, collected on formvar coated nickel grids and processed for immunogold labeling with an antiserum produced against glutamate-glutaraldehyde-BSA conjugate.

The density of gold particles was assessed over 104 SCT terminals and compared with the gold particle density over terminals containing flattened or pleomorphic vesicles. The gold particle density over the SCT terminals was found to be significantly higher (by a factor of 2.44) than that over the terminals containing flattened or pleomorphic vesicles. Neuronal cell bodies in the LCN were also labeled by the glutamate antiserum.

The above findings suggest that glutamate may be a transmitter in the synapses between SCT terminals and LCN neurons. The labeling of neuronal cell bodies in the LCN is more difficult to interpret because of possible interference of metabolic pools of glutamate.

372.4

TWO CLASSES OF GLUTAMATE-IMMUNOREACTIVE SYNAPTIC TERMINALS IN THE GUINEA PIG SUPERIOR OLIVARY COMPLEX. R.H. Helfert, J.M. Juiz, S.C. Bledsoe, Jr., J.M. Bonneau*, R.J. Wenthold+, and R.A. Altschuler. Kresge Hearing Research Institute, Univ. of Michigan, Ann Arbor, MI, 48109; +Lab. of Neuro-Otolaryngology, NIDCD, NIH, Bethesda, MD, 20892.

The excitatory amino acid neurotransmitter glutamate is thought to play an important role in processing auditory information in the brain stem. To provide evidence for its presence and determine its localization, colloidal gold immuno-electron microscopy was used to identify glutamate-like immunoreactivity (GLU-LI) in specific classes of synaptic terminals in two nuclei of the superior olivary complex, the lateral superior olive (LSO) and the medial nucleus of the trapezoid body (MNTB).

The synaptic terminals exhibiting the most intense GLU-LI were those that contained large, electron-lucent vesicles. A second type of terminal, which contained flattened pleomorphic vesicles, exhibited a moderate level of GLU-LI. Only background labeling was found in terminals with oval pleomorphic vesicles and those with small, round vesicles.

In previous studies we have demonstrated that, in the LSO, terminals containing flattened pleomorphic vesicles exhibit intense glycine (GLY)-LI, and that they appose postsynaptic areas immunopositive for the glycine receptor. Thus, the possibility now exists that flattened pleomorphic vesicle terminals may actually co-contain GLU and GLY as neurotransmitters and/or neuromodulators. Studies are currently in progress to determine if co-containment of GLU and GLY in these terminals does indeed occur.

COMBINATION OF D-[3H]ASP RETROGRADE LABELLING AND IMMUNOCYTOCHEMICAL DETECTION OF L-GLU AND L-ASP IN THE PAG PROJECTION TO RAPHE MAGNUS. M. MULLETT*, S. ARANEDA*, G. GHILINI*, L. WIKLUND*, AND A. BEITZ. Dept. Vet. Biol., Univ. of Minn., St. Paul, MN 55108 and Lab. Physiol. Nerv., CNRS, Gif-sur-Yvette, France.

Neuronal connections using excitatory amino acids (EAA) can be identified with selective D-[^{3}H]ASP retrograde labelling. EAAs have been proposed as putative transmitters in the periaqueductal gray (PAG)-raphe magnus (RM) projection. The present study combines D-[^{3}H]ASP retrograde labelling with immunocytochemistry (ICC) to define which EAAs are involved in this pathway. In rats, D-[^{3}H]ASP (0.01M, 50 nl) was injected into the nucleus RM. After 17 hr. survival, the perfused brains were cut on a freezing microtome. Alternate floating sections were treated for ICC with mouse anti-L-Glutamate or rabbit anti-L-Aspartate serum. The tissue was subsequently processed for autoradiography. L-GLU immunoreactivity was found in 97% of the D-[^{3}H]ASP PAG cells in GLU reacted sections, while 94% of the D-[^{3}H]ASP cells contained L-ASP immunoreactivity in alternate sections. This study shows that autoradiographic D-[^{3}H]ASP retrograde labelling can be combined with ICC detection of EAA on the same sections. EAA transmission in the PAG projection to RM has been suggested, and the present results indicate that these neurons contain L-GLU and/or L-ASP. Supported by NSF grant BNS8607520 and NIH grants DE06682 and NS19208.

RELEASE OF EXCITATORY AMINO ACIDS (EAA) IN HIPPOCAMPUS: FROM K^+- INDUCED STIMULATION OF SLICES TO ELECTRICAL STIMULATION OF PATHWAY IN ORGANOTYPIC CULTURES. K.Q.Do, F.X.Vollenweider*, Z.P.Jian-Zhang*, B.Gähwiler and M.Cuénod. Brain Research Institute, University of Zürich, Switzerland.

Release of endogenous EAA induced either by 50 mM K^+ - depolarisation in rat hippocampal slices (A) or by electrical stimulation in organotypic cultures (B) was investigated. In (B), Schaffer's collateral (SC) pathway was stimulated by monopolar field stimulation (4 Hz, 1msec/pulse, 20-40 μA, 4 min) and the population response recorded in area CA1. The perfusate was collected with a cannula, the tip of which was centered above the stratum radiatum or the pyramidal cell layer of area CA1. The released materials from (A) or (B) was analyzed by precolumn derivatization HPLC to detect amino acids at the femtomole level. In (A), K^+ increased the efflux of Glu from 5.9 ±1.7 to 536.1 ±132.0 pmol/mg /min and of Asp from 2.6 ±0.5 to 66.0 ±11.7 pmol/mg /min. In (B), the resting efflux of Glu and Asp in area CA1 ranged from 0.3 to 7 pmol/min and 0.3 to 2 pmol/min respectively. Following stimulation of SC, Glu and Asp efflux was increased by 60-600 %. These results suggest that both Glu and Asp or a precursor of these amino acids are released from synaptic terminals of the SC. Moreover, in (A) the efflux of homocysteic acid which is a NMDA receptor preferring agonist in cat striatum was also increased from 0.08 ±0.01 to 0.5 ±0.2 pmol/mg /min. The combined analysis with sensitive methods of the released material induced by K^+ in slices and by electrical stimulation of pathways in cultures has proved to be an useful approach for the search of transmitters in identified neuronal pathways.

DISTRIBUTION OF GLUTAMINASE AND GLUTAMIC ACID DECARBOXYLASE IN THE HUMAN CEREBRAL CORTEX. H. Akiyama*, T. Kaneko*#, H. Tago*, P.L. McGeer, E.G. McGeer, H. Kimura*, N. Mizuno#. (SPON: E. Manuelidis). Kinsmen Lab., Univ. British Columbia, 2255 Wesbrook Mall, Vanc., B.C. V6T 1W5, Canada, #Dept of Anatomy, Kyoto Univ. Japan.

The glutamate-glutamine cycle has been considered to play a major role in generation of transmitter glutamate as well as of γ-aminobutyric acid (GABA) precursor glutamate. Phosphate activated glutaminase (PAG) catalyses conversion of glutamine to glutamate. In GABAergic structures, the glutamate is further synthesized into GABA by glutamic acid decarboxylase (GAD). The distribution of PAG and GAD were studied immunohistochemically in postmortem human cerebral cortex. Large to medium-sized pyramidal neurons in layer III and V stained intensely for PAG, while the majority of smaller pyramidal neurons were labeled either lightly or moderately. Modified pyramids, such as Betz cells, pyramidal cells of Meynert and solitary cells of Ramón y Cajal also stained intensely for PAG. Fusiform cells in layer VI showed moderate to intense labeling. In addition, a number of non-pyramidal neurons stained moderately to intensely. Observations of GAD stained nearby sections indicated that many and perhaps PAG(+) non-pyramidal neurons were GABAergic. Together with other evidence, PAG positive projecting neurons are considered to be glutamatergic, while PAG positive interneurons are GABAergic.

HOMOCYSTEATE-LIKE IMMUNOREACTIVITY IS LOCALIZED IN CEREBELLAR CLIMBING FIBERS. P. Grandes*, M. Cuénod and P. Streit. Brain Research Institute, University of Zürich, CH-8029 Zürich, Switzerland

Homocysteate has recently been proposed as transmitter candidate in the olivocerebellar climbing fiber pathway (Cuénod et al., 1988, Exp. Brain Res. Series 17:161, also for review). To investigate this issue further, we attempted to localize this sulphur containing, excitatory amino acid by means of immunohistochemistry.

Mice were immunized with glutaraldehyde-linked homocysteate-albumin conjugates, and polyclonal antibodies were obtained in ascitic fluids. These antibodies exhibited a high specificity for homocysteate in experiments involving various aminoacid-albumin conjugates and absorption (ELISA and immunohistochemistry) as well as staining tests (conjugates embedded; sections processed together with tissue). Immunohistochemistry at the level of light microscopy was performed on semithin sections of perfusion-fixed rat cerebellar tissue by means of a silver-intensified peroxidase-antiperoxidase method (Liu et al., 1989, Histochem. 90:427).

The most conspicuous elements containing homocysteate-like immunoreactivity (HCA-LI) were terminal-like dots and beaded fibrous profiles mostly in close association with Purkinje cell perikarya and dendrites. Occasionally, small labeled elements were noticed in the granule cell layer and in the white matter. HCA-LI was totally abolished in climbing fiber deprived cerebellar cortex 10 days following treatment with 3-acetyl-pyridine. This observation in cases with a lesioned inferior olive and the immunohistochemical findings in normal tissue strongly indicate that HCA-LI is contained in a considerable population of climbing fibers projecting to hemispheres and vermis of the rat cerebellum. Additional evidence, thus, has been obtained for the role of homocysteate as a climbing fiber transmitter.

TRANSECTION OF THE OPTIC NERVE CAUSES LARGE DECREASES IN N-ACETYLASPARTYLGLUTAMATE, BUT NOT GLUTAMATE OR ASPARTATE IN SELECTED AREAS OF THE VISUAL SYSTEM IN THE RAT. L.Williamson, J.R.Moffett, D.Garrison, #A.C.Murphy, +M.Palkovits, J.H.Neale and M.A.A.Namboodiri. Department of Biology, Georgetown University, Washington, DC 20057, +Lab. of Cell Biology, NIMH and #Lab. of Cell Biology, NHLBI, NIH, Bethesda, MD 20892.

Several lines of evidence have been presented in recent years that support the hypothesis that N-acetylaspartylglutamate (NAAG) may be a transmitter of the optic tract in mammals. Glutamate has also been considered for a long time to be a transmitter of the optic system in many species. In the present study, we have determined the relative distribution of these two potential transmitters in the optic projections of the rat using the disappearance of their levels on transection as a reliable index.

The levels of NAAG, aspartate and glutamate were measured in ten selected areas of the rat visual system ten days following bilateral optic nerve transection and were compared with sham operated controls. Brain regions were microdissected by the punch technique and NAAG levels were measured by RIA (IC50: NAAG = 2.5 nM, NAA = 100 uM; smallest detectable amount = 1-2 pg/assay), while aspartate and glutamate levels were determined using an amino acid analyzer.

Large decreases (50-60%) in NAAG levels were detected in the suprachiasmatic nucleus, lateral geniculate and superior colliculus, while moderate losses (25-50%) were noted in the pretectal nucleus, nucleus of the optic tract, parietal cortex and occipital cortex 18. Little or no changes were detected in the paraventricular nucleus, pretectal area and occipital cortex 17. Also, no significant changes in glutamate or aspartate levels were detected in any of the above areas. These results support a transmitter role for NAAG but not for glutamate or aspartate in the visual system of the rat. (Supported by NIH Grant DK 37024 to MAAN and NIDA grant DA 02297 to JHN).

A POSSIBLE EXPLANATION FOR THE PURPORTED EXCITATION OF PIRIFORM CORTICAL NEURONS BY N-ACETYL-L-ASPARTYL-L-GLUTAMIC ACID (NAAG). Edward R. Whittemore and James F. Koerner. Department of Biochemistry and Neuroscience Grad. Program, Univ. of Minn., Minneapolis, MN 55455.

The excitation of piriform cortical neurons by iontophoresis of NAAG isolated from rat brain is frequently cited as major support for the possible neurotransmitter role of NAAG in the CNS (ffrench-Mullen, et al., PNAS 82 (1985) 3897). However, using synthetic NAAG, we are unable to reproduce this observation, and we offer an alternative explanation. Specifically, 23 neurons from 16 slices of rat piriform cortex which responded vigorously to iontophoresis of L-glutamate did not respond to iontophoresis of synthetic NAAG. Responses to NAAG were never observed despite extensive probing for NAAG-sensitive sites and ejection of NAAG using negative currents (10 mM NAAG in H_2O, pH=8) and positive currents (10 mM NAAG in 100 mM NaCl, pH=6.2). In contrast, iontophoresis of the potassium salt of synthetic NAAG (10 mM NAAG/20 mM KCl/100 mM NaCl), or of potassium ions (20 mM KCl/100 mM NaCl) using positive currents evoked single unit spiking. Iontophoretic responses to NAAG/K^+ and K^+ were inhibited by 200 μM L-2-amino-4-phosphonobutanoic acid (L-AP4) and desensitized rapidly, as reported previously. This suggests that residual potassium ions, remaining after the original purification, were responsible for the excitation attributed to NAAG. Supported by NIH NS 23935.

N-Acetylaspartylglutamate (NAAG): A Possible Modulator of [^{3}H]MK801 Binding in Rat Hippocampal Membranes. P.S. Puttfarcken and J.T. Coyle. Depts. of Neuroscience and Psychiatry. The Johns Hopkins School of Med., Balto., MD 21205.

Although NAAG is localized to putative glutamatergic pathways, its role as an excitatory neurotransmitter remains controversial because of variable neurophysiologic effects. The effect of NAAG on the specific binding of [^{3}H]MK801, the noncompetitive NMDA receptor antagonist, was examined in rat hippocampal membranes. To inhibit NAALADase activity, the assay was performed at 25°C in 20 mM Tris/Acetate buffer/1mM EGTA. The homogenates were incubated for 90 min with 5 nM [^{3}H]MK801; and the reaction was terminated by rapid filtration. Glutamate (GLU) has previously been reported to stimulate [^{3}H]MK801 binding by 100-200% with an IC_{50} of 250 nM. Preliminary data suggest that NAAG may be more potent, yet not as efficacious as GLU. NAAG stimulates [^{3}H]MK801 binding by approximately 40% above control levels with an IC_{50} of 50 nM. However the addition of NAAG to maximally stimulatory concentrations of GLU inhibited the augmentation of [^{3}H]MK801 binding by 55%. While N-acetyl aspartate exhibited activity in these two conditions, it was 20-fold less potent than NAAG. These results suggest that NAAG acts as a mixed agonist/antagonist at NMDA receptors.

372.12

HPLC ANALYSIS OF RADIOLABEL FOLLOWING RECEPTOR BINDING ASSAY WITH N-ACETYLASPARTYL-[3H]-GLUTAMATE REVEALS [3H]-GLUTAMATE TO BE THE BOUND ENTITY. H.M. Valivullah. Dept. of Biology, Georgetown University, Washington, D.C. 20057.

Studies of peptidase sensitivity of NAAG have called into question equilibrium binding data, which provided evidence of receptor-ligand-like interaction of radiolabeled N-acetylaspartyl-[3H]-glutamate with brain cell membranes.

Incubation (45 min, 37°C) of brain cell membranes and [^{3}H]-NAAG was followed by HPLC analysis of membrane bound radioligand. About 95% of the bound radiolabel comigrated with glutamate while only 5% comigrated with NAAG on HPLC. Assay of radioligand binding, in the presence of peptidase inhibitors, resulted in 85-95% reduction of radiolabel binding, relative to binding in the absence of peptidase inhibitor. These data suggest that speculation on the existance of high affinity binding sites for NAAG are not warranted in the absence of more rigorous analyses than previously reported. SPATIALLY RESOLVED TRANSIENT AND SUSTAINED [Ca^{2+}]i SIGNALS EVOKED BY EXCITATORY AMINO ACIDS IN CULTURED RAT HIPPOCAMPAL PYRAMIDAL NEURONS. Steven R. Glaum, Wendy K. Scholz and Richard J. Miller. Dept. Pharmacol. and Physiol. Sci., Univ. of Chicago, 947 E. 58th St., Chicago IL, 60615.

We examined $[Ca^{2+}]_i$ signals evoked by excitatory amino acids in cultures of hippocampal pyramidal neurons (see Abele et al., this volume) using a fura-2 based digital imaging technique. In HEPES/Hank's balanced salt solution, depolarization with 50mM K^+ or addition of NMDA (500μM in Mg^{2+}-free, 1μM glycine supplemented solution) increased $[Ca^{2+}]_i$ throughout the cell soma as well as in proximal and distal dendrites. Addition of glutamate (GLU, 500μM, normal medium) increased $[Ca^{2+}]_i$ primarily in the cell soma and in proximal dendrites. In Ca^{2+}-free medium, 50mM K^+ was ineffective, but GLU and caffeine (10mM) still produced a single, transient increase in $[Ca^{2+}]_i$. When challenged with GLU or NMDA more than once, cells exibited long lasting increases in $[Ca^{2+}]_i$ that persisted >20 min after drug washout. These sustained increases in $[Ca^{2+}]_i$ were due to maintained Ca^{2+} influx, as they were rapidly abolished in Ca^{2+}-free medium or reduced (25-50%) by the addition of nitrendipine (1μM) or Ni^{2+} (500μM). Tetrodotoxin (1μM), however, produced no inhibition. Replacement of extracellular Cl^- with SO_4^{2-} during and after addition of agonist prevented sustained Ca^{2+} influx, indicating that it may involve GLU-induced cell swelling. Thus GLU can differentially increase $[Ca^{2+}]_i$ in different parts of the neuron by activating both Ca^{2+} influx and mobilization from intracellular stores. Furthermore, GLU can produce long term changes in $[Ca^{2+}]_i$ that may be important for synaptic plasticity and/or excitotoxicity.

372.14

VARIATION IN GLUTAMATE RECEPTOR DENSITY IN CENTRAL NEURONS. L.O. Trussell & G.D. Fischbach. Dept. of Anatomy & Neurobiology, Washington U. Sch. of Med. 660 S. Euclid, St. Louis, MO.

Responses of NMDA (G1) and non-NMDA (G2) receptors to glutamate were examined in outside-out patches isolated from chick spinal neurons. Mg^{++}-insensitive channels of 18 pS maximal conductance were activated by 1 mM glutamate with an ensemble rise time of 1.2 msec and a rapid desensitization (τ = 2.2 msec). G1 receptors exhibited a much slower desensitization (τ > 100 ms) and a much higher agonist affinity than G2 receptors (K_d < 3 μM versus 500 μM).

G2 receptor response amplitudes varied considerably among patches, from 2 to 95 pA at -60 mV, corresponding to 2 to 110 channels/μm^2 (patch area, 0.8 μm^2). The variation in receptor density over the neuronal surface was examined in patches as well as in whole-cell ionophoretic studies. Some membrane regions exhibited G2 responses that were 5-13 fold greater than background (modal) values. These areas may contain subsynaptic clusters.

Removal of Mg^{++} block of G1 receptors in patches increased the steady-state glutamate current 6-fold. Taking this added current as a measure of G1 activity, we found a direct relation between G1 and G2 currents. However, the estimated number of active G2 receptors varied from 2 to 88, while G1 receptors in the patches varied only from 0 to 5. Thus, either G1 receptors have a lower opening probabililty than G2 receptors or are present at much lower density. Furthermore, the distribution of G1 receptors is apparently more uniform than that of G2 receptors.

GLUTAMATE AND GABA RECEPTORS ON BASAL FOREBRAIN NEURONS IN TISSUE CULTURE. A.A. Khan and R.W. Baughman. Department of Neurobiology, Harvard Medical School, Boston MA 02115.

The basal forebrain receives descending glutaminergic input from neocortex and gabaergic input from local circuit neurons. Cholinergic basal forebrain neurons are selectively damaged in some neurodegenerative diseases, and they are very sensitive to excitotoxins. We investigated the excitatory and inhibitory receptor profile of large (20-40 um) basal forebrain neurons in tissue cultures prepared from 8-10 day-old Long-Evans rat pups. Neurons were enzymatically dissociated (Baughman and Huettner '86) and plated on glial feeder layers. Whole-cell-patch voltage clamp recordings were made from cells in cultures 20-40 days old. The medium contained 0.5 μM TTX, 1 μM Gly and no added Mg^{2+}. Pipettes 1-1.5 μm ID were used for pressure application of glutamate, kainate, quisqualate, NMDA and Gaba. Kainate (20 μM-1.0 mM), quisqualate (1-50 μM) and NMDA (50 μM-1.0 mM) produced inward currents; the kainate and quisqualate responses were blocked by CNQX (20 μM), and the NMDA response was blocked by APV (50 μM). With focal application of glutamate, at a distance of 2-5 μm from the cell, a rapidly adapting response was observed (Trussell and Fischbach '88). Gaba application (100 μM) produced an outward current that was blocked by bicuculline (20 μM). These results indicate that magnocellular basal forebrain neurons have NMDA, non-NMDA and $Gaba_A$ receptors. (Supported by NIH NS26422 and ADRDA)

372.16

HETEROGENEOUS DISTRIBUTION OF EXCITATORY AMINO ACID RECEPTORS ON POSTNATAL NEURONS ACUTELY DISSOCIATED FROM RAT DORSAL HORN. O. Arancio, K. Murase, M. Yoshimura and A.B. MacDermott Dpt. Physiology and Center for Neurobiology and Behavior, Columbia Univ., NYC, NY 10032

Mapping of glutamate receptors on the soma and neurites of rat spinal cord neurons in culture has revealed heterogeneity of receptor distribution for each receptor subtype activated by its selective agonist, kainate, quisqualate or NMDA. Furthermore, areas of high sensitivity to one agonist do not always correspond to high sensitivity to the other two agonists. We have tested whether such differential patterns of receptor distribution occur on neurons allowed to develop *in vivo* rather than in culture. Neurons with long dendrites were obtained from 6–11 day old rats by mechanical dissociation following enzyme treatment and placed in a rapidly flowing bath. Recordings were made in voltage clamp using whole cell recording. Drugs were applied by pressure through thin–tipped (<1um id) pipettes. Responses to the three agonists were always present on both the soma and the neurites in all cells tested. In some cells, agonist sensitivity fell off with distance from the soma while in others, response to agonists occurred in an irregular pattern along the neurite with hot spots (areas of membrane with higher amplitude responses than adjacent areas on the same neurite). The percentage of cells with hot spots was 70%, 72% and 80% respectively for kainate, quisqualate and NMDA. In addition, comparison of the responses for two agonists at the same site on the neurite showed that hot spots for different agonists did not necessarily correspond. Thus, data from acutely isolated neurons support the results previously obtained with cells in culture.

372.17

SOMADENDRITIC BUT NOT AXONAL PRESYNAPTIC GLUTAMATE RECEPTORS MEDIATE GLUTAMATE-INDUCED STIMULATION OF GABA RELEASE IN DISSOCIATED CELL CULTURES FROM THE RAT SUPERIOR COLLICULUS. M. Perouansky* and R. Grantyn* (SPON: Y. Yaari). Max Planck Inst. Psychiatry, Martinsried, F.R.G. After 1 week in vitro cultured neurons from the superficial gray layer of the neonatal rat superior colliculus form synaptic networks where about half of the terminals display GAD-immunoreactivity (Warton, Perouansky and Grantyn, Dev.Brain Res.1989). Application of glutamate (Glu) to these cultures increased the frequency of spontaneous bicuculline-sensitive synaptic Cl currents, even if a TTX- and Cd-induced block of voltage-activated Na and Ca channels prevented generation and conduction of action potentials along the axons. To answer the question whether Glu receptors on GABAergic axon terminals would account for this effect we used a push-pull type microsuperfusion system for selective chemical stimulation of voltage clamped somata and attached terminals. Under these conditions stimulation of GABA release was still observed with 30 mM KCL, while Glu and its agonists failed to increase the frequency of bicuculline-sensitive synaptic Cl currents. A role of axonal Glu receptors in the regulation of GABA release is therefore unlikely.

EXCITATORY AMINO ACIDS: ANATOMY AND PHYSIOLOGY III

373.1

MK-801: EFFECTS ON PIRIFORM EEG AND EVOKED RESPONSES. Tim Otto, John Larson, Michel Baudry, and Gary Lynch. Center for the Neurobiology of Learning and Memory, Univ. Cal., Irvine, CA 92717.

MK-801, a non-competitive NMDA receptor antagonist, was administered (ip, 1 mg/kg) to rats implanted with a bipolar stimulating electrode in the LOT and a monopolar recording electrode in the ipsilateral superficial plexiform layer (1a) of piriform cortex. Piriform EEG was recorded continuously for several hours after administration of MK-801. EPSPs evoked by single pulse activation of the stimulating (LOT) electrode every 15 sec were recorded also, and were subsequently analyzed for slope and amplitude.

The effects of MK-801 on piriform physiology can be best described as a repeating cycle of three distinct stages. During Stage 1, EEG consisted of smooth, rhythmic, high frequency (200 Hz) activity. EPSPs during Stage 1 remained unchanged relative to baseline. Stage 2 EEG was composed of dramatically depressed low voltage activity and was accompanied by severely attenuated EPSPs. Stage 3 was characterized by high voltage seizure-like discharges and EPSPs approximately 200% of baseline. The cycle period remained consistent within subjects, but varied across subjects (10 -24 min). Within a cycle, Stages 2 and 3 lasted not longer than 1 min each, with Stage 1 comprising the remaining time. Eight to ten cycles, each composed of these three stages, were typically observed. An extended period (approximately 1 hr.) of highly attenuated EEG and EPSPs followed, succeeded by baseline EEG activity and EPSPs.

373.2

THE EFFECTS OF THE NON-COMPETITIVE NMDA ANTAGONIST, MK-801 ON MONO AND POLYSYNAPTIC REFLEXES IN THE SPINALIZED CAT. M.E. Mann and P.A. Boxer. Parke-Davis Pharm. Res. Div., Warner-Lambert Co., Ann Arbor, MI 48105.

The dissociative anesthetic, ketamine, has been shown to selectively decrease spinal cord polysynaptic reflexes in cats at doses from 1 to 10 mg/kg, IV (Campbell et al., 1987). Ketamine has a variety of pharmacological actions, including non-competitive antagonism of the NMDA receptor through an interaction at the PCP site in the channel. The present experiments were designed to determine if the more potent and specific non-competitive NMDA antagonist, MK-801, had similar effects on reflex activity. Experiments were performed in C1-sectioned mongrel cats (2-4 kg) maintained under artificial respiration. Following isolation and cutting, a dorsal root (L6-S1) was stimulated (10X threshold) and reflex responses were recorded from a ventral root. The area under the curve of the monosynaptic reflex was unaffected by MK-801 at cumulative doses from 0.2 to 2.0 mg/kg IV, while the polysynaptic reflex showed a significant dose and time dependent decrease. The effects of 2.0 mg/kg MK-801 were similar to those seen with 10 mg/kg ketamine, indicating that in this system the potency ratio between these 2 drugs is very different from that predicted from binding at the PCP receptor. These data support the hypothesis that NMDA receptors are not involved in spinal cord monosynaptic reflexes, but do partially mediate polysynaptic reflexes.

373.3

SUSTAINED DEPOLARIZATIONS DURING SEIZURE-LIKE ACTIVITY IN CULTURED RAT HIPPOCAMPAL NEURONS. W.J. Koroshetz and E. J. Furshpan. Department of Neurobiology, Harvard Medical School, Boston, MA 02115.

Hippocampal neurons cultured for weeks or months in the presence of 1mM kynurenate and 11.3 mM Mg^{2+} showed, after withdrawal of these blocking agents, intense spontaneous activity including runs of paroxysmal depolarization shifts and, often, large (25-60 mV) sustained depolarizations (SDs); when prolonged, this seizure-like activity killed many of the neurons. SDs were often reversed by kynurenate or by APV (Furshpan, E. J. & Potter, D. D., 1989, Neuron, in press). SDs may be an indicator or precursor of impending cell death; we have studied the role of glutamate receptors and of action potentials in their generation and maintenance. We now report that, unlike APV, the non-NMDA antagonist, CNQX (10-20 μM; plus glycine, 500μM) was usually ineffective in reversing SD's although it often enhanced repolarization when added to APV; large SDs sometimes arose in the presence of CNQX, but not in the presence of APV. These observations emphasize a special role for NMDA receptors in the generation and maintenance of SDs. Tetrodotoxin (TTX; 1 μM) sometimes caused full reversal of SDs, especially when applied soon after SD onset; in other cases it failed to cause repolarization despite the continued effectiveness of APV or of kynurenate plus elevated Mg^{2+}. In addition, some neurons generated large APV-reversible SD's in the continuous presence of TTX. These observations suggest the presence, under some circumstances, of substantial glutamate release in the absence of Na-dependent action potentials. Cultures chronically grown in the presence of APV ($[Mg^{2+}]$ = 1.3 mM) also displayed SDs after washout of APV; however, paroxysmal depolarization shifts were less prominent in these cultures.

373.4

IN-VIVO INTERACTIONS OF PCP-RECEPTOR AGONISTS WITH MOUSE CEREBELLAR PURKINJE AND DOPAMINERGIC PROJECTIONS. J. CLER*, T.S. RAO, S. MICK*, S. IYENGAR and P.L. WOOD. (SPON: J. MICHEL). CNS Diseases Research, G.D. Searle & Co., St. Louis, MO 63198.

A number of pharmacological studies indicate a tight functional coupling between N-methyl-D-aspartate [NMDA] and phencyclidine [PCP] receptors. However, recent studies indicate the presence of a sub-population of PCP receptors which modulate dopamine [DA] metabolism in rat pyriform cortex to be uncoupled from NMDA receptor. The present study examined the effects of PCP agonists on mesolimbic, nigrostriatal and mesocortical DA metabolism, as well as cerebellar cyclic GMP in mouse. PCP agonists, (+)-MK-801 [5 mg/kg], ketamine [50 mg/kg], PCP, TCP and dexoxadrol [5 mg/kg each] potently decreased cGMP while (-)-MK-801 [0.3 mg/kg] and levoxadrol [5 mg/kg] were less effective than their active isomers. (+)-MK-801, ketamine and dexoxadrol increased striatal DA metabolism without affecting its release, while TCP, PCP, levoxadrol and (-)-MK-801 were ineffective. In olfactory tubercle, (+)-MK-801 and ketamine increased DA metabolism, while TCP, PCP, dexoxadrol, levoxadrol and (-)-MK-801 were ineffective. In pyriform cortex none of the PCP agonists were effective at increasing DA metabolism. These studies indicate differential interactions of PCP agonists with dopaminergic pathways and also suggest that mouse pyriform cortex is less responsive to PCP receptor agonists than rat pyriform cortex.

373.5

SYSTEMICALLY ADMINISTERED NMDA PRODUCES TOLERANCE IN RAT EEG. GEORGE P. ALBERICI, JACQUI-LINN GASKILL AND GEORGE F. STEINFELS. E. I. DuPont de Nemours & Co., Med. Prod. Dept., Wilmington, DE 19880-0400 USA.

NMDA has been implicated in a variety of physiological processes including learning and memory and neuronal cell death. Behavioral effects following systemic administration have been observed in drug discrimination and learning/memory paradigms. This study examined the effects of NMDA, administered subcutaneously (sc) on rat EEG. Two major EEG changes were noted: first, there was a large decrease (over 50%) in EEG amplitude approx. 6 minutes after dosing that returned to control levels within 6 minutes: second, there was a dose dependant (6.8,15.0 and 48.0 mg/kg) increase in relative spectral power of EEG delta band frequencies with the peak increase occurring approx. 15 to 30 minutes after dosing. When NMDA was re-administered 2 days later to previously dosed rats (15.0 mg/kg) , no EEG changes were seen, which suggested tolerance. In a second experiment 15.0 mg/kg NMDA was administered to 2 groups of rats. Two days later rats received either 15.0 or 48.0 mg/kg NMDA. Again no EEG changes occurred in the 15.0 group however EEG changes were seen in the 48.0 mg/kg group which suggests that the tolerance could be overcome by a higher dose. Pre-treatment with the NMDA antagonist CPP, prevented both the immediate EEG effects and tolerance development. The time course of tolerance was also evaluated. The onset of tolerance began 4-24 hours and was maximal at 48 hours. Quite surprisingly tolerance persisted up to 8-12 weeks.

NMDA-STIMULATED RELEASE OF TAURINE FROM ELECTRO-PHYSIOLOGICALLY-MONITORED RAT HIPPOCAMPAL SLICES. K.R. Magnusson, J.F. Koerner, and A.J. Beitz. Dept. of Veterinary Biology, Univ. of Minnesota, St. Paul, MN 55108.

The amino acid taurine has been shown to protect against neurotoxicity caused by certain excitatory amino acid analogs and has been shown to be released *in vivo* in response to high doses of N-methyl-D-aspartate (NMDA). The present study was undertaken to determine whether taurine release could also be stimulated by low (μM) concentrations of NMDA. Rat hippocampal slices were bathed with an artificial CSF media in an open flow-through chamber. The electrical field potential of the CA1 region was monitored throughout the experiment. The slices were exposed to varying concentrations of NMDA for a 4-6 minute period. With the use of 15μM NMDA, taurine release, measured by HPLC, peaked at 127% of prestimulation baseline levels between 2-6 min. following the initial exposure to NMDA and returned to baseline release levels by 8 minutes. The CA1 field potential recovered fully following exposure to 15 μM NMDA. With the use of 30, 60 and 120μM NMDA, taurine release peaked at 500%, 1000%, and 1300%, respectively, during the 4-6 min. sample and returned to baseline only after 30 minutes, 24 minutes after NMDA was totally cleared from the chamber. The CA1 field potential did not recover fully at these higher NMDA concentrations. The pattern of recovery resembled the events which occur during spreading depression. Taurine release may in part be due to direct stimulation by NMDA, however, taurine also appears to be released as a consequence of recovery events which follow NMDA exposure. Supported by NIH grant AG00329.

INTERACTIONS BETWEEN GLYCINE (GLY) AND N-METHYL-D-ASPARTATE (NMDA) ON RAT RED NUCLEUS CELLS RECORDED IN VIVO. J.M. Goldstein, L.M. Koch*, L.C. Litwin* and A.I. Salama. Dept. of Pharmacology, ICI Pharmaceuticals Group, ICI Americas Inc., Wilmington, DE 19897.

Recent in vitro electrophysiological studies have shown that GLY markedly potentiates NMDA responses in mammalian neurons and this effect is blocked selectively by the putative GLY antagonists 1-hydroxy-3-aminopyrrolidone-2 (HA-966) and 7-chlorokynurenic acid (7-CL KYN). We now report that this GLY modulatory site is functional in the intact adult rat brain. Extracellular single unit recording techniques and iontophoresis were employed in chloral hydrate anesthetized rats to measure the response of red nucleus cells to NMDA, GLY, d-serine, HA-966 and 7-CL KYN. Iontophoretic application of NMDA (50 mM) caused a marked excitatory effect which could be greatly enhanced by coiontophoresis of either GLY (100 mM) or d-serine (200 mM). Both HA-966 and 7-CL KYN antagonized the excitatory effects of NMDA, but there were differences in potency and efficacy. Whereas 7-CL KYN produced near maximal inhibition of NMDA at 25 mM, the inhibitory effects of HA-966 plateaued at less than maximal at concentrations up to 64 mM. The inhibitory effects of HA-966 and 7-CL KYN were reversed by subsequent iontophoretic application of GLY or d-serine. These results show that agonists and antagonists acting at the GLY modulatory site of the NMDA receptor complex interact similarly under in vivo or in vitro conditions.

VASOPRESSIN INDUCED EXCITATIONS IN THE RAT LATERAL SEPTUM ARE DISPLAYED VIA ACTIVATION OF THE NMDA RECEPTOR. P. van den Hooff, M. Peppelenbosch and I.J.A. Urban. (SPON: D. Bradford). Rudolf Magnus Institute for Pharmacology, University of Utrecht, Vondellaan 6, 3521 GD Utrecht, The Netherlands.

The excitatory effect of vasopressin (VP) on lateral septum neurons was studied with intracellular micro-electrodes in brain slices. Recordings were made different membrane potentials using current injection through the electrode. At membrane potentials at least 10 mV below the firing level (which is around -55 mV), bath application of $10^{-6}/10^{-8}$ M VP in only 10% of the cells resulted in a reversible membrane depolarization accompanied by the generation of action potentials. At membrane potentials around the firing level 90% of the cells responded to VP by increased firing rates. These effects could be prevented by the V1 receptor-antagonist and be reversed with $5*10^{-5}$ M 2APV, a specific antagonist for the NMDA receptor. In 5 slices superfused with with a "zero" magnesium medium 1uM VP caused in 3 neurons a membrane depolarization of 7 ± 0.7 mV. We conclude that magnesium ions interfere with the excitatory action of VP, presumably in a voltage-dependent way that may involves NMDA receptors.

373.10

EFFECTS OF POLYAMINE SPIDER TOXINS ON NMDA RECEPTOR-MEDIATED TRANSMISSION IN RAT HIPPOCAMPUS *IN VITRO*. A.L. Mueller[1], A.H. Ganong[2], B.C. Albensi[1]* and H. Jackson[1]. [1]Natural Product Sciences, Inc., Salt Lake City, UT 84108 & [2]Pfizer Central Research, Groton, CT 06340.

Previous reports have demonstrated that polyamine-containing toxins from spider venoms block glutamate-mediated synaptic transmission in the mammalian CNS. Further, such toxins have more recently been reported to selectively suppress transmission mediated by non-NMDA (quisqualate and kainate) type glutamate receptors (Ashe et al., Brain Res. 480:234, 1989; Saito et al., Brain Res. 481:16, 1989). Our results, however, suggest that at least some of the polyamine-type spider toxins are selective NMDA receptor antagonists. Standard techniques were used for preparing and recording from submerged hippocampal slices. Stratum radiatum was stimulated every 60 sec and the effects of bath applied toxins on population spike (PS) and field EPSP responses in CA1 were monitored. Responses mediated primarily via non-NMDA receptors were largely insensitive to the spider toxins. Argiotoxin636 (ARG636), from *Argiope aurantia*, NSTX3, from *Nephila maculata*, and three polyamine toxins from the funnel-web spider *Agelenopsis aperta* had no significant effect on the PS at concentrations up to 100 µM. However, the induction of long-term potentiation, an NMDA receptor-mediated phenomenon, could be blocked by application of the *Agelenopsis* toxins (100 µM) or ARG636 (10-50 µM). This effect was variable and is under further investigation. Similarly, the normal field EPSP was unaffected by 10 µM ARG636 or ARG659. However, the NMDA receptor-mediated EPSP, recorded in the presence of DNQX and lowered Mg^{2+}, is suppressed about 70% by 10 µM ARG636 or ARG659. These results suggest that at least some of the polyamine-type spider toxins selectively suppress NMDA receptor-mediated synaptic transmission in the mammalian CNS.

373.11

EFFECTS OF CALCIUM ANTAGONIST PEPTIDE SPIDER TOXINS ON HIPPOCAMPAL SYNAPTIC TRANSMISSION STUDIED *IN VITRO*. B. C. Albensi*, A. L. Mueller and H. Jackson. Natural Product Sciences, Inc., Salt Lake City, UT 84108.

A peptide fraction termed AG1 from funnel web spider (*Agelenopsis aperta*) venom suppresses synaptic transmission in the CNS by blocking voltage-sensitive calcium channels (VSCC) (Jackson and Parks, Ann. Rev. Neurosci. 12:405, 1989). We have examined the ability of purified peptides from *A. aperta* to suppress synaptic transmission in rat hippocampal slices maintained *in vitro*.

Rat hippocampal slices were submerged and superfused with oxgenated aCSF (recirculating system, volume 2 ml). Stratum radiatum was stimulated every 60 sec, and the effects of bath applied toxins on population spike (PS), field EPSP, and afferent volley (AV) responses in CA1 were monitored.

Two peptides, tentatively designated K and 19, totally suppressed the PS at concentrations of 2 µM or less. This effect is quite similar to that seen with 1-5 µM omega-conotoxin. The effects of peptide K were largely reversible over a 30-60 min wash whereas no significant recovery from peptide 19 was seen. These peptides also blocked the field EPSP with no significant effect on the AV. Results of changing extracellular $[Ca^{2+}]$ as well as results from other experimental approaches [e.g. Artman et al., this meeting] indicate that these toxins are novel VSCC antagonists in the mammalian CNS.

373.12

EVIDENCE FOR A ROLE OF GLYCINE IN AREA TEMPESTAS FOR TRIGGERING CONVULSIVE SEIZURES J. Wardas*, J. Graham* and K. Gale Dept. Pharmacology, Georgetown University Medical Center, Washington, D. C. 20007

Previous studies have demonstrated that convulsions induced by the unilateral microinjection of bicuculline in area tempestas (AT; an epileptogenic site in the deep prepiriform cortex) are prevented by the focal application of competitive NMDA receptor antagonists in the same site. If glycine is involved in the activation of NMDA receptors in AT, then blockade of the glycine site should also prove anticonvulsant in this region. Therefore, we evaluated the effect of 7-chloro-kynurenic acid (7-CLKYN) in AT on bicuculline-evoked convulsions. Bicuculline methiodide (118 pmol in 120 nl) was unilaterally microinjected into AT 5 min after the application of 7-CLKYN into the same locus. 7-CLKYN (2.5 nmol in 250 nl) protected 100% of the animals against convulsions; a lower dose (1.25 nmol) protected 33% of the animals. Kynurenic acid (KYN) was also effective, but 6.25 nmol was required in order to protect the majority of animals against convulsions. Thus, 7-CLKYN was at least four-fold more potent than KYN for preventing convulsions triggered from AT. As 7-CLKYN is known to be significantly more potent than KYN as an antagonist at the glycine regulatory site, but is of comparable potency to KYN as a direct antagonist at NMDA receptors, our results implicate glycine antagonism as a mechanism for preventing convulsions triggered via NMDA-receptor activation. This would suggest that endogenous glycine participates in the process of seizure induction from AT.

373.13

SEX DIFFERENCES AND INVOLVEMENT OF THE DOPAMINE SYSTEM IN BEHAVIORAL RESPONSIVENESS TO MK-801. H.E. Criswell, R.A. Mueller and G.R. Breese. Univ. of North Carolina School of Medicine Chapel Hill, NC 27514.

Dose response curves for the effect of the NMDA antagonist MK-801 on activity were shifted to the left when female rats were compared to males indicating that females were more sensitive. Furthermore, repeated administration of doses as low as 0.03 mg/kg to females resulted in behavioral sensitization to MK-801, while a dose of 0.3 mg/kg was required for a similar effect in males. Several lines of evidence suggest that the dopamine system was only minimally involved in these actions of MK-801. Neither neonatal- nor adult- 6-OHDA lesions blocked the effects of MK-801. In fact, neonatal-6-OHDA lesions augmented its activating effect. When individual behaviors were examined in neonatal-6-OHDA lesioned rats, MK-801 did not produce the same behaviors as a dopamine agonist. There was, however, some interaction between the NMDA and dopamine systems as MK-801 blocked some of the behaviors including self-biting induced by L-DOPA in these rats. The increased activity level following MK-801 administration was only partially blocked by pretreatment with α-methyltyrosine or the combination of a D_1- and D_2-dopamine antagonist. neither dopamine antagonist was effective alone. These data suggest that there is a functional link between dopamine and NMDA receptor mediated systems but that other neural systems contribute to behavioral changes accompanying NMDA receptor blockade. Supported by USPHS grants NS21345, HD23042 and HD03110.

EVIDENCE FOR IN VIVO POTENTIATION BY GLYCINE OF THE ACTIVITY OF A GLUTAMATE-SENSITIVE SYMPATHOINHIBITORY AREA IN CAT MEDULLA. C.W. Dempesy, D.E. Richardson, and C.J. Fontana*. Lab. of Neurosurgery, Tulane Univ. School of Medicine, New Orleans, LA 70112.

We have previously detected in cat anesthetized with pentobarbital sodium a sympathoinhibitory area located adjacent to the rostral end of the compact division of the ambiguus nucleus (Neurosci. Abst. 14:192, 1988). Microinjections of glutamic acid (Glu, 5 nmol) into this area induce hypotension and bradycardia, and bilateral lesions of this area eliminate the sympathetic component of baroreflex induced by phenylephrine (PeSBR). We now report that, although serial microinjections of glycine (Gly, in increments of 50 ng) in this area will finally inhibit its activity, in approximately half the cases tested the initial doses of Gly potentiated its activity. Within the range of 50-200 ng of Gly: 10 of 23 sites yielded enhanced hypotension (in mmHg, 30 ± 5 before to 45 ± 6 after, from baseline 125 ± 8) and bradycardia (in bpm, 13 ± 3 before to 24 ± 4 after, from baseline 197 ± 8) in response to Glu; 13 of 20 sites (treated bilaterally) led to enhanced PeSBR (as a ratio of heart rate fall to blood pressure rise, .30 ± .08 before to .54 ± .07 after). Cats were vagotomized or prepared with atropine (1 mg/kg) to ensure sympathetic activity only. Further work is needed to establish that this Gly-potentiation is similar to that seen in cultured cell preparations (J.W. Johnson and P. Ascher, Nature 325:529, 1987).

PHENCYCLIDINE AND ITS ANALOGUES INTERACT SELECTIVELY WITH NMDA RECEPTORS TO DEPRESS THE POLYSYNAPTIC REFLEX IN NEONATAL RATS, *IN VITRO*. Y. Ohno and J.E. Warnick. Dept. of Pharmacol. & Exp. Ther., Univ. of MD Sch. of Medicine, Baltimore, MD 21201.

The differential sensitivity of mono- and polysynaptic reflexes to phencyclidine (PCP) and its analogues was examined in a Mg^{2+}-free physiological solution using an *in vitro* spinal cord preparation. The cords were removed from male Wistar rats (6-9 days old), hemisected and superfused with oxygenated physiological solution. Stimulation of an L_{3-5} dorsal root evoked a response in the corresponding ventral root which was recorded with a suction electrode. The monosynaptic reflex was relatively resistant to NMDA antagonists [Mg^{2+}, 2-amino-5-phosphonovalerate (APV) and 2-amino-7-phosphonoheptanoate (AP7)] while the polysynaptic reflex was markedly reduced in a concentration-dependent manner. The magnitude of the monosynaptic reflex only decreased 20-30% at concentrations of Mg^{2+} (1.3 mM), APV (10 μM) and AP7 (10 μM) which completely depressed the polysynaptic reflex. PCP and its analogues also selectively depressed the polysynaptic reflex in a concentration-dependent manner and had relative potencies consistent with those for the PCP receptor [*i.e.*, 1-(1-*m*-aminophenylcyclohexyl)piperidine = MK-801 [(+)-5-methyl-10,11-dihydro-5*H*-dibenzo[*a,d*]-cyclohepten-5,10-imine maleate] > 1-[1-(2-thienyl)cyclohexyl]piperidine $\geq$ PCP > > (+)-*N*-allylnormetazocine > > 1-(1-*m*-nitrophenylcyclohexyl)piperidine. The latter compounds depressed the monosynaptic reflex to the same extent as Mg^{2+}, APV and AP7 at concentrations which completely depressed the polysynaptic reflex. Furthermore, the depression of the reflexes by PCP was unaffected by haloperidol and methiothepin precluding the involvement of sigma and serotonin receptors in PCP-induced depression of the polysynaptic reflex. Our results suggest that PCP and its analogues selectively depressed the polysynaptic reflex through PCP receptors associated with the NMDA-aspartate receptor complex. (Supported in part by USPHS grant DA-02804.)

EXCITATORY AMINO ACIDS: ANATOMY AND PHYSIOLOGY IV

374.1

KAINIC ACID ACTIVATES FUNCTIONAL PATHWAYS FROM CORTEX AS SHOWN BY ACUTE 2-DG AUTORADIOGRAPHY IN THE GERBIL. H. Scheich, H. Steffen*. Inst. Zool., Univ. Darmstadt, FRG. Local injections of Kainic acid (KA) have been widely used to produce selective brain lesions. We have mapped the primary KA induced neuronal activation in 2-deoxyglucose (2DG) sessions shortly after unilateral small injection of KA into auditory, visual or somatosensory cortex (2 nMol KA in 1 µL saline injected under halothane, injection i.p. of 20µCi 14-C-fluoro-2DG in awake animals 15 min after KA, 45 min 2 DG exposure in lighted sound proof box). Beside local increase of metabolic activity around injection sites through the depth of cortex specific patterns of activation and suppression occurred in distant ipsilateral brain areas. Largely independent of modality of injected cortex the limbic structures med. prefrontal, entorhinal and olfactory cortex, basolat. n. of amygdala, n. accumbens, tuberculum olfactorium and parts of the striatum showed massive increase. Specific thalamic nuclei, some neocortical areas, and hippocampus showed regional activation depending on modality of injected cortex while other thalamic structures were suppressed. The lack of mirror foci of activation contralateral to injected cortices was remarkable. It is assumed that neuron classes in sensory cortices have different responses to global saturation of KA type glutamate receptors. This could lead to preferential activation of limbic output from cortex over several synapses, to differential activation of cortico-thalamic and cortico-striatal feedback and to sparing of callosal and other connections.

374.2

DIFFERENTIAL EFFECTS OF NMDA, QUISQUALATE AND KAINATE ON [^{3}H]DOPAMINE RELEASE FROM MESENCEPHALIC CELL CULTURES P. Boksa, H. Mount, I. Chaudieu*, J. Kohn* & R. Quirion. Douglas Hospital Res. Ctr., Depts. Psychiat. & Pharmacol. McGill Univ., Verdun, PQ, Canada H4H 1R3.

NMDA, quisqualate (QA) and kainate (KA), respective agonists for 3 excitatory amino acid (EAA) receptor subtypes, stimulated [^{3}H]dopamine ([^{3}H]DA) release from rat dissociated mesencephalic cells in culture (Mount et al. Soc. Neurosci. 13:937, 14:481). Release evoked by all 3 agonists was Ca^{2+}-dependent and inhibited by broad-spectrum EAA antagonists (cis-2,3-PDA, & kynurenate). However, kynurenate and cis-2,3-PDA were more potent against KA than QA and only KA-evoked release was blocked by GAMS (IC_{50} 700µM). NMDA-stimulated [^{3}H]DA release was selectively inhibited by competitive (CPP & APV) and non-competitive (PCP & MK-801) NMDA-receptor antagonists. In 1.2mM Mg^{2+}, NMDA-stimulated [^{3}H]DA release was Na^+-dependent and inhibited by tetrodotoxin (TTX). However, in 0 Mg^{2+}, NMDA-evoked release was neither TTX-sensitive, nor Na^+-dependent. Thus, TTX-sensitivity of the NMDA response in 1.2mM Mg^{2+} apparently occurs because Na^+-action potentials are required to alleviate a Mg^{2+} blockade. Neither QA-, nor KA-evoked release was affected by Mg^{2+} or TTX. In low Na^+ buffer, the QA response was increased more than 4X, while KA-evoked release was unaltered.

It is concluded that NMDA, QA and KA may release [^{3}H]DA via separate receptor subtypes. TTX-insensitivity of EAA-stimulated release suggests that interneurons do not mediate EAA-stimulated DA release. Supported by FRSQ.

374.3

PHENCYCLIDINE EVOKES RELEASE OF [^{3}H]DOPAMINE FROM MESENCEPHALIC CELL CULTURES H. Mount, P. Boksa, I. Chaudieu* & R. Quirion. Douglas Hospital Research Centre, Depts. Pharmacol. & Psychiat., McGill Univ., Verdun, PQ, Canada, H4H 1R3.

Phencyclidine (PCP) inhibits dopamine (DA) release stimulated by excitatory amino acids at the NMDA-receptor. Conversely, PCP may also enhance DA release, by inhibiting DA reuptake or directly stimulating release. We examined the effect of PCP and related compounds on [^{3}H]-DA release from rat dissociated mesencephalic cells in culture. PCP and MK-801 inhibited NMDA-evoked [^{3}H]-DA release (IC_{50}s of 2.3µM & .25µM, respectively). At concentrations $\geq$ 100µM, PCP, MK-801 and TCP stimulated Ca^{2+}-independent [^{3}H]-DA release. A competitive NMDA-receptor antagonist, dl-APV, had no such effect on basal DA release. The effect of PCP was not mediated by inhibition of DA uptake, since MK-801, which has low potency in blocking DA uptake (Snell et al. '88), evoked release while the DA uptake inhibitor, GBR 12783 (.01µM-1mM), did not. Also, TCP-evoked release was not inhibited by the σ-opiate antagonist, haloperidol (100µM). It is unlikely that [^{3}H]-DA release was mediated by an anaesthetic effect of PCP since naloxone (0.1µM-1mM), which has been reported to release DA via an anaesthetic action, failed to evoke release from the cells. These data concur with an earlier suggestion (Rao et al. Soc. Neurosci. 14:1049) that PCP-receptor agonists may evoke DA release by a mechanism independent of effects on DA uptake, or on NMDA- or σ-opiate-receptors. Supported by FRSQ.

374.4

INHIBITION OF EXCITATORY AMINO ACID STIMULATED [^{3}H]DOPAMINE RELEASE BY CYCLOHEXYLADENOSINE IN CELL CULTURES OF RAT MESENCEPHALON. I. Chaudieu*, H. Mount, J. Diorio*, R. Quirion & P. Boksa. (SPON: A. Fournier) Douglas Hosp. Res. Ctr., Depts. Psychiat. & Pharmacol., McGill Univ., Verdun, PQ., Canada.

Numerous reports suggest a close relationship between A1 adenosine receptors and excitatory amino acid (EAA) neurotransmission. For e.g., adenosine A1 and NMDA receptors are similarly distributed in rat brain, and both adenosine agonists and NMDA antagonists protect against neuronal death following seizures or ischaemia. To test for a functional interaction between adenosine and EAA receptors at the cellular level, the present study examined the effects of cyclohexyladenosine (CHA), an A1 receptor agonist, on [^{3}H]dopamine ([^{3}H]DA) release stimulated by EAAs from cell cultures of fetal rat mesencephalon. CHA (100µM) inhibited release evoked by NMDA, quisqualate and kainate (preferred agonists at 3 EAA receptor subtypes) and glutamate by 90%, 39%, 37% and 50%, respectively. Neither K^+-evoked, nor basal [^{3}H]DA release were affected by CHA, indicating that the effect of CHA is somewhat specific for the EAA-receptor mediated response. [^{3}H]DA release evoked by the Na^+ channel activator, veratridine, was also inhibited by CHA. These results indicate that A1 adenosine receptors and EAA receptors (mainly but not exclusively of the NMDA subtype) may interact to modulate DA release. Supported by FRSQ.

374.5

EFFECTS OF THE EXCITATORY AMINO ACIDS ON NEURONS ISOLATED FROM SPINAL TRIGEMINAL NUCLEI. Y.-P. Gu* and L.-Y.M. Huang (SPON: F.A. Kutyna). Marine Biomedical Institute, University of Texas Medical Branch, Galveston, TX 77550.

L-glutamate is a major excitatory transmitter involved in synaptic transmission between primary sensory neurons and projection neurons in trigeminal nuclei. In order to identify various glutamate receptors mediating synaptic transmission in this system, we have studied the actions of quisqualate (QA), kainate (KA) and N-methyl-D-aspartate (NMDA) in acutely dissociated neurons isolated from spinal trigeminal nuclei using whole cell patch recordings. Under voltage clamp conditions, QA, KA and NMDA elicited currents in all the cells tested. The current voltage relations of QA and KA were relatively linear. In the presence of Mg^{++}, the NMDA receptor mediated current voltage curve had a negative slope conductance between -90 and -50 mV. The NMDA responses were abolished 2mM D(-)-2aminophosphovaloric acid (APV). The dose-response experiments were also performed for the three agonists. The apparent dissociation constants were 9 μM for QA, 48 μM for NMDA and 260 μM for KA. Among the three agonists, QA had the highest affinity and KA had the lowest affinity for their respective receptors. The maximum response produced by KA was 3-4 times that produced by QA. Glycine greatly potentiated the magnitude of NMDA responses but only produced a small reduction of the apparent dissociation constant for NMDA. Supported by NS23061 and NS01050.

374.6

THYROTROPIN RELEASING HORMONE INDUCED GLUTAMATE RELEASE FROM THE LATERAL HYPOTHALAMUS IN VIVO. A.-L. Sirén, K. Xu* and G. Feuerstein. Dept. of Neurol., USUHS, Bethesda, MD 20814.

We recently reported that the glutamate (GLU) n-methyl-d-aspartate receptor blocker MK-801 attenuated the pressor and vasoconstrictor responses produced by hypothalamic microinjections of thyrotropin releasing hormone (TRH). To prove that GLU mediates the hemodynamic responses to TRH we studied the effect of TRH on GLU release from LH in conscious male Sprague-Dawley rats (325-350 g, n=5-7). Twenty-four to 48 hrs after unilateral implantation of a microdialysis probe into the LH, the rats were perfused with artificial CSF for 3 hrs; TRH (20 mg/kg i.p.) was administered and perfusion fluid collected and analyzed by HPLC for several amino acids. The baseline levels of GLU, aspartate (ASP) and glutamine (GLN) before TRH were 1.9±0.4 pmol/μl, 1.2±0.2 pmol/μl and 23.4±2.9 pmol/μl, respectively. TRH increased ASP by more than 4-fold and GLU by 1.5 fold with no significant effect on GLN output. Perfusion of LH with K^+ (20 mM, 80 mM) increased ASP and GLU levels in the perfusate in a dose-related manner but had no effect of GLN, alanine or histidine release. Together with the previous findings the present results imply a role for GLU and ASP in the hypothalamus in mediation of the cardiovascular effects of TRH.

ROLES OF NMDA AND NON-NMDA EXCITATORY AMINO ACID RECEPTORS IN THE COMPUTATION OF MOTION BY NEURAL CIRCUITS. P.S. Ulinski, L.J. Larson-Prior, and N.T. Slater. Dept. of Physiology, Northwestern University Medical School and Dept. of Organismal Biology and Anatomy, Univ. of Chicago, Chicago, IL U.S.A.

While excitatory amino acids (EAAs) are known to play central roles in synaptic transmission in a variety of neural systems, there are few examples where their functional role in a *defined* behavior has been demonstrated. We have used data on the anatomy and synaptic physiology of turtle visual cortex to develop a model that links the functional properties of EAA receptors in cortical circuitry to the turtle's ability to follow moving objects in visual space. Single unit studies indicate that cells in turtle visual cortex respond well to small moving stimuli anywhere in binocular visual space and likely participate in visually guided tracking behaviors. Anatomical studies explain how a convergence of points in visual space onto such cortical cells generate these receptive field properties. They show that the azimuth lines of visual space are represented in isoazimuth lamellae that extend from lateral to medial in visual cortex. Cells within a lamella receive inputs from geniculate neurons responsive to stimuli anywhere on a given vertical meridian. A stimulus on the horizontal meridian at time t=0 excites neurons throughout the appropriate isoazimuth lamella in visual cortex via fast geniculocortical responses mediated by non-NMDA receptors. Intracortical systems then excite neurons in adjacent isoazimuth lamellae through both non-NMDA and NMDA receptors with delays of several msec. As the stimulus moves past the turtle, these same neurons are activated continuously for several hundred msec, resulting in a short-term potentiation of synaptic transmission that lasts up to 1.8 sec and is NMDA receptor-mediated. Consequently, cortical neurons respond robustly to moving stimuli, but only weakly to stationary stimuli. An ensemble of such neurons can code for objects moving continuously past the animal for distances much larger than the receptive fields of individual retinal ganglion or geniculate cells. Supported by NS17489 & NS25682.

EXCITATORY AMINO ACID RECEPTOR-MEDIATED TRANSMISSION IN GENICULOCORTICAL AND INTRACORTICAL PATHWAYS IN VISUAL CORTEX. L.J. Larson-Prior, P.S. Ulinski, and N.T. Slater. Dept. of Physiology, Northwestern University Medical School and Dept. of Organismal Biology and Anatomy, Univ. of Chicago, Chicago, IL. U.S.A.

Excitatory amino acid (EAA) receptors have been shown to play important roles in both synaptic transmission and plasticity in visual cortex. However, the EAA receptor subtypes that mediate transmission in the geniculocortical and intracortical pathways have not been clearly differentiated. Such a differentiation is of considerable importance in understanding how cortical circuitry mediates visual function. We have used a preparation of turtle brain in which the integrity of the visual cortex and geniculocortical inputs are maintained *in vitro* to compare the EAA receptor subtypes involved at geniculocortical and intracortical synapses. Stimulation of the geniculocortical fibers at subcortical loci produces monosynaptic EPSPs in visual cortical neurons which are blocked by the broad spectrum EAA receptor antagonist kynurenate (1-2 mM). These fast responses are also blocked by the non-NMDA antagonist DNQX (10 μM), but not by the NMDA antagonist DL-AP-5 (100 μM). Stimulation of intracortical fibers evokes multicomponent EPSPs. An early component is reduced by kynurenate and DNQX, but not DL-AP-5. An EPSP of intermediate latency and time course remains in the presence of any of the EAA receptor antagonists tested. The late component is blocked by DL-AP5, but not by DNQX. These results provide evidence that the fast, monosynaptic EPSP arising from activation of geniculocortical fibers is mediated via non-NMDA receptors. The multicomponent intracortical EPSP is more complex, and is mediated by non-NMDA, non-EAA, and NMDA receptors. These components of the intracortical EPSP are likely to arise from both mono- and polysynaptic elements which play a role in motion analysis in turtle visual cortex. Supported by NS17489 & NS25682.

AN *IN VIVO* EVALUATION OF NMDA AND QUISQUALATE RECEPTOR-MEDIATED TRANSMISSION AT THE COMMISSURAL SYNAPSE ON CA1 PYRAMIDAL CELLS. Edda Thiels and Donald J. Weisz, Department of Behavioral Neuroscience and Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.

The electrophysiological responses of hippocampal CA1 pyramidal cells following application of L-glutamate are mediated by various receptor subtypes, most notably the quisqualate (QUIS) and *N*-methyl-D-aspartate (NMDA) receptors. As part of the development of a method for the identification of compounds that selectively modulate NMDA receptor-mediated transmission at the commissural-CA1 synapse in the intact hippocampus, we determined the effects of 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX), a selective QUIS antagonist, and D-2-amino-5-phosphonovalerate (APV), a selective NMDA antagonist, on CA1 dendritic field excitatory postsynaptic potentials (EPSP) elicited by either low or high frequency stimulation in vivo. Pressure injections (0.4 μl at a distance of 300 μm from the recording tip) of CNQX reduced EPSP amplitude, measured at 2 ms after EPSP onset, in a dose-dependent fashion, whereas APV had no effect on EPSP topography elicited by low frequency stimulation. Both CNQX, at doses that completely suppressed the EPSP, and APV blocked the induction of long-term potentiation (LTP) following high frequency stimulation that reliably produced LTP in control rats. Using the same test arrangement, we delineated the novel compound azetidine-2,4-dicarboxylic acid (AZT) to function as a selective NMDA agonist: low doses (≤ 100 μM) produced spontaneous bursting, whereas high doses caused local seizures; EPSP amplitudes subsequently were suppressed in a dose-dependent fashion. These effects of AZT were blocked by prior administration of either APV or MK-801, a noncompetitive NMDA receptor antagonist. EVIDENCE FOR AN EXCITATORY AMINO ACID PROJECTION FROM THE VENTROMEDIAL HYPOTHALAMUS TO THE MEDIAL ZONA INCERTA. M.J. Eaton and R.L. Moss Dept. of Physiol., Univ. Texas Southwestern Med. Ctr., Dallas, TX 75235

Anatomical studies have shown afferent input to the medial portion of the zona incerta (ZI) from the ventromedial hypothalamic nucleus (VMH). In previous *in vitro* electrophysiological studies, we have demonstrated that VMH neurons project to and terminate in the medial ZI. The predominant orthodromic response is excitation. The present study was designed to elucidate the identity of the transmitter mediating this excitatory response, by attempting to block the orthodromic excitation of medial ZI neurons with kynurenic acid (KYN), an excitatory amino acid antagonist. Transverse vibratome sections (425 microns) through the ZI and VMH were obtained from Sprague-Dawley female rats. Extracellular single cell recordings were made from 17 orthodromically excited neurons located in the medial ZI. Using peristimulus time histograms, a neuron was considered to be orthodromically excited, if it showed a reproducible and a variable, short latency increase in firing rate following ipsilateral VMH stimulation. If three successive histograms showed good consistency, the normal artificial cerebrospinal fluid (ACSF) superfusing the slice was switched to ACSF containing 100 or 500 uM KYN. Peristimulus time histograms were used to determine if KYN blocked the orthodromic response and to check for recovery after replacement with normal ACSF. In 12 of the 17 cells tested, the orthodromic response was either totally abolished or partially blocked by application of KYN. The time course for this response was 4 to 10 minutes and varied according to the position of the tissue in the in vitro slice chamber and to the depth in the brain slice of the neuron being recorded. In all cases, recovery occurred within minutes. These data suggest that an excitatory amino acid, such as, glutamate or aspartate, may be the transmitter mediating the orthodromic response. ELECTROPHYSIOLOGY AND PHARMACOLOGY OF THE CORTICOTHALAMIC RESPONSE. M. Deschênes and B. Hu*, Lab. of Neurophysiology, Laval Univ. Sch. of Med., Québec, Canada.

Though most electrophysiological results suggest that the corticothalamic (CT) pathway is excitatory, inhibitory effects have also been reported. A methodological problem in these studies, however, was that corticofugal effects could not be separated from those mediated by collateral activation of reticular thalamic neurons. In the present study, the reticular complex was lesionned by kainic acid and the CT response of thalamic (T) cells was recorded intracellularly in cats under pentobarbital or urethane anesthesia. Results show that (1) CT pathway activation depolarized T cells and that this response potentiated when stimulation rate exceeded 2 Hz. (2) Potentiation was completely abolished by ketamine injection (5 mg/kg i.c.) or by local pressure application of APV. (3) Though CT pathway stimulation could facilitate subthreshold EPSPs of cerebellar origin, this facilitation resulted from simple summation rather than from an heterosynaptic potentiating mechanism. It is then concluded that CT neurons depolarizes T neurons, partly through the activation of NMDA receptors. The numerical importance of the CT neuronal population and the autopriming mechanisms operating at CT synapses indicate that the role of the thalamus is not only to transfer peripheral information toward the cortex, but also and mainly to relay to the cortex a fac-simile of its own neuronal constructs.Supported by the Canadian MRC.

EFFECTS OF KYNURENIC ACID ON VISUALLY EVOKED POTENTIALS IN THE ALBINO RAT. D.F. Sisson, J. Siegel and S.J. Grant. School of Life and Health Sciences and Department of Psychology, University of Delaware, Newark, DE 19716.

The putative transmitter of neurons that project from LGN to visual cortex (OC1) is thought to be an excitatory amino acid (EAA). Since early components of the VEP are indicative of geniculo-cortical activity, we investigated the effects of kynurenic acid (KYN), a non-selective EAA antagonist, directly applied to OC1 on flash VEPs of chloral hydrate anesthetized albino rats.

A cortical cup was used for superfusion of CSF over left OC1. VEPs were recorded from this cortical surface and simultaneously from the intact right cortex.

Within one minute of the addition of 0.1 mM KYN to the superfusate, VEP components N_1 and those after P_2 were abolished. P_1 was lost by 5 min, and an anomalous P_2 remained after 10 min. After 1 hr or more of CSF wash, all VEPs returned and were again comparable to VEPs recorded from right OC1.

The elimination of all components of the VEP by KYN except P_2 indicates that an EAA is the transmitter in the geniculate afferents and that P_2 is generated either by commissural afferents from contralateral OC1 or by non-geniculate afferents. The lack of a P_2 effect in right OC1 argues against the commissural explanation.

CYSTEINE REDUCES SPIKE AFTERHYPERPOLARIZATION OF CA3 PYRAMIDAL CELLS IN HIPPOCAMPAL SLICE CULTURES S. Charpak*, T. Knöpfel, K.Q. Do* and B.H. Gähwiler (Spon:G.Kato). Brain Research Institute, University of Zürich, CH-8029 Zürich (Switzerland)

Recently, it has been described that endogenous cysteine (Cys) could be released from various rat brain regions upon potassium stimulation in a calcium-dependent manner (Keller et al. J. Neurochem. 1989, in press). In the present work, we investigated whether Cys affects membrane properties of hippocampal CA3 pyramidal cells.

Organotypic cultures of rat hippocampus were prepared as described previously. After 2-5 weeks in vitro, the cultures were superfused with a balanced salt solution containing 1 µM TTX and single-electrode voltage-clamp techniques were used to record currents from CA3 pyramidal cells.

Cys (500 µM to 1 mM) induced an inward current and reversibly reduced slowly decaying outward tail currents induced by short lasting depolarizing voltage jumps. These tail currents reversed at the potassium equilibrium potential and were blocked by the Ca^{++} antagonist Cd^{++} suggesting that they are produced by the Ca^{++}- activated potassium conductance underlying spike afterhyperpolarization and accommodation.

These observations support the hypothesis that Cys is involved in chemical neurotransmission.

c-fos AND HEAT SHOCK (hsp72) GENE EXPRESSION FOLLOWING INTRAVENTRICULAR ADMINISTRATION OF QUISQUALATE AND QUINOLINIC ACIDS. J.W. Sharp, S.M. Sagar, P. Jasper*, T. Marsh*, and F.R. Sharp, Depts. Neurology & Physiology, UCSF and VA Med Ctr, San Francisco, CA 94121.

Since systemic kainic acid induces HSP72 in brain (Gonzalez et al., Mol. Brain Res., in press), the effects of 5ul of 50mM intraventricular quisqualate (QQ) and quinolinic (QL) acid, which acts at the NMDA receptor, were studied. Expression of the c-fos proto-oncogene and the inducible heat shock gene, hsp72, were examined 24 hours later. QQ induced Fos bilaterally in limbic structures, including hippocampal pyramidal neurons, amygdala, piriform cortex, basal forebrain, and septal neurons, but not in neocortex or hippocampal granule cells. QQ markedly induced HSP72 in Golgi like patterns bilaterally in hippocampal pyramidal neurons, dentate hilus, amygdala, and parvocellular PVN. QL induced Fos in ipsilateral neocortex, septum, basal forebrain, amygdala, and piriform cortex, and bilaterally in hippocampal pyramidal neurons and dentate granule cells. QL minimally induced HSP72 in a few CA4 pyramidal neurons and in scattered patches of cortical neurons. The data show that excitatory amino acids induce c-fos and hsp72 genes in brain, that different receptors may mediate induction in different populations of neurons, and that a subset of neurons in which Fos is induced express the stress protein, HSP72.

EXTRACELLULAR pH and Ca SHIFTS EVOKED BY GLUTAMATE AND ASPARTATE IONTOPHORESIS IN TURTLE CEREBELLUM. **M. Chesler[1,2] & M.E. Rice[2].** Depts. of Neurosurgery[1] and Physiology & Biophysics[2], NYU Med. Ctr, 550 1st Ave, NY, NY 10016.

Parallel fiber (PF) stimulation causes an extracellular alkaline shift (AS) that is blocked by Mn (Kraig et al. J. Neurophys. 49:831) and kynurenate (Chesler & Chan, Neuroscience 27(3):941). We studied the pharmacologic sensitivity of the AS and its relationship to Ca_o shifts in the isolated turtle cerebellum. pH_o and Ca_o shifts, recorded with ion-selective microelectrodes, were evoked by afferent stimulation, or iontophoresis of aspartate (asp) or glutamate (glu).

Stimulation of PF's or peduncular afferents evoked AS's in only the molecular layer (ML). Kynurenate (0.5-4 mM) and Cd (0.1 mM) reversibly blocked the PF-evoked AS. APV (.02-.10 mM) had no effect. GABA (1 mM) blocked the PF-evoked AS, with no effect on pH_o. The AS is therefore not generated by NMDA or GABA-gated channels. With asp or glu iontophoresis, AS's occured in all layers (up to 0.4 pH units). Ca_o transients and AS's corresponded in time course and spatial profile, however, in the GL, application of 5 mM Mn only partially (50%) blocked the AS. In the ML, 100 mM Cd blocked synaptic transmission with no effect on the iontophoretic-evoked AS.

The correspondence between Ca_o and pH_o shifts suggests a relationship between Ca currents and the AS. However, the small effect of Mn and Cd suggests that voltage-dependent calcium channels are not necessary. The block of the afferent response by GABA indicates that the AS is not generated by acid flux through excitatory post-synaptic channels. Assuming GABA "clamps" dendritic membrane potential, its block of the AS suggests that the response is triggered by dendritic depolarization. Whether the AS arises due to acid-base flux across a channel is still undetermined. Supported by USPHS grant NS-13742.

COMPUTER SIMULATION OF EXCITATORY POSTSYNAPTIC CURRENTS DUE TO VARYING RATIOS OF NMDA TO NON-NMDA RECEPTORS. W.R. Shankle*, Matthew Wilson, D.R. Stevens, Don Perkel, James Bower, Carl W. Cotman(SPON:C.W. Cotman). Cotman Lab., Dept. of Psychobiology, UC Irvine, Irvine, CA 92717. Bower Lab,Division of Biology, California Instit.itute of Technology, Pasadena, CA 91125

We have simulated currents resulting from synaptic release of glutamate onto a mixture of NMDA and non-NMDA receptors at the postsynaptic membrane. NMDA activated currents were fit with voltage dependence derived from the voltage clamp results of Mayer and Westbrook(1984) on cultured mouse spinal cord neurons. Depolarizing current injections produced small transient changes in membrane potential(low resistances); in contrast, hyperpolarizing current injections produced much larger transient changes in membrane potential(high input resistances) to voltage clamped membranes over a range of clamped potentials. Synaptic currents were simulated over a range of ratios of NMDA to non-NMDA receptors(1:10 to 3:1). Under voltage clamp conditions, membranes with as low as 10% of their receptors being NMDA showed voltage dependence of the peak current plus a voltage dependent increase in the amplitude and time of the decay phase of the excitatory postsynaptic currents(epsc). In contrast, increasing the NMDA channel conducting time did not affect the peak current but did affect the time course and voltage dependence of the epsc decay phase. NMDA to non-NMDA receptor ratios of 3:1 may be closer to ratios seen in the hippocampus. The epscs changes polynomially with membrane potential at this ratio. The capacity for more temporal summation of epscs and the greater current amplitudes along the decay phase provided by a more heavily weighted NMDA receptor fraction may have fundamental effects on new memory formation.

AMINO ACID INDUCED MODULATION OF DOPAMINERGIC NEURONS IN THE SUBSTANTIA NIGRA. M.F.Pozza*, S.Margarson*, E. Kueng*, H.-R.Olpe* (SPON: G.E.FAGG). Res. and Dev. Dept. Pharmaceuticals Div., CIBA-GEIGY Ltd., CH-4002 Basel.

The actions of amino acid transmitters were tested on the activity of single dopaminergic neurons in the substantia nigra pars compacta (SNpc). Extracellular recordings were made in 400 um midbrain slices. All drugs were bath-applied. Dopamine (100 μM) reduced the firing rate of all neurons tested by 55 ± 8 % (n = 15).

Effects of GABA-A and -B agonists and antagonists: L-baclofen (1.0 μM) and muscimol (1.0 μM) strongly reduced the spontaneous firing rate of the cells. Bicuculline (1.0 um) potently antagonized the effects of muscimol without affecting the action of L-baclofen. Phaclofen (1 mM) blocked the action of L-baclofen but did not affect the muscimol response. Neither phaclofen nor bicuculline alone had a significant effect on the spontaneous firing rate. These results indicate that GABA-A and GABA-B receptors are present.

Effects of excitatory amino acids: NMDA and kainate increased the firing rate of SNpc cells in a concentration dependent manner (5-20 μM) without causing any burst firing. The NMDA effect was selectively antagonized by the NMDA-receptor antagonist CGP 37 849. Quisqualate had no effect. The results suggest that NMDA and kainate receptors but not quisqualate receptors may be involved in the regulation of nigral dopaminergic cell activity.

DEVELOPMENTAL EXPRESSION OF A NOVEL EXCITATORY AMINO ACID RESPONSE IN CEREBELLAR PURKINJE NEURONS. C.L. Franklin* and D.L. Gruol (SPON: W. Young). Res. Inst. Scripps Clinic, La Jolla, CA 92037.

Cerebellar Purkinje neurons (PNs) in culture respond to micropressure application of the excitatory transmitter glutamate (Glu) and the selective agonists quisqualate (QA) and kainate (KA). In mature PNs recorded extracellularly, the agonist responses are characterized by an initial excitatory period, a period of burst activity and an inhibitory period. Glu, Quis and KA differ in the effectiveness of evoking the three response components. In intracellular recordings, the excitatory component of the response is associated with a membrane depolarization; the inhibitory phase is associated with a small hyperpolarization or no change in membrane potential; bursting occurs during the repolarizing and inhibitory phases (Yool and Gruol, Soc. Neurosci. Abstr, 1988). In the present study, we have examined the developmental expression of the agonist responses using extracellular recording techniques and micropressure application of agonists. Immature PNs without visible dendritic structure also exhibited the novel response when tested with Glu, QA and KA. However, response components were generally less robust than in mature neurons. Developmental changes in the response properties were agonist dependent, suggesting that multiple excitatory amino acid receptor subtypes were involved The most dramatic developmental changes were observed with QA, which was also the most potent agonist at all culture ages. The novel features of the amino acid responses in the PNs may be due to the involvement of more than one QA receptor subtype. Supported by NIAAA 06665.

NMDA AND NON-NMDA EXCITATORY AMINO ACID NEUROTRANSMISSION IN CONSTRUCTION OF RECEPTIVE FIELDS OF RAT BARREL-FIELD NEURONS. M. Armstrong-James* (SPON: K. Chapman). Physiology Dept., London Hospital Medical College, London, E1 2AD, England.

Vibrissal excitation of 135 neurons in layers II-V was found to be dominated by NMDA-dependent somato-sensory neurotransmission, as tested against adequate APV iontophoresis, although for all layers, except V, excitatory surround-receptive fields (SRFs) were more depressed by APV than the single - vibrissa centre-receptive field (CRFs). Layer II and upper layer III neurons were almost exclusively NMDA-dependent, both CRFs and SRFs being 80-100% eliminated (20-30 nA APV). CRFs and SRFs of lower layer III and IV neurones were progressively less (60-80%). In contrast to their SRFs however, CRFs of very short latency (6-8 ms) layer IV neurones, were only marginally affected by APV (0-18%). Both SRFs and CRFs of layer V neurones were depressed about 50% by 40-80 nA of APV. Similar results were achieved using kynurenate (blocker of both NMDA and non-NMDA receptors) although (1) greater suppression of RFs was generally achieved and (2) Short latency CRFs of layer IV neurons were additionally suppressed to 50-85%. These results suggest that most intracortical neurotransmission for constructing total RFs of upper layer and lower layer SI cortical neurons, and SRFs of layer IV neurons is dominated by NMDA-receptor activation. CRFs of layer IV/lower layer III neurons, reflecting the thalamo-cortical inputs, are more non-NMDA dependent, (presumably quis, kainate or other unknown receptor types).

NEUROENDOCRINE REGULATION: PHOTOPERIOD/PINEAL

375.1

A SINGLE BLOCK OF PHOTOPERIODIC INFORMATION EACH YEAR CAN SYNCHRONIZE THE ANNUAL REPRODUCTIVE CYCLE OF EWES. C. J. I. Woodfill, B. Malpaux*, J.E. Robinson* and F. J. Karsch*. Reproductive Sciences Program and Department of Physiology, The University of Michigan, Ann Arbor 48109.

Although many species display circannual cycles of biological activity that are synchronized by daylength, the specific photic requirements for synchronizing such cycles are not established for any species. We tested the hypothesis that the circannual reproductive cycle of sheep can be synchronized by just one discrete block of photoperiodic information a year. Ewes were functionally disconnected from their photoperiodic environment by pinealectomy (pnx). Specific photoperiodic signals were restored via replacement of 24-hr patterns of melatonin (mel), the pineal hormone which transmits photic information to the reproductive neuroendocrine axis. Two groups of pnx ewes were kept in a 12-month photocycle which alternated between short (8L:16D) and long (16L:8D) days every 6 months for 5 years. Non-infused controls (pnx) did not exhibit synchronous reproductive cycles. Experimental ewes (pnx+mel) received alternating 70-day infusions of short- and long-day patterns of mel every 6 months each year for the first 2-1/2 years; thereafter, ewes received just one 70-day infusion of long-day mel a year. Infusion onsets coincided with photoperiodic shifts. Pnx+mel ewes exhibited synchronous annual reproductive cycles throughout the study, including the final two years when they received only one block of photoperiodic information (ie., mel infusion). Cycle period was 365 ± 3 days; standard deviation of the date of onset of reproductive induction averaged only 3 days. Our study provides the first direct evidence that a single block of photoperiodic information each year can synchronize a circannual cycle. (NSF-DCB-8316364 & DCB-8710099)

375.2

THE EFFECT OF OVARIECTOMY AND ESTRADIOL TREATMENT ON THE COHERENCE OF CIRCADIAN ACTIVITY RHYTHMS IN CONSTANT LIGHT. E.M.Thomas* and S.M.Armstrong* (SPON: R.F.Mark), Dept. Physiol. Monash Univ. Vic 3168 and Dept. Psych. LaTrobe Univ. Vic 3183, Australia.

Whilst exposure to constant bright light (LL) often leads to the disruption of rat circadian rhythms, in dim LL, rhythms usually persist and free-run. 16 ovariectomized rats (ovx), 8 implanted with estradiol-17β and 8 with empty implants, 8 intact rats and 6 sham operated rats were maintained in dim LL (<20 lux) for 70 days. The circadian activity rhythms of the intact and sham operated animals free-ran as expected but the wheel-running and drinking activity rhythms of the ovx, blank-implanted rats were rapidly disrupted. The ovx, estradiol-implanted rats displayed activity rhythms that were more similar to those of intact rats than to those of ovx rats. Rather than being arrhythmic, the disrupted activity data of the ovx, blank-implanted rats appeared to contain free-running, ultradian components. These data appear consistent with the concept of a multioscillatory basis to the circadian system and suggest a role for ovarian estradiol in the maintenance of synchrony between component oscillators.

NEURAL PROCESSING OF ENVIRONMENTAL INFORMATION IN THE SIBERIAN HAMSTER (PHODOPUS SUNGORUS). K.S. Matt* and S.R. Morgan*. (SPON: A. Kammer). Dept. of Zool., A.S.U., Tempe, AZ 85287.

Seasonally breeding animals must carefully integrate information from their external environment with information regarding their internal physiological environment. These studies were designed to examine the neuroendocrine mechanisms involved in integrating photoperiodic, behavioral and dietary information. Siberian hamsters are particularly suited to these studies because it seems that reproductive success may be dependent on pair bond formation, and parental care by both the male and female. We examined changes in brain catecholamines in the pre-optic area, medial basal hypothalamus, and cortex in animals housed under various conditions. These studies demonstrate that separation of previously paired animals in a long photoperiod results in a decrease in norepinephrine and dopamine in the medial basal hypothalamus. Similarly, exposure of short photoperiod males to a sexually receptive female mate, or a female mate with young, results in increases in norepinephrine and dopamine in the medial basal hypothalamus. Furthermore, exposure of short photoperiod males to different dietary regimes results in changes in norepinephrine and dopamine concentrations in the pre-optic area. These results strongly suggest that a variety of environmental stimuli can alter and override photoperiod effects on neurotransmitters and that processing of this information may occur in different regions of the brain. LHRH AND GAP IMMUNOCYTOCHEMISTRY AND LHRH IN-SITU HYBRIDIZATION IN GOLDEN HAMSTERS EXPOSED TO DIFFERENT PHOTOPERIODS. E. Ronchi*, L. Krey*, D.W. Pfaff. (SPON: R. Lustig). The Rockefeller University, New York, NY 10021.

Hypothalamic luteinizing hormone releasing hormone (LHRH) and gonadotropin releasing hormone associated peptide (GAP) biosynthesis and storage were estimated by immunocytochemistry and in-situ hybridization in male golden hamsters maintained in different photoperiods. Intact or castrated male hamsters (with testost. capsules) were exposed to long-day (14:10) or short-day photoperiods (LD 10:14) for four to eight weeks. Brains were rapidly processed using a novel free-floating procedure which allows immunocytochemistry and in-situ hybridization on alternate tissue sections. Exposure to short photoperiod is associated with an increase in the number of LHRH and GAP immunoreactive cells in the diagonal band of Broca/medial septum. This increase is correlated with augmented steady state LHRH mRNA levels, as measured by in-situ hybridization and RNAase protection assay. Furthermore, morphometric analysis revealed that animals exposed to short daylengths display significantly more LHRH but not GAP immunoreactivity in the median eminence as opposed to hamsters exposed to long-day photoperiods. Thus, suppression of release but not synthesis of LHRH may be associated with reproductive quiescence in the golden hamster.

375.5

THYROIDECTOMY BLOCKS TRANSITION TO ANESTROUS SEASON BY SUSTAINING LH-PULSE GENERATING ACTIVITY IN EWES. S.M. Moenter*, C.J.I. Woodfill, F.J. Karsch*(SPON: F.J.P. Ebling) Reprod. Sci. Prog., Dept. Physiol., Univ. Mich., Ann Arbor.

Seasonal reproductive transitions in ewes are endogenously generated and are synchronized by annual changes in photoperiod. Previous evidence implies thyroidectomy prevents the transition to anestrus in ewes maintained in a fixed day length, suggesting the thyroid is needed for endogenously generated reproductive arrest (Reprod Nutr Develop 28: 375, 1988). Here we tested the hypothesis that the thyroid is needed for endogenous seasonal suppression of the neuroendocrine system which generates pulsatile secretion of luteinizing hormone (LH). Ewes were thyroidectomized (THX, n=6) in summer, 6 weeks prior to onset of the breeding season, or left intact (INT, n=6). They were housed in simulated natural photoperiod until the winter solstice; thereafter they remained on that photoperiod (10L:14D). To monitor pulsatile LH secretion, ewes were ovariectomized, implanted with estradiol, and LH was measured in both frequent (6 min) and infrequent (twice/week) blood samples. In this model, high LH indicates reproductive induction, low LH reproductive arrest. Although LH levels (samples twice/week) rose concurrently in both groups in September, levels remained high longer in THX ewes (onset low values INT, 15 Feb ± 14 d; values still high in THX at end of study, mid-April). Frequent sampling in autumn (breeding season) revealed both THX and INT exhibited frequent LH pulses (THX 7.0 ±0.6 vs INT 6.0 ±0.7 pulses/4 hr). In spring (anestrus), THX ewes still had frequent pulses (9.8 ± 1.1 pulses/ 4 hr), whereas INT had no pulses/4 hr. This supports the hypothesis that the thyroid is necessary for endogenous suppression of neuroendocrine systems which generate LH pulses, a suppression crucial for transition to anestrus.(NIH-HD-18337)

375.6

DAILY RHYTHMS OF LUTEINIZING HORMONE IN FEMALE HAMSTERS STERILIZED WITH MONOSODIUM GLUTAMATE. R.S. Donham*, K.M. Ogilvie* and M.H. Stetson*. (SPON:S. Binder-Macleod). Physiol. Sect., Sch. of Life and Health Sci., Univ. Delaware, Newark, DE 19716.

The prepubertal female golden hamster has a daily rhythm of circulating luteinizing hormone (LH) with a maximum at 1700h each afternoon. At puberty, the daily rhythm is replaced by a 4d estrous cycle rhythm. Injection of monosodium glutamate (MSG) into neonatal rodents sterilizes the adult as a consequence of specific degeneration of the retina and arcuate nucleus perikarya. We used MSG to evaluate the hypothalamic components necessary for the expression of the daily rhythms of gonadotropins in female hamsters. We injected MSG (8 mg/g b.w.) into 8d old females. Animals were weaned at 21d of age and blood samples were obtained at 24d of age at 1300 and 1700h. In saline-injected controls, the levels of LH were 0.7 ± 0.46 and 5.5 ± 1.6 ng/ml (1300 and 1700h, respectively, mean ± SEM, n=6, both times; $p<0.05$, Mann-Whitney test) and regular, 4d vaginal estrous cycles were initiated between 29 and 37d of age. MSG-treated animals had levels of LH that were 0.2 ± 0.03 and 3.0 ± 1.1 ng/ml, $p<0.01$); none of these had initiated regular estrous cycles by 50d of age. Thus MSG did not affect daily, circadian-based rhythmicity in LH secretion even though it made the adult-age animals infertile.

375.7

ALTERATIONS IN HYPOTHALAMIC SEROTONIN METABOLISM IN HAMSTERS WITH PHOTOPERIOD-INDUCED TESTICULAR REGRESSION. R.W. Steger*, C. Dennis*, A. VanAbbema*, E. Gay-Primel* (SPON: D. Molfese). Dept. of Physiology, Southern Illinois Univ School of Medicine, Carbondale, IL 62901.

Exposure of male hamsters to a short photoperiod (<12.5h light/day) results in decreased levels of LH, FSH, Prl and atrophy of the reproductive system. These changes are preceded by decreases in hypothalamic norepinephrine and dopamine turnover but the effects of photoperiod on 5-HT metabolism are unknown. In the present study, the rate of 5-HT synthesis in several brain regions of long day (LD, 16:8 light:dark) and short day (SD, 8:16) hamsters was estimated by measuring 5-hydroxytryptophan (5-HTP) accumulation after inhibiting aromatic amino acid decarboxylase with NSD-1015 (150mg/kg, ip). Exposure to SD led to decreases in testicular weight and plasma levels of LH and Prl. Concentrations of 5-HTP in the median eminence (ME), medial basal hypothalamus (MBH), anterior hypothalamus (AH) and olfactory bulbs (OLFB) increased linearly with time after NSD administration in both LD and SD hamsters. The accumulation of 5-HTP in the MBH was significantly greater in the SD than in the LD controls. 5-HTP accumulation did not differ in other brain areas. Similar results were seen in a 2nd experiment where it was also shown that 5-HT synthesis was restored to control levels within 2 days after transferring SD hamsters to LD. ME, MBH, AH and OLFB 5-HT and 5-HIAA levels in uninjected hamsters were not affected by photoperiod but the ratio of 5-HT to 5-HIAA in the MBH was reduced in the SD animals. The significance of the increase in MBH 5-HT synthesis in SD hamsters is not known but may be related to changes in Prl secretion since we have shown that hypophysectomy increases MBH 5-HT synthesis and this effect can be reversed by Prl replacement (Supported by NSF - DCB-8619702).

375.8

EFFECT OF SHORT-DAY INDUCED GONADAL REGRESSION ON THE GnRH NEURON SYSTEM IN THE ADULT MALE DJUNGARIAN HAMSTER. S.M. Yellon, Div. Perinatal Biology, Depts. Physiology, Pediatrics and Anatomy, Loma Linda Univ. Sch. of Med., Loma Linda, CA 92350.

In the Djungarian hamster, exposure to short days inhibits gonadotropin secretion and induces gonadal regression. During sexual maturation, the effect of short days to arrest testes growth is correlated with reduced numbers of immunoreactive-GnRH neurons in the diagonal band of Broca (DBB) and medial preoptic area (MPOA). However, in adult white-footed mice, short-day mediated gonadal atrophy is associated with increased GnRH neuron number. Because similar data are lacking for the adult hamster, the present study determined the effect of short days on the number and morphology of GnRH neurons in the DBB and MPOA, a region that contains the majority of GnRH cell bodies. Males reared in long days (LD, 16L:8D) were either maintained in LD or transferred to short days (SD, 10L:14D) at 30 d of age. Hamsters were killed 10, 30, or 60 d later by intracardiac perfusion (40, 60, or 90 d of age, respectively, n = 4 each). Testes were weighed and brains were sectioned (60 μm) from just rostral to the corpus callosum decussation to the suprachiasmatic nucleus. Every section was processed for GnRH immunocytochemistry (LR1 gift of R. Benoit). Testes weights were significantly reduced by 10 d of SD (398 ± 137 mg) and atrophied by 60 d (44 ± 2 mg) compared to LD controls (about 850 mg). Total number of GnRH immunoreactive perikarya was increased after 10 d of SD (133 ± 8 vs 97 ± 12, $p < 0.05$, SD vs LD). This change was small and restricted to the DBB (both unipolar and bipolar subtypes). At other ages, GnRH neuron number and ratio of unipolar to bipolar subtypes in the DBB and MPOA remained unchanged in SD compared to LD hamsters despite gonadal regression. The findings indicate that a relatively stable population of GnRH immunoreactive neurons are present in adulthood compared to that found in the peripubertal male hamster or white-footed mouse. (Sup. NIH HD22479)

THE DECREASE OF HYPOTHALAMIC LHRH CONTENT IN CONSTANT LIGHT CANNOT BE REVERSED BY MELATONIN ADMINISTRATION. T.Porkka-Heiskanen, M-L.Laakso*, D.Stenberg*. Inst.Physiology, Univ.Helsinki, 00170 Helsinki, Finland

Adult male Wistar rats were kept in constant (LL) or periodical (LD) light for one week, where they received either saline or melatonin (50 ug/0.1 ml saline) injections s.c. daily at 9 A.M. or 4 P.M. After decapitation the hypothalamus was dissected and the hypothalamic LHRH content was measured with radioimmunoassay. Hypothalamic LHRH content was lower in constant light exposed rats than in periodical light exposed rats, and melatonin given either in the morning or in the evening was unable to inhibit the decrease.

We conclude that the constant light effect on hypothalamic LHRH content is not mediated via melatonin.

PHOTOPERIODIC HISTORY MECHANISMS IN SYRIAN HAMSTERS. J. D. Karp*, M. E. Dixon*, and J. B. Powers. Dept. Psychology, Vanderbilt Univ., Nashville, TN 37240.

The reproductive response of Syrian hamsters to altered daylengths is affected by their photoperiodic history (PPH). Two features of PPH were evaluated; (a) the melatonin (MEL) signal experienced, and (b) the circadian after-effects on tau. Male hamsters in LD 14:10 were administered single daily injections of MEL (15 μg; n=22) or saline (SAL) (n=10) 1 hr prior to the onset of darkness for 8 weeks. Their subsequent reproductive response to 8 weeks without injections in LD 12:12 or LD 8:16 was evaluated (grps=MEL 12:12; MEL 8:16; SAL 12:12). MEL caused significant testicular regression (TR); SAL did not. Regressed Ss experienced testicular stimulation (TS) in LD 12:12 and this occurred significantly faster than the TS caused by photorefractoriness among the MEL 8:16 males. The SAL 12:12 hamsters exhibited TR, indicating that MEL history and not photoperiod duration per se was important in mediating PPH effects.

In a second study, PPH consisted of daily light cycles (8 hr duration) with periods shorter (T=23.33; n=20) or longer (T=24.67; n=21) than 24 hrs, followed by transfer to LD 12:12. These T-cycles were chosen because both would be stimulatory to the reproductive system, but their after-effects on tau would qualitatively mimic those produced by conventional long or short days. After 5 weeks in the assigned T-cycle, all hamsters maintained large testes. Subsequent exposure to LD 12:12 for 11 weeks caused some TR in both groups, but not nearly as much as was shown by the SAL 12:12 males in the first experiment. Because both groups interpreted LD 12:12 as a short day, the PPH effect of their prior T-cycle exposure was consistent with its being interpreted as a long day by the reproductive system, even though the two T-cycles did generate different circadian after-effects on tau.

REGULATION OF GAP JUNCTION EXPRESSION BETWEEN ADULT RAT PINEALOCYTES. V.M. Berthoud* and J.C. Sáez*. (SPON: J.A. Connor). Dept. Neurosci., A. Einstein College of Medicine, Bronx, NY 10461.

Gap junctions mediate electrotonic and metabolic coupling. We previously showed that rat pinealocytes are electrically and dye coupled and that they express at least connexin 26 (Sáez et al., Soc. Neurosci. Abstr. 14: 1175, 1988). We now report the effect of norepinephrine (NE) and second messengers on the incidence of dye coupling between pinealocytes in culture. Pineal glands of Sprague-Dawley rats (ca. 200 g) were used to prepare primary cultures of enzymatically dissociated pinealocytes. After 8 days in culture, the cells were treated with NE (6.6 μM) plus ascorbic acid (66 μg/ml), cAMP (0.1 mM) or DAG (100 nM). Dye coupling was evaluated by injecting Lucifer yellow into one cell of a pair or cluster. NE (plus ascorbic acid) markedly increased the incidence of dye coupling (from 0-20% to 50%-70%), reaching a plateau at 6 h. Four to 6 h after NE was washed out, the incidence of coupling decreased to values near those seen in control cultures. cAMP and DAG treatment also increased the incidence of dye coupling 6 h after its addition, but to a lower and more variable extent than NE. Experiments are underway to determine the extent to which each second messenger contributes to the NE effect on coupling. These data suggest that coupling between pinealocytes is regulated by NE, the neurotransmitter released during darkness by SCG nerve terminals that innervate the epiphysis. Since NE-induced melatonin secretion is maximal at about 6 h of the dark half of a 12:12 h light:dark cycle when NE would increase coupling maximally, we suggest that gap junctions play a role in melatonin secretion induced by NE.

ULTRASTRUCTURAL AND BIOCHEMICAL COMPARISON OF THE CAT AND RAT PINEAL GLAND. L. Kus*, L.M. Fox*, J.A. McNulty* (SPON: A. LaVelle). Dept. of Anatomy, Stritch School of Medicine, Maywood, IL 60153

The mammalian pineal gland exhibits species variability in morphology and biochemistry. As a potential model for studies on pineal function in a seasonal breeder, this study compared the ultrastructure and biochemistry of the cat pineal with that of the rat. 19 adult cats and 10 Sprague-Dawley rats housed under standard laboratory conditions (L:D 12:12) were sacrificed during the light period and the pineal glands processed for either TEM or HPLC of monoamines and free amino acids. Compared to the rat, the cat pineal was less well vascularized by non-fenestrated capillaries, contained larger bundles of neural elements, and more glia. Important biochemical differences between these species were observed in the ratios (cat/rat per mg protein) of NE (3/1), 5HT (1/20), 5HIAA (1/2), and the neuroactive amino acids glutamate (1/10) and taurine (1/3). A rich sympathetic innervation of the cat pineal (J. Pineal Res.3:15, 1986) is consistent with high levels of NE in this species. Low concentrations of 5HT and 5HIAA in the cat may reflect species differences in indole turnover. Finally, the sparcer vascularity and reduced steady state levels of free amino acids suggests a generally lower metabolic rate in the pineal gland of the cat compared to the rat.

FREE AMINO ACIDS IN THE PINEAL GLAND: CIRCADIAN CHANGES AND EFFECTS OF SUPERIOR CERVICAL GANGLIONECTOMY. J.A. McNulty*, L.M. Fox*, L. Kus* (SPON: F. LaVelle). Dept. of Anatomy, Stritch School of Medicine, Maywood, IL 60153.

The neuroactive amino acids (aa) glutamate and taurine are present in high concentrations in the pineal gland and may function to regulate melatonin production. To further elucidate possible role(s) of aa in pineal neuroendocrine function, steady state levels of aa were measured over a light: dark cycle in intact and denervated pineals. 108 male Sprague-Dawley rats were equally divided into 3 groups (intact, shams, SCGx), entrained to a 10:14 L:D cycle, and sacrificed at 6 circadian time points. HPLC was used to measure monoamines (HPLC-EC) and aa (OPA Fluor) in individual pineals (6/group/time point). In intact and sham controls, significant circadian differences were found in the monoamines NE, 5HT, 5HIAA, NAS, MEL, and the aa GLU, TAU, ASP, ALA, GLY, ARG, and GLN. SCGx abolished each of the rhythms. SCGx also resulted in a significant (ANOVA) reduction of GLU (52%), ASP (69%), ALA (68%), ARG (67%). Effects of SCGx on TAU and GLY were found only at 1 time point. There was no effect of SCGx on the aa SER and total protein. Our findings that circadian changes in aa depend on an intact innervation are consistent with metabolic demands related to melatonin production. The magnitude of the reduction of GLU after SCGx suggests that this aa is particularly important to these metabolic processes.

SUPPRESSION OF PINEAL MELATONIN CONTENT IN LONG-EVANS HOODED RATS: DOSE-RESPONSE CURVE AT 640 NM. Brian J. Broker*, J.P. Hanifin*, M. D.Rollag*, W.A. Thornton*, and G.C. Brainard, Department of Neurology, Jefferson Medical College, Philadelphia, PA, Department of Anatomy, USUHS, Bethesda, MD, and Prime Color Inc., Cranford, NJ.

It has been thought that wavelengths of red monochromatic light above 610 nm would not influence rat pineal physiology due to the belief that rods are relatively insensitive to this part of the spectrum. The purpose of this study was to examine the capacity of red monochromatic light at 640 nm (10 nm half-peak bandwidth) to suppress typically high nocturnal pineal melatonin content in rodents. Groups of adult male Long-Evans Hooded rats were entrained to a 10:14 light:dark (L:D) cycle (lights on 0700-1700 h) and then exposed to different irradiances of 640 nm for five minutes during their dark phase. Matched groups of control animals were handled similarly but were not exposed to 640 nm pulses. Following exposure animals were held in darkness for 15 minutes and then sacrificed. Pineal glands were dissected out, frozen at -20° C, and later assayed for melatonin content by RIA. Irradiances used were; 0.03, 0.3, 3, 6, 18, 30, 136, and 243 uW/cm^2. Control groups all showed typically high nocturnal pineal melatonin contents while experimental groups exposed to 18, 30, 136, and 243 uW/cm^2 showed a significant suppression of pineal melatonin content ($p<0.001$). Groups exposed to lower irradiances showed high melatonin contents which were not significantly different from those of matched control groups. The results demonstrate that wavelengths of monochromatic light at 640 nm are capable of influencing rat pineal physiology and therefore should not be used indiscriminantly for observation of rats during the dark phase of their L:D cycle. BOVINE PINEAL GLAND SYNTHESIZES TRANSTHYRETIN. R.L.Martone* and J.Herbert*. Dept. of Neurology, Columbia Univ., New York, NY 10032. (SPONSOR: M.L.Shelanski).

Transthyretin (TTR) is a 56 kDa tetrameric protein that plays an important role in the serum transport of thyroxine and retinol. TTR is synthesized by the liver, yolk sac endoderm and choroid plexus (CP) epithelium. Because of the functional homology between the CP epithelium and the retinal pigment epithelium (RPE), we previously investigated and reported specific synthesis of TTR by the RPE. We now report synthesis of TTR by the phylogenetic "vestigial eye" - the pineal gland. Northern blot anlaysis of total RNA isolated from bovine pineal glands revealed the presence of TTR mRNA at levels significantly lower than those present in bovine CP. Western blot analysis of bovine pineal gland confirmed the presence of immunoreactive TTR protein. By immunohistochemical methods, TTR was restricted to the cytoplasm of pinealocytes. While the function of TTR in the CNS is unknown, the expression of TTR by the pineal gland suggests that it may play a role in mediating the effects of thyroxine on pineal neuroendocrine function.

CIRCANNUAL ANALYSIS OF PINEAL INDOLES IN RATS KEPT ON CONSTANT PHOTOSCHEDULES. M.M. Prechel*, T.A. Dombrowski*, W.H. Simmons, J.A. McNulty*. Depts. of Anatomy and Biochemistry, Loyola Univ., Maywood, IL 60153.

Photoperiod is the primary regulator of circadian and seasonal changes in melatonin synthesis in the pineal gland. The extent to which other inputs are superimposed on this photic control has not been clearly established. This study was undertaken to determine if there are seasonal effects on circadian indole metabolism in rats housed under a constant photoperiod. Male, adult S/D rats were kept in L:D 12:12 with lights on at 0700 h. Pineal glands (n=4-8/time point) were collected over 15 monthly intervals at 4 time points (1200, 1900, 2400, 0500 h) over each L:D cycle. Individual pineal extracts were assayed either for indoles by HPLC-EC or RIA for neurohypophsyeal hormone activity. Results demonstrated circadian cycles in 5HT, 5HIAA, N-acetylsertonin and melatonin (MEL), and the August increase in immunoreactive arginine vasotocin (iAVT). Reduction in the amplitude of the MEL rhythm coincided with elevated iAVT, and 5HT levels tended to be greater during the winter months. Seasonal differences were also observed in correlation coefficients between indole constituents in individual glands. These findings suggest seasonal effects on the pineal melatonin pathway and peptide content even under controlled laboratory photoschedules.

PROPRANOLOL AND MELATONIN MODULATION OF SHORT PHOTOPERIOD-INDUCED GONADAL REGRESSION. T. H. Champney. Dept. of Med. Anat., Texas A&M Univ., College Station, TX 77843.

Daily propranolol (PROP) injections, given late in the day, block short photoperiod(SP)-induced gonadal regression in male Syrian hamsters, but not gonadal regression produced by daily injections of melatonin (MEL). Since MEL implants block gonadal regression produced by SP or MEL injections, the interaction of PROP, MEL implants and MEL injections was examined. Male hamsters were placed in SP (10L:14D, lights on at 0700 h, n=7 or 8 per treatment) and received daily sc injections (1645 h) of vehicle (ethanolic-saline), PROP (125 µg), MEL (25 µg) or PROP + MEL. Additional hamsters received biweekly implants of MEL (1 mg in 24 mg beeswax), daily PROP + implants, daily MEL + implants or daily PROP + daily MEL + implants. After ten weeks, body weights, testes weights and spleen weights were recorded. Plasma was collected and assayed for testosterone, thyroxine and cortisol levels. PROP injections blocked SP-induced testicular regression ($p<0.001$), but not MEL-induced regression. Hamsters implanted with MEL did not undergo SP- or MEL-induced gonadal regression ($p<0.001$) irrespective of any other treatments. These results indicate that PROP does not alter the ability of MEL implants to block gonadal regression. This adds further support to the hypothesis that PROP acts at the pineal to prevent SP-induced gonadal regression.

Fluorescent Dye Labeling of Retinal Cells with Projections to the Hypothalamus and Basal Forebrain. T.G. Youngstrom & A.A. Nunez. Dept. Psychology & Neuroscience Prog., Michigan State Univ., E. Lansing, MI 48824-1117.

In the Syrian hamster, several forebrain structures contain stained fibers after eye injections of Cholera toxin conjugated to horseradish peroxidase (Youngstrom, Weiss, & Nunez, *Soc. Neurosci. Abstr.* 14:52, '88). The present experiment sought to confirm some of these retinal ganglion cell projections using pressure injections of rhodamine labeled microspheres (RLM) aimed at several brain targets. Adult male and female Syrian hamsters (*Mesocrecitus auratus*; 130-190 gr) received bilateral pressure injections of 80 nl of RLM while under Equithesin anesthetic. After 7 days, animals were sacrificed with an overdose of the anesthetic. The upper torso was perfused with heparinized saline, the eyes were removed, then the upper torso was perfused with 10% buffered formaline. The retinae were removed from the eyes and fixed overnight in the same fixative. To confirm the location of the injections, the brains were sectioned (80 µm) and alternate sections mounted to subbed slides. Retinae were mounted without attempting to maintain visual field orientation. All tissue was examined with epifluorescence illumination. Because of the nature of the RLM labeling, only the somata and proximal dendrites were consistently labeled. The retinal projection to the paraventricular nucleus previously described (Pickard, *Soc. Neurosci. Abstr.* 14:50, '88) was confirmed in the present study. In addition, retrogradely labeled retinal ganglion cells were seen following injections into the preoptic area/diagonal band of Broca and rostral pole of the thalamus (Anteroventral/Anteromedial thalamic nuclei). Supported in part by NIMH Grant MH 37877 to AAN and by Biomedical Research Funds from Michigan State University.

SYMPOSIUM. THE BASAL GANGLIA: STRUCTURE AND FUNCTION. M.R. DeLong, Johns Hopkins Univ. (Chairperson); C. Gerfen, NIMH; S. Kitai, Univ. of Tennessee; O. Hikosaka, National Institute for Physiological Sciences, Okazaki, Japan; G.E. Alexander, Johns Hopkins Univ.

This symposium will be focused on recent developments in our understanding of the structure/function relations of the basal ganglia and the broader role of these structures in cerebral function. DeLong will give a brief overview of the recently proposed scheme of multiple parallel reentrant circuits linking specific regions of the cerebral cortex, basal ganglia and thalamus. Recent data suggest the existence of functionally segregated circuits concerned with skeletomotor, oculomotor, cognitive and limbic functions which selectively influence discrete frontal cortical areas, namely the supplementary motor area, the frontal eye fields, the prefrontal cortex and the anterior cingulate area. Gerfen will discuss recent anatomic findings on the intrinsic patch/matrix organization of the striatum and its relation to striatal afferent and efferent systems. Kitai will discuss recent concepts of the functional organization of the basal ganglia circuits at the cellular level, with emphasis on specific neurotransmitter/neuropeptide actions. Hikosaka will present recent physiologic findings obtained in behaving primates concerning the role of the basal ganglia in oculomotor function. Alexander will discuss recent findings on the physiology of the basal ganglia-thalamocortical 'motor circuit,' focusing on single cell recording studies in behaving primates that indicate this circuit may play a role in some of the highest levels of planning and preparation for movements, as well as in movement execution. DeLong will close the session with a consideration of the role of the 'motor circuit' in the pathophysiology of movement disorders, such as Parkinson's disease and Huntington's disease.

378

SYMPOSIUM. INSTRUCTIVE EFFECTS OF NEURONAL ACTIVITY IN THE DEVELOPING VISUAL PATHWAY. M. Constantine-Paton, Yale Univ. (Chairperson); C. Shatz, Stanford Univ.; M. Stryker, UCSF; M. Sur, MIT; S. Udin, SUNY Buffalo.

A popular explanation for the effects of early activity on the development of vision is that correlations in the patterns of activity carried by young retinal ganglion cells are used to determine the position of labile visual synapses. Only synapses that are simultaneously active remain together in central target zones. Implicit in this hypothesis is the idea that neural activity actually controls the structure of developing neural pathways rather than just permits normal development to occur. This symposium will present recent data relevant to the instructive hypothesis in the retinotectal pathway of developing amphibians and the geniculocortical pathway of developing cats. The presentations will cover experiments in which normal developmental dynamics are well understood and where activity has been manipulated surgically and pharmacologically. M. Constantine-Paton will present data indicating that pharmacologically induced changes in the sensitivity of the NMDA receptor alter the morphology of amphibian retinal ganglion cell terminal arbors and change the degree of segregation between retinal inputs within developing amphibian tecta. S. Udin will demonstrate that correlated patterns of activity working through an NMDA receptor are the critical determinants of registration between the left and right eye maps in *Xenopus laevis* tecta and that registration is achieved by selective afferent terminal arborization in the region of correlated activity. C. Shatz will describe the effects of prenatal activity block on the differentiation of retinal axon terminals and their segregation within the dorsal lateral geniculate nucleus of the fetal kitten. M. Sur will present data illustrating the interactions between X & Y type retinal terminals in the postnatal lateral geniculate and he will outline studies demonstrating activity-dependent aspects of these interactions. M. Stryker will close the symposium with his studies of the effects of activity manipulations and chronic drug infusions in the primary visual cortex of the postnatal cat.

379.1

DOES ENDOGENEOUS NGF PLAY A ROLE AS A NEUROTROPHIC FACTOR DURING REGENERATION? G.Raivich*, R.Hellweg* and G.W.Kreutzberg
Max-Planck Institute for Psychiatry, Munich, FRG

NGF is a well known neurotrophic factor which exherts its effects after retrograde axonal transport together with NGF receptor (NGFR) to the NGF-sensitive neuronal perikarya. Here we have studied changes in this axonal transport of endogeneous NGF, NGFR and NGFR saturation (NGF/NGFR) following axotomy and during regeneration of the rat sciatic nerve using NGF Enzyme-linked Immunoassay (ELISA) and quantitative *in situ* NGFR autoradiography.

The retrograde transport of NGF decreased dramatically to 10% of the normal levels one day after axotomy (1daa) but then returned to a stable plateau of 30-37% 3-13daa. The retrograde transport of NGFR decreased more gradually, reaching a similar plateau of approximately 40% 3-13daa. Starting with 21daa the axonal transport of both endogeneous NGF and its receptor gradually increased, reaching normal levels 45daa. Interestingly, the NGFR saturation dropped precipitously to 15% of the normal values 1daa but then rapidly recovered to normal levels (70-130%) during the whole course of nerve regeneration (6-45daa).

This normal NGFR saturation suggests that the endoneurium of the regenerating sciatic nerve provides the regenerating axons with NGF levels very similar to those in the normal peripheral target tissues. Despite this apparent ability of the axotomised endoneurium to replace the periphery, there is a 3-fold reduction in the axonal transport of NGF due primarily to the strong decrease in axonal NGFR expression and retrograde transport in the regenerating sciatic neurites. These data strongly suggest a similar dramatic decrease in the neuronal sensitivity to the neurotrophic effects of NGF during regeneration.

379.2

β-AMYLOID PROTEIN PRECURSOR GENE EXPRESSION: NERVE GROWTH FACTOR EFFECTS. W.C. Mobley, J. Valletta,* T. Barrall,* J. Long, F.M. Longo, D. Price and R. Neve. Dept. of Neurology, UCSF, San Francisco, CA 94143; Dept. of Pediatrics, Children's Hospital, Boston, MA 02115

The β-amyloid protein (β-AP) is present in the amyloid deposits that serve as a pathological marker of Alzheimer's disease (AD). Interest in discerning a role for β-AP in AD pathogenesis has focused attention on the mechanism of β-AP formation and plaque deposition. β-AP is derived from the β-amyloid precursor protein (APP), a membrane glycoprotein normally expressed in neurons in the central nervous system. APP expression alone is insufficient to explain plaque formation. However, the recent finding of three different APP mRNA species (Nature 331:525, 528 & 530, 1988) has raised the possibility that distinct forms of APP may contribute differentially to β-AP production. If so, controls regulating APP transcripts might influence β-AP and plaque formation.

Previously we examined APP expression in developing hamsters and found regionally specific patterns for APP mRNA (PNAS 85:9811, 1988). To examine further APP regulation we designed APP transcript-specific oligonucleotide probes. APP mRNA levels in the developing rat septum and caudate-putamen paralleled the patterns in hamster; levels were low immediately postnatally and rose to adult values within the first two weeks. APP-695 mRNA predominated throughout development and into adulthood, exceeding the level of APP-751/770 mRNA by at least 10-fold. The developmental increase in APP mRNA was thus due almost exclusively to an increase in APP-695 mRNA. In contrast to the rat brain, the predominant APP mRNA in undifferentiated PC12 cells is APP-751/770. NGF was shown to increase APP mRNA in the developing hamster septum; preliminary data show that NGF also induces an increase in the rat. In addition, PC12 cells treated with NGF showed a 2-fold increase (50 ng/ml for 24 hr in 2% FCS, 1% HS). It will now be possible to determine whether NGF influences APP expression through a differential effect on specific transcripts.

STUDIES ON THE EXPRESSION OF NGF mRNA AND PROTEIN IN THE DEVELOPING HIPPOCAMPUS IN VITRO. J.D. Roback+, T.H. Large#, U. Otten@, and B.H. Wainer+. +The University of Chicago, Chicago, IL 60637, #UCSF, San Francisco, CA 94143, and @Biocenter of the University, Basel, Switzerland.

Nerve growth factor (NGF) is a putative trophic factor for the basal forebrain cholinergic neurons of the central nervous system. NGF is synthesized at high levels in the target regions of these cholinergic neurons, the hippocampus and neocortex. In order to understand the physiologic signals which regulate NGF expression in the developing hippocampus, we have isolated the hippocampus from E_{15} mouse embryos and grown it in three-dimensional reaggregating culture.

At the developmental stage at which the hippocampus is removed it is "naive" with respect to septal interactions: no synaptic contacts have yet formed with the septal cholinergic neurons. Previously, we reported that NGF protein expression in aggregates from naive hippocampus increases approximately 10-fold between days 7 and 21 in culture. More recently, we have used Northern Blot analysis to quantitate NGF mRNA expression in hippocampal aggregates. Surprisingly, NGF mRNA does not undergo a similar developmental increase over the same culture period. Between days 7 and 21 in culture (a time during which NGF mRNA levels *in situ* increase approximately 12-fold), NGF mRNA levels in hippocampal reaggregates remain approximately constant (ca. 50 fg/25 ug total RNA). The observed increase in NGF protein thus appears to reflect accumulation of the protein within the aggregates rather than a developmental increase in NGF mRNA. Therefore, when the hippocampus is removed from its normal developmental environment, it retains the ability to synthesize NGF mRNA and protein, but has apparently not encountered appropriate signals for NGF mRNA upregulation as observed *in situ*. Supported by NIH grants 5-T32HD070009, NS-25787, and NS-21824 (to LFR).

Expression of the NGF Gene in Dissociated, Cultured Rat Hippocampal Cells. B. Lu, M. Yokoyama, C. F. Dreyfus and I. B. Black. Div. Dev. Neurol., Cornell Univ. Med. Coll., New York, N.Y., 10021.

We have used the hippocampus (Hi) as a model to study regulation of nerve growth factor (NGF) gene expression in the central nervous system (CNS). Sensitive nuclease protection assays detected Hi gene expression as early as embryonic day 16 (E16) in vivo, well before innervation by afferents. Hi explantation to culture, with consequent isolation, resulted in a time-dependent increase of NGF mRNA, mimicking development in vivo. These results suggest that the Hi has an intrinsic ability to produce NGF, independent of ongoing innervation.

To define the particular cell types that express NGF mRNA, we used dissociated cultures of relatively pure populations. In Hi neuronal cultures, NGF mRNA increased with time, further supporting the contention that the Hi is able to synthesize NGF in the absence of extrinsic innervation. In addition, NGF mRNA was highly expressed in nonneuronal support cell cultures. Levels of message were extremely high in glia-like cells plated at low density, undergoing rapid growth. With confluence, and decreased growth, the levels of NGF mRNA decreased. Transfer to serum-free medium further decreased message expression. These observations suggest that Hi glia-like cells also contribute to the elevation of NGF message in vitro, especially under rapid growth conditions.

To determine whether glial cells normally synthesize NGF in vivo, we measured the message in optic nerve, which presumably consists of astrocytes and oligodendrocytes, but no neuronal cell bodies. No detectable NGF mRNA was observed in adult rat optic nerve. Consequently, glial expression of NGF mRNA in vitro may reflect cell damage, analogous to peripheral Schwann cell expression of the gene after axotomy. We are currently studying glial-neuronal relations in the elaboration of NGF in the brain. (supported by NIH grants HD 22315, NS 10259, and a grant from the Bristol Myers Co. Inc.)

379.5

REGULATION OF NGF EXPRESSION IN RAT HIPPOCAMPAL CULTURES BY INTERLEUKIN-1 AND OTHER INFLAMMATORY MEDIATORS. W.J. Friedman[1,3], L. Larkfors*[3], C. Ayer-LeLievre*[1,2], T. Ebendal*[3], L. Olson*[2], and H. Persson*[1]. [1]Lab. of Molecular Neurobiology, [2]Dept. of Histology and Neurobiology, Karolinska Institute, Stockholm, and [3]Dept. of Developmental Biology, Uppsala University, Uppsala, Sweden

Nerve growth factor (NGF) is known to be expressed in the rat hippocampus, providing trophic support for afferent neurons such as the cholinergic projection from the basal forebrain. Lesions of this input elicit an increase in the level of NGF mRNA in the hippocampus. We have been using a dissociated culture system to examine regulation of NGF mRNA and protein. Rat hippocampi were dissected from embryonic day (E) 19 or 21 and maintained for periods of time up to 1 week in culture.

We have previously demonstrated that treatment of hippocampal dissociates with interleukin-1 (IL-1) elicited significant increases in NGF mRNA and protein. We have now used the culture system to further analyze the influence of IL-1 as well as other factors known to mediate responses to inflammation and injury. We have found that glucocorticoids inhibit expression of NGF, and that prostaglandin E_2 (PGE_2) enhances levels of NGF mRNA. Further studies are in progress to identify which populations of cells in these cultures express NGF and respond to these factors.

379.6

NERVE GROWTH FACTOR (NGF) REVERSES AXOTOMY-INDUCED ATROPHY OF MEDIAL SEPTUM CHOLINERGIC NEURONS. S. Varon, T. Hagg, J.M. Conner*, H.L. Vahlsing*, B. Fass-Holmes, M. Manthorpe. Dept.Biology, M-001, UCSD, La Jolla, CA 92093.

Delayed intraventricular NGF infusion in the adult rat can rapidly reverse the disappearance of most axotomized medial septum cholinergic neurons (MSC) immunostained for choline acetyltransferase (ChAT) or NGF receptor. We have utilized the delayed NGF treatment protocol to evaluate changes in MSC somal size following unilateral aspirative fimbria-fornix transection and subsequent NGF treatment. The cross-sectional size (μm^2) of ChAT-positive MSC neurons was determined in brain tissue sections at a total magnification of 500X using a digitizing computer program. Seven or 14 days post-lesion, the expected reductions in total numbers of ChAT-positive MSC neurons was accompanied by a reduction in average size, and frequency distribution analysis revealed an actual increase in the number of small neurons ($\leq 100\ \mu m^2$). That number increased even further after one day of NGF infusion started on day 7 or 14. The next several days of delayed NGF infusions reversed the average size reduction as well as the apparent reduction in total ChAT-positive neuronal numbers. With 2-week infusions, the average MSC somal size increased beyond normal values reflecting both a numerical increase of large ($>200\ \mu m^2$) and a numerical decrease of small neurons compared to normal.

These results suggest that the loss of endogenous NGF consequent to axotomy leads to a progressive cellular atrophy (rather than to the preferential loss of stainability of a subset of large MSC neurons). Furthermore, NGF treatments can reverse somal atrophy and can even induce hypertrophy of some MSC neurons. The finding that NGF can regulate neuronal size, in addition to the presence of several neuronal proteins, e.g. ChAT and NGF-receptor, confirms the view that NGF has a genuine trophic function for adult basal forebrain cholinergic neurons. A CELL LINE PRODUCING RECOMBINANT NGF EVOKES GROWTH RESPONSES IN INTRINSIC AND GRAFTED CENTRAL CHOLINERGIC NEURONS. P.Ernfors#[1], T. Ebendal[2], L. Olson[3], P. Mouton[3] J. Strömberg[3], V. Chan-Palay[4], H. Persson[1]. (SPON: O. Johansson) [1]Dept. of Chemistry, Lab. of Molecular Neurobiology and [3]Dept. of Histology and Neurobiology, Karolinska Institute, Stockholm, Sweden, [2]Dept. of Developmental Biology, Uppsala University, Uppsala, Sweden. [4]Dept. of Neurology, University hospital, 8091 Zurich, Switzerland.

The rat β-nerve growth factor gene was inserted into a mammalian expression vector and cotransfected with a plasmid conferring resistance to neomycin into mouse 3T3 fibroblasts. From this transfection a stable cell line was selected that contains several hundred copies of the rat NGF gene and produces excess levels of recombinant NGF. Such genetically modified cells were implanted into the rat brain as a probe for new in vivo effects of NGF on central nervous system neurons. In a model of the cortical cholinergic deficits in Alzheimer's disease (AD), we demonstrate a marked increase in the survival of, and fiber outgrowth from, grafts of fetal basal forebrain cholinergic neurons, as well as a stimulation of fiber formation by intact adult intrinsic cholinergic circuits in the cerebral cortex. Adult cholinergic interneurons in intact striatum also sprout vigorously towards implanted fibroblasts. It is suggested that this model has implications for future treatment of neurodegenerative diseases. To evaluate the possible role of NGF in AD, expression of NGF and NGF receptor were examined in brains from AD patients.

NGF REGULATES GABA-ERGIC NEURONS IN THE CULTURED RAT BASAL FOREBRAIN. C. F. Dreyfus and I. B. Black. Div. Devel. Neurol., Cornell Univ. Med. Coll., New York, N.Y. 10021.

Recent studies have indicated that high-affinity NGF receptors are associated with at least two basal forebrain (BF) populations. Radioautographic visualization of high-affinity NGF receptors (NGF-R's) and immunocytochemistry have localized high-affinity NGF-R's to choline acetyltransferase (CAT)+, cholinergic neurons, as well as to gamma-aminobutyric acid-ergic (GABA) cells. However, while biological actions of NGF on the cholinergic population have been extensively described, it has been difficult to define actions of the trophic factor on GABA neurons. The present study was designed to determine whether NGF regulates this BF population.

Dissociated cultures of embryonic day 17 rat BF were grown for up to 3 weeks. GABA neurons were monitored by immunocytochemical visualization of GABA and catalytic assay to detect levels of glutamic acid decarboxylase (GAD), the GABA synthetic enzyme.

Initial studies indicated that GABA neurons underwent dramatic development in control medium. GABA+ cells exhibited extensive neurite elaboration during the first 7 days in culture, accompanied by a significant increase in GAD catalytic activity. To define the actions of NGF, cultures were grown in the presence of growth factor and assayed for GAD activity after 5, 7, 10, 14 or 21 days. After 10 days, NGF elicited a marked 2-fold increase in GAD activity. Our observations suggest that the action of NGF in the BF is not limited to the cholinergic population, but extends to GABA cells as well. We are presently further characterizing the actions of NGF on these different forebrain populations. (Support: NIH grant HD 23315, NS 10259)

SEXUALLY DIMORPHIC EXPRESSION OF THE NGF RECEPTOR GENE IN RAT BRAIN. D.R. Kornack, B. Lu, and I.B. Black. Div. Devel. Neurol., Cornell Univ. Med. Coll., New York, NY 10021.

While sexually dimorphic traits are well-recognized in brain systems, associated dimorphism in trophic, regulatory molecules has not been defined. We now report evidence for sexually dimorphic gene expression of a trophic receptor molecule in the brain.

Recent work has detected sexually dimorphic development of cholinergic enzyme activity in the rat basal forebrain (BF); females attain adult levels of choline acetyltransferase (CAT) activity earlier than males. Moreover, these neurons are known to express nerve growth factor (NGF) receptors. Further, NGF increases activity of BF CAT. Is the sexually dimorphic development of transmitter phenotype a reflection of dimorphic expression of trophic elements? We have measured levels of NGF receptor (NGF-R) mRNA in rat BF and NGF mRNA in hippocampus, examining sex differences during development.

BF NGF receptor message levels were consistently greater in females than in males during the first two postnatal weeks; by the third week, however, male and female levels did not differ, a finding that parallels sexually dimorphic cholinergic development in the BF. In contrast to the sexually dimorphic NGF-R message development, hippocampal NGF mRNA levels did not differ between sexes, suggesting that regulation of trophic effects in the mammalian brain may occur at the level of trophic receptor gene expression.

Our observations suggest that sex differences in transmitter phenotype in specific brain nuclei are associated with sexually dimorphic gene expression of trophic, regulatory elements. (Supported by NIH grants HD 23315 and NS 10259.)

CO-LOCALIZATION OF NGF AND ESTROGEN RECEPTORS: IMPLICATIONS FOR THE BASAL FOREBRAIN. C. D. Toran-Allerand[1] and N. J. MacLusky[2]. Dept. Anat. & Cell Biol.[1], Columbia Univ., P&S, New York, NY 10032 and Div. Reprod. Sci.[2], Univ. Toronto, Toronto, Canada M5G IL4.

While research on aging and Alzheimer's disease has focused on the importance of NGF for the basal forebrain, scant attention has been paid to other survival- and growth-promoting substances which influence those neurons such as estrogen. We report for the first time the co-localization of estrogen and NGF receptors to a subset of neurons in the medial septum/nuclei of the diagonal band, using ^{125}I-estrogen autoradiography combined with immunocytochemistry. P12 female rats received a single dose of 2 nmol/kg 16α-^{125}I-iodo-11β-methoxyestradiol (2,200 Ci/mmol), a synthetic estrogen. 4% paraformaldehyde fixed, 10 μm brain sections were processed for steroid autoradiography, followed by NGF receptor immunocytochemistry, using monoclonal IgG 192. Neurons were found interspersed in the medial septum/diagonal band that expressed NGF receptor immunoreactivity with or without discrete localization of ^{125}I-estrogen. Other neurons exhibited estrogen receptors alone or neither marker.

Growth-promoting effects of estrogen have been demonstrated not only during development but in estrogen receptor-containing regions of the traumatized adult CNS as well. Our observations suggest that the potential for interactions between NGF and estrogen exists and that both NGF and estrogen may be trophic for the development and maintenance of basal forebrain circuits, which may have considerable clinical relevance. (Supported by NIH (AG08099) and the American Health Assistance Foundation.)

PURKINJE CELLS IN THE DEVELOPING RAT CEREBELLUM EXPRESS HIGH- AND LOW-AFFINITY NERVE GROWTH FACTOR RECEPTORS. S. Cohen-Cory, C.F. Dreyfus and I.B. Black. Lab. of Neurobiol., Rockefeller Univ. and Div. of Dev. Neurol., Cornell Univ. Med. Coll., New York, N.Y., 10021.

In the cerebellum, Nerve Growth Factor (NGF) and NGF receptor are highly expressed during late embryonic and early postnatal development, suggesting that NGF may play an important role in cerebellar ontogeny. While receptor has been localized to some cerebellar populations, delineation of receptor subtypes, and potential physiologic function, remain to be defined.

The objective of the present work was to localize NGF binding sites to cell types in the developing cerebellum, and to define receptor subtypes. We employed ^{125}I-NGF binding to delineate low- and high-affinity receptor sites in the postnatal day 10 rat cerebellum. High-affinity receptor sites were detected by displacement of low-affinity binding with a chase of excess unlabeled NGF. We observed both high- and low-affinity receptor sites on developing Purkinje cells immunostained with anti Vitamin D-dependent Calcium Binding Protein antibodies (kindly provided by Dr. S. Christakos). ^{125}I-NGF-generated silver grains were localized to cell bodies, dendrites and axonal processes of all Purkinje cells. On some cells, a higher density of silver grains was localized to the distal dendrites, while in others, the highest density was on the basal pole of the cell body. Grain density per Purkinje cell varied within and among folia, and appeared to be correlated to maturation of Purkinje cells. Our observations indicate that the biologically active, high-affinity sites are localized to cerebellar Purkinje cells. (NIH grant HD23315)

EVIDENCE FOR A PHYSIOLOGICAL ROLE OF NGF IN THE CNS OF ADULT RATS. M. Fusco*, N. Schiavo*, L. Bigon*, M. Fabris*, A. Leon and G. Vantini. Fidia Research Laboratories, 35031 Abano Terme, Italy.

We have recently shown that intracerebroventricular (i.c.v.) administration of rabbit anti-NGF IgG (6 ug injected daily from postnatal day 2 to 8) significantly reduces choline acetyltransferase (ChAT) activity in the septum and hippocampus of 9-day-old rats. These results provide direct demonstration that endogenous NGF plays a physiological role in the septo-hippocampal cholinergic system of newborn animals. In addition, following the injection protocol described above, a significant reduction in ChAT activity was also observed in the striatum of newborn rats.

To further investigate the extent to which endogenous NGF is involved in maintenance or regulation of function of mature forebrain cholinergic neurons we have examined the effect of continuous infusion of anti-NGF IgG (via miniosmotic pump) in CNS of adult rats. Results indicate that i) i.c.v. (right lateral ventricle) infusion of anti-NGF IgG induces a moderate decrease of ChAT activity in the striatum ipsilateral to the infusion side, ii) intrastriatal continuous infusion of anti-NGF IgG induces a marked decrease of ChAT activity in the area adjacent to the injection side.

These data provide evidence for a physiological role of endogenous NGF in adult mammalian CNS.

PURIFICATION AND CHARACTERIZATION OF BRAIN L-GLUTAMATE RECEPTOR. J.-Y. Wu,[1,2,3] C.C. Liao,[*2,3] C.J. Lin,[*2,3] Y.H. Lee,[1*] J.Y. Ho,[1*] and W.H. Tsai.[*1] (SPON: B.Dworkin). [1]Inst. Biomed Sci., Academia Sinica, Taipei, Taiwan, [2]Neurosci. Program & Dept. of Anatomy, Penn. St. Univ., Hershey, PA 17033, and [3]Dept. Physiol. & Cell Biol., Univ. Kansas, Lawrence, KS 66045.

L-Glutamate receptor (GluR) was isolated from pig brain by initial homogenization in 0.32 M sucrose, followed by differential centrifugation to obtain the crude mitochondrial fraction (P2 fraction) and finally by hypotonic shock to lyse the P2 fraction resulting in the receptor enriched P2 membrane. The basic binding characteristics of membrane-bound GluR were studied over a wide range of L-Glu from 5.36 nM to 5 μM. The dissociation constant, K_d and the total receptor concentration, B_{max} were obtained from Scatchard plot as 102 nM and 2.23 pmol/mg protein, respectively. A Hill coefficient of 0.99 was obtained from Hill plot suggesting a single site model for the binding of L-Glu to the receptor. GluR could be solubilized by incubating P2 membrane (15 mg/ml) with 10 times of 50 mM Tris-Cl, pH 7.2 containing 0.5% (^{V}/v) of Triton X-100 at 4^{o}C for 30 min. The solubilized GluR has binding characteristics similar to the membrane-bound receptor. Further purification of GluR has been achieved by a combination of ultrafiltration and repetitive column chromatographies, e.g. AcA 34 gel filtration. (Supported in part by grants from National Science Council, Taiwan & grants NS 20978, NS 20922, and EY 05385 from NIH, U.S.A.)

ANALYSIS OF A KAINIC ACID RECEPTOR IMMUNO-RELATED PROTEIN IN RAT AND FROG BRAIN. D.R. Hampson, C. Banner, C.J. Dechesne, R.J. Wenthold. Faculty of Pharmacy, University of Toronto, Lab of Molecular Biology and Lab of Molecular Otology NIH, Bethesda MD.

Monoclonal antibodies raised against a kainic acid receptor purified from frog brain label a 48 kDa protein on immunoblots of frog brain. One of these antibodies also labels a 99 kDa protein in both frog and rat brain. This protein appears to be brain-specific in both species. On immunoblots of frog brain, reducing agents are capable of modulating the relative intensities of the Mr=48,000 and the Mr=99,000 proteins, suggesting the possibility of a monomer/dimer relationship. However, reducing agents had no effect on the intensity of the 99 kDa protein in rat brain. Immunocytochemical localization demonstrated that the immunoreactivity was widely distributed in frog brain; the pattern of immunoreactivity in frog brain coincides with the pattern of ^{3}H-kainic acid binding sites. In rat brain, the pattern was more restricted. Pyramidal cells in the hippocampus and purkinje cells in the cerebellum stained intensely with this antibody.

Further characterization of the protein in rat brain is being conducted by analysing cDNA clones identified through immunoscreening of rat brain expression libraries. We suggest that the Mr=99,000 protein in rat brain may be part of, or associated with, a mammalian kainic acid receptor or a related receptor subtype.

INHIBITION OF [^{3}H]MK-801 BINDING BY 7-CHLOROKYNURENIC ACID, A NON-COMPETITIVE INHIBITOR OF THE NMDA RECEPTOR, IS SELECTIVELY REVERSED BY GLYCINE. R. Sircar, M. Frusciante* and S.R. Zukin. Departments of Psychiatry, Neuroscience and Neurology, Albert Einstein College of Medicine, Bronx, NY 10461.

Glycine, D-serine and related amino acids stimulate NMDA receptor mediated neurotransmission and PCP receptor binding via the activation of a non-strychnine-sensitive glycine recognition site situated on the NMDA receptor complex. 7-chlorokynurenic acid (7-CK) has been reported to inhibit [^{3}H]glycine binding and to abolish NMDA-induced currents in rat cortical neurons, effects selectively reversed by glycine but not by NMDA. Here we present evidence that 7-CK inhibits [^{3}H]MK-801 binding to the PCP receptor and that this effect is also selectively reversed by glycine. Aliquots of thoroughly-washed rat forebrain synaptosomal membranes were incubated with 1 nM [^{3}H]MK-801 and graded concentrations of 7-CK in the presence and absence of glutamate and/or glycine. Non-specific binding was determined by addition of 10 μM unlabeled MK-801. Bound radioligand was separated from free by filtration under reduced pressure and radioactivity was measured by liquid scintillation spectrometry. Under all experimental conditions 7-CK inhibited [^{3}H]MK-801 binding. In the absence of any added glutamate and/or glycine 7-CK attenuated the binding with an IC_{50} of 6.8 $\pm$ 1.5 μM. 50 μM glycine, both in the presence and absence of glutamate, significantly shifted the dose response curve of 7-CK to the right. These data support the concept that 7-CK acts as a competitive antagonist at the glycine modulatory site of the NMDA receptor complex. Since [^{3}H]MK-801 binding is an index of NMDA receptor associated ion channel function, reduced [^{3}H]MK-801 binding in the presence of 7-CK is consistent with the concept that glycine is required for channel activity.

380.4

IN VIVO EVIDENCE THAT D-CYCLOSERINE IS A PARTIAL AGONIST AT THE NMDA-ASSOCIATED, GLYCINE RECEPTOR SITE. M.R. Emmett*, P.L. Wood, T.S. Rao, S. Mick*, J. Cler*, and S. Iyenger. (Spon: D.L. Cheney). CNS Diseases Research, G.D. Searle & Co., St. Louis, MO 63198.

The antibiotic D-cycloserine has been shown to be a partial agonist at the NMDA coupled, strychnine-insensitive glycine receptor by in vitro receptor binding (Hood et al., 1989). This partial agonism was demonstrated in an in vivo system by monitoring NMDA mediated cerebellar cyclic GMP levels in mice.

Both direct intracerebellar and systemic (subcutaneous) injections of D-cycloserine produced a biphasic, partial dose response curve. When intracerebellar co-injections were made with NMDA, D-cycloserine decreased the NMDA elicited increase in cyclic GMP by approximately 50%. D-cycloserine was also able to block D-serine (glycine agonist) induced increases in cyclic GMP. Systemic injections of D-cycloserine elicited a much wider window of agonism than seen with intracerebellar injections. These data are important in the study of NMDA mediated neurotransmission since D-cycloserine is a parenterally bioavailable compound with both agonist and antagonist properties at the NMDA-associated, glycine receptor.

380.5

IN VIVO MODULATION OF CEREBELLAR NMDA RECEPTORS BY THE GLYCINE AGONIST, D-SERINE: SUPPORT FOR COMPARTMENTATION OF GLYCINE IN THE CEREBELLUM. P.L. Wood, M. Emmett*, T.S. Rao, S. Mick*, J. Cler* and S. Iyengar. CNS Diseases Research, G.D. Searle and Co., St. Louis, MO 63198.

Direct intracerebellar injections of NMDA elicited dose-dependent increases in mouse cerebellar cGMP levels. The Hill slope for this logit-log dose relationship suggested that 3 molecules of NMDA are required per NMDA receptor for activation. In contrast, direct intracerebellar injections of D-serine increased cGMP levels with a Hill slope of unity, indicating a unimolecular interaction with its receptor.

The actions of D-serine were antagonized by the competitive NMDA antagonist, CPP and by a partial agonist (D-cycloserine) and competitive antagonist (HA-966) of the NMDA-coupled glycine receptor. These data are all consistent with D-serine activation of the NMDA-coupled glycine receptor resulting in a potentiation of ongoing NMDA-dependent neuronal activity in the cerebellum. These data also argue that the glycine receptor is not saturated at physiological concentrations of glycine.

380.6

DIFFERENT ACTION OF 3-AMINO-1-HYDROXY-2-PYRROLIDONE (HA-966) AND 7-CHLOROKYNURENIC ACID IN THE MODULATION OF N-METHYL-D-ASPARTATE SENSITIVE GLUTAMATE RECEPTORS. W. Danysz*, E. Fadda*, J.T. Wroblewski and E. Costa. (SPON: A.P. Kozikowski). Fidia-Georgetown Institute for the Neurosciences, Georgetown Univ. Sch. of Med., Washington, D.C. 20007.

N-methyl-D-aspartate (NMDA)-sensitive glutamate receptors were reported to be inhibited by HA-966 and 7-chlorokynurenic acid (Cl-KYN) that counteract the positive glycine modulation. In rat brain synaptic plasma membranes Cl-KYN and HA-966 inhibited completely [^{3}H]glycine binding. Moreover, Cl-KYN inhibited completely the binding of [^{3}H]glutamate and of the NMDA antagonist [^{3}H]3-(2-carboxypiperazin-4-yl)propyl-1-phosphonic acid (CPP). In contrast, HA-966 only partially inhibited [^{3}H]glutamate binding, but increased the affiniy of [^{3}H]CPP binding with a potency similar to its inhibition of [^{3}H]glycine binding. This increase was inhibited by glycine and Cl-KYN. The binding of [^{3}H](+)5-methyl-10,11-dihydro-5H-dibenzocyclohepten-5,10-imine maleate (MK-801), used as an index of NMDA receptor activation, was completely inhibited by Cl-KYN, but only partially by HA-966. Moreover, HA-966 antagonized the inhibitory action of Cl-KYN to the level seen with HA-966 alone. In addition, HA-966, but not Cl-KYN, increased the potency of CPP to inhibit [^{3}H]MK-801 binding. One might infer that Cl-KYN is an antagonist of the glycine modulatory site, while HA-966 acts as a negative modulator of NMDA-sensitive glutamate receptors.

380.7

N-METHYL-D-ASPARTATE SENSITIVE GLUTAMATE RECEPTORS IN CEREBELLAR GRANULE CELLS INDUCE A CALCIUM-MEDIATED RELEASE OF ARACHIDONIC ACID. J.W. Lazarewicz*, J.T. Wroblewski and E. Costa. Fidia-Georgetown Institute for the Neurosciences, Georgetown Univ. Sch. of Med., Washington D.C. 20007

In primary cultures of cerebellar granule cells, glutamate, aspartate and N-methyl-D-aspartate (NMDA) induced a dose-dependent release of [^{3}H]arachidonic acid (AA). This release was inhibited by NMDA receptor antagonists and was potentiated by the positive modulator D-serine. The observed effect was selective for NMDA receptor agonists and was not induced by kainate or quisqualate. The agonist-induced [^{3}H]AA release was reduced by quinacrine at concentrations which inhibited phospholipase A_2 but failed to affect the activity of phospholipase C or the hydrolysis of phosphoinositides induced by glutamate or quisqualate. This indicates that the increased formation of AA is due to a receptor-mediated activation of PLA_2 rather than the action of PLC followed by diacylglycerol lipase. The receptor-mediated [^{3}H]AA release was dependent on the presence of extracellular Ca^{2+} and was mimicked by the Ca^{2+} ionophore ionomycin. The pretreatment of granule cells with pertussis toxin failed to inhibit the receptor-mediated [^{3}H]AA release. The results suggest that the stimulation of NMDA receptors in cerebellar granule cells leads to an activation of PLA_2 that is mediated by Ca^{2+} ions entering through the NMDA channel, rather than by a direct coupling involving a pertussis toxin-sensitive GTP-binding protein.

380.8

KAINIC ACID RECEPTORS MEDIATE THE RELEASE OF ALANINE AND GLYCINE THROUGH A MECHANISM THAT DIFFERS FROM THE RELEASE OF GLUTAMATE. M. Ulivi*, E. Costa, and W. J. Wojcik, FGIN, Georgetown University, Washington D.C. 20007

In primary cultures of cerebellar granule cells, kainic acid (KA) induces the release of glutamate (GLU), a putative neurotransmitter for these cells, and two other amino acids: alanine (ALA) and glycine (GLY). These amino acids can be separated by HPLC and measured after derivatization to fluorescent compounds. The KA-receptor mediated release of GLU is Ca^{++} dependent and probably results from kainic acid induced depolarization. In contrast, KA releases ALA and GLY in a Ca^{++} independent, but Na^+ dependent manner with a IC_{50} of approximately 30 uM. The KA receptor antagonists, 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX), was used and found to inhibit the KA-induced release of ALA and GLY indicating that this effect was KA receptor-mediated. The IC_{50} for CNQX against 100 uM KA was 0.5 uM. Quisqualate was also tested and found to have no action by itself. However, it antagonized KA, 300 uM, with an IC_{50} of 50 uM. The amount of ALA and GLY released into the incubation buffer was greater during the first five minutes after KA exposure than the amount of released GLU. However, the KA induced release of ALA and GLY stops after five minutes due to a depletion of intracellular stores. The KA induced GLU release continues to increase with continuous exposure to KA. An action on ALA and GLY transport may be operative in the KA induced release of these two amino acids.

380.9

A NEW GLUTAMATE RECEPTOR SUBTYPE: THE QUISQUALATE RECEPTOR COUPLED TO THE INOSITOL PHOSPHATE RESPONSE AND C-KINASE. F. A. J. Sladeczek*, O. J. J. Manzoni*, I. Sassetti*, F. Fignels*, C. Le Peuch*, and J. Bockaert* (SPON: B. Rouot). C.C.I.P.E. Rue de la Cardonille, F-34094 Montpellier Cedex 2, France.

In striatal neurons in primary culture we discovered a glutamate receptor of the quisqualate (Q) subtype able to stimulate the formation of inositol phosphates (IPs) (Sladeczek F. et al., *Nature*, 317: 717, 1985). Here we show that quisqualate induced the rapid formation of IP_1, IP_2, IP_3 and IP_4 and potently increased intracellular calcium concentrations ($(Ca^{++})_i$) in the cell bodies of these cells as measured by photometer microscopy with Fura-2. The $(Ca^{++})_i$ increase but not the formation of IPs depended on the presence of extracellular Ca^{++}. AMPA stimulated with higher affinity the $(Ca^{++})_i$ increase (EC_{50} = 2· μM) than the IP-response (EC_{50} = 560 μM). Kainate and Domoate potently stimulated the $(Ca^{++})_i$ increase but had only very small effects on the IP response. CNQX decreased both types of responses, whereas GAMS only affected the $(Ca^{++})_i$ -response. Quisqualate (10 μM) but not AMPA (10 μM) activated C-kinase as assessed by its translocation. 10 nM of the phorbol ester PdBu completely blocked the quisqualate evoked IP-response but had no effect on the $(Ca^{++})_i$ increase. Phorboldidecanoate was without effect and staurosporine (100 nM) completely reversed the PdBu-blockade. These results demonstrate that there exist two different types of quisqualate receptors. A classical ionotropic receptor, increasing $(Ca^{++})_i$ most probably via depolarization and opening of voltage sensitive Ca^{++}-channels and a new metabotropic quisqualate receptor able to stimulate the formation of inositol phosphates, to activate C-kinase and which can be desensitized by protein kinase C activation. In order to distinguish these two receptors we recently proposed the nomenclature Q_i for the ionotropic receptor and Q_P for the metabotropic receptor (Sladeczek et al., *Trends in Neurosc.*, 11: 545, 1988).

380.10

EXCITATORY AMINO ACIDS STIMULATE INOSITOL PHOSPHOLIPID HYDROLYSIS AND CA^{2+} FLUX, AND INDUCE NEURODEGENERATION, IN CULTURED RETINAL CELLS: EFFECT OF GM1 GANGLIOSIDE. S.D. Skaper, D. Milani*, L. Facci and A. Leon. Fidia Research Laboratories, 35031 Abano Terme, Italy.

Excitatory amino acid (EAA) recognition sites located in synaptic membranes have been widely studied. However, little is known concerning the molecular processes operating in the transduction of their chemical signals across the plasma membrane. To investigate whether EAAs activate membrane phosphoinositide breakdown and alter Ca^{2+} homeostasis in neurons of the visual system, cultures of retinal cells were prepared from 8-day chicken embryo, labeled with [^{3}H]inositol at day 5, and at day 7 challenged with various EAA receptor agonists. Kainate stimulated the formation of inositol mono-, bis- and trisphosphates in a concentration and time-dependent manner. The rank order of agonist potency was: glutamate›kainate›NMDA››ibotenate ≈ quisqualate. External Ca^{2+} was required, with Mg^{2+} blocking the action of glutamate and NMDA. EAA agonists induced an increase in $[Ca^{2+}]i$ in selected cells, as measured using Fura-2. Glutamate, NMDA and kainate were also neurotoxic (sparing photoreceptors); ganglioside GM1 pretreatment reduced this neurodegeneration. The role of these biochemical events in the pathophysiological response of retinal neurons to EAA agonists, and the effect of GM1 on their action, is under investigation.

380.11

EXCITATORY AMINO ACID RECEPTORS. NOVEL SELECTIVE AGONISTS AND ANTAGONISTS FOR NMDA AND NON-NMDA RECEPTORS. U. Madsen*, L. Brehm*, J.J. Hansen* P. Krogsgaard-Larsen, Dept. Org. Chem., Royal Danish Sch. Pharmacy, Dk-2100 Copenhagen, Denmark.

The excitatory amino acid (EAA) receptors are at present subdivided into three classes: NMDA, QUIS/AMPA, and KAIN receptors, some of which appear to be heterogeneous.

A number of highly selective NMDA and QUIS/AMPA receptor agonists, derived from ibotenic acid, have been developed. Structure-activity studies on these compounds have disclosed different conformational and stereochemical requirements for activation of NMDA and QUIS/AMPA receptors. The results of electrophysiological studies indicate different agonist characteristics of cortical and spinal NMDA receptors. Further development of these ibotenic acid analogues have led to the two non-NMDA antagonists, AMOA and AMNH. In a rat cortical slice model AMOA was shown to be a selective QUIS/AMPA antagonist (ED_{50}, 200μM), whereas AMNH selectively blocked KAIN receptors (ED_{50}, 100 μM). Using microelectrophoretic techniques the excitatory effects on cat spinal neurones of AMPA and KAIN were equally sensitive to blockade by AMOA or AMNH. Receptor binding and electrophysiological studies have shown that neither AMOA nor AMNH interact with NMDA receptors.

380.12

REGULATION OF GLUTAMATE/ASPARTATE RELEASE BY NMDA RECEPTORS. D. Martin, G.A. Bustos, M.A. Bowe, S.D. Bray* and J.V. Nadler. Depts. Pharmacology and Neurobiology, Duke Univ. Med. Ctr., Durham, NC 27710.

The synaptic release of the excitatory transmitters glutamate and aspartate can be regulated by a variety of neuroactive compounds present in the vicinity of the synapse. We have addressed the issue of regulatory mechanisms by studying the actions of transmitters and modulators upon glutamate/aspartate release from the Schaffer collateral-commissural-ipsilateral associational (SCCIA) pathway in area CA1 of the rat hippocampus.

Transmitter release was evoked from superfused slices of the CA1 area (excluding stratum lacunosum-moleculare) by exposing the slices to two 1-min pulses of 50 mM K^+. Test compounds were present only during the second K^+ exposure, and their effects were determined on the ratio of amino acid released by the second exposure compared to the first. Previous studies showed that under our conditions nearly all the release of glutamate and aspartate is Ca^{2+}-dependent and it originates predominantly from the SCCIA pathway.

TTX (0.1 uM) reduced the K^+-evoked release of glutamate and aspartate by about 40%, suggesting that a portion of the release depended on the generation of action potentials as the K^+ concentration within the tissue was rising. NMDA (100 uM) did not affect glutamate/aspartate release evoked by either 50 or 33 mM K^+. However, the NMDA receptor antagonists CPP (20 uM) and phencyclidine (20 uM) reduced the release of both amino acids by 22-36%. CPP was effective only in the absence of Mg^{2+}, whereas phencyclidine had similar effects in the absence or presence of Mg^{2+}. The action of CPP was entirely confined to the TTX-sensitive component of release. These finding suggest that NMDA receptors regulate glutamate/aspartate release from SCCIA terminals. These receptors appear to be fully occupied by agonist during exposure to elevated K^+ and agonist occupation enhances the further release of transmitter. The mechanism of this enhancement more likely involves a block of K^+ channels than the facilitation of Ca^{2+} influx. (Supported by NIH grant NS 16064.)

381.1

TRANSCRIPTIONAL CONTROL OF NGF GENE EXPRESSION. S.R. D'Mello, J.M. Alexander* and G. Heinrich, Dept of Med, University Hospital and BUSM, Boston, MA 02118.

Transient expression of 5' deletion mutants of the cloned mouse NGF gene promoter in L929 cells indicated that several regions within 250 bps upstream of the transcription initiation site affect basal transcription. To identify transcription factors that bind to the functionally defined regions, DNAse I footprint analysis was undertaken. L929 cell nuclear extracts protected three regions within the 250 bp mouse promoter. A fourth region displayed partial protection. Competition experiments indicated that binding of the factors to these sites is specific. The nucleotide sequence within two of these footprints share a 'GGAGGG' motif, suggesting that these regions are bound by the same factor. An additional footprint was found at the first intron-exon junction. Comparisons of the nucleotide sequences contained within these protected regions with the binding sites of known regulatory factors revealed no significant similarities, suggesting that as yet unknown factors may regulate NGF gene expression. The L929 cell footprint patterns are being compared with those of mouse SMG as a first step towards understanding the mechanisms underlying the high level of NGF gene transcription in that tissue.

NEURON-SPECIFIC ENOLASE PROMOTER DIRECTS β-GALACTOSIDASE EXPRESSION TO NEURONS IN TRANSGENIC MICE. S.Forss-Petter, P.E.Danielson*, E. Battenberg, J.Price* and J.G.Sutcliffe. Research Institute of Scripps Clinic, La Jolla, CA 92037.

To analyze regulatory elements for neuron-specific gene expression, mouse oocytes were injected with a hybrid gene, composed of 2 kb 5' upstream sequence from the rat neuron-specific enolase (NSE) gene and E.coli β-galactosidase (β-gal) coding sequence. Of seven mice carrying complete trans-gene integrations, four gave rise to offspring with detectable transgene mRNA and β-gal activity (analyzed in situ using the chromogenic substrate X-gal) in the brain. Two of the lines showed a high level of expression in most CNS-neurons and, like endogenous NSE, the amount varies in different neuronal types. Testes were the only other site of expression. A third line showed moderate but widespread neuronal β-gal activity, whereas the fourth line expressed β-gal in a limited set of neurons. Though the integration site affects expression, these results indicate that neuron-specific transcription elements are located within 2 kb upstream from the NSE gene. These mice should be valuable in cell-lineage studies, as neurons of this genotype are easily identifiable.

GAP-43 GENE STRUCTURE. E. Grabczyk*, M.X. Zuber*, H. Federoff*, S.-C. Ng, A. Pack* and M.C. Fishman. Howard Hughes Medical Institute, Developmental Biology Laboratory of the Massachusetts General Hospital, Boston, MA 02114

GAP-43 is a protein believed to be important to the function of growth cones and to nerve terminal remodelling. Many features of its gene regulation suggest it to be an excellent guide to the molecular biology of the developing neuron. It will be important to determine what causes restriction of its expression to neurons, regional restriction of expression in the adult CNS, and increased expression during periods of axonal elongation and regeneration. In order to begin to pursue the nature of cis- and trans-acting GAP-43 gene control we have isolated genomic GAP-43, and mapped its intron-exon boundaries and transcriptional start sites. The promoter is quite unusual in its structure, containing a repetitive sequence capable of forming unusual conformations and lacking some canonical promoter components. Transcription can initiate from more than one site, and some of the start sites are utilized differently in the central and peripheral nervous systems.

GENERATION AND REGULATION OF THE DIVERSITY OF MURINE NCAM TRANSCRIPTS DURING BRAIN DEVELOPMENT AND SELF-REPAIR OF THE CNS. W.Wille[1], D.Barthels[1*], A.Jungblut[1*], C.Ruppert[1,*], S.W. Scheff[1,2], M.J.Santoni[3*], and C.Goridis[3*] [1]Inst. f. Genetik, Univ. of Cologne, Köln, **FRG**, [2]Dept. Anat. Univ. of Kentucky, Lexington KY **USA**, and [3]Centre d' Immunol., INSERM-CNRS, Marseille, **France**

The neural cell adhesion molecule (NCAM) of the mouse exists in several isoforms which are selectively expressed by different cell types and at different stages of development. Four isoform-related transcripts are generated from just one primary messenger and code for NCAM-180, -140 & -120. Since the differences between these isoforms are due to alternative splicing in the coding region for the transmembrane and cytoplasmic domains, the extracellular, N-terminal portion of NCAM seemed to be shared by all three protein forms. Extensive studies revealed a number of alternatively spliced-in extra exons generating a complex hinge region in the membrane proximal domain and an altered Ig-like domain IV. The alternative splicing does not only generate a high number of distinctive NCAM transcripts at a given developmental stage, but changes the composition of NCAMs during CNS neurogenesis. This age-dependent process is distinguishable from NCAM gene induction during CNS self-repair.

MOLECULAR CLONING AND EXPRESSION OF TYPE II ADENYLATE CYCLASE FROM BOVINE BRAIN. P.G. Feinstein*, H.A.Bakalyar* J.Krupinski*, A.G.Gilman*, and R.R.Reed(SPON:B.Largent). Howard Hughes Med. Inst. and Department of Molecular Biology and Genetics, Johns Hopkins Univ. Sch. of Medicine,Balt., MD 21205. Department of Pharmacology, University of Texas Southwestern Medical Center, 5323 Harry Hines Blvd.,Dallas, TX 75235

Adenylate cyclase has been extensively characterized at the biochemical level during the past 15 years. These studies have suggested two basic forms of the enzymes, a calcium/calmodulin sensitive form as well as an insensitive species. Adenylyl cyclase protein has been characterized from several tissue sources by biochemical and immunological techniques. We have undertaken a molecular genetic approach to further our understanding of the basis for the various forms of the adenylate cyclase enzyme. A calcium/calmodulin sensitive bovine brain adenylate cyclase was purified over a forskolin-sepharose column and the sequence of several tryptic peptides determined. An oligonucleotide probe deduced from the sequence of one peptide was used to screen cDNA libraries derived from bovine and rat tissues. Two classes of cDNA clones were isolated. One class of cDNA's encodes a protein predicted to contain all of the tryptic peptides whose sequences were determined. We refer to the protein encoded by this cDNA as adenylate cyclase,Type I. Additional cDNAs were identified and predicted to encode a protein which is similar in size and topological arrangement. The considerable amino acid homology (55% overall) and the extensive similarity in the proposed catalytic domains (80-90%) argues that this cDNA encodes an alternative form of adenylate cyclase (Type II). Northern analysis indicates that Type II adenylate cyclase is expressed in a variety of tissues.

NEUROEPITHELIAL EXPRESSION OF A THY-1.2/*lacZ* FUSION GENE IN THE DEVELOPING CNS OF TRANSGENIC MICE. K.A. Kelley, G.S. Manjunath* and K. Herrup. The Fishberg Research Center for Neurobiology, The Mount Sinai School of Medicine, New York, NY 10029 and The E.K. Shriver Center, Waltham, MA 02254.

Transgenic mice were prepared from a Thy-1.2/*lacZ* hybrid gene. As previously reported (Kelley and Herrup, Soc. for Neuro. Abst., 14: 622, 1988), neuron-specific expression was observed in adult offspring from one transgenic animal. Embryos from this line were examined to determine the temporal pattern of expression, if any. Intense ß-galactosidase (ß-gal) activity was detected in the neural tube as early as embryonic day 10 (E10). By E13, the neuroepithelial cells lining the ventricular zone are heavily labeled, and this staining persists through later stages. Labeled cells are present that appear to be moving away from the ventricular zone, reminiscent of migrating neurons. In addition to the neuroepithelial expression, ß-gal is also present at very high levels in the dorsal root ganglia (DRG) from E13-E14. The DRG staining is absent at E15, and is never detected in the adult.

Thy-1/*lacZ* transgene activity in cells of the early neuroepithelium, and its persistence in migrating neurons, suggests that the ß-gal staining can be used to trace developing neurons from their genesis in the ventricular zone. At E13, for example, labeled spinal cord motoneurons in the lateral motor column that have migrated out from the ventrolateral region of the ventricular zone are visible; mature adult motoneurons express relatively high levels of transgene activity. The utility of this marker as a tool for the study of cell lineage and cell maturation is thus quite high.

FUNCTIONAL ANALYSES OF THE CALMODULIN (CaM)-BINDING DOMAIN OF CAM-KINASE II (CK-II) USING SYNTHETIC PEPTIDES AND SITE-DIRECTED MUTAGENESIS. P. Kelly, T. Honeycutt, R. Weinberger, D. Blumenthal, R. Yip, and N. Waxham, Dept. of Neurobiol. and Anatomy, and Neurology, Univ. of Texas Med. Sch., Houston, TX 77225.

Recombinant DNA and synthetic peptide studies have localized the CaM-binding domain of CK-II to residues 295-309 of the 50 kDa (alpha) subunit (ARRKLKGAILTTMLA). Synthetic peptides encompassing this domain are potent inhibitors (IC_{50}=90 nM) of CaM-dependent activation of CK-II. This regulatory domain has properties similar to many CaM-binding peptides, namely an amphipathic alpha-helix with basic amino acids near one end and hydrophobic residues near the other. A series of deletion peptides with the same C-terminus (Ala-309) were synthesized to more accurately define the minimum CaM-binding domain of CK-II. Removal of the two N-terminal arginines only slightly decreased the CaM antagonist properties (IC_{50}=200 nM), whereas deletion of the N-terminal sequence ARRK produced a peptide (residues 299-309) that displayed very poor CaM antagonism (IC_{50}=75 uM). Similar CaM-antagonistic properties were observed with this series of peptides using myosin light chain kinase, an enzyme activated at much lower [CaM] (K_a=4 nM) then CK-II. Analyses of site-directed mutations of bacterially-expressed CK-II supported results with synthetic peptides and showed the importance of basic amino acids at the N-terminus of its CaM-binding domain with Lys-298 being a critical determinant. Mutational studies further revealed that the CaM-dependent activation of CK-II does not require the hydrophobic sequence ILTTMLA (residues 303-309) near its C-terminus. These results indicate that the important features of CaM-dependent activation of CK-II reside in the basic amino acids KLK (residues 298-300).

MOLECULAR CHARACTERIZATION OF BRAIN CALMODULIN-DEPENDENT PROTEIN PHOSPHATASE, R. L. Kincaid*, D. Amorese*#, J. Tamura*, S. Higuchi*, S. C. Dixon*, C. A. Marietta*, P. Rathnagiri* and B M. Martin*+ (SPON: M. Billingsley) Immunology Sect., NIAAA, Rockville, MD 20852; #Molecular Genetics Group, DuPont Co., Wilmington, DE 19898; and +Molecular Neurogenetics Sect., NIMH, Bethesda, MD 20892.

Full-length cDNA and partial genomic clones for calcineurin were isolated and characterized from murine and human brain libraries using non-isotopic methods. A biotinylated restriction fragment corresponding to the 5' end of a partial cDNA (Kincaid, et al, PNAS 85: 8983, 1988) was used to identify clones, the gross structures of which were deduced by Southern blot analysis with biotinylated oligonucleotide probes. The DNA sequence for the catalytic subunit, determined by automated sequencing using fluorescent dideoxy nucleotides, showed >40% identity with those of the protein phosphatases 1 and 2A. Analysis of mRNA expression showed a major species of ~4000 bp, present in highest amounts in brain, with minor bands in other tissues such as testis. The 59 kDa subunit was expressed in bacteria and purified in high yield (0.8 mg/liter) by affinity chromatography. Studies using recombinant forms with specific deletions have identified the site of interaction with calmodulin.

TISSUE SPECIFIC EXPRESSION OF A GENE WHICH IS MUTATED IN A MPP'-SELECTED PC12 MUTANT. S.G. Carlson*, M.J. Kadan, R.C. Douglas*, K.A. Marcus, M.M.S. Lo. NIDA, ARC, Baltimore, MD 21224

Pheochromocytoma (PC12) cells were mutated by infection with a recombinant retrovirus, and selected on 500uM MPP'. The proviral position was examined in 30 drug selected clones. A particular locus was found to contain integrated virus in 3 different mutant clones. The provirus and 12 Kb of flanking genomic DNA downstream to the virus was cloned from one mutant (M39). The flanking genomic DNA contained a specific 0.9 Kb coding region which hybridized to a distinct messages of about 1.5 Kb in normal PC12 cells. This coding sequence was used to isolate cDNA clones from a PC12 cDNA library. A near-full length cDNA of 1.4 Kb was used to screen Northern blots of the MPP' selected mutant lines, and found to be reduced in several lines. The same cDNA was used to screen Northern blots prepared from various rat tissues. Significant levels of this gene were detected in salivary gland, but not in brain, liver or adrenal gland. The DNA sequence of this gene was also determined, and was not found to be related to any other known gene sequences. Elucidating the function of this gene, which is differentially expressed in salivary gland, may provide some clues to its role in MPP' toxicity in PC12 cells.

MOTOR NEURON-SPECIFIC GENES: A HYBRID CELL cDNA CLONING STRATEGY. S. Pasternak*, N.R. Cashman, K. Hastings*. Dept. of Neurology, McGill University, Montreal, Qc H3A 2B4.

Studies of the cell biology of specific neuronal populations are hampered by the limited purity and yield of primary cultures. In the attempt to provide a potentially unlimited homogenous supply of motor neuron-like cells, we have developed a series of neuroblastoma-spinal cord (NSC) hybrid cell lines (Soc Neurosci Abs, 1987). The subclone NSC-34-6 expresses a variety of differentiated motor neuron characteristics not observed in the neuroblastoma parent N18TG2, including choline acetyltransferase activity and formation of stable neurite-myotube contacts. We employed a cDNA cloning and screening strategy designed to identify cloned copies of mRNAs which are more abundant in NSC-34-6 than in the N18TG2 parent. Differential plaque hybridization yielded 3 such clones; two correspond to a mitochondrial mRNA (cytochrome oxidase subunit 1) and one corresponds to an unknown mRNA containing a copy of the B1 repeat sequence. A separate subtraction hybridization screening yielded one clone whose mRNA was undetectable in the N18TG2 parent. This NSC-34-6 specific mRNA encodes chromogranin B. Because chromogranins are known to be expressed in motor neurons, this result suggests that neural hybrid cell-specific gene expression may reflect a contribution from the non-tumor parent cell. Further subtraction hybridization screening of the library is being undertaken in the hope of identifying additional NSC-34-6 specific and possibly motor neuron-specific mRNA.(Supported by MDA)

PROTO-ONCOGENE C-FOS IN THE LEECH CNS. Susan A. DeRiemer & Lara Gussman* Columbia University, New York, NY 10027

A majority of proto-oncogenes appear to be elements of signaling pathways and exist in high levels in the brain. The levels of c-fos are modulated in mammalian cells by synaptic activity and calcium influx. In order to study the evolution and function of these genes, we looked for homologues in the simpler nervous system of the leech.

Using monoclonal antibodies raised against peptides from the mouse c-fos protein, we have found a c-fos immunoreactive protein in the leech CNS which shares many properties with that found in mammals. It appears as a doublet on SDS gels with M_rs=52 and 62 kDa. Its levels are increased by high potassium depolarizations and forskolin within 30 min. of stimulation, and there appear to be both nuclear and cytosolic fos-like proteins in intact cells. Comparison of the cross-reactivity with two antibodies recognizing different parts of the protein suggest that the C-terminal region (amino acids 359-378) which is c-fos specific is more highly conserved than a region (amino acids 132-154) found in both c-fos and v-fos.

We are now analyzing the relationship between c-fos levels and the activity of single cells in vivo and in vitro.

This work was begun as a Westinghouse Science Project (L.G.) with support from a Sloan Research Fellowship (SAD).

EARLY PROCESS OUTGROWTH OF SPINAL ACCESSORY MOTOR NEURONS STUDIED WITH diI IN FIXED TISSUES. V. Palavali* and W.D. Snider, Dept. of Neurology, Washington Univ. Sch. Med., St. Louis, MO 63110.

Spinal accessory neurons are unique among motor neurons in the spinal cord because their axons do not exit in ventral roots but rather exit dorsally as rootlets of the spinal accessory nerve. A description of axon outgrowth of accessory neurons is thus pertinent to understanding how the axons of spinal motor neurons make correct pathway choices. We have utilized lateral diffusion of diI in fixed tissues (Godement et al.1987) to study early process outgrowth of these neurons in embryonic rats. Growth cones of accessory neurons were labelled on E11 by placing tiny crystals of diI near the ventral commissure of the cervical cord. Accessory growth cones are found in the lateral region of the cord and project dorsally to exit midway betwen the dorsal and ventral poles. Upon exiting the cord, accessory axons immediately turn rostrally to form the accessory nerve. In the cord, growth cones are broad with filopodia until they near the external limiting membrane where they elongate. In the area of the turn growth cones are quite complex with numerous branches and filopodia, whereas within the nerve growth cones are narrow with few filopodia.

It was also possible to label the somata of spinal accessory neurons by placing crystals on the lateral region of the spinal cord as early as E11, and on the accessory nerve itself, thereafter. Many spinal accessory neurons on E11 possess an apical process directed toward the central canal. By E12 neurons are unipolar. By E13 many neurons have assumed a bipolar configuration and one or more dendrites with secondary branches have appeared. Our results demonstrate that axonal and dendritic processes can be revealed in striking detail from the earliest stages of motor neuron differentiation using diI. We show here that growth cone morphology changes with position along the accessory pathway. Use of diI in fixed tissue should allow study of process outgrowth in mammalian spinal cord in a way previously possible only for lower vertebrates.

382.2

RHOMBOMERES AND LONGITUDINAL BOUNDARIES IN THE CHICK EMBRYO BRAINSTEM SUBDIVIDE VESTIBULAR NEURONS ACCORDING TO AXONAL PATHWAY. J.C. Glover, Physiol.Inst., Univ.of Oslo, Norway

Vestibulospinal and vestibulo-ocular neuron groups can be distinguished on the basis of position and axonal pathway in the brainstem of the 11 day chicken embryo (Glover & Petursdottir, J.comp.Neurol.,270:25, 1988; Petursdottir & Glover, Neurosci.Abstr., 13:1504, 1987). To investigate how this spatial organization arises, retrograde tracers were injected into the vestibular axons as they were growing towards their targets. To label vestibulo-oculomotor neurons, the tracers were injected unilaterally into the medial longitudinal pathway at pontine levels. To label vestibulospinal neurons, they were injected unilaterally into the lateral longitudinal pathway at medullary levels.

At all stages, vestibulospinal and vestibulo-ocular neurons were spatially segregated, the former sandwiched in the longitudinal axis by the latter. Two-tracer studies, coupled with the visible morphological boundaries of the rhombomeres (r) on day 4, revealed that 1) vestibulospinal neurons projecting in the lateral pathway are restricted to r4, and 2) their caudal vestibulo-ocular neighbors neatly span the length of r5/6, and are subdivided into a contra-projecting column lying just medial to an ipsi-projecting column. Thus, axonal pathway is correlated with vestibular neuron position in an appealing geometric pattern that suggests that pathway choice may be determined by a simple array of segmental and mediolateral positional cues.

382.3

FORMATION OF THE MEDIAL LONGITUDINAL FASCICLE IN WILD-TYPE AND MUTANT ZEBRAFISH EMBRYOS. W. K. Metcalfe and K. Hatta*. Inst. of Neuroscience, U. of Oregon, Eugene, OR 97403

In 1941, J. Oppenheimer suggested that midbrain neurons may establish pathways that are necessary for hindbrain reticulospinal axons to project normally to the spinal cord. In zebrafish embryos, this pathway, the medial longitudinal fascicle (mlf) forms as a tight fascicle of axons descending on either side of the midline from reticulospinal neurons of the midbrain (the nucleus mlf) and hindbrain. In the cyclops mutant of zebrafish, *cyc-1((b16)*, midbrain axons do not form a normal mlf, and hindbrain axons are dispersed over the floor of the hindbrain rather than forming discrete fascicles as they descend. These observations are consistent with Oppenheimer's hypothesis.

To test this hypothesis in wild-type embryos, we examined the time course of axon outgrowth. We found that many hindbrain reticulospinal neurons began to grow axons directly along the appropriate pathway nearly simultaneously, regardless of their longitudinal position and before the arrival of the first descending fibers from the midbrain nucleus mlf. Further, we found that the hindbrain reticulospinal axons grew normally following laser ablation of the midbrain nucleus mlf.

We conclude that hindbrain reticulospinal axons are capable of growing along their normal pathways independently of influences from the midbrain nucleus mlf.

CLIMBING FIBERS CONTACT TARGET PURKINJE CELLS IN EMBRYONIC MOUSE CEREBELLUM

C.A. Mason and R. Blazeski*, Dept.of Pathology, College of Physicians and Surgeons of Columbia University, New York, N.Y. 10032.

Prior to synaptogenesis in complex brain regions, afferent axons must coordinate their ingrowth with the migration and settling of their target cells. We have witnessed three novel features of this process in embryonic mouse cerebellum by simultaneously labeling climbing fibers with DiI applied to the inferior olivary nuclei in fixed tissue, and Purkinje cells with antisera to calbindin (gift of S. Christakos). 1). At E14-15, olivary axons approach the cerebellum in a tract running under the pia, meeting the external granule layer as it spreads from the rhombic lip. By E15-16, olivary axons enter the cerebellum during Purkinje cell migration. The axon entry zone is surrounded by Purkinje cells and many axons enter this mass, while others grow toward migrating cells. By E18, fine, unbranched olivary axons project within the Purkinje cell zone, by now in a wide band beneath the external granule layer. 2) Growth cones display different forms during these stages: long and foliated in the tract leading to the cerebellum, complex with filopodia as they exit the tract, foreshortened, flat and lamellopodial as they grow toward targets, and minute and tapered within the Purkinje cell zone. 3) After relatively rapid entry and approach onto target cells, unbranched olivary axons make simple synaptic contacts with target Purkinje cells, and maintain this configuration from E18-P2.

These results constitute evidence that climbing fibers do not 'wait' to advance onto targets, as suggested by lower-resolution tracing methods, but pause after first interactions with targets and before arborization. In addition, consistent with our findings in the retinal axon pathway, growth cones change shape with locale and behavior.

382.5

EXPRESSION OF THE DISIALOGANGLIOSIDE GD3 IN DEVELOPING AXON TRACTS OF THE FETAL MOUSE BRAIN. **M.A. Edwards, G.A.Schwarting* and M. Yamamoto. Depts. of Devel. Neurobiol. and Biochem., E.K. Shriver Ctr., and Harvard Med. Sch., Waltham, MA 02145**

Previously, we reported that the monoclonal antibody 7C7, recognizes the ganglioside GD3 as its major antigenic species and immunocytochemically stains the early primary optic pathway of the mouse (E12-15) (Edwards and Yamamoto, Neurosci. Abstr. 11, 316, '85). In addition, dense staining was associated with proliferative neuroepithelial zones, as described by others using anti-GD3 antibodies in embryonic vertebrates. Further studies with 7C7 using various fixation protocols indicate that GD3 expression is concentrated transiently (2-4 days) in most or all fetal CNS axon systems. Comparisons were made with a new monoclonal antibody, PPATH, inferred to recognize acetylated GD3 based on antigen mobility with TLC and conversion to 7C7 reactivity with ammonia vapor treatment. PPATH stains only restricted ventricular zone sites and a subset of fetal CNS axon systems, including optic axons and trigeminal and vestibular fiber systems as far as the cerebellar rudiment. Ultrastructural observations reveal that both 7C7 and PPATH stain sites of axon-axon apposition as well as axon-radial glia contacts. (Funded by NIH Grants EY06080, HD21018, HD04147 and NS25580).

382.6

SELECTIVE EXPRESSION OF A NOVEL CADHERIN IN THE PATHWAYS OF DEVELOPING MOTOR- AND COMMISSURAL AXONS B.Ranscht and M.T.Dours (SPON: J.Dodd) La Jolla Cancer Research Foundation, NCI, La Jolla, CA 92037

Developing nerve fibers find the way to their targets with temporal and spatial precision even in the face of a changing environment. One possible explanation for this selectivity is that the pattern of neuronal connections is established by the interaction of neuronal cell surface components with molecules in the extracellular milieu. We have isolated and cloned a cell surface glycoprotein from chick embryo brains which is a novel member of the family of cadherin cell adhesion molecules. Our cDNAs exhibit 47 percent sequence identity with the extracellular domains of chick N-cadherin and less with E- and P-cadherin and L-CAM. In developing chicken embryos the expression of this new molecule has two striking features that suggest a role in establishing the pattern of nerve fiber growth. In the neural tube at the time of commissural axon growth, our antibodies recognize a small ventral area including the floor plate. This expression pattern correlates with the suggested role of the floor plate in controlling the pattern of commissural axon growth. In developing somites, staining is observed in a striking segmental pattern in the posterior region of the somitic sclerotome at the time of motor axon growth. This localization coincides with the establishment of the segmental pattern of motor nerve fibers, which is based on motor axons selecting only the anterior region of the somite segments to project into the periphery. It is an attractive hypothesis to speculate that cell adhesion molecules of the cadherin family could influence the pattern of neuronal connections in the developing nervous system.

382.7

SUBPLATE NEURONS PIONEER THE FIRST AXON PATHWAY OUT OF THE CEREBRAL CORTEX. S.K. McConnell, A. Ghosh and C.J. Shatz, Dept. of Neurobiology, Stanford Univ. School of Medicine, Stanford, CA 94305.

During the embryonic development of the mammalian cerebral cortex, the earliest-generated neurons form a transient structure known as the subplate (SP). SP neurons in the cat are born between E24 and E30; they reach a high degree of morphological maturity in fetal life, and disappear by cell death postnatally. To explore the possible roles of SP neurons in early cortical development, we placed tiny crystals of DiI into the cerebral cortex of cat fetuses at E26 and E30, times before the permanent neurons of the cortical plate have been generated. In E30 fetuses (but not E26), the DiI labeled long-distance axon pathways that headed directly toward, and sometimes entered, the internal capsule (the gateway from cortex to thalamus). There was a gradient of development of this pathway: temporal cortical injections labeled axons extending through the capsule and into the thalamus, whereas axons labeled from more dorsal injections did not yet reach these structures. Next, to identify the cells of origin of this pathway, we placed DiI in the internal capsule or thalamus of E30 fetuses. These experiments resulted in the retrograde labeling of temporal SP neurons and their axons, showing that SP cells form the early axon pathways. At later fetal ages (from E36 on), DiI-labeled axons could be traced even from the far dorsal areas of cortex (e.g., visual cortex) to the thalamus and tectum. Many of these axons must arise from SP neurons, since SP cells could be retrogradely labeled from these target structures well into fetal life. The present results suggest that one function of SP neurons is to pioneer the first axon pathways from the cortex to subcortical targets, at a time before the permanent neurons of the cerebral cortex have been generated. This raises the possibility that the pioneering axons of SP neurons may be required for the development of permanent subcortical projections from the deep-layer neurons of the cortex.

382.8

ABLATION OF SUBPLATE NEURONS ALTERS THE DEVELOPMENT OF GENICULOCORTICAL AXONS. A. Ghosh, A. Antonini, S.K. McConnell and C. J. Shatz, Dept. of Neurobiology, Stanford Univ, Stanford, CA 94305.

During development of connections between thalamus and cortex, ingrowing thalamic axons wait in the subplate (SP) below the cortical plate (CP) for several weeks before growing into layer 4. The SP contains a special class of transient neurons, the SP neuron, which has led to the suggestion that interactions between SP neurons and waiting axons are essential for the normal development of thalamocortical projections. To investigate this suggestion, we (1) studied morphological changes in individual axons from the lateral geniculate nucleus (LGN) during development in fetal and neonatal cats by making DiI injections into the LGN and (2) ablated SP neurons by injecting kainic acid into the waiting zone. In normal development, as early as E30, LGN axons tipped with growth cones are present in the internal capsule. As the axons grow caudally towards visual cortex, they send out simple collaterals that are restricted to the SP and do not enter the CP. On reaching the visual cortex (E42), axons branch extensively within the SP. At about E55, axons begin to invade the CP and arborize, so that by P7 (birth=E65) a highly branched but fairly compact terminal arbor is restricted to layers 4 and 6.

Kainic acid injections into the SP zone at E42, when axons are waiting there, radically alters the trajectories of LGN axons. The lesion itself almost completely eliminates SP neurons but leaves the CP intact. LGN axons examined at E60 fail to form dense arborizations within the remaining zone of future white matter below the CP and instead run past the visual cortex in a tight fascicle of axons. By P5, LGN axons should normally have invaded the CP, but in lesioned cases they fail to do so and again continue past visual cortex, seemingly unaware of their correct destination. These observations indicate that subplate neuron-LGN axon interactions during the waiting period play a critical role in permitting thalamic afferents to select the appropriate cortical target area. Supported by NIH grant EY02858.

382.9

STIMULATION OF TECTAL CHEMOTROPIC INFLUENCE IN ANOPHTHALMIC MICE BY TRANSPLANT-DERIVED RETINAL AXONS M.H. Hankin & R.D. Lund, Dept. Neurobiol., Anat. & Cell Sci., Univ. Pittsburgh, Pittsburgh, PA 15261

Our previous work based on transplantation studies in rodents has indicated that retinal axons are guided to the tectum by several types of cues (Hankin and Lund, *J. Comp. Neurol.* (1987) 263:455). The outgrowth patterns in normal rat hosts exhibited by transplant-derived optic axons suggest that local outgrowth-promoting cues are expressed along the optic tract in a 200 um wide region just below the glia limitans (***subpial pathway***). The distance-dependent outgrowth towards the tectum by the earliest axons emerging from retinae placed in the midbrain parenchyma indicates that, in addition to these substrate pathway cues, optic axons may also be attracted to the tectum by diffusible factors emanating from the target region.

In the present study we have used the ocular retardation (or^J) mutant mouse as a transplant recipient to test whether optic innervation stimulates the tectal chemotropic influence (the genetic mutation in these mice leads to optic nerve aplasia during embryogenesis and by birth results in anophthalmia). Our results show that transplant-derived optic axons can innervate the or^J tectum via the subpial pathway. However, directed outgrowth towards the tectum through the or^J parenchyma takes place only in the presence of input to the tectum from a second retina placed along the subpial pathway.

It is suggested that the tectum in mammalian vertebrates produces a diffusible factor whose production (or release) is regulated by the initial population of ingrowing retinal axons. The possible function of this factor, in addition to that suggested by its chemotropic effect on transplant axons, may be to signal optic axons in the vicinity of the target to change from an elongation mode to one favoring the formation of terminal branches.

Supported by NIH grants NS26777 and RR05416 (MHH) and EY05308 (RDL).

382.10

AXON PATHFINDING IN THE EMBRYONIC MOUSE VISUAL SYSTEM. D.W.Sretavan. Lab. of Neurobiology, Rockefeller Univ., New York, NY 10021

At the mammalian optic chiasm, axons of retinal ganglion cells (RGC) project along either the ipsilateral or contralateral optic tract to reach CNS targets. In the mouse, ipsilaterally projecting RGCs are restricted to ventral temporal retina while those projecting contralaterally are found throughout the retina. This pattern of chiasmatic routing could result from specific axon growth at the chiasm or by initial randomly directed growth followed by elimination of incorrectly projecting RGCs. To differentiate between these possibilities, retinal projections were examined during the period of RGC neurogenesis between embryonic days 11 to 18 (E11-18; Drager, U., Proc. R. Soc. Lond. B224:57, 1985). By using either an anterograde tracer technique (small local retinal injections of fluorescent dye, DiI) or a retrograde labeling method (fluorescent latex microspheres injected into the optic tract), an adult-like pattern of axon routing at the chiasm can be demonstrated as early as E15. Thus, embryonic RGC axons make appropriate pathway choices at the optic chiasm.

The trajectories of individual axons were reconstructed in order to examine how these pathway choices are made. To do so, E14-E18 DiI labeled axons which have just grown past the chiasm into the contralateral or ipsilateral tract were photoconverted to form a DAB reaction product. Ipsilaterally and contralaterally projecting axons were found throughout all portions of the optic nerve and were intermixed at the entrance of the chiasm. Contralateral axons entering the chiasm close to the origin of the ipsilateral optic tract either grow well past this region without entering or once within this region turn away abruptly and head towards the origin of the contralateral tract. Similarly, ipsilateral axons up to 250μm away from the origin of the ipsilateral tract were observed to turn sharply at right angles and head directly into the ipsilateral tract crossing over axons growing towards the opposite side. These observations suggest that retinal axons are not merely passively channeled into the correct pathway but instead appear to be capable of active pathfinding at the optic chiasm.

SELECTIVE AXON GROWTH NOT AXON LOSS PRODUCES CONNECTIONAL DISTINCTIONS BETWEEN CALLOSAL AND SUBCORTICALLY PROJECTING LAYER 5 CORTICAL NEURONS. Susan E. Koester and Dennis D.M. O'Leary (SPON: G. Harding) Dept of Neurosurgery, Washington Univ Sch Med, St. Louis, MO 63110

In the cortex of adult rats, layer 5 neurons send axons through the corpus callosum to contralateral cortex or through the internal capsule to subcortical targets, but individual neurons reportedly do not have both connections. Here we confirm this separation and address whether it develops by extension of axon collaterals to both sets of targets with later elimination of one or the other (a phenomenon common in developing cortex) or by initially selective axon outgrowth. Retrograde tracers Fast Blue and Diamidino Yellow were injected in the subcortical path at the pyramidal decussation and in contralateral cortex, respectively, of adult and newborn rats. In 16 adults, no cortical neurons are double-labeled, indicating that none project to both sites. In 17 neonates, we found only one double-labeled cell, while in each brain hundreds of thousands of layer 5 neurons are single-labeled. This result rules out that this connectional distinction in adults is achieved by the elimination of long transient callosal or subcortical collaterals. To determine if shorter transient collaterals are extended subcortically by callosal neurons, we injected DiI into one cortical hemisphere of 7 aldehyde fixed E21 brains. In months, DiI retrogradely fills callosal neurons, including their axons and all branches. Two types of axons are seen in the white matter of the cortex opposite the injection: those which turn and extend through the callosum and those which branch, sending collaterals both to ipsilateral and contralateral cortex. None of the callosal neurons extend collaterals into or toward the internal capsule. We conclude that from early stages of axon extension, callosal and subcortically projecting cells are distinct classes of neurons and, apparently in response to cues present in cortex, initiate growth toward class-specific and non-overlapping sets of targets. SPECIFIC OUTGROWTH SHAPES THE ORIENTED DENDRITIC ARBORS OF DEVELOPING NEURONS IN RAT SOMATOSENSORY CORTEX. A. Peinado and L.C. Katz. Laboratory of Neurobiology, The Rockefeller University, 1230 York Avenue, New York, NY 10021.

In several cortical and subcortical systems, including monkey striate cortex and the 3-eyed frog optic tectum, postsynaptic dendrites respond to borders between segregated afferent inputs. In the rat primary somatosensory cortex these biases are dramatic: spiny stellate neurons within layer 4 of the rat barrel cortex have their dendrites confined to the cortical territory of the thalamic afferents representing a single whisker. We examined the emergence of these biased dendritic arbors using brain slices from rats at postnatal days 4-11 (P4-P11), in which thalamocortical afferents were identified by anterograde transport of rhodamine injected into the ventrobasal thalamus at P2. Dendrites were visualized by intracellular injection of Lucifer Yellow.

Between P4 and P5, afferent labeling in layer 4 segregated from a continous band of label to increasingly obvious clusters. Even before clusters were completely segregated, the dendrites of postsynaptic cells were oriented away from the boundaries between afferent clusters. Dendrites growing towards a barrel border either terminated or turned abruptly upon encountering the boundary. At P4-5, most layer 4 dendrites still lacked their characteristic spines, yet they behaved like dendrites of adult animals. At later ages (P7-11) dendrites became longer, more highly branched, and spinous. With the increasing arbor size, initial biases became even more pronounced. We conclude that the dendritic bias observed in layer 4 cells results from early specific outgrowth, and not elimination of inappropriately situated dendrites. These results further suggest that the thalamic afferents themselves carry some signal that triggers dendritic growth. One difference between afferents in different barrels is the degree of correlation of electrical activity among incoming fibers. Postsynaptic dendritic growth may require a threshold level of temporally correlated inputs. Supported by NS08466 and the L.P. Markey Charitable Trust.

PAVLOVIAN CONDITIONING INDUCES REDUCTION OF BRANCHING VOLUME OF AN IDENTIFIED NEURON IN *HERMISSENDA*. D.L. Alkon, J. Dworkin*, H. Ikeno*, D.L. McPhie*, J.L. Olds, I.I. Lederhendler, L.D. Matzel, B.G. Schreurs*, A. Kuzirian*, and C. Collin*. NIH, NINDS, LMCN, Bethesda, MD 20892.

Storage of a learned association of discrete sensory stimuli has previously been shown in the mollusc *Hermissenda crassicornis* to be related to changes of protein phosphorylation, synthesis of specific proteins, and of membrane currents of a specific neuron, the medial Type B cell (causally implicated in the memory storage). Blind electrophysiologic measurements revealed that 4-5 days after training, conditioned Type B cells had significantly higher ($p < 0.02$ by ANOVA and post-hoc analyses) input resistance (inversely related to K^+ channel conductance) than cells from either Unpaired or Naive animals (which showed no between group differences). Images of Ni^{2+}-lysine-injected Type B cells' terminal branches were then analyzed with a computer-based system for measuring the limits of branching. Limiting boundary volume for the terminal arborization was obtained as a product of x, y, and z values. One way ANOVA and Scheffe contrasts demonstrated that both Unpaired and Naive Type B branch volumes (EV) were not different from each other but were significantly greater ($p < 0.01$) than volumes for the Paired animals. The degree of branching volume reduction was correlated (inversely) ($p < 0.014$) with the magnitudes of the blindly obtained input resistance values.

383.2

PHORBOL ESTER, AN ACTIVATOR OF PROTEIN KINASE C, INDUCES MORPHOLOGICAL CHANGES OF *HERMISSENDA* PHOTORECEPTORS. I. Lederhendler, R. Etcheberrigaray*, & D. L. Alkon. LMCN-NINDS, NIH, Bethesda, MD 20892.

In *Hermissenda* voltage-dependent K^+ currents within the Type B photoreceptor remain reduced for days following classical conditioning. Activation of protein Kinase C (PKC) induces changes in these same currents. PKC activation has also been implicated in learning-specific modifications of specific protein substrates in the photoreceptors. Since the Type B photoreceptor undergoes persistent conditioning-specific changes in structure (Alkon *et al.*, Soc. Neurosci. Abstr., 1989) we asked whether PKC activation alters cell shape. We isolated the eye, consisting of five photoreceptors, a single spherical lens, and a central area of screening pigment. We measured the area of individual photoreceptors from photographs obtained on an inverted microscope. In the presence of light, 220nM phorbol produced a significant increase (9.2 ± 3%) in the size of individual photoreceptors. Phorbol application in the absence of light, or application of 220nM inactive phorbol did not change the photoreceptors (ANOVA, $p<0.01$; $df = 2,17$). Because the photoreceptors were partially obscured by the screening pigment, any reduction in the size of the pigment could cause artifactual increases in the size of the photoreceptors, and therefore we measured the area enclosed by the screening pigment relative to the dimensions of the whole eye. The pigment increased equally in all the groups. However the overall dimensions of the eye increased only in the group which received phorbol in the presence of light (ANOVA, $p<0.005$; $df = 2,11$). The increases induced by phorbol-with-light in the photoreceptors' size are therefore independent of any increases in the pigment. These results suggest that phorbol activation of PKC induces morphological changes, which may be relevant to the learning process, in addition to biochemical and biophysical modifications of these cells.

ALAPROCLATE REDUCTION OF *HERMISSENDA* POTASSIUM CURRENTS MIMICS EFFECTS OF CLASSICAL CONDITIONING. C. Collin*, L.D. Matzel, M. Sakakibara,† and D.L. Alkon. LMCN-NINDS, NIH, Bethesda, MD 20892; †Dept Computer Sci, TUT, Toyohashi 440, Japan.

Alaproclate (ALA), a 5HT re-uptake inhibitor, also reduces calcium-dependent K^+ currents (I_c) in mammalian cultured neurons (Hedlund, Pharmacol. Toxicol, 61: 236, 1987). Behavioral experiments show enhancement of performance in a one-trial avoidance task in rats (Altman *et al*, Behav. Neur.Biol, 48: 49, 1987). Here we report that ALA also reduces the early voltage-dependent K^+ current (I_A) and the calcium-dependent K^+ current(I_c) in isolated type B photoreceptors of the marine snail *Hermissenda*, in two-electrode voltage-clamp experiments. 3 min after extracellular application of 250nM ALA, peak amplitudes of I_A and I_c were significantly reduced by 7 ± 2% and 12 ± 4% respectively (n = 4, $p<0.002$). Reductions of more than 50% in both currents were reached with 25 to 50 μM drug applications. This effect reversed spontaneously at concentrations lower than 10μM, but only partially at concentrations of 10 - 50μM. No recovery was observed for either current at concentrations larger than 50μM. There is no synaptic input to these axotomised cells, thus the effects of ALA could be mediated *via* intracellular messengers. To test this possibility, the effects of 10μM ALA were examined after intracellular injections of the calcium chelator EGTA, or bath application of 25μM TFP, a calmodulin-dependent protein kinase (Cam-K) inhibitor, or 200μM sphingosine, a protein kinase C (PKC) inhibitor. All three conditions prevented any ALA effect upon K^+ currents after 10 min. These results indicate that ALA reduction of K^+ currents is a calcium-dependent process, and is mediated by the modulation of Cam-K or PKC, or both, in a similar way to classical conditioning-induced changes in *Hermissenda*.

383.4

CHANGES IN A GTP-BINDING PROTEIN FOLLOWING ASSOCIATIVE CONDITIONING OF *HERMISSENDA*. T. J. Nelson and D. L. Alkon, Lab. of Molecular and Cellular Neurobiology, NINDS/NIH, Bethesda, MD 20892.

Classical conditioning of *Hermissenda* (*H*) increases the phosphorylation state of a 20 kDa protein (cp20) known to be a C-kinase substrate (Neary et al., 1981). To identify the proteins modified by conditioning, we trained *H* with paired light and rotation, dissected the eyes 24h after conditioning and analyzed the proteins by ion-exchange HPLC. Conditioning increased the peak area of cp20 by 3.3x (paired=1.23±.27, random=0.37±0.09, naive= 0.22±0.11 (mean±SD, p<.01)). We also purified cp20 from *H* CNS by ion-exchange HPLC followed by size-exclusion HPLC. A single peak from the 2nd column exhibited both GTPase and GTP binding activity, indicating cp20 is a G protein.

Iontophoretic injection of cp20 blocked the K^+currents I_{K+} (I_A) and $I_{Ca2+-K+}$ (I_C), which are also reduced after associative conditioning. I_A decreased from 47.5±7.3 to 34.8±5.7 nA(mean±SD,n-5,p<.05); I_C decreased from 30.5±3.2 to 21.1±3.3 (p<.005), whereas no change was observed after injection of KAc control solution, suggesting that cp20 may play a central role in mediating the reduction of these currents in vivo. Cp20 could play a role in memory storage analogous to that of *ras* in cell proliferation.

MECHANISMS OF EPENDYMIN PHOSPHORYLATION IN GOLDFISH BRAIN ECF. P.M. Nolan* and V.E. Shashoua. McLean Hospital, Harvard Medical School, Belmont, MA 02178.

Ependymin is a brain extracellular glycoprotein which consists of three related dimers. Much evidence has shown that this protein may be actively involved in the modification of neural circuits following memory consolidation. Recently, it has been suggested that its action may be mediated by a Ca^{2+}-dependent polymerization of ependymin, the stimulus being a reduction in extracellular Ca^{2+} concentration. Because of the importance linked with Ca^{2+}-dependent protein phosphorylation in events leading to memory formation, it was considered relevant to study ependymin phosphorylation. Ependymin or ECF fractions from goldfish brain were incubated with ^{32}P-ATP and were analyzed by SDS PAGE and autoradiography. In ECF, all three ependymin dimers appear to be phosphorylated whereas reduced monomers are not. Also in ECF, a band at approximately 130 kDa and a doublet at 18 kDa are phosphorylated. Experiments exploring the requirement for phosphorylation of ependymin were carried out to determine whether autophosphorylation or a possible extracellular protein kinase is required. No phosphorylation is seen with pure ependymin although pretreatment of ependymin with E. coli phosphatase results in monomer phosphorylation. In ECF, dimer phosphorylation is stimulated by 1mM EGTA and inhibited by higher concentrations (5-30 mM). The latter would suggest that polymerization of ependymin and its phosphorylation may be related events. We are currently exploring this possibility. This research was supported by NINCDS grant No: NS25748.

NEURAL NETWORK SIMULATION OF PERIPHERAL CUTANEOUS NERVE SECTION AND REGENERATION IN ADULT OWL MONKEYS. K.A.Grajski and M.M.Merzenich Coleman Labs., UCSF, San Francisco, CA 94143.

Thalamic and cortical consequences of peripheral cutaneous nerve section and regeneration are modelled by randomizing and progressively reestablishing peripheral-to-central targets in a simple multi-layer neural network operating under competitive conditions with a correlation-based (Hebbian) synaptic plasticity rule.

The network consists of three (15x15) layers: skin, subcortex and cortex. Projections between layers are topographically organized and refined by stimulus-driven activity. Intrinsic circuitry in the (sub) cortical layers includes local excitation and local inhibition, as well as mutually excitatory connections in the cortical layer. Model neurons linearly summate input and pass it through a sigmoidal nonlinearity to generate an output. Synaptic strength increases in direct proportion to pre- and post-synaptic activation; a passive decay acts to weaken unstimulated synapses. Competitive synaptic modification is enforced by increasing strengths at the expense of others.

The model reproduces the following experimental observations on the representation of the reinnervated skin: 1.) disrupted topographic organization in the thalamus, including large and discontinuous receptive fields; 2.) more complete cortical topography, characterized by small continuous receptive fields; 3.) small regions of incomplete cortical topography; and 4.) plasticity - newly co-activated skin sites across the denervation border are represented in both the thalamus and cortex. DYNAMIC ASPECTS OF RECEPTIVE FIELDS OF NEURONS CHRONICALLY RECORDED IN RAT VIBRISSA CORTEX. P.R.Kennedy & D.Banks* (Spon: M. Luskin), Bioeng. Center, Georgia Institute of Technology, Atlanta, Georgia 30332.

The ability to record cortical units continuously over months allows testing of the allegiance of receptive fields to these units following experimental manipulations. Such recording is now possible with a new electrode that records from neurites that grow from parent neurons onto its recording surface (P.R.Kennedy, J.Neurosci.Methods, 1989, in press). In the present experiments, the electrode was implanted in rat SM1 vibrissa cortex about 500 to 800 microns below the surface (layer 3b, 4; thalamocortical input layer) in order to record neural activity evoked by vibrissae deflections.

In 4 rats the electrode was placed just under the cortical surface (confirmed histologically in one rat). In other rats with deep placements, activity was recorded to jaw and neck, but not vibrissae. Manipulations were performed either by gluing adjacent vibrissae together or by trimming some vibrissae (thus allowing the untrimmed vibrissa(e) to be naturally and selectively stimulated). Recordings were performed under Ketamine sedation every 24 or 48 hours. In recent experiments, a touch-sensitive probe was used to deflect the vibrissae. Both the voltage output of this probe and the neural activity were archived simultaneously on an HP tape recorder for later analysis.

After determining the receptive field (RF) of the neural activty, two vibrissae not in the field were glued together. The rat separated these vibrissae overnight and the next day recordings revealed that these vibrissae evoked neural activity. The RF had widened in less than 24 hours. It contracted back to its original size within a week. These manipulations were repeated with similar results. In vibrissae trimming experiments, all vibrissae were cut off except C5. The RF contracted from 3 vibrissae (C4, C5 and D5) to 2 (C5 and D5). After C5 was cut off, the RF widened. When only vibrissa D5 was allowed to grow out, the RF moved ventrally to include C5, D5 and E5. After D5 was cut off, the RF widened again. Allowing E5 and E6 to grow out, produced a similar result. Deflecting the vibrissae with the touch-sensitive probe disclosed an average latency less than 10 ms between touch and response, and allowed analysis of responses as a percentage of the deflections.

These results suggest that receptive fields of chronically recorded neurons are dynamic when selective stimulation of vibrissae is employed.

IN VITRO ANTIGENIC AND ULTRASTRUCTURAL CHARACTERIZATION OF NEUROBLASTS DERIVED FROM A NEUROGENIC REGION OF THE ADULT CANARY BRAIN S.A.Goldman and W.Y.Clarke*, Dept. Neurology, Cornell Medical College., N.Y., N.Y. 10021.

The vocal control nucleus, HVc, of the songbird forebrain undergoes neurogenesis in adulthood, as ventricular zone precursor cells divide, migrate and differentiate into neurons (Goldman and Nottebohm, Proc. Natl. Acad. Sci. 80:2390-94, 1983). We now describe the in vitro antigenicity and ultrastructural maturation of adult-derived new neurons. The HVc ventricular zones of one year old canaries were placed into explant culture. One week later, the cellular outgrowths of selected explants were stained for a variety of neuron selective antigens. Morphologically-evident neurons were immunoreactive for MAP-2, neuron specific enolase, synaptic vesicle protein-2, and the tetanus toxin and A2B5 ligands. These cells failed to react with antisera against GFAP. Combined immunostaining and autoradiography of HVc cultures taken from brain exposed to ^{3}H-thymidine in vivo revealed a population of newly generated neurons positive for both MAP-2 and ^{3}H-thymidine. New neurons were also identified in plastic sections of adult explant outgrowths, and examined by electron microscopy of adjacent 80 nm. sections. These cells displayed typical neuronal ultrastructure, including dendrites with parallel arrays of microtubules, dendritic spines, multivesicular bodies, and immature dendro-dendritic synapses.

383.9

THE DEVELOPMENT OF LONG PROJECTIONS BY NEURONS BORN IN THE ADULT CANARY BRAIN. J. R. Kirn and F. Nottebohm, Rockefeller University, New York, N.Y. 10021.

Previous work from this laboratory indicates that neurons are born in the adult canary telencephalon. Many of these cells are incorporated into nucleus HVC (higher vocal center) where they become interneurons. Other new HVC neurons develop long projections to nucleus RA (robustus archistriatalis) and thus become part of the efferent pathway for song control. The present work employs [^{3}H]-thymidine and the retrograde tracer fluorogold to follow the birth, differentiation, and survival of HVC neurons born in adulthood. Thirty 18 month old male canaries were injected with [^{3}H] thymidine and killed 1,2,3,4,5 or 8 months later. Three days prior to sacrifice, flourogold was stereotaxically injected bilaterally into RA. Preliminary results suggest that roughly 28% of new HVC neurons project to RA by one month after [^{3}H]-thymidine treatment (n=3; range=15-36%). By 5 months, this fraction increases to 59% (n=2; range=46-71%). Thus, within the population of HVC neurons born in adulthood, there is a relative increase in the proportion of long-projection neurons with time.

383.10

SEASONAL AND SPECIES DIFFERENCES IN THE PRODUCTION OF LONG PROJECTION NEURONS IN ADULT BIRDS. A. Alvarez-Buylla and F. Nottebohm. The Rockefeller University, New York, NY 10021.

Combining retrograde tracers (fluorogold or rhodamine beads injected to RA) with [3H]-thymidine, we show that long projection neurons continue to be added to the Higher Vocal Center (HVC) of adult canaries and zebra finches. In both these species, about half of all HVC neurons are backfilled with fluorogold. However while in canaries 56% of the [3H]-thymidine labeled neurons projected to RA, in zebra finches only 23% of the labeled neurons were projection neurons. We compared May (n=3) and September (n=4) in canaries. The proportion of labeled projection neurons did not change between the two times of year. However the absolute number of all labeled neurons increased 6 fold in September when compared to May. (11.23 [sd=6.81] to 66.07 [sd=18.97] labeled neurons/mm2 and 6.65 [sd=3.59] to 33.8 [sd=11.30] labeled projetion neurons/mm2). New RA projection neurons may play a role in the motor learning of song that happens every year in adult canaries; however zebra finches do not learn new songs in adulthood.

383.11

HOUSING ADULT MALE RATS IN ENRICHED CONDITIONS INCREASES NEUROGENESIS IN THE DENTATE GYRUS. A.D. York[1]*, S.M. Breedlove[2], M.C. Diamond[3], and E.R. Greer[3]* (SPON: L. Proenza). Depts. Zoology[1], Psychology[2], and Physiology-Anatomy[3], University of California, Berkeley, CA 94720.

Postnatal neurogenesis has been shown in the granule cell layer of the dentate gyrus (DG) of the hippocampus. Adult rats housed in enriched conditions show changes in hippocampal neurohistology (Walsh, R.N., Intern. J. Neurosci., 12:33, 1981). The present study looked for changes in adult neurogenesis in DG due to different housing conditions. Twelve 60-day-old male Long-Evans rats were housed 30 days in enriched conditions: one common 70x70x45 cm cage with novel objects which changed daily. Eleven age-matched rats were housed in standard conditions: 3 rats per 11x19x8 cm cage with no objects. Rats were given a total dose of 5 uCi/g BW of ^{3}H-thymidine in 5 semi-weekly i.p. injections starting day 1 of differential housing. After standard autoradiography, 58 standardized regions of DG were examined in each animal. "Enriched" rats had significantly more heavily-labelled granule cells than did "standard" rats. More heavily-labelled neurons were seen in the anterodorsal quadrant and the endal limb of DG of "enriched" rats. The two groups had no differences in cell density or volume of whole DG, number of labelled glial cells, or number of labelled undifferentiated cells. Thus, neuroblasts appear to migrate to and mature in specific areas of the DG in response to enriched housing conditions.

CHRONIC HYPOXIA CAUSES MORPHOLOGICAL ALTERATIONS IN THE PHRENIC NUCLEUS OF YOUNG ADULT RATS. H.G. Goshgarian and X.-J. Yu*. Department of Anatomy/Cell Biology, Wayne State University Medical School, Detroit, MI 48201.

A recent study from our laboratory has shown that a spinal cord hemisection rostral to the phrenic nucleus in rats results in rapid morphological alterations of the normal ultrastructure of the phrenic nucleus. These alterations include: 1) increases in the number of double and multiple synapses contacting phrenic profiles, and 2) increases in both the length and number of phrenic dendrodendritic membrane appositions. The membrane appositions are due to the retraction of astroglial processes away from their normal position between adjacent dendrites. We have suggested that the morphological alterations may be related to the enhanced expression of a latent motor pathway which is responsible for restoring function to a paralyzed hemidiaphragm after spinal cord injury.

The present study was carried out to determine if prolonged hypoxia in non-injured rats causes alterations in the phrenic nucleus similar to those caused by spinal cord injury. Normal rats were subjected to chronic hypoxia in an atmosphere chamber for 48 hours. A Bioquant system was used to quantitatively analyze electron micrographs through the phrenic nucleus of chronically hypoxic and normal rats. The results in dicate that chronic hypoxia causes astroglial processes to retract away from their normal position in between adjacent phrenic dendrites, but it does not induce the synaptogenesis that is induced by spinal cord injury. Specifically, the mean length of the dendrodendritic appositions increased significantly from a normal value of 1.42 ± 0.09 um to 1.84 ± 0.08 um in hypoxic animals. Moreover, the mean number of dendrodendritic appositions in the normal phrenic nucleus (0.67 ± 0.08) increased significantly to 0.96 ± 0.10 in the phrenic nucleus of hypoxic rats. There was no significant difference between the mean number of double (0.71 ± 0.08) or multiple (0.80 ± 0.09) synapses in control animals as compared to the mean number of double (0.74 ± 0.09) or multiple (0.81 ± 0.1) synapses in the phrenic nucleus of hypoxic animals.

ENDOGENOUS CCK PARTICIPATES IN NUTRIENT-INDUCED SUPPRESSION OF FOOD INTAKE BY A NON-ENDOCRINE MECHANISM. D. Yox, L. Brenner*, E. Simon* and R.C. Ritter. Dept of VCAPP, Washington State University, Pullman, WA 99164-6520.

To investigate the mechanism by which endogenous CCK participates in the suppression of food intake by intestinal nutrient infusion, we compared the effects of the CCK antagonist CR 1409 (Rotta Research) on suppression of sham ingestion and stimulation of amylase secretion by intestinal nutrient infusions. CCK stimulates pancreatic amylase secretion by an endocrine route of action, which we confirmed in these experiments by measuring plasma CCK concentrations. Suppression of food intake by intraintestinal maltose was abolished by CR 1409. However, maltose did not elevate intestinal amylase concentrations or increase plasma CCK. Intraintestinal oleate increased plasma CCK. Oleate also suppressed food intake and increased intestinal amylase concentration. Both of these effects were antagonized by CR 1409. Finally, casein increased plasma CCK and elevated intestinal amylase but did not suppress food intake. These results suggest that suppression of food intake by some intraintestinal nutrients is mediated by endogenous CCK. However, the CCK participating in suppression of food intake by intestinal nutrients is not reaching its target by an endocrine route. (Supported by NIH RO1 NS 20561).

EFFECTS OF ACUTE AND CHRONIC TREATMENT WITH POTENT CHOLECYSTOKININ (CCK) ANTAGONIST L-364,718 ON FEEDING AND PLASMA CCK IN RATS. RD Reidelberger and R-M Liehr*. Dept Physiol, Univ Kansas Med Sch, KC, KS 66103; VA Med Ctr, KC, MO 64128.

L-364,718 (L) stimulates feeding after acute (Reidelberger and O'Rourke, 1987) and chronic (Schneider et. al., 1988) treatment, thus supporting a role for CCK in control of food intake. We sought answers to the following questions: ***Exp. 1.*** Is the feeding response to L due to competitive antagonism of CCK action? ***Exp. 2.*** Is the feeding response to L due to its inhibitory effect on pancreatic secretion? ***Exp. 3.*** Is the return to baseline food intake after several days of L treatment due to elevated plasma CCK levels? ***Methods and Results***: ***Exp. 1.*** L (0 or 0.03 mg/kg) and CCK8 (1-128 nmol/kg, 25 min after L) were given i.p. to 1-h food deprived rats (288±4 g, *n=12/group*) during the dark phase. L inhibited CCK-8 action competitively (ED_{50} increased 16 fold with similar maximal inhibition). ***Exp. 2.*** Rats (413±3 g, *n=8-9/group*) received continuous duodenal infusion of bile-pancreatic juice or saline for 2 h; L (0 and 0.5 mg/kg i.v. on different days) was given 15 min after start of infusion. Infusion of pancreatic juice to mimic postprandial conditions did not alter the feeding response to L (37 vs 24% increase in controls). ***Exp. 3.*** Rats (130-175 g, *n=6-16/group*) fed ground chow ad libitum, received L (0, 0.5, or 1 mg/kg i.p.) every 8 h for 5 d; blood was obtained from fed and fasted rats 8-12 h after the last injection (3-7 h after lights on). Food intake was stimulated significantly only by 1 mg/kg of L, and only on days 1 (15%) and 2 (10%). L (1 mg/kg) significantly increased plasma CCK levels in fed animals (5.6±0.9 pM vs 3.8±0.5 pM), while neither dose altered fasting levels. ***Conclusions***: (1) Antagonism of CCK-8-induced suppression of feeding by L exhibited competitive-like kinetics. (2) Stimulation of feeding by L is apparently not due to its inhibitory effect on pancreatic enzyme secretion. (3) Chronic treatment with L transiently increased solid food intake, confirming results of Schneider et al. using liquid food. (4) Because CCK and L compete for the same binding sites, an increase in plasma CCK with time of L treatment may explain this transient effect.

THE SELECTIVE CCK RECEPTOR ANTAGONIST MK 329 BLOCKS THE ANORECTIC EFFECT OF D-FENFLURAMINE. S.J. Cooper, C.T. Dourish and D.J. Barber*. School of Psychology, University of Birmingham, Birmingham B15 2TT, U.K. and Merck Sharp & Dohme Research Labs., Harlow, Essex, CM20 2QR, U.K.

D-Fenfluramine reduces food intake in rats through a serotonergic mechanism that utilises 5-HT_1 receptors (Neill, J.C. and Cooper, S.J., Psychopharmacol., 97:213, 1989). We have investigated the further possibility that d-fenfluramine anorexia is dependent upon endogenous CCK activity. In the first set of experiments, d-fenfluramine (3.0 mg/kg, i.p.) significantly ($p<0.005$) reduced palatable food intake in nondeprived rats. This anorectic effect was blocked by the selective CCK receptor antagonist MK 329 (formerly L-364,718), injected in doses of 30 and 100 ug/kg (s.c.). Administered alone, MK 329 did not affect food intake. Furthermore, it did not block the anorectic effect of the selective dopamine D_2 receptor agonist quinpirole (0.3 mg/kg, s.c.) or that of the beta-carboline FG 7142 (10 mg/kg, i.p.). In further studies, d-fenfluramine (3.0 mg/kg, i.p.) significantly ($p<0.005$) reduced nocturnal free-feeding in rats over a 6 hr period. The anorectic effect was significantly attenuated by MK 329 (30 and 100 ug/kg). Hence, d-fenfluramine's anorectic effect appears to require endogenous CCK activity.

BLOCKADE OF CCK RECEPTORS REVERSES THE EFFECT ON GASTRIC EMPTYING BUT NOT FEEDING IN ZUCKER RATS. A.J.Strohmayer, R. von Heyn* D. Greenberg and L.Dornstein*, Dept Psychiatry, North Shore U Hosp - Cornell U Med Coll, Manhasset NY 11030, USA.

CCK slows gastric emptying (GE) and reduces food intake in rats. We have shown that the CCK receptor antagonist, L364,718 (>375 ug/kg), increased 30 min food intake in lean but not obese Zucker rats suggesting the obese did not release active CCK. Intragastric (IG) loads of trypsin inhibitor (TI) stimulate CCK release and inhibit GE. We measured GE in Zucker rats after IG TI or saline and with L364,718 pretreatment. TI (200 mg/kg) slowed GE in both genotypes. L364,718 (200 ug/kg, IP), completely reversed this effect in both genotypes. We conclude that TI inhibited GE by CCK release in both obese and lean rats. This mechanism may be distinct from the CCK inhibition of food intake, and obese Zucker rats may be deficient only in the food intake response.

Median % Remaining in Stomach

	Sal	TI	TI+L
Lean (n=3)	13	28	8
Obese (n=3)	25	50	19

IVT CHOLECYSTOKININ (CCK-8) REDUCES SINGLE MEAL SIZE IN THE BABOON OVER A 200-FOLD RANGE OF DOSAGES. P.K.Green, D.P.Figlewicz*,A.J.Sipols,D.Porte,Jr.,S.C.Woods. Dept. of Psychology, Univ. of Washington/Dept. of Med., Seattle Veterans Admin. Med. Research Ctr., Seattle, WA 98195.

CCK-8 reduces meal size when given intravenously in the baboon. We previously found that doses as low as 0.1 ug/kg, when given IVT, also decrease meal size, and that centrally-administered CCK is more effective in producing satiety than similar doses given IV. We have now extended the range of doses given IVT to as low as .01 ug/kg. Eight male baboons implanted with chronic intraventricular cannulae were adapted to a liquid diet (Ensure) on a fixed meal schedule. Food intake was measured in overnight fasted animals during a 30-min meal immediately following a 5-min IVT infusion of CCK-8 or CSF vehicle, each animal serving as its own control on an adjacent day. Doses ranged from .01 to 2.0 ug/kg. Not all animals received all eight dosages, but at least three animals received each of the lowest doses. Each dose produced a reduction of single meal size relative to the control condition. The lowest dose (.01 ug/kg) reduced meal size by 45±23% (n.s.); the next lowest dose tested (.025 ug/kg) reduced meal size 87±5% ($p<.10$). CCK's action at the lower doses was not reliably diminished relative to that observed after higher doses. These data provide further evidence of CCK's efficacy as a centrally-acting satiety factor in the baboon.

INHIBITORY EFFECTS OF CHOLECYSTOKININ DEVELOP THROUGH INTERACTION WITH DUODENAL SIGNALS. J.E. Cox, Dept. Psychology, Univ. Alabama at Birmingham, Birmingham, AL 35294.

Low doses of cholecystokinin octapeptide (CCK-8) produce marked impairment of runway performance if given after rats have consumed a partial meal of 30% sucrose (Cox, J.E., Behav. Brain Res., 21: 29, 1986). This effect is also produced by gastric sucrose infusion (Cox, J.E. & Smith, M.J., Neurosci. Abs. 13: 588, 1987). To further investigate the site of origin of feeding-contingent signals interacting with CCK-8, the current experiments assessed changes in runway performance produced by 1 ug/kg CCK-8 in conjunction with duodenal and hepatic portal infusions. Duodenal infusions of 30% sucrose were as effective as prefeeding and gastric infusions. After infusions, CCK-8 reduced running speed by 67% compared to tests with sucrose infusions and saline injections. Glucose appeared to be as effective as sucrose, whereas equiosmotic saline and mannitol were not. Intraportal glucose was relatively ineffective; some synergism with CCK-8 was produced by very large infusions, but the effect was relatively small. These results suggest that 1 ug/kg CCK-8 can reduce feeding motivation through synergism with a carbohydrate-sensitive signal generated within the small intestine. (Supported by NSF grant BNS-8606768.)

NEAR-COELIAC ARTERIAL CCK INJECTIONS SUPPRESS FOOD INTAKE AT HEPATIC PORTAL CCK LEVELS COMPARABLE TO THOSE OBSERVED POSTPRANDIALLY. N. Calingasan, S. Ritter, R. Ritter and L. Brenner*. Dept. of VCAPP, Washington State University, Pullman, WA 99164-6520.

Both exogenous and endogenous CCK appear to suppress food intake by acting on the vagal sensory innervation to organs within the hepatic portal drainage. To determine whether exogenous CCK can reduce feeding at physiological concentrations of hepatic portal CCK, we made automated measurements of liquid food intake before, during and after injection of CCK-8 through a chronic aortic catheter with its tip seated at the coeliac juncture. In a second group of rats, we made similar injections while collecting blood for CCK assay from the hepatic portal vein. In a third group we collected hepatic portal blood 10 min after a 10 ml spontaneously ingested liquid meal. Injection of 10, 30, 50 and 70 pmols of CCK-8 suppressed feeding in a dose dependent manner beginning within 1 min. While 10 pmol of CCK suppressed feeding in 50% of the rats, 30 pmol was the lowest dose to produce statistically significant suppression of preinjection intake (45.7 ± 10.6%). Near-coeliac injection of 30 pmol CCK produced portal plasma CCK concentrations averaging 3.1 ± 0.5 pM, compared to 0.6 ± 0.3 pM during saline injection. Ten min after a 10 ml liquid meal, portal CCK was 3.0 ± 0.5 pM, compared to 0.9 ± 0.4 pM in fasting controls. Thus, when infused near its site of action, exogenous CCK inhibits feeding at doses producing hepatic portal CCK concentrations similar to postprandial levels. The results are consistent with CCK's participation in the physiological process of satiation.

CAUDAL HINDBRAIN PARTICIPATION IN SUPPRESSION OF FEEDING BY CENTRAL AND PERIPHERAL BOMBESIN. E.E. Ladenheim and R.C. Ritter. Dept. of VCAPP, Washington State University, Pullman, WA 99164-6520

Our previous studies have shown that bombesin (BBS) infused into the fourth cerebral ventricle in rats suppresses food intake at doses 1/10 to 1/1000 of those required following lateral ventricular administration. These results suggest that centrally administered BBS acts in the caudal hindbrain to suppress feeding. In order to investigate the participation of caudal hindbrain structures in fourth ventricular BBS-induced suppression of feeding, we made lesions that destroyed the following: 1) the area postrema (AP) and 2) the AP and a majority of the adjacent medial nucleus of the solitary tract (mNST). In addition, we examined the role of the AP/NST in suppression of feeding following peripheral BBS administration. We have found that lesions which destroy the AP and extensively damage the mNST abolished suppression of food intake by fourth ventricular BBS and attenuated suppression by peripherally administered BBS. Lesions restricted to the AP attenuated fourth ventricular BBS-induced suppression of feeding but had no effect on suppression by peripheral BBS. These data suggest that the NST may be a common neural substrate for both central and peripheral BBS-induced suppression of feeding (Supported by NIH RO1 NS20561).

CLONIDINE MIMICS FEEDING PATTERN OF CARBOHYDRATE-PREFERRING RATS. G. Shor-Posner, G. Brennan, C. Ian *, R. Kalimi* and S.F. Leibowitz. The Rockefeller University, New York, New York 10021.

Recent work from this laboratory indicates that approximately 50% of albino Sprague-Dawley rats exhibit a pattern of carbohydrate preference expressed through ingestion of small, frequent meals. In light of evidence suggesting a role for a hypothalamic α 2 noradrenergic system in stimulating carbohydrate intake, this study examined the effects of the α 2 agonist, clonidine (CION: 3-25 ug/Kg, i.p.) on feeding patterns of self-selecting rats (N=12).

Computer-assisted analyses of feeding patterns after CION administration, at dark onset, revealed a dose-dependent increase in consumption of carbohydrate-rich meals. This response was apparent during the first 4 hr of the dark, when small, frequent and carbohydrate-rich meals were observed, and carbohydrate preference was increased from 45 to 64% ($p<0.01$), despite an overall decrease in total caloric intake. Little change was observed in the middle and late phases of the dark period. This meal pattern, after CION administration, appears similar to that exhibited by carbohydrate-preferring rats.

A RAPID ONSET SODIUM APPETITE INDUCED BY YOHIMBINE. A.K. Johnson, T.G. Beltz*, and G.L. Edwards. The Departments of Psychology and Pharmacology and The Cardiovascular Center, Univ. of Iowa, Iowa City, IA 52242

Male rats (n=9) were given several days of ad lib access to 1.8% NaCl (1.8%) and to tap water (TW). On separate days the fluid intake of animals was studied in 3 hr drinking tests following s.c. injection of isotonic saline (CONT) or 6 mg/kg of yohimbine (YOH). With both 1.8% and TW present YOH significantly increased the intake of both fluids (CONT=0.1±0.03 vs. 0.1±0.02; YOH=9.0±1.80 vs. 5.7±2.03 mls; TW to 1.8%, respectively). In a second series 1.8% was the only solution available to the rats during testing. YOH treatment induced a significant increase in intake of 1.8% at 1, 2, and 3 hrs (7.0±1.88, vs. 0.0; 17.0±4.97 vs. 0.0; 24.3±6.45 vs. 0.0; cumulative mls intake; YOH vs. CONT, respectively). YOH treated rats did not drink .001M quinine when it was offered as the only fluid in a 3 hr test. The YOH-induced ingestion of large quantities of hypertonic NaCl suggests that YOH treatment generates a sodium appetite in replete rats. This finding is consistent with other observations indicating that alpha-2 adrenoceptor antagonists can act to reduce central adrenergic inhibitory tone exerted by afferent input from sytemic volume/pressure receptors and that such an attenuation causes the activation of a constellation of responses consistent with the animals achieving an expansion of extracellular fluid volume.

384.11

EFFECTS OF SYSTEMIC CLONIDINE ON SIMULTANEOUS MEASUREMENTS OF FEEDING, LOCOMOTOR ACTIVITY AND RESPIRATORY GASES IN THE RAT. D.V. Coscina and J.W. Chambers*. Sect.of Biopsychology, Clarke Inst. of Psychiatry, Toronto, Canada, M5T 1R8.

The A2-adrenergic agent clonidine (CLON) has been shown to elicit feeding in sated rats when given peripherally. However, it has also been shown to depress locomotory activity as well as several metabolic indices. To help clarify the potential relationships which may exist among these variables, we recorded feeding, activity, oxygen consumption, and carbon dioxide output in adult male rats over a 3 hr period following subcutaneous CLON (50 ug/kg) or saline. Drug x time analyses of variance revealed no main effect of drug treatment. However, highly significant drug x time interactions were seen on all variables. The time course of each behavior remained essentially constant after CLON whereas it started relatively high and diminished after saline. These findings may indicate that CLON-induced feeding occurs to compensate for hypo-metabolic events induced by this drug treatment. Studies are underway to test this possibility further after direct CNS injections of this and related agonists.

OBESITY PRONE AND RESISTANT RATS DIFFER IN THEIR BRAIN ^{3}H PARAMINOCLONIDINE BINDING. B.E. Levin, Neurology Service, VA Med. Ctr., E.Orange, NJ 07019; Dept. of Neurosciences, N.J. Med. Sch., Newark, NJ 07103

Half the rats chronically fed a high energy diet develop diet-induced obesity (DIO); the rest are diet-resistant (DR). Before high energy diet exposure, rats prone to develop DIO have high plasma norepinephrine (NE) levels in response to i.v. glucose while DR-prone rats have little NE response. Here 28 chow-fed rats were tested for glucose-induced NE release. The 6 rats with the highest plasma NE responses (DIO-prone) had areas under the NE curve of 27803±4095 versus -2330±1127pg/ml/60min for the 6 lowest NE responders (DR-prone; P=0.0001). There were no differences between the groups in body weight or in plasma glucose or insulin responses to i.v. glucose. In these 12 rats, binding to brain α-adrenoreceptors was studied by receptor autoradiography using 1nM ^{3}H prazosin (PRZ; α_1-) and 1nM ^{3}H paraminoclonidine (PAC; α_2-). There were no differences in ^{3}H PRZ binding in any of 18 brain areas examined. However, the DR-prone rats had higher ^{3}H PAC binding (257-721%) compared to DIO-prone rats in 4 amygdalar nuclei, the lateral area, dorso- and ventromedial hypothalamic nuclei, the median eminence and medial dorsal thalamic nucleus. These pre-existing differences in brain ^{3}H PAC binding between rats which are prone to develop DIO or DR when subsequently fed a high energy diet may play an etiological role in the phenotypic expression of these weight gain traits.

GLUTAMATE IS CONTAINED IN AXON TERMINALS OF NEURONS IN THE ROSTRAL VENTROLATERAL MEDULLA THAT PROJECT TO THE SPINAL SYMPATHETIC INTERMEDIOLATERAL NUCLEUS. S.F. Morrison, J. Callaway*, T.A. Milner and D.J. Reis, Division of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.

We have previously shown that (a) the glutamate receptor antagonist, kynurenic acid, blocks the excitation of sympathetic preganglionic neurons in the intermediolateral nucleus (IML) evoked by stimulation of the rostral ventrolateral medulla (RVL) and (b) within the IML, axon terminals with glutamate-like immunoreactivity (GLU-LI) primarily form asymmetric (excitatory) synapses with the dendrites of local neurons. To determine whether RVL neurons are a source of the glutamate-containing terminals in the IML, anterograde transport of *Phaseolus vulgaris*-leucoagglutinin (PHA-L) iontophoretically injected into the RVL was combined with glutamate immunocytochemistry in the same sections of thoracic spinal cord. By light microscopy, PHA-L immunoreactivity was found in fine varicose processes which had an overlapping distribution with perikarya and processes containing GLU-LI. Electron microscopic analysis revealed PHA-L immunoreactivity in axons and axon terminals within the IML. Terminals with PHA-L immunoreactivity ranged in diameter from 0.5-2.0 µm, contained numerous small clear and 0-3 large, dense-core vesicles, and formed primarily asymmetric synaptic contacts on small dendrites of IML neurons. Some of the PHA-L immunoreactive terminals also contained GLU-LI. We conclude that at least a portion of the input to the IML from the RVL uses glutamate as its transmitter. These findings support the hypothesis that the release of glutamate onto sympathetic preganglionic neurons plays a key role in the regulation of arterial pressure by reticulospinal, sympathoexcitatory pathways from the RVL. Supported by NIH HL18974.

385.2

SPINAL N-METHYL-D-ASPARTIC ACID (NMDA) RECEPTORS MEDIATE PRESSOR AND TACHYCARDIC RESPONSES EVOKED BY EXCITATION OF THE ROSTRAL VENTROLATERAL MEDULLA (RVM). M.K. Bazil* and F.J. Gordon (SPON: P.J. Conn). Dept. of Pharmacology, Emory Univ. Sch. of Med., Atlanta, GA 30322.

The purpose of these studies was to investigate a potential role for spinal NMDA receptors in the mediation of sympathoexcitatory responses evoked by L-glutamate (Glu) stimulation of the RVM. Rats were anesthetized with urethane, vagotomized, paralyzed and artificially ventilated. Microinjections of Glu (0.1-30 nmol/50 nl) into the RVM produced increases in mean arterial pressure (MAP) ranging from 9 ±2 to 60 ±8 mmHg and tachycardia of 4 ±1 to 55 ±10 bpm. Intrathecal (IT) administration of the NMDA receptor antagonist D-2-amino-7-phosphonoheptanoic acid (D-AP7; 100 nmol/10 µl) lowered MAP from 93 ±3 to 56 ±3 mmHg. After IT D-AP7, pressor responses evoked by microinjections of Glu into the RVM were reduced to 3 ±1 to 16 ±6 mmHg ($p < .01$). Tachycardic responses after IT D-AP7 averaged 3 ±1 to 30 ±6 bpm ($p < .01$). In other rats, IT NMDA (ED50=56 nmol/10 µl) increased MAP by 45 ±12 mmHg and heart rate by 57 ±15 bpm. IT kainic acid (ED50=3.7 nmol/10 µl) produced pressor responses of 39 ±6 mmHg and tachycardia of 42 ±7 bpm. Prior blockade of spinal NMDA receptors with IT D-AP7 abolished cardiovascular responses produced by IT NMDA without reducing those of kainic acid. These results indicate that: 1) cardiovascular responses evoked by Glu stimulation of RVM neurons requires synaptic activation of spinal NMDA receptors, and 2) excitatory amino acid neurotransmitters may participate in sympathoexcitation produced by activation of descending bulbospinal pathways. (Supported by NIH HL-36907 and American Heart Association)

385.3

EXCITATORY AMINO ACID (EAA) TRANSMISSION IN ROSTRAL VENTROLATERAL MEDULLA (RVL): EAA ANTAGONISTS AS POTENTIAL CENTRALLY ACTING ANTIHYPERTENSIVES? S.P. Arnerić, C.R. Kelley*, F.D. Tingley*, D.R. Luthin*, W.H. Cline, Department of Pharmacology, Southern Illinois University School of Medicine, Springfield, IL 62702

EAAs released from pathways arising from hypothalamic structures increase sympathetic drive from RVL-spinal neurons (Sun & Guyenet, Brain Res. 368:1, 1986). This study sought to determine: 1) Is release of the EAA glutamate (Glu) increased in RVL of spontaneously hypertensive rats (SHR)? 2) If so, are antagonists of N-methyl-D-aspartate (NMDA) receptors effective antihypertensives? Studies were performed in 4-6 wk (pre-hypertensive) and 12-16 wk (hypertensive) SHR and in age-matched normotensive Wistar-Kyoto (WKY) rats. Release of endogenous Glu was measured from micropunches of RVL and, for comparison, intermediolateral cell column (IML) using HPLC. No strain differences in spontaneous or K+ (35mM)-evoked release of Glu were seen at 4-6 wks ($p > 0.05$; N=4). In contrast, 12-16 wk SHR with established hypertension had marked 2- to 4-fold increases in spontaneous and K^+-evoked release of Glu in RVL ($p < 0.05$; N=4), but not IML ($p > 0.05$; N=6). Non-competitive NMDA antagonists MK-801 (1 mg/kg, s.c.) and dextromethorphan (DXT; 10 mg/kg, s.c.) significantly lowered arterial pressure (AP) by 20-35 mmHg in conscious 12-16 wk SHR ($p < 0.05$; N=3-12) but not WKY. In vitro and in vivo preparations suggest that MK-801 and DXT do not lower AP by interruption of pre- or postsynaptic peripheral sympathetic transmission. In particular, pressor responses to intravenous phenylephrine and norepinephrine (NE) are not attenuated and release of endogenous NE elicited by periarterial nerve stimulation from isolated-perfused mesenteric vasculature is not diminished by MK-801 or DXT (N=5). CONCLUSION: NMDA antagonists may lower AP by interrupting derangements in central sympathoexcitatory drive elicited by enhanced EAA neurotransmission (Supported by the American Heart Association., IL Affiliate).

385.4

INTERACTIONS OF NMDA AND ITS ANTAGONISTS DURING CAROTID CLAMPING. Y.WANG, M.C.KAO*, H.K.LEE*. DEPT. OF PHARMACOLOGY, NATIONAL DEFENSE MEDICAL CENTER, TAIPEI, TAIWAN, R.O.C.

The purpose of this experiment was to study the interactions of N-methyl-d-aspartate (NMDA) with baroreflex induced by temporary carotid clamping. Adult male Sprague -Dawley rats (250 - 300 g) were anesthetized with urethane (1.25 g/kg, i.p.). We found that clamping common carotids resulted in a reversible and reproducible hypertensive effect in the vagotomized animals. This reaction was blocked by intraventricular injection of NMDA antagonists, such as 2-amino- 7-phosphono-heptaneoate (AP-7) and phencyclidine. Furthermore, using pressure microejection and single unit recording, we found that clamping of common carotids resulted in excitation of the cardiovascular neurons of ventral lateral medulla (VLM). This evoked excitation, similar to that induced by NMDA, was blocked by locally applied AP-7. In conclusion, our experiment demonstrated that NMDA was involved in the hypertensive reaction during carotid clamping in the VLM.

385.5

DOES THE AREA POSTREMA MEDIATE THE PRESSOR EFFECTS OF ANGIOTENSIN II IN NORMOTENSIVE OR RENAL HYPERTENSIVE RATS? CJ Tseng, M Appalsamy*, D Robertson, R Mosqueda-Garcia. Dept. of Pharmacology, National Defense Medical Center, Taiwan and Vanderbilt University, Nashville, TN 37232.

We have previously reported that microinjection of angiotensin II (AII) into the area postrema (AP) of renal hypertensive rats (RHT) decreases BP and HR. In the present study we fully characterize the hypotensive response of AII and evaluate if the AP mediates the pressor response of AII in RHT rats. Sprague-Dawley RHT (2-kidney, 1-clip) and sham normotensive control rats (NT) were used 4 weeks after surgery. Under urethane anesthesia, BP was intra-arterially recorded and a microsyringe was stereotaxically positioned in the AP. Microinjection of AII (2 to 2,000 ng) or saralasin (96 ng) were done with recording of sympathetic nerve activity (SNA) from the left renal nerve.

Basal BP of RHT was significantly higher than in NT controls. A dose-dependent decrease in BP and HR was observed with AII in the RHT rats (peaked at 200 ng, -38±4 mmHg; -46±8 b/m for BP and HR, respectively), and with the two lowest doses of AII in the NT rats, whereas only the two highest doses of AII in the NT animals evoked a modest pressor effect (12±4 mmHg with 200 ng). In both groups of animals, all doses of AII decreased SNA. Saralasin increased BP and HR in the two groups of animals, and the AII antagonist was able to inhibit only the depressor effects of low doses of AII. The pressor effects remained unchanged in the normotensive group. These results suggest that a tonic depressor AII effect is present in the AP and indicate that inhibition of sympathetic activity mediates at least part of the hypotensive response of AII. The pressor effect of AII in the normotensive rats is probably not mediated in the AP. These results do not support a role of the AP for the pressor effects of AII.

385.6

ELECTROPHYSIOLOGICAL AND CARDIOVASCULAR EVIDENCE FOR ENDOTHELIN ACTIONS WITHIN THE AREA POSTREMA. A.V.Ferguson and P.Smith*. Dept.of Physiology, Queen's University, Kingston, CANADA K7L 3N6.

Vascular endothelial cells have recently been demonstrated to produce a 21 amino acid peptide named endothelin (ET), one of the most potent endogenous vasoconstrictors known to date. Recent studies suggest that this peptide has long lasting biphasic effects on cultured muscle cell membrane potential. In the rat binding sites for ET have now been localised in CNS regions such as the area postrema (AP). Therefore we have examined the potential cardiovascular and neuronal effects of ET within this circumventricular organ.

In urethane anaesthetised male Sprague Dawley rats microinjection of ET (0.2-5.0 pmol) into AP resulted in dose dependent biphasic changes in blood pressure (BP). Such effects consisted of initial rises followed by a longer lasting decrease in BP. The latter of these two affects appeared dominant at higher doses of ET (2.0 and 5.0 pmol). Optimal increases (15.5 ± 4.9mmHg), followed by maximal decreases (48.0 ± 8.5 mmHg), in BP were observed in response to 5.0 pmol ET. Such effects were specific to AP injection sites.

Extracellular single unit recordings revealed effects of intravenous ET on the spontaneous activity of AP neurons. The effect of this peptide on the activity of 15 AP neurons was examined in pentobarbital anaesthetised rats. A total of 7 of these neurons demonstrated increases in activity following systemic endothelin (1-20 pmol) followed by return to baseline. Higher doses of this peptide resulted in instability of AP such that neuronal recordings were seldom maintained throughout a test.

These data support a potential physiological role for ET within the rat AP. They suggest ET may activate AP neurons and thus influences cardiovascular function. These findings are in accordance with previous studies showing activation of AP neurons results in decreased BP.

SPINAL MICROINJECTIONS OF ANTAGONISTS TO SUBSTANCE P AND SOMATOSTATIN ATTENUATE THE EXERCISE PRESSOR REFLEX. L.B. Wilson*, P.T. Wall, K. Matsukawa*, L.W. McCallister and J.H. Mitchell* (SPON: P.M. Adams). Moss Heart Center, UT-Southwestern, Dallas, TX, 75235-9034.

We investigated at a spinal level the role of substance P (SP) and somatostatin (SOM) in the pressor response to static muscle contraction using anesthetized cats. The L_7 ventral root was electrically stimulated (3X motor threshold; 40 Hz; 0.1 msec) to elicit 2 types of triceps surae contractions: 1) a 1-min continuous, tetanic contraction, and 2) a 1-min period of intermittent, tetanic contractions. These were performed before and after the microinjection of the SP antagonist, (D-Pro^2-D-Phe^7-D-Trp^9)-substance P, or the SOM antagonist, cyclo(7-aminoheptanoyl-Phe-D-Trp-Lys-Thr[BZL]), into the L_7 dorsal horn region. Continuous and intermittent tetanic contractions increased mean arterial pressure (MAP) 51±5 and 51±13 mmHg, respectively, before microinjecting the SP antagonist, but only 33±4 and 28±5 mmHg after. Prior to the injection of the SOM antagonist, continuous and intermittent contractions increased MAP 38±4 and 40±8 mmHg, respectively, but only 21±6 and 28±6 mmHg following SOM antagonist. Microinjecting saline had no affect on the pressor response to either type of contraction. These data suggest that SOM and SP release into the dorsal horn of the spinal cord plays a role in the cardiovascular response to static muscle contraction.

PRAZOSIN INDUCED SYMPATHO-INHIBITION VIA PREJUNCTIONAL FACILITATION OF α_2-ADRENERGIC INHIBITION. M.C. Koss, J.A. Hey and T. Ito. Dept. Pharmacology, Univ. Okla. Hlth. Sci. Ctr., Oklahoma City, OK 73190.

We have previously reported, using CNS evoked electrodermal responses, that prazosin enhances inhibition mediated by alpha$_2$-adrenoceptor mechanisms with at least part of the effect being at the level of the spinal cord (Europ. J. Pharmacol. 158:225-231, 1988). The present study was undertaken to further evaluate this action of prazosin using spontaneous sudomotor activity. Tonic sympathetic-cholinergic electrodermal activity was measured in intact anesthetized and unanesthetized decerebrate and decerebrate-spinalized cats. Intravenous prazosin (3-300 µg/kg, i.v.) depressed spontaneous electrodermal activity in intact cats in a dose-dependent fashion. The alpha$_2$-adrenoceptor blocker, yohimbine (0.5 mg/kg i.v.), antagonized this prazosin-induced sympatho-inhibition and prazosin's effect was totally abolished by monoamine depletion. Prazosin also reduced tonic sudomotor activity in unanesthetized decerebrate cats, but had no effect in spinalized preparations. These results support the hypothesis that prazosin produces sympatho-inhibition via an alpha$_2$-adrenoceptor mediated mechanism, and that this effect appears to be prejunctional. It is proposed that prazosin acts at the level of the spinal cord to facilitate ongoing adrenergic inhibition arising from supra-spinal loci. (Supported by NSF and OCAST)

INVOLVEMENT OF GUANINE NUCLEOTIDE-BINDING PROTEIN IN GUANABENZ-INDUCED CARDIOVASCULAR SUPPRESSANT EFFECTS IN THE RAT. C.H. Chen* and S.H.H. Chan. Department of Psychiatry, Veterans General Hospital and Institute of Pharmacology, National Yang-Ming Medical College, Taipei 11221, Taiwan.

Previous work from our laboratory suggests that guanabenz, a potent antihypertensive agent, promotes its cardiovascular suppressant actions via the α_2-adrenoceptors, possibly located in the medullary nucleus reticularis gigantocellularis (NRGC). The present study further addresses the question of whether guanine nucleotide-binding protein(s) is involved in the circulatory depressive effects of the aminoguanidine compound, using male, adult Sprague-Dawley rats anesthetized with pentobarbital sodium. Pretreating animals by microinjecting pertussis toxin (125 or 250 ng) bilaterally into the NRGC significantly blunted the hypotensive and negative inotropic and chronotropic effects of guanabenz. Microinjection of Gi uncoupler (n-ethylmaleimide, 12.5 or 25 ng), Gs activator (cholera toxin, 125 or 250 ng), or adenylate cyclase activator (forskolin, 1.25 or 2.5 µg) into bilateral NRGC, however, did not appreciably affect the cardiovascular suppressant actions of guanabenz. These results suggest that a pertussis toxin-sensitive, cAMP-independent, guanine nucleotide-binding protein(s) located in the NRGC, possibly Go, may be involved in the expression of the circulatory depressive effects produced by the amino-guanidine compound.

LOCALIZATION OF SYMPATHETIC AND PARASYMPATHETIC PREGANGLIONIC NEURONS IN THE PIGEON SPINAL CORD AND BRAIN STEM AFTER INJECTIONS OF THE C-FRAGMENT OF TETANUS TOXIN INTO THE HEART. J.B. Cabot, N. Bogan* and J. Carroll*. Department of Neurobiology, State University of New York at Stony Brook, Stony Brook, NY 11794.

Previous studies in our laboratory have shown that the C-fragment of tetanus toxin (TTC) is transported retrogradely and transsynaptically by avian sympathetic preganglionic neurons (SPN's). Our aim in the present study was to take advantage of these transport properties in order to define anatomically the location(s) of putative "cardiac" sympathetic and parasympathetic preganglionic neurons. TTC was injected into the left ventricle (10 ul, 1-2 mg) of 5 pigeons. Twenty-four to 42 hrs later the animals were sacrificed and TTC-labeled neurons were visualized using a monoclonal antibody to TTC and standard immunohistochemical methods.

In all experiments, TTC-labeled parasympathetic preganglionic neurons were distributed bilaterally and restricted to: (a) the caudal portions of the nucleus ambiguus (nA; -0.70 to 0.30, obex = 0.0); and (b) a subset of cells in the ventrolateral subnucleus of the dorsal motor nucleus complex (VL; 0.70 to 0.80) (Katz and Karten, JCN, 242:358). The majority of TTC-labeled neurons were located in nA; most labeled cells were medium-sized, multipolar neurons. The limited number of TTC labeled cells within VL were similar morphologically to those labeled in nA.

Transneuronal TTC labeling of SPN's within spinal cord was much more difficult to detect. TTC labeling of SPN's was identified in only 3 of the 5 experiments. In these cases, TTC-labeled SPN's were: (a) distributed bilaterally; (b) located within the caudal portions of C14 (last brachial spinal segment), and throughout T1-4; and (c) restricted to the principal cell column (column of Terni). The majority of TTC-positive SPN's were located in T1-2. On average, fewer than 3 SPN's / 40 um transverse section (< 8% of the SPN's in T1-2) were TTC-positive in T1-2. CENTRAL HISTAMINE DEPLETION ATTENUATES PRESSOR RESPONSE TO HYPERTONIC SALINE INFUSION. V. Schaumloffel* and S.L. Bealer (SPON: L. Share). Dept. Physiol. and Biophys., Univ. Tenn., Memphis, TN 38163.

The effect of central histamine (HA) depletion on the cardiovascular response to increased plasma osmolality (pOsm), induced by hypertonic saline infusion, was studied. Conscious male Sprague-Dawley rats were pretreated with alpha-fluoromethylhistidine (FMH, 500 µg icv), an irreversible inhibitor of the histamine synthetic enzyme, histidine decarboxylase, or vehicle (CONT). Two hours after FMH or vehicle, an iv infusion of 2.5 M (HT) or 0.17 M (ISO) NaCl was started (10 µl/100 g/min) and continued for 30 minutes. Mean arterial pressure (MAP), heart rate (HR), pOsm before and after infusion, and hypothalamic HA concentration were measured.

FMH pretreatment resulted in a 50% depletion in hypothalamic HA, but did not alter baseline MAP. ISO infusion had no effect on MAP or HR in either CONT or FMH rats. The pressor response to HT infusion was significantly attenuated in FMH rats (n=10) compared to CONT (n=10) (0.83 ± 0.17 vs. 1.37 ± 0.21 mm Hg blood pressure increase per mOsm increase in pOsm). Bradycardia was similar in CONT (-12 ± 8 beats/min) and FMH (-21 ± 9.5 beats/min) rats. These results suggest a role for brain histamine in osmotic regulation. (Supported by NIH grant HL 25877.)

SUBSTANCE P (SP) INNERVATION OF VAGAL CARDIOMOTOR NEURONS (VCN) IN THE NUCLEUS AMBIGUUS. M.M. Caverson[1] and T.-X. Zhang[2]. Departments of Anatomy[1] and Physiology[2], The University of Western Ontario, London, Canada N6A 5C1.

Central peptidergic pathways have been implicated in the control of the circulation. However, little is known about the peptidergic innervation of VCN. In the present study, two series of experiments were done in rats to investigate the SP innervation of VCN in nucleus ambiguus and the function of this innervation. In the first series, injections of wheat germ agglutinin (WGA) conjugated horseradish peroxidase (HRP) were made into either the right atrial myocardium or the pericardial sac. After a 1-3 day survival period, the animals were perfused transcardially and transverse brain stem sections were processed using HRP (TMB) histochemistry to reveal WGA retrogradely labeled perikarya and subsequently for SP-immunohistochemistry using the avidin-biotin (DAB) method. Within the nucleus ambiguus, a dense network of SP-immunoreactive fibers and presumptive nerve terminals were observed surrounding WGA labeled VCN. In the second series, microinjections of L-glutamate were made into the region of nucleus ambiguus in anesthetized C1 spinal cord transected rats to identify vagal cardioinhibitory sites. These sites were then tested with an injection of SP. SP elicited decreases in heart rate of 20-80 beats/min. These results provide evidence for the involvement of SP in the central control of VCN function. (Supported by MRC)

AFFERENT PATHWAYS MEDIATING SYSTEMIC SEROTONIN (5-HT)-INDUCED SYMPATHOINHIBITION. K.J. Varner, S.J. Lewis* and M.J. Brody, Dept. of Pharmacol. & Cardiovascular Center, University of Iowa, Iowa City, IA 52242.

Activation of cardiopulmonary (CP) vagal trunk afferents by intravenously (iv) injected 5-HT elicits the Bezhold-Jarisch reflex characterized by hypotension and sympathoinhibition. The purpose of this study was to determine the specific afferent pathways mediating 5-HT-induced sympathoinhibition. Experiments were performed in urethane-anesthetized rats prepared for recording arterial pressure and lumbar chain sympathetic nerve activity (LSNA). Administration of 5-HT (0.6-40 µg/kg) elicited dose-dependent decreases in LSNA (17-70%). Bilateral transection of the vagus nerve and superior laryngeal (SLN) nerve attenuated but did not abolish the decreases in LSNA. Subsequent bilateral transection of the glossopharyngeal (GL) nerves removed the remaining sympathoinhibitory responses at all doses. Section of GL nerves alone attenuated the 5-HT-induced falls in LSNA by approximately 30%. The GL contribution was abolished by removal of the superior cervical ganglion and SLN. These studies are the first demonstration that in addition to the vagus, afferents mediating 5-HT-induced sympathoinhibition also course in the GL nerve.

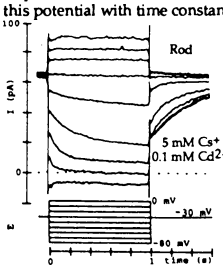
HUMAN CONES CAN PROCESS ONE MILLION QUANTA PER MILLISECOND
C.W. Tyler, R.D. Hamer and L. Lei, (SPON: E.E. Sutter) Smith-Kettlewell Institute, San Francisco, CA 94115

How many quanta can be processed by the photochemical reactions of light transduction before saturation? With about 600 disks in each human peripheral cone, each disk surface appears to act as an independent transduction unit. Thus, linear response behavior should be expected at least up to levels of about 600 quanta absorbed per cone within the cone response time (i.e. simultaneously). Beyond this level, progressive response saturation would be expected if each disk surface were fully activated by absorption of a single quantum.



We measured human light response properties at high intensities, where brief flashes were at the psychophysical detection threshold - a 30' field of 660 nm at 35° eccentricity with an equiluminant white surround. Temporal integration thresholds for pulses of different durations analyzed response linearity as stimulus duration was reduced. Complete linearity with no evidence of saturation was obtained for durations down to 100 usec, where one million quanta were absorbed by each cone at threshold. This amounts to about 1000 quanta absorbed and processed linearly in each outer segment disc surface. These results strongly refute the hypothesis that each disk surface can be fully activated by a single quantum.

386.2

The K^+ current that speeds photoreceptor responses to dim light. S. Barnes*, D.I. Beech* and B. Hille. Univ. of Washington Sch. of Med., Seattle WA 98195.

The voltage response of photoreceptors reaches a peak earlier than the photocurrent at all light intensities. Ionic mechanisms shaping the response to bright light are well characterized: the pronounced sag in the voltage waveform is produced by I_h, a Cs^+-sensitive cation current activated by hyperpolarization beyond -50 mV. But a different ion channel type must speed responses to dim light: even a 1 mV response peaks sooner than the corresponding photocurrent, and this is Cs^+-insensitive.

Using whole-cell patch-clamped, mechanically isolated rods and cones from salamander we have characterized a new potassium current, I_{Kx}, with the right properties to perform this role. I_{Kx} is almost maximally activated at a dark resting potential of -35 mV (activation curve midpoint -46 ± 7 mV, slope factor 5 ± 1 mV, s.d., n=23) and deactivates with hyperpolarization from this potential with time constants of 100-300 ms. It contributes about 40 pA of current at -35 mV in rods, accounting for the return (outward) flow of inward dark current. I_{Kx} is insensitive to 5 mM Cs^+ or 4-AP but is blocked by 5 mM Ba^{2+} or TEA (40% at 10 mM). The block by Ba^{2+} at -35 mV is due to an apparent 40 mV positive shift of the activation curve. The current is much smaller in cones (12 ± 4 pA). I_{Kx} runs-down in 30 minutes. We have not seen it modulated by GABA, glutamate, glycine, ACh, cadaverine or LHRH. Supported by NIH NS08174 and a McKnight Neuroscience Research Award.

VOLTAGE- AND TRANSMITTER GATED CURRENTS IN ISOLATED ROD BIPOLAR CELLS OF THE RAT RETINA.
Andreas Karschin* and Heinz Wässle (SPON: G.Pilar). Max-Planck-Institut für Hirnforschung, D-6000 Frankfurt, FRG.

We isolated bipolar cells from the adult rat retina using enzymatic and mechanical dissociation procedures. Based on their morphology and protein kinase C immunocytochemistry, isolated cells were identified as rod bipolar cells. Several voltage-gated conductances could be measured in the cells when studied with the whole-cell recording technique. In response to depolarizing voltage pulses, bipolar cells revealed a fast transient and a delayed sustained K^+ outward current, as well as a small Ca^{2+} inward current. In addition, an inwardly rectifying current, I_h, was observed upon hyperpolarization.

In almost all cells tested GABA- and glycine-activated Cl^- conductances could be antagonized by bicuculline/picrotoxin and strychnine, respectively. Local drug application revealed a higher GABA sensitivity at the bipolar axonal endings compared to their somatic/dendritic region. Similar experiments and also glycine-gated channels identified in excised somatic patches indicated a higher glycine sensitivity close to the bipolar cell body. Conductances induced by the putative photoreceptor transmitter glutamate and its agonists kainate, NMDA, and 2-amino-4-phosphonobutyric acid (APB) were observed in a proportion of the cells. In the majority of responding cells APB activated currents which reversed at 0 mV under symmetrical Cl^- conditions (Sol. electrode: CsCl; bath: NaCl). These responses were associated with the *opening* of ion channels. Only in a minority of cells (5%) did APB induce the *closure* of ion channels resulting in an outward current at negative clamp potentials.

TOPOGRAPHIC RELATIONSHIPS BETWEEN ROD-SIGNAL INTERNEURONS IN RABBIT RETINA. I.C. Gynther, H.M. Young* and D.I. Vaney*. Vision, Touch & Hearing Research Centre, Univ. of Queensland, St Lucia, Qld 4067, Australia

In mammalian retina, rod bipolar cells and AII amacrine cells are the second- and third-order neurons, respectively, in the rod-signal pathway. These two cell types have been identified in rabbit retina using selective neuronal markers and then characterized by Lucifer Yellow injection under direct visual control, enabling us to examine their dendritic morphologies, topographic distributions and structural relationships. The rod bipolar cells were stained in retinal wholemounts using protein kinase C immunohistochemistry (Negishi, K. et al., *Neurosci. Lett.*, 94: 247,1988). The rod bipolars reach maximum densities of 6,000 cells/mm^2 on the inferior and superior flanks of the horizontal streak, dropping to lower values over the peak visual streak. Their centre-to-periphery density ratio (3:1) is much less than that of the retinal ganglion cells (30:1). Rod bipolar axons give rise to multiple lobes within S5 of the inner plexiform layer, with the axonal-field diameter increasing from 11 µm in the visual streak to 20 µm in peripheral retina, and the axonal-field overlap ranging from 0.5 to 0.9.

In rabbit retina, the AII amacrine nuclei can be selectively labelled by injecting 5 µg Nuclear Yellow into the vitreous 2 days before enucleation and then incubating the eyecup in Ames medium for several hours; the stained retina is metachromatic under UV excitation, with the AII cells fluorescing yellow and other amacrines fluorescing blue. The AII amacrines reach a maximum density of 3,000 cells/mm^2 in the peak visual streak, and show a centre-to-periphery density ratio of 6:1. Although the somata of AII amacrines are distributed irregularly, their dendrites achieve uniform coverage of the retina; in the mid-periphery, the dendritic-field overlap of the sublamina *a* and *b* dendrites is 0.9 and 2.3, respectively. Photoconversion of Lucifer-filled AII cells with DAB followed by immunostaining of the rod bipolars using a contrasting chromagen, shows that the AII dendrites wrap around the axonal lobes of the bipolar cells.

POLYAXONAL AMACRINE CELLS OF THE RETINA. E. V. Famiglietti. Dept. of Anat. and Lions Sight Ctr., Univ. of Calgary, Calgary, AB, Can. T2N 4N1.

Two types of polyaxonal amacrine cell have been identified previously in rabbit retina (Famiglietti and Siegfried,'80, Famiglietti,'81, SNS Abs.). A third type (PA3) has been found resembling PA1 and PA2. All 3 give rise in the proximal dendritic tree to 1-6 "axons" of small and uniform caliber, branching sparsely at right angles, exhibiting boutons en passant, and extending for 2-3 mm in the same strata as the dendrites branch. PA1 amacrine cells are unique in the interstitial position (mid-IPL) of their cell bodies. Their wide dendritic trees are sparsely branched with zig-zag dendritic terminations, small dendritic spines near the cell body, and broad stratification at the a/b sublaminar border. Bodies of PA2 and PA3 cells are "displaced" to the ganglion cell layer. PA2 cells are smaller with branching at the stratum (S)4/5 border, and occasionally S1. PA3 cells resemble PA1 cells, but are more highly branched, multistratified (S1-S4), and have clusters of long spines. EM study of a PA2 cell reveals presynaptic dendrites, supporting an amacrine, rather than ganglion cell identity for PA amacrine cells.

SYNAPTIC CONNECTIONS OF AII AMACRINE CELLS IN THE RABBIT RETINA. E. Strettoi*, E. Raviola, and R.F. Dacheux*, Istituto di Neurofisiologia del CNR, Pisa, Italy and Dept. of Anatomy and Cell Biology, Harvard Medical School, Boston, MA 02115.

In the rabbit retina the scotopic information generated in rod photoreceptors is conveyed to the inner plexiform layer (IPL) through a single type of rod bipolar that, in turn, has its major output onto the narrow-field, bistratified (AII) amacrine cell. We have examined the synaptic connections of this amacrine cell type by the electron microscopical analysis of serial ultrathin sections. In the vitreal part of the IPL (on-sublamina) the AII dendrites receive ribbon synapses from rod bipolars; in this sublamina, the transfer of scotopic information to the on-channel is mediated by large gap junctions between AII dendrites and the axonal arborization of cone bipolars. In the scleral part of the IPL, scotopic information reaches the off-channel through chemical synapses established by the lobular appendages of AII amacrines on the axonal arborization of cone bipolars. Only exceptionally, either the main dendrite of the AII or its lobular appendages are presynaptic to ganglion cell dendrites in the scleral half of the IPL. Thus, the rod pathway in the rabbit retina consists of five neurons arranged in series: rods, rod bipolars, AII amacrines, cone bipolars and ganglion cells. Supported by grants EY01344 and EY03011.

GAP JUNCTIONS BETWEEN AII AMACRINE SOMAS IN CAT RETINA. N.Vardi & P.Sterling. Anat Dept, U of P, Phila PA 19104

The AII amacrine cell is a narrow-field interneuron on the pathway from rod bipolars to ganglion cells. Neighboring AII cells are potentially coupled in sublamina b via large gap junctions ($0.5 \pm 0.3\mu m^2$) between their dendrites and b_1 cone bipolar axons and also by occasional, smaller junctions directly between AII dendrites. We report that neighboring AII cells are also extensively coupled by gap junctions between their somas in the inner nuclear layer and between somas and AII processes in sublamina a. We studied electron micrographs of serial, radially cut, thin sections in a patch of retina 25 x 90 μm within the area centralis. The patch contained 43 amacrine cells of which 12 were AII. In every case (4) where AII somas abutted they were connected by a large, discoid gap junction ($3 \pm 2.5\mu m^2$). These were the only gap junctions observed between amacrine somas. Where neighboring AII somas were not in apposition, they were coupled via large ($1\mu m^2$) gap junctions between their appendages and the somas and also between their appendages in sublamina a. Apparently, the quantal signal carried by a rod bipolar cell is first amplified by multiple, chemical synapses onto the AII and then pooled spatially with other such signals into an AII syncytium created by these extensive electrical synapses.

386.8

LOCALIZATION OF GLUTAMATE DECARBOXYLASE (GAD) mRNA IN THE RAT RETINA BY IN SITU HYBRIDIZATION HISTOCHEMISTRY. M.F.Humphrey, K. Anderson*, C. Sternini and N. Brecha. Dept. of Psychology, University of Western Australia, Australia; Depts. of Medicine and Anatomy & Cell Biology and CURE, UCLA School of Medicine and VAMC-West Los Angeles, LA, CA.

The cellular expression of GAD mRNA was examined in the adult and developing rat retina using in situ hybridization histochemistry with a ^{35}S-labeled rat GAD-encoding RNA probe. Cryostat and paraffin sections were incubated with antisense or sense RNAs at 55°C, treated with RNase A, washed at high stringency (0.1x SSC @ 60°C) and then autoradiographed. In adult retina, GAD mRNA was expressed in numerous cells located in the inner INL and GCL, and in some cells within the IPL. There was negligible labeling of INL cells located adjacent to the OPL. A similar distribution and density of labeled cells were observed in retinas at postnatal day (PND) 5, 10 and 20. However, in PND 1 retinas, labeled cells were only located in the INL adjacent to the presumptive IPL border. No significant label was observed in sections incubated with sense RNA probes. This pattern of GAD mRNA expression closely resembles the distribution of GAD- and GABA-like immunoreactivity in the adult rat retina suggesting that the majority of cells containing GAD mRNA-encoding transcripts are amacrine and displaced amacrine cells.

We would like to thank A. Tobin for the rat GAD cDNA. Supported by NIH grants EY 04067, DK 40469, VAMC Research Funds and NH&MRC (Aust) grant 890174.

EFFECTS OF GLUTAMATE AGONISTS AND ANTAGONISTS ON ISOLATED GOLDFISH RETINAL GANGLION CELLS. Bruce Yazejian, B.N. Cohen* and G.L. Fain. Jules Stein Eye Institute, UCLA School of Medicine Los Angeles, CA 90024-1771.

We have used patch-clamp techniques to explore the effects of glutaminergic agonists and antagonists on ganglion cells isolated from the goldfish retina. Most cells responded to kainate (KA), quisqualate (QA) and AMPA 2-36 hrs after retinal dissociation, as well as to glutamate (Glu), aspartate, and NMDA when they were co-applied with 1 μM glycine (Gly). We saw responses to QA and AMPA at concentrations as low as 0.3 μM, and responses to Glu plus Gly at 1 μM. Responses to Glu, QA and AMPA reached saturation near 30 μM but even 30 mM KA failed to fully saturate the whole-cell response. Under our recording conditions (symmetric Na^+, 1mM Ca_o^{2+}, and no Mg^{2+}), most of the Glu response appeared to be mediated by NMDA-type channels; NMDA-activated single-channel currents had a slope conductance of 24 pS between -80 mV and 0 mV (10°C). Kynurenic acid competitively blocked responses to KA, QA and AMPA but was much less potent against QA than KA or AMPA. KA-activated currents were also competitively blocked by QA and AMPA. Low external pH antagonized the current activated by KA. Supported by NIH EY 01844 and NRSA 06092.

386.10

VOLTAGE-ACTIVATED SODIUM AND CALCIUM CURRENTS IN GOLDFISH RETINAL GANGLION CELLS. A. T. Ishida. Department of Animal Physiology, University of California, Davis CA 95616.

Although it has long been known that retinal ganglion cells produce sodium (Na)-dependent action potentials (e.g. Murakami & Snigematsu, 1970), it has recently been shown that they can also produce calcium (Ca)-dependent action potentials in situ (e.g. Murakami & Takahashi, 1988). We have recently described methods for identifying ganglion cells in vitro after dissociation from adult goldfish retinas (Ishida & Cohen, 1988), and have now identified two voltage-activated currents which should contribute to the action potentials described above. One current (i_{Na}) appears to be carried by Na ions, whereas the other (i_{Ca}) appears to be carried inwardly by Ca ions. These currents were recorded with the whole-cell patch-clamp method, from single ganglion cells within 3-36 hours after dissociating them from adult goldfish (Carassius auratus) retinas. Patch-electrodes were usually filled with (in mM) 140 CsCl, 3 NaCl, 10 EGTA, 0.5 $CaCl_2$, 2 $MgCl_2$, 3 HEPES; the bath contained 140 NaCl, 2.5 $CaCl_2$, 10 glucose, 10 HEPES; pH 7.5; routinely, holding potential was -95 mV. Large, transient i_{Na} was elicited in all ganglion cells by step depolarizations positive to -50mV. Inward i_{Na} decreased when external [Na] was decreased, and appeared to be completely blocked by 300 nM tetrodotoxin (TTX). In the presence of 300 nM TTX, i_{Ca} with a transient peak and sustained plateau was elicited by step depolarizations positive to -50 mV. Inward i_{Ca} increased when external [Ca] was increased, was augmented by BAY K8644 (100 nM), and was blocked by 3 mM Co or 20 μM Cd. In preliminary experiments, i_{Ca} appeared to be unaffected by the $GABA_B$ agonist baclofen (30 μM).

Supported by NIH grant EY08120.

386.11

KYNURENIC ACID REVERSES THE EFFECTS OF A DOPAMINE D_1 ANTAGONIST ON ON-CENTER GANGLION CELLS IN THE RABBIT RETINA. R.J.Jensen. Southern College of Optometry, Memphis, TN 38104.

Dopamine D_1 antagonists increase the spontaneous activity and reduce the light-evoked responses in On-center ganglion cells (Neuroscience 17:837, 1986). A major target of dopaminergic neurons in mammalian retinas appears to be rod AII amacrine cells. These cells form electrical synapses with depolarizing cone bipolar cells, which in turn make chemical synapses with On-center ganglion cells. Since the bipolar cells are thought to use an excitatory amino acid (EAA) transmitter, I examined the possibility that the effects of D_1 antagonists on On-center ganglion cells were due to an increased release of an EAA from the bipolar cells.

Ganglion cell action potentials were recorded extracellularly with microelectrodes from a rabbit retinal strip preparation. The general EAA antagonist kynurenic acid, bath-applied at 380-600 uM, reversed the effects of the D_1 antagonist (+)-SCH 23390 on both On-center brisk-sustained cells and On-center brisk-transient cells. The spontaneous activity and light-evoked responses in these cells were now similar to control records.

In conclusion, dopamine D_1 antagonists appear to disinhibit AII amacrine cells which results in an increased release of an EAA onto On-center ganglion cells.

386.12

FACILITATION IN ON-OFF DIRECTIONALLY SELECTIVE GANGLION CELLS OF THE RABBIT RETINA. Norberto M. Grzywacz and Franklin R. Amthor. MIT E25-201, Cambridge, MA 02139, and Dept. Psychol., Univ. Alabama at Birmingham.

Although Barlow and Levick (1965) reported that inhibition underlies directional selectivity in ON-OFF retinal ganglion cells, they also observed small facilitations for preferred direction motions. These facilitations appeared in two-slit apparent motions, which elicited cell responses larger than the sum of the responses to the isolated slits. Due to the reported smallness, this effect has been neglected. However, we found that sometimes this facilitation augments responses by threefold or more. We investigated the facilitation's spatiotemporal properties with two-slit apparent motions. Facilitation only occurs if the first slit precedes the second by at least 100 *msec* and remains on. This effect is sustained, occurring even after a 700 *msec* delay. Although the strongest facilitations happen for small slit separation, they often occur for separations up to 200 μm. Facilitation occurs for most motions, whose projections to the preferred-null axis point to the preferred direction. However, facilitation occurs, in some cases, even when the projections point to the null direction. Our data suggest that facilitation is directionally selective. Particularly, it is strongest for small slit separation, even if at a larger separation, the first slit would elicit more response alone. This shows that facilitation does not depend directly on the first slit's response and thus, it is not the cell's threshold masked by null-direction inhibition. Alternative mechanisms include a depolarizing shunting synapse (Torre and Poggio, 1978) or a first-transient-then-sustained excitatory synapse. *Supported by NSF (BNS-8809528), NIH (EY05070), and Sloan.*

386.13

CENTRAL PROJECTIONS OF RABBIT RETINAL GANGLION CELLS M.L. Pu* & F. R. Amthor[1]. *School of Optometry
Dept. of Psychology & Neurobiology Research Center[1]
Univ. of Alabama at Birmingham 35294

The ganglion cells that project to specific brain nuclei in rabbit have been identified by retrograde transport of fluorescent dyes, followed by intracellular recording and staining of labeled somas. Focal injections of Fast Blue and Rhodamine latex beads were made in CNS areas includng the dLGN, pretectum, and superior colliculus. Fluorescent ganglion cell somas in the retina were then intracellularly impaled in an isolated, living retina preparation and stained with Lucifer Yellow or Rhodamine-HRP to reveal the the projecting cells' dendritic morphologies. Because the dendritic morphologies of most major classes of retinal ganglion cells in rabbit retina have now been directly identified by intracellular recording and staining (Amthor et al. JCN '89), the physiology of many of these cells is known.

At least 6 ganglion cell classes project to the dLGN. Cell types labeled varied with injection location within the dLGN. In some cases all the injected cells were alpha-like (brisk-transient physiology), but in other cases beta-like (brisk-sustained physiology), sparse dendritic trees (sluggish physiologies), and bistratified cells (On-Off directionally selective) were labeled.

Focal injections in the nucleus of the optic tract (NOT) labeled unistratified cells in the visual streak corresponding to the On directionally selective (DS) ganglion cells. Other pretectal injections revealed On and On-Off DS ganglion cell classes in the visual streak.

CHANNEL PERMEANT CATIONS BLOCK NONCOMPETITIVE INHIBITOR BINDING TO THE NICOTINIC ACETYLCHOLINE RECEPTOR. J.M. Herz, T.P. Erlinger* and S.J. Kolb*. Institute for Neuroscience and Cell Research Institute, Univ. of Texas at Austin, Austin, TX. 78713.

Electrophysiological studies have shown that permeant cations bind to certain sites within the receptor channel as part of the permeation process. Since allosterically coupled noncompetitive inhibitor (NCI) ligands are postulated to bind within the channel, we have investigated whether NCI ligands and cations bind to a common site. Using ethidium as a probe of the NCI site, we have shown that bound ethidium can be completely displaced from Torpedo AChR by inorganic monovalent cations (rank order $Tl^+ > K^+ > Na^+ \sim Li^+ > Cs^+$). The cation K_ds vary markedly and range from 1.7 to 200 mM. Hill plots of the competitive dissociation of ethidium in the presence of carbamylcholine show slopes of 1.0 indicating the cations bind to a single class of independent sites, as previously shown for PCP and HTX. Forward titrations of ethidium in the presence of 5 and 20 mM Tl^+ and 100 µM carbamylcholine were carried out. Scatchard analysis revealed a reduction in the equilibrium affinity and no changes in $B_{(max)}$ indicating a competitive interaction. The divalent cations, Ca^{2+} and Mg^{2+} (K_d= 45 and 86 mM, respectively) also displaced ethidium. Inhibition of ethidium binding by Tl^+, K^+ and Mg^{2+} was reversed after removal of these ions by ultracentrifugation. The kinetics of ethidium dissociation induced by the addition of Tl^+, Na^+, Mg^{2+}, Ca^{2+} and PCP are similar indicating that the dissociation rate of ethidium is the rate limiting step. Our cation K_ds are in close agreement with the K_ds for channel saturation calculated from single channel conductances for these cations (Adams, et al. (1981) J. Gen Physiol. 78, 593-615). We suggest that the cation binding site(s) is the same site to which noncompetitive inhibitors bind and block channel function.

387.2

AN α-BUNGAROTOXIN BINDING PROTEIN FROM *APLYSIA* ISOLATED BY BROMOACETYLCHOLINE AFFINITY CHROMATOGRAPHY
J. T. McLaughlin and E. Hawrot Dept. of Pharmacology, Yale Univ. School of Medicine New Haven, CT. 06510

The body wall musculature of *Aplysia californica* contains an α-bungarotoxin (α-BTX) binding protein that is biochemically similar to a functional acetylcholine receptor (AChR) in *Aplysia* ganglia. Earlier studies (McLaughlin and Hawrot, *Mol. Pharm.* 35, in press) had established that both *Aplysia* α-BTX binding activities resided on multimeric proteins resistant to dissociation in SDS. We have now used affinity chromatography on bromoacetylcholine-coupled Affigel 15 to isolate the *Aplysia* α-BTX binding activity from muscle membrane extracts. Analysis of eluted samples by SDS gel electrophoresis reveals a major polypeptide at 260 kDa (which retains α-BTX binding activity) and minor polypeptides at 60 kDa and 45 kDa. The 260 kDa polypeptide was further purified by electro-elution from SDS gels. Amino acid composition analysis of the electroeluted sample was characteristic of an integral membrane protein, and was similar to that of the AChR from *Torpedo*. When the electroeluted protein is re-analyzed on SDS gels the minor polypeptides reappear despite inclusion of protease inhibitors throughout the isolation. This suggests that the smaller polypeptides eluted from the affinity column may be subunits of the partially dissociated 260 kDa protein. In combination with earlier crosslinking studies that identified an α-BTX binding subunit in both *Aplysia* tissues of 58-65 kDa, we conclude that the *Aplysia* α-BTX binding protein is a multisubunit AChR which appears to include at least two distinct polypeptides, including a 60 kDa ligand-binding subunit .

EXPRESSION OF RAT MUSCLE ACETYLCHOLINE RECEPTOR EPSILON SUBUNIT IN XENOPUS OOCYTES. P.Camacho, R. H. Goodman*, G. Mandel*, and P. Brehm. Dept. of Physiology., Tufts Univ. Med. Sch., Boston, MA 02111 and Div. Mol. Med., New England Med. Ctr., Boston, MA 02111.

The nicotinic acetylcholine receptor channel from muscle is a pentameric protein assembled from alpha, beta, gamma, and delta subunits. A fifth subunit, epsilon, has been cloned from calf and more recently, from rat (Criado et al., Nucleic Acids Res.,16,1988 and Camacho et al., Biophysics J.,55,1989). Using the Xenopus oocyte translation system, we have studied the single channel properties of acetylcholine receptor channels expressed from synthetic mRNA transcripts. We have obtained functional expression of AChR channels by injecting alpha, beta and delta from mouse, in conjunction with mRNA transcripts from rat epsilon subunit. Injection of mRNAs encoding alpha, beta, delta, epsilon subunits results in inward currents of several microamperes at the macroscopic level. Single channel recordings from outside-out patches revealed two amplitude classes of ACh-activated channels. Both had briefer open times and higher conductances than those obtained by alpha, beta, gamma and delta. Injection of alpha, beta and gamma subunit RNAs result in the expression of substantial macroscopic currents. However, in one experiment injection of alpha, beta and epsilon transcripts did not express functional channels, suggesting that receptors containing epsilon may be conditional on the presence of delta subunit.

SYNTHESIS OF A CHANNEL PROTEIN AND CHARACTERIZATION OF ITS SINGLE CHANNEL PROPERTIES. M. Montal, M.S. Montal* and J. M. Tomich*, UCSD, La Jolla, CA 92093 and Children's Hospital, Los Angeles, CA 90027

A 23-mer peptide with the sequence of the M2 segment of the *Torpedo* acetylcholine receptor δ-subunit (EKMSTAISVLLAQAVFLLLTSQR) forms cation-selective channels in lipid bilayers (*PNAS* 85:8703-8707). Channel formation presumably involves self-assembly of conductive oligomers. Here, we synthesized a tethered parallel tetramer with M2δ peptides attached to a multifunctional carrier template (*Tetrahedron* 44:771-785): a 9-aminoacid backbone $K^*KK^*PGK^*EK^*G$ with K containing N^{α} -tboc, N^{ε}-fmoc(*) to generate 4 branch points. M2δ was then attached to template in a stepwise manner at the 4 base-deprotected K side chains. The complete 101 residue protein was cleaved in HF and purified by RP-HPLC. It migrates as a single band in SDS-PAGE (15%) with apparent M_r 11 000. The synthetic channel protein does indeed form channels in phosphatidyl choline bilayers. The single channel conductance γ, channel open (τ_o) and closed (τ_c) lifetimes and percent open time (Po) in symmetric 0.5M NaCl or KCl (10 mM Hepes, 0.5mM $CaCl_2$, pH 7.5) at 100 mV are:

NaCl-γ=18 pS; τ_{o1}=0.8 ms, τ_{o2}=25 ms; τ_{c1}=1.0 ms,τ_{c2}= 17 ms; Po=66%.

KCl- γ=24 pS; τ_{o1}=1.7ms, τ_{o2}=11 ms; τ_{c1}=0.9 ms,τ_{c2}= 4.5 ms; Po=47%.

Membrane conductance increased in discrete steps, integral multiples of these elementary conductances, indicating that the tethered tetramer is the conductive species. We conclude that a four-helix bundle protein is a plausible structure underlying the conductance events.

SINGLE-CHANNEL CURRENTS ACTIVATED BY GABA, MUSCIMOL AND ISOGUVACINE IN OUTSIDE-OUT MEMBRANE PATCHES FROM CULTURED CHICK CEREBRAL NEURONS. D.K.Mistry* and J.J.Hablitz, Neurobiology Res Ctr, Univ. of Al. at Birmingham.

Single-channel currents activated by GABA (500nM-1μM) muscimol (200-500nM) and isoguvacine (500nM-2μM) were recorded from outside-out patches in isotonic Tris-Cl solutions. Under these conditions GABA-activated channels had multiple conductance states of 12, 19, 26 and 31 pS. Transitions between this and the other conductance levels were found. Muscimol and isoguvacine activated similar conductance levels. For all agonists, the main conductance level was around 26 pS. I-V relations for all agonists were linear and reversed around 0 mV. Analysis of the main-state openings gated by GABA revealed two time constants of 0.15 ± 0.04 and 2.07± 0.37 ms (n=5). Similar time constants of 0.48 ± 0.22 and 2.21 ± 0.43 ms (n=4) were obtained for isoguvacine. Open time distributions for muscimol were best described by the sum of three exponentials having time constants of 0.16 ± 0.08, 1.15 ± 0.43 and 6.53 ± 4.07 ms. GABA, muscimol and isoguvacine activate similar multiple conductance levels in chick cerebral neurons. Opentime kinetics for GABA and isoguvacine are similar while muscimol openings displayed an additional longer open state. Additionally, in some patches the occurrence of subconductance levels were more frequent with muscimol and isoguvacine. Supported by NS11535, NS18145 and NS22373.

TWO NOVEL $GABA_A$ RECEPTOR SUBUNITS EXIST IN DISTINCT NEURONAL SUBPOPULATIONS. B.D. Shivers, I. Killisch*, R. Sprengel*, H. Sontheimer*+, M. Köhler*, P.R. Schofield* and P.H. Seeburg*. Center for Molecular Biology, INF 282 and +Institute for Neurobiology, INF 364, University of Heidelberg, D-6900 Heidelberg, F.R.G.

Two cDNAs encoding novel $GABA_A$ receptor subunits were isolated from a rat brain library. These subunits, named γ_2 and δ, share approximately 35% sequence identity with α and β subunits and, like these, form functional GABA-gated chloride channels when expressed alone in cultured cells. The γ_2 subunit represents the rat homolog of the recently described human γ_2 subunit shown to be important for benzodiazepine (BZ) pharmacology (D.B. Pritchett et al., Nature, 338:582, 1989). Cellular localization of the mRNAs encoding the γ_2 and δ subunits in rat brain revealed that largely distinct neuronal subpopulations express the two subunits. The distribution of the δ subunit resembles that of high affinity $GABA_A$ receptors labeled by ^{3}H-muscimol while the localization of the γ_2 subunit resembles that of $GABA_A$/BZ receptors labeled with ^{3}H-flunitrazepam. These findings have implications for the subunit composition of two different $GABA_A$ receptor subtypes and for information processing in neural networks using GABA for signaling.

HUMAN $GABA_A$ RECEPTORS ASSEMBLED FROM DIFFERENT COMBINATIONS OF CLONED SUBUNITS HAVE DIFFERENT ELECTROPHYSIOLOGICAL PROPERTIES

Todd A. Verdoorn, Andreas Draguhn*, Bert Sakmann*, Dolan B. Pritchett, Peter H. Seeburg*

Max-Planck-Institut für medizinische Forschung and ZMBH, Heidelberg, FRG

Cultured human embryonic kidney cells were transiently transfected with cDNA clones encoding α_1, β_1, and γ_2 subunits of the human $GABA_A$ receptor. Chloride currents activated by GABA were examined using patch clamp in the whole cell and outside-out configurations (symmetrical Cl-, 140 mM). In cells transfected with cDNAs encoding the α_1 and β_1 subunits whole cell currents (-60 mV) elicited by fast application of 10 μM GABA desensitized markedly to 16 ± 4% (mean ± SD, n=4) of the initial peak current after 10 sec. In contrast, cells transfected with cDNAs encoding the α_1, β_1, and γ_2 subunits (74 ± 18 % of peak after 10 sec., n=4, 10 μM GABA) or only α_1 and γ_2 (no detectable desensitization over 10 sec., n=5, 30 μM GABA) showed much less desensitization. Single channel GABA-activated currents in outside-out patches (-50 mV) from cells transfected with DNAs encoding α_1 and β_1 subunits had a mean conductance of 19.9 ± 1.2 pS (n=4, 10 μM GABA). The single channel conductance was higher in cells cotransfected with DNA encoding the γ_2 subunit: α_1, β_1, and γ_2 transfected together yielded a mean single channel conductance of 36.4 ± 2.5 pS (n=4, 10 μM GABA); cells transfected with α_1 and γ_2 showed a mean conductance of 34.5 ± 2.5 pS (n=3, 30 μM GABA). The reduced desensitization and higher single channel conductance upon cotransfection with DNA encoding the γ_2 subunit may result from the formation of a new $GABA_A$ receptor subtype or the expression of a mixture of subtypes.

PRIMARY CULTURES OF MOUSE SPINAL CORD EXPRESS THE NEONATAL ISOFORM OF THE INHIBITORY GLYCINE RECEPTOR. W. Hoch*, H. Betz and C.-M. Becker*. ZMBH, Universität Heidelberg, Im Neuenheimer Feld 282, D-6900 Heidelberg, FRG.

Glycine receptor expressed by primary cultures of spinal cord is predominantly of the recently identified neonatal isoform characterized by a low affinity for strychnine. Its ligand binding subunit differs from that of adult receptor in antigenic epitopes and molecular weight. Whereas in vivo the neonatal receptor isoform is completely replaced by the adult isoform within three weeks after birth, this exchange of subtypes is not seen in culture. However, the increased expression of the cytoplasmic glycine receptor-associated 93 kD protein occurring after birth is also observed in culture. Purification of glycine receptor from cultures yielded polypeptides of 49 kD and 93 kD suggesting that the membrane-spanning core of the neonatal receptor may be a homooligomer composed of 49 kD subunits. Pulse-labeling experiments revealed the 49 kD subunit to be a metabolically stable glycoprotein (half life ≈2 days).
