Previous work demonstrated two high affinity PCP binding sites in guinea pig brain labeled by [^{3}H]TCP: site 1 (NMDA-coupled) and site 2 (DA-reuptake complex coupled). The present study examined brain membranes prepared from various species, including human, for the presence of site 2, defined as binding in the presence of 1 μM (+)MK801 minus binding in the presence of 10 μM TCP. The results demonstrated detectable levels of site 2 in brain membranes of rabbit, chicken, mouse, sheep, human, but not rat. Using human cortical membranes, high affinity DA (GBR12935, GBR12909) and 5-HT reuptake inhibitors (paroxetine, fluoxetine) produced a wash-resistant inhibiton of [^{3}H]TCP binding to site 2, but not site 1. Site 2 was the predominant binding site in the human cortex. These results demonstrate that human cortex, possesses a high affinity PCP binding site associated with biogenic amine reuptake binding sites, and that guinea pig , but not rat brain, may be an appropriate animal model for studying the PCP binding sites of human brain.

86.10

ALLOSTERIC REGULATION OF NMDA-COUPLED AND DOPAMINE UPTAKE CARRIER COUPLED PHENCYCLIDINE BINDING SITES IN GUINEA PIG BRAIN. A.A. Reid, J.A. Monn*, A.E. Jacobson*, K.C. Rice and R.B. Rothman. Lab of Medicinal Chemistry, NIDDK and Unit on Receptor Studies, LCS, NIMH, Bethesda, MD 20892.

Recently, we described the presence of two high affinity PCP binding sites in guinea pig brain, with one site coupled to the NMDA receptor (site 1) and the other site associated with the dopamine reuptake carrier (site 2). (+)MK801 is 129-fold selective for site 1. In this study, we conducted kinetic experiments to examine the ability of PCP and (+)MK801 to allosterically modulate the two PCP binding sites. [3H]TCP (5 nM) was utilized to assess effects at site 1 (total binding - binding in the presence of 1 μM (+)MK801) and site 2 [binding in the presence of 1μM (+)MK801-nonspecific binding (1 μM TCP)]. [3H]MK801 (2.5 nM) was used to determine effects at site 1. Guinea pig brain homogenates were incubated with the ligands in 5 mM Tris-HCl pH 8.2 buffer for 2 h at 0°C. The reaction was terminated by centrifugation, the pellets were resuspended with buffer and then filtered (1 ml aliquots) at 15 min intervals to assess the degree of dissociation of the ligands over time. PCP (1 μM) and (+)MK801 (500 nM) were each added to the suspensions at the 30 min time point.

	% OF CONTROL BINDING AT 2.5 HOURS		
	[3H]TCP		[3H]MK801
	SITE 1	SITE 2	SITE 1
CONTROL	74.2±7.6	95.4±3.4	91.4±4.2
PCP	46.5±2.2*	55.4±3.3*	80.0±1.5
(+)MK801	39.3±1.9*	92.0±0.6	78.7±1.6

These data provide evidence for allosteric binding sites associated with PCP site 1 and 2 and indicate that [3H]MK801 predominantly labels the allosteric site associated with PCP site 1.

CHARACTERIZATION OF SIGMA AND PHENCYCLIDINE BINDING SITES ON NEURAL CELL LINES

A. Friedl* and T. Glaser, Department of Neurobiology, Troponwerke GmbH & Co. KG, Berliner Str. 156, 5000 Köln 80, F.R.G.

The psychotomimetic effects of benzomorphane opiates and phencyclidine (PCP) in man are hypothetized to be mediated by both haloperidol sensitive sigma and PCP receptors. In the present study several cell lines including the NCB-20 hybrid, rat pheochromocytoma PC-12, neuroblastoma x glioma hybrid NG 108-15, rat glioma C6-BU-1 lines were investigated for the presence of these receptors by radioligand binding studies. For these assays, the sigma receptor ligands ^{3}H-DTG (di-o-tolylguanidine), ^{3}H-(+)-3-PPP-(3-(3-hydroxyphenyl)-N-(1-propyl)piperidine), the sigma/PCP-receptor ligand ^{3}H-(+)$_5$SKF 10047 (N-allylnormetazocine) and the PCP-receptor ligand ^{3}H-TCP (n-(1-(2-thienyl)cyclohexyl))piperidine were used. Binding sites for the sigma ligands were found on membranes of all cell lines investigated the K_D- and B_{max}-values varying between 20 and 120 nM and 2 and 20 pmol/mg protein, respectively. TCP-specific sites could only be detected in membranes of NCB-20 and NG 108-15 cells. The various cell lines differed in their profile of expressed binding sites. Furthermore, the pharmacological characterization of these sites revealed at least in part marked differences as compared to corresponding sites in rat brain. The present results suggest in some neural cell lines the existence of several types of sigma and PCP receptors. Thus, these cell lines may serve as useful tools for the further characterization of these sites and for the investigation of their functional role.

86.12

IFENPRODIL, A NOVEL NMDA ANTAGONIST, BINDS TO A POLYAMINE-SENSITIVE SITE. H. Schoemaker*, J. Allen* and S.Z. Langer, Synthélabo Recherche (L.E.R.S.), 58, rue de la Glacière, 75013 Paris, France.

It has been suggested that ifenprodil exerts its cerebral anti-ischaemic activity through a noncompetitive antagonism at the NMDA-sensitive glutamate receptor. Recent evidence suggests that it acts through the polyamine modulatory site of the NMDA receptor complex (Carter et al., Eur. J. Pharmacol., in press). We therefore studied the binding of [^{3}H]ifenprodil (spec. act. 31 Ci/mmol) to thrice-washed membranes of the male rat cerebral cortex. Following 120 min of incubation in 50 mM Tris-HCl buffer (pH 7.4) at 0°C, membranes were recovered by filtration over 0.05% polyethylenimine-treated Whatman GF/B filters. Specific [^{3}H]ifenprodil binding, defined using 10 µM unlabeled ifenprodil, was of high affinity (K_d = 45 nM, B_{max} = 5.5 pmol/mg protein) and sensitive to the polyamines spermine (IC_{50} = 7.3 µM) and spermidine (IC_{50} = 87 µM), but not putrescine (IC_{50} > 1000 µM). The ifenprodil analog SL 82.0715 inhibits specific [^{3}H]ifenprodil binding with an IC_{50} of 136 nM. Saturation analysis indicates that spermine decreases the affinity of [^{3}H]ifenprodil binding. Thus, the present experiments indicate that [^{3}H]ifenprodil is a novel ligand that labels a polyamine-sensitive site possibly associated with the NMDA receptor in the rat brain.

86.13

IS IFENPRODIL AN NMDA ANTAGONIST? L. J. Robichaud, L. J. Brahce*, L. L. Coughenour*, and P. A. Boxer. Parke-Davis Pharm. Res. Div., Warner-Lambert Co., Ann Arbor, MI 48105.

Ifenprodil has been reported to be an atypical NMDA receptor antagonist and to reduce ischemic damage in the cat and rat (Gotti et al., 1988). In the rat cortical wedge model bathed with Mg^{++}-free buffer ifenprodil reduced the amplitude of spontaneous epileptiform discharges (SED) by 70% at a concentration (10 µM) that increased the SED rate (39%). At 30 µM, ifenprodil blocked all SED reversibly, as did CPP (1 µM) and ketamine (10 µM). However, ifenprodil differs from CPP in that it binds very weakly to the NMDA recognition site (44% inhibition of [^{3}H]CPP binding at 100 µM vs an IC_{50} of 0.08 µM for CPP. Similarly ifenprodil displaces [^{3}H]TCP binding (IC_{50}=57 µM vs 0.86 µM for ketamine). Another difference is that ifenprodil (300 µM) had no effect on repeated depolarizations induced by NMDA in the cortical wedge. In contrast, CPP and ketamine inhibited NMDA responses $\geq$ 50% at concentrations which blocked SED. Ifenprodil (100 µM) also failed to inhibit quisqualate or kainate induced depolarizations. In summary ifenprodil weakly inhibits the binding to at least 2 sites on the NMDA receptor channel complex, but fails to inhibit a direct response to NMDA. However, the inhibition of SED indicates that ifenprodil can modulate a response which is apparently mediated by endogenous activators of NMDA receptors, perhaps through an interaction at another modulatory site.

86.14

DIFFERENTIAL NEUROPSYCHOPHARMACOLOGICAL PROFILES OF PCP-LIKE AND IFENPRODIL-LIKE NMDA ANTAGONISTS. B. Zivkovic, Gh. Perrault*, E. Morel* and D.J. Sanger*. Synthélabo Recherche (L.E.R.S.), 31, ave P.V. Couturier, 92220 - Bagneux, France.

Neuroprotective agents ifenprodil and its congener SL 82.0715 have been shown to inhibit NMDA receptor function by acting at a site distinct from those involved in the actions of competitive antagonists such as APV and CPP or non-competitive agents like PCP and MK-801. The present studies show that the neuropsychopharmacological profiles of ifenprodil and SL 82.0715 differ from those of both the competitive and PCP-like NMDA antagonists. In mice, PCP and MK-801 produce stimulant effects whereas ifenprodil and SL 82.0715, like the competitive antagonists, decrease locomotor activity. In contrast to these latter drugs ifenprodil-like and PCP-like antagonists do not induce myorelaxation. The anticonvulsant spectrum of activity of all three groups of NMDA antagonists is similar. However, rats trained to discriminate PCP or MK-801 do not show drug lever responding after ifenprodil or SL 82.0715. Thus, the differences in the mode by which NMDA antagonists interact with the receptor appear important for their pharmacological profiles.

CHARACTERIZATION OF POLYAMINE EFFECTS ON ^{3}H-TCP AND NMDA-SPECIFIC ^{3}H-GLUTAMATE BINDING. **A. I. Sacaan and K. M. Johnson. Department of Pharmacology and Toxicology, Univ. of Texas Med. Br., Galveston, TX 77550.**

Reciprocal interactions between glutamate, glycine and spermidine on ^{3}H-TCP binding to rat brain membranes were previously reported (Ransom and Stec, 1988). This study was conducted to further investigate these interactions. Putrescine (N-4C-N) and cadaverine (N-5C-N) which alone did not alter ^{3}H-TCP binding, blocked both spermidine (N-3C-N-4C-N) and spermine (N-3C-N-4C-N-3C-N) enhancement of ^{3}H-TCP binding. Moreover, putrescine blocked glutamate- and glycine-induced ^{3}H-TCP binding. Putrescine blockade of both spermidine- and glutamate-induced ^{3}H-TCP binding was of an uncompetitive nature, i.e. the receptor density and affinity of ^{3}H-TCP for its receptor decreased and increased, respectively, with increasing concentrations of putrescine. This result not only suggests a unique mechanism of action of putrescine on glutamate- and spermidine-induced ^{3}H-TCP binding, but also points out that spermidine and putrescine are acting via two different sites to alter ^{3}H-TCP binding. Spermidine, spermine and putrescine exhibited little displacement of NMDA-specific ^{3}H-glutamate binding, suggesting that the polyamines do not exert their effects on ^{3}H-TCP binding via direct action on the NMDA receptor. In addition, magnesium and spermidine had opposite effects on ^{3}H-TCP binding when tested in the presence of glutamate and glycine, suggesting that spermidine does not act at the voltage dependent site for divalent cations. Supported by DA-02073.

CHARACTERIZATION OF POLYAMINE EFFECTS ON THE STRYCHNINE-INSENSITIVE GLYCINE RECEPTOR. **K. M. Johnson and A. I. Sacaan. Department of Pharmacology and Toxicology, Univ. of Texas Med. Br., Galveston, TX 77550.**

Spermine (N-3C-N-4C-N-3C-N) and the propanediamine derivative (N-3C-N-3C-N-3C-N) enhanced strychnine-insensitive ^{3}H-glycine binding to rat cortical membranes with EC_{50} values of 27 + 3.1 and 18 + 0.7 µM respectively. The ethylenediamine derivative (N-3C-N-2C-N-3C-N) exhibited a partial agonist effect of similar potency. Spermidine (N-3C-N-4C-N) and putrescine (N-4C-N) were without effect. Neither spermidine nor the partial agonist inhibited the effect of spermine. Eadie-Hofstee analysis revealed that spermine increased the affinity of glycine for its receptor without a significant change in receptor density. This effect of spermine is thought to be distinct from that reported on ^{3}H-TCP binding (see Sacaan & Johnson, this volume). First, spermidine mimicked the effects of spermine on ^{3}H-TCP binding but was without effect on ^{3}H-glycine binding. Secondly, spermine enhancement of ^{3}H-TCP binding was blocked by putrescine, whereas its enhancement of ^{3}H-glycine binding was not altered by putrescine. Moreover, spermine's effect on ^{3}H-glycine binding persisted in the presence of glycine or NMDA receptor antagonists, whereas spermine's effect on ^{3}H-TCP binding was blocked by NMDA and glycine receptor antagonists. Inasmuch as the effect of spermine on ^{3}H-TCP binding, but not on ^{3}H-glycine binding, is blocked by putrescine, the significance of the effect of spermine on NMDA receptor function mediated through the glycine receptor remains to be determined. Supported by DA-02073.

POLYAMINE STIMULATION OF [^{3}H]MK-801 BINDING: IMPLICATIONS FOR NMDA RECEPTOR FUNCTIONING. M.-L. Wong*, M.J. Frusciante*, D.C. Javitt and S.R. Zukin, Departments of Psychiatry and Neuroscience, Albert Einstein College of Medicine, 1300 Morris Park Avenue, Bronx, NY 10461.

Both polyamines and Mg^{2+} have been reported to stimulate the functioning of *N*-methyl-D-aspartate (NMDA) receptors. In order to study the mechanisms of these effects, the actions of spermidine upon [^{3}H]MK-801 binding to the phencyclidine (PCP) receptor of the NMDA-gated ion channel were compared with those of Mg^{2+}. In extensively washed rat cortical membranes, both agents produced concentration-dependent increases in specific binding of [^{3}H]MK-801. The maximal stimulatory effect produced by spermidine was significantly greater than that produced by Mg^{2+}. In the presence of a maximally-stimulatory concentration of spermidine, Mg^{2+} produced no further increase in [^{3}H]MK-801 binding. By contrast, in the presence of a maximally-stimulatory concentration of Mg^{2+}, spermidine dose-dependently produced a further four-fold increase in specific [^{3}H]MK-801 binding. Above their maximally stimulatory doses, both spermidine and Mg^{2+} caused dose-dependent inhibition of [^{3}H]MK-801 binding. The dose-response curve and maximal stimulatory effects of spermidine were not significantly altered in the presence of glycine. In the presence of a saturating concentration of L-glutamate, the spermidine dose-response curve was shifted to the left compared to the absence of L-glutamate. In the presence of L-glutamate, the addition of glycine shifted the dose-response curve of spermidine to the left but did not alter the maximal spermidine effect. Association studies indicate that the stimulatory effects of spermidine involve alterations in the kinetics of [^{3}H]MK-801 binding.

POLYAMINES ENHANCE N-METHYL-D-ASPARTATE RECEPTOR FUNCTION IN VITRO AND IN VIVO. L.M. Pullan, L.C. Litwin*, R.J. Stumpo*, J.M. Goldstein, M. Britt*, and A.I. Salama. Dept. of Pharmacology, ICI Pharmaceuticals Group, ICI Americas Inc., Wilmington, DE 19897.

The polyamines spermine and spermidine have recently been reported to enhance [^{3}H] MK-801 binding. We report here the correlation of polyamine effects on [^{3}H] TCP binding in rat brain synaptosomes and on NMDA excitation in vivo in the red nucleus. The polyamines enhance the binding of [^{3}H] TCP, but do not displace [^{3}H] glycine binding to the strychnine insensitive glycine site associated with the N-methyl-D-aspartate receptor complex. The enhancement of TCP binding is additive to that seen with glycine and NMDA. The inhibition of TCP binding by the glycine antagonist 7-chlorokynurenic acid (7-Cl-Kyn) is not reversed by spermine or spermidine. Iontophoretically applied spermidine enhances the excitation induced by NMDA as seen with extracellular single unit recordings. The potentiation by spermidine of NMDA excitation is additive to maximally effective applications of D-serine. Thus, both in vitro and in the intact adult brain, polyamines enhance the function of the NMDA receptor, apparently at a unique site.

86.19

EFFECTS OF POLYAMINES ON THE BINDING OF [^{3}H]MK-801 TO THE NMDA RECEPTOR: AGONIST AND ANTAGONIST EFFECTS AT A PUTATIVE POLYAMINE RECOGNITION SITE. K. Williams, C. Romano and P.B. Molinoff. Dept. of Pharmacology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104-6084.

Experiments were carried out to examine the effects of polyamines on the binding of [^{3}H]MK-801 to membranes prepared from rat brain. Spermine and spermidine increase the affinity of NMDA receptors for [^{3}H]MK-801 in the presence of 100 μM L-glu and 100 μM gly. The effects of other polyamines on the binding of [^{3}H]MK-801 were determined in the presence of L-glu and gly in the absence and presence of 10 μM spermine. In the absence of spermine, $NH_2(CH_2)_3NH_2$, $NH_2(CH_2)_3NH(CH_2)_2NH_2$, and $NH_2(CH_2)_3NH(CH_2)_3NH_2$ (1-300 μM) increased the binding of [^{3}H]MK-801 in a manner similar to that of spermidine. It is concluded that these compounds are agonists at the polyamine site. Putrescine, cadaverine, $NH_2(CH_2)_2NH(CH_2)_2NH_2$, and $CH_3NH(CH_2)_3NHCH_3$, at concentrations of 1-100 μM, inhibited the binding of [^{3}H]MK-801 in the presence of spermine down to the level seen with only L-glu and gly, but did not affect binding of [^{3}H]MK-801 in the absence of spermine. The data indicate that these compounds are selective antagonists of the effects of spermine at the NMDA receptor. Several long-chain diamines including $NH_2(CH_2)_{10}NH_2$ were nonspecific inhibitors of the binding of [^{3}H]MK-801 in the absence or presence of spermine. The results suggest that there is a specific polyamine recognition site associated with the NMDA receptor complex and that this site is distinct from the binding sites for glutamate and glycine. *(Supported by a grant from the PEW Charitable Trusts).*

PRESYNAPTIC MODULATION OF GABA MEDIATED SYNAPTIC EVENTS BY GLYCINE IN IMMATURE RAT HIPPOCAMPAL SLICES
by I.L. Gaiarsa*, A. Coradetti*, E. Cherubini & Y. Ben Ari (SPON: G. Barbin. INSERM U-29, 123 Bd de Port-Royal, 75014 PARIS (France)

In neuronal cultures, glycine in micromolar concentrations potentiates NMDA currents by acting on an allosteric site of the receptor (Johnston and Ascher, Nature, 325, 529,1987). Although strychnine insensitive glycine binding sites are present in the hippocampus, bath applications of glycine have no effect on NMDA mediated events in adult hippocampal slices ; this is likely due to concentrations of endogenous glycine in the slice which saturate this site. We report now a powerful effect of glycine on synaptic mediated events in immature slices.

Intracellular recordings made from CA3 neurons in slices revealed during the first week of life the presence of spontaneous recurrent network driven -giant depolarizing potentials (GDPs), these are mediated by GABA which has an exclusively depolarizing action at this age -and modulated presynaptically by NMDA receptors (Ben Ari et al, J. Physiol. (London) 1989, In Press). Glycine (10-30 μM) and D serine (5-20 μM) considerably augmented the synaptic noise and frequency of GDPs. Glycine and D serine also considerably potentiated the effects of bath applications of NMDA, thus in presence of these agents, a subtreshold application of NMDA (1 μM) produced a large response. These effect was blocked by APV (30 μM), kynurenate (100-200 μM), 7 cl· kynurenate (10μM) but not by strychnine (1 μM). Glycine (up to 100 μM) had no effect on spontaneous activity or NMDA responses after P7. We conclude that glycine during the first week of life has a powerful potentiating effect on GABA mediated GDPs through the allosteric modulation NMDA receptor.

87.2

Glycine and glutamate regulation of the NMDA receptor-gated ion channel: allosteric interactions. Douglas W. Bonhaus, Geng-Chang Yeh* and James O. McNamara V.A. and Duke Medical Centers, Durham, NC 27705

Sustained activation of the N-methyl-D-aspartate (NMDA) receptor-gated ion channel requires the simultaneous presence of agonists for both the NMDA and glycine recognition sites. To investigate the mechanism by which glycine and NMDA receptor ligands interact to control channel activation we measured [3H]glycine and [3H]L-glutamate binding in a hippocampal membrane preparation. To examine the consequences of glutamate and glycine interactions on channel activation we measured the binding of TCP {[3H]N-(1-[thienyl] cyclohexyl) piperidine} (a ligand whose binding is dependent upon activation of the NMDA channel). This allowed direct comparison of receptor occupancy and channel activation in an identical preparation. As previously reported glycine was virtually an absolute requirement for NMDA stimulation of TCP binding. However, in this preparation, glycine had no effect on glutamate binding. These findings suggest that the mechanism by which glycine maintains NMDA evoked currents is not by regulating agonist binding to the NMDA recognition site. Rather, NMDA and glycine receptor ligands act by independent and mutually required mechanisms.

87.3

DIFFERENTIAL MODULATION OF THE NMDA RECEPTOR ASSOCIATED GLYCINE RECOGNITION SITE BY COMPETITIVE NMDA ANTAGONISTS.
W.F. Hood, R.P. Compton, J. Biesterfeldt* and J.B. Monahan. G.D. Searle R & D, CNS Diseases Research, St. Louis, MO 63198.

Recent studies have shown that NMDA responses may be modulated through an associated strychnine-insensitive [^{3}H]glycine binding site. Additionally, several reports indicate that competitive NMDA antagonists may negatively modulate interactions at this glycine recognition site. Using rat forebrain synaptic plasma membranes (SPM), we found that the binding of [^{3}H]glycine to the NMDA associated strychnine-insensitive glycine recognition site was differentially inhibited to a maximum of 35-50% by competitive NMDA antagonists. Those antagonists with a 5-carbon chain backbone (eg. CGS 19755, D-AP5, and 3-(2-carboxypiperazin-4-yl)-methyl-1-phosphonate) were potent displacers of [^{3}H]glycine binding whereas the 7-carbon analogs (eg. 4-methylphosphono phenylglycine, D-AP7, and CPP) were ineffective. The potency of 5-carbon antagonists for displacing [^{3}H]glycine binding correlated with their affinity at the NMDA recognition site. In addition, NMDA recognition site agonists (eg. L-glutamate and NMDA) were shown to reverse this antagonist induced inhibition of [^{3}H]glycine. In conclusion, the data suggest that competitive NMDA antagonists with 5-carbon and 7-carbon chain backbones differentially modulate the glycine recognition site. The difference may be due to either their binding at dissimilar pharmacophores or inducing distinct conformational changes through interactions at a common site.

87.4

EVIDENCE FOR FUNCTIONAL COUPLING OF THE GLYCINE AND [^{3}H]CGS 19755 RECOGNITION SITES.
R.P. Compton, W.F. Hood and J.B. Monahan. CNS Diseases Research, G.D. Searle & Co., St. Louis, MO 63198.

We report a functional coupling between the [^{3}H]CGS 19755 recognition site and the NMDA receptor associated strychnine-insensitive glycine recognition site. Glycine agonists (glycine, 1-aminocyclopropyl-1-carboxylate (ACC) and D-serine) inhibit [^{3}H]CGS 19755 binding to a maximum of 70% in a dose dependent manner over a range of 1-100 μM. This inhibition is reversible by glycine antagonists (1-aminocyclobutyl-1-carboxylate (ACBC) and HA-966) which alone have no effect on [^{3}H]CGS 19755 binding over the range of 1-100 μM.

These results complement our earlier findings concerning the interactions between the glycine and [^{3}H]3-(2-carboxypiperazin-4-yl)propyl-1-phosphonate ([^{3}H]CPP) recognition sites (Compton et al., Miami Winter Symposium 9:35, 1989). [^{3}H]CPP binding is stimulated by glycine antagonists (ACBC and HA-966) and is reversible by glycine agonists (ACC, D-serine and glycine). These findings add support for the functional coupling of the glycine and NMDA recognition sites. Furthermore, differences in the coupling of glycine agonist and antagonist recognition site(s) to the 5-(CGS 19755) and 7-carbon (CPP) NMDA antagonist recognition sites may exist.

87.5

[^{3}H]CGS-19755 BINDING TO NMDA RECEPTORS: INTERACTIONS WITH THE GLYCINE MODULATORY SITE.
W.F. White, P.B. Senatus*, S.A. Lipton, R.H. Loring, and E. Aizenman. Department of Neurology, The Children's Hospital & Harvard Medical School, and Department of Pharmacology, Northeastern University, Boston, MA 02115.

The binding of the NMDA receptor antagonist [^{3}H]CGS-19755 was studied in extensively washed membranes prepared from rat telencephalon. Fifteen minute incubations containing 10 nM [^{3}H]CGS-19755 were performed in 50 mM Tris-HCl pH 8.0 at 4°C. Non-specific binding was determined using 1 mM L-glutamate. Specific binding represented about 80% of total binding. Equilibrium binding analyses revealed a single population of sites with a $K_D = 51 \pm 6$ nM and a Bmax = 4.71 ± 0.71 pmoles/mg protein. Glutamate displacement curves were complex with an IC_{50} of 138 ± 84 nM. Glycine displacement curves were shallow suggesting multiple sites. Nonlinear least-squares curve fitting analyses suggested to populations of sites with IC_{50}'s of 139 ± 39 nM and 1.18 ± 0.04 mM; 37 ± 3% of the total [^{3}H]CGS-19755 sites were displaced with high affinity, and the remaining sites were displaced with low affinity. 7-chlorokynurenate (5 µM), an antagonist at glycine modulatory site, blocked the displacement produced by 1 µM glycine. These results suggest that [^{3}H]CGS-19755 binding is to a site or sites which are sensitive to modulation by compounds active at the glycine modulatory site but which appear to be distinct from the site(s) recognized by glycine and 7-chlorokynurenate. Supported by Morgan Memorial.

GLYCINE SITE AGONISTS OF THE NMDA RECEPTOR; THE ROLE OF HYDROGEN BONDING.
C.J.McBain*, N.W.Kleckner, S.Wyrick* and R.Dingledine, Department of Pharmacology and School of Pharmacy, University of North Carolina, NC, 27599-7365.

Voltage-clamp and molecular modelling studies highlighted five structural features important for activation of the glycine modulatory site on NMDA receptors in *Xenopus* oocytes injected with mRNA isolated from rat brain. First, the presence of sterically unhindered carboxyl- and amino-termini were essential. Second, an increase in the inter-terminal separation by greater than one carbon markedly attenuated potency. Third, activity at the modulatory site was stereoselective. Fourth, only small, sterically unobtrusive substitutions at the α- carbon could be tolerated. Finally, hydrogen bonding of the β-carbon substituent promotes activity. The hydroxyl of D-serine is envisioned as hydrogen bonding to an additional site on the receptor, since isosteric substitutions on the β-carbon incapable of hydrogen bonding are inactive. The position and size of the hydroxyl containing group is critical for activity. Glycine analogs capable only of proton acceptance (β-F-D-alanine and β-Cl-D-alanine) possess modulatory action, while those capable of only proton donation (D-cysteine, 1,2 diamino propionic acid) are inactive. Full dose-response curves were constructed for those analogs displaying >25% of the effect of glycine. Most compounds were nearly full agonists and had Hill coefficients ~1. The potency order was 1-amino-cyclopropane-carboxylic acid > glycine > D-serine > D-alanine > β-F-D-alanine > R(+)-cycloserine. These data offer compelling evidence that the active site of the glycine modulatory site is a small pocket containing at least three points of possible attachment; negative and positive ionic sites and an hydrogen bond donating site.

87.7

GLYCINE-LIKE MODULATION OF NMDA RECEPTORS BY A MONOCLONAL ANTIBODY THAT ENHANCES LONG-TERM POTENTIATION.
J.R. Moskal, P.K. Stanton and R. Haring, Dept. Neurosurgery, Neurology and Neuroscience, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

A monoclonal antibody, B6, that modulates long-term potentiation in rat hippocampal slices was examined for its ability to interact with NMDA receptor-ionophore complexes (NMDAR). [^{3}H]-TCP (1-[1-(2-thienyl)cyclohexyl]-piperidine) binding to extensively washed hippocampal membranes has been shown to be specifically enhanced by NMDAR agonists and thus can serve as an index of functional activation of the NMDAR. 5 µg of affinity purified B6 per 100 µg of membranes gave a 2 to 3-fold elevation in TCP binding. No significant elevation in TCP binding was observed using rabbit IgG, bovine serum albumin or another affinity purified monoclonal antibody from the same panel as B6. When TCP binding was stimulated by the combined addition of maximal concentrations (50 µM) of glutamate, glycine and magnesium, no further stimulation of TCP binding was found upon the addition of B6. Like glycine, B6 enhanced the effect of NMDA and glutamate in stimulating TCP binding but it had no effect on the inhibition of TCP binding by AP5. Similar to the effect of NMDAR agonists, B6 increased the rate of association and dissociation of TCP binding but had no effect on the equilibrium binding of TCP. AP5 prevented these antibody effects. However, glutamate enhanced the effect of B6 whereas there was no effect of glycine on B6. Taken together these results strongly suggest that B6 binds directly to the NMDAR and that B6 displays properties similar to glycine.

GLYCINE ANTAGONIZES ETHANOL-MEDIATED INHIBITION OF NMDA-STIMULATED CALCIUM UPTAKE INTO PRIMARY CULTURES OF CEREBELLAR NEURONS.
C.S.Rabe and B.Tabakoff, Unit for Special Projects, NIAAA, Rockville, MD 20852.

We have shown that NMDA-stimulated $^{45}Ca^{2+}$ uptake in cultures of cerebellar neurons is quite sensitive to inhibition by ethanol (EtOH). Examination of the effects of EtOH on NMDA-stimulated cGMP formation in these cultures suggested that glycine-NMDA interactions may be particularly sensitive to inhibition by EtOH (Hoffman et al., in press). Since NMDA-stimulated cGMP formation is believed to be the result of NMDA-stimulated calcium influx, we have now directly examined the effects of glycine on EtOH-mediated inhibition of NMDA-induced $^{45}Ca^{2+}$ uptake. In the absence of added glycine, EtOH (50 mM) caused approximately a 40% decrease in NMDA (50 µM) stimulated (Mg^{2+}-free buffer) $^{45}Ca^{2+}$ uptake. As progressively larger concentrations of glycine were added to the assay medium, the amount of inhibition of NMDA-stimulated $^{45}Ca^{2+}$ uptake produced by 50 mM EtOH decreased. The threshold for antagonism of the EtOH (50 mM) mediated inhibition was approximately 300 nM glycine and essentially complete antagonism was observed at 100 µM glycine. These results suggest that endogenous levels of glycine acting as a cotransmitter may affect the amount of EtOH-induced inhibition of NMDA-mediated events evidenced in the brain.

Additional studies examining the selective effects of sedative/hypnotics on NMDA and kainate responses revealed that EtOH but not the barbiturates (pentobarbital or phenobarbital) or the benzodiazepine, flurazepam, demonstrated preferential inhibition of NMDA- over kainate-stimulated $^{45}Ca^{2+}$ uptake into cerebellar neurons in culture.

GLYCINE AND SEROTONIN MODULATE NMDA-INDUCED EXCITATION IN CEREBELLAR PURKINJE CELLS. J.G. Netzeband*, J.C. Strahlendorf and H.K. Strahlendorf. Depts. of Physiology and Neurology, Texas Tech Univ. Health Sciences Center, School of Medicine, Lubbock, TX 79430.

Actions of glutamate have been linked via the N-methyl-D-aspartate (NMDA) receptor to learning, neurotoxicity and epilepsy. Glycine has been shown to allosterically modulate the NMDA receptor in *in vitro* preparations. We have used extracellular recording and iontophoretic drug application in urethane-anesthetized male rats to support recent findings that cerebellar Purkinje cells (PCs) contain NMDA receptors. Glycine (+5nA) potentiated (36±6%; mean+S.E.M.) NMDA-induced excitations in 9 of 17 cells tested and attenuated (43±9%) the response in the remaining 8 cells. Cells in which glycine potentiated the NMDA-induced excitation showed a significantly higher predrug firing frequency (44±4 Hz) than those responding with attenuation (18±3 Hz) as shown by a t-test ($p<0.05$). In addition, analysis by linear regression showed that with increasing firing rates, higher percentages of cells responded to glycine with potentiation of the NMDA-induced excitation ($r=0.98$). In other experiments, we have shown that serotonin (5-HT) potently attenuates (41±7%; 22 of 25 cells) NMDA-induced excitation in PCs. These results represent a functional demonstration of glycine modulation of the NMDA response in an *in situ* preparation and further supports that NMDA receptors do exist in PCs. This is the first demonstration that glycine modulation of the NMDA response is rate-dependent and together with the 5-HT data provides strong evidence that the NMDA receptor is under complex, multiple control mechanisms. Supported by NS19296.

CHANGES IN BINDING DENSITY OF N-METHYL-D-ASPARTATE (NMDA) RECEPTORS PRODUCED BY GLYCINE AND 7-CHLORO-KYNURENATE. **S.M. Jones, L.D. Snell* and K.M. Johnson. Dept. Pharmacol. & Toxicol., Univ. Texas Med. Branch, Galveston, TX 77550.**

Recent reports have stated that agonists at the strychnine-insensitive glycine site associated with the NMDA receptor increase the apparent affinity of ^{3}H-L-glutamate binding (GLU; Fada et al., Neuropharm. 27: 1183, 1989) and, conversely, that agonists at the NMDA recognition site increase the apparent affinity of ^{3}H-glycine binding (GLY; Kessler et al., J. Neurochem. 52: 1319, 1989). We have found that the binding of NMDA-specific ^{3}H-L-GLU and ^{3}H-GLY can both be assayed in a "buffy coat" preparation of rat cerebral cortices. Membranes were incubated in the presence of 10 nM ^{3}H-GLU or 20 nM ^{3}H-GLY for 30 min at 4°C in 50 mM Tris acetate (pH 7.4) and then rapidly filtered over GF/C filters using a Brandel M-24 cell harvester.

The selective NMDA antagonist 3-((±)-2-carboxypiperazin-4-yl)propyl-1-phosphonate (CPP), displaced ^{3}H-GLY binding with similar affinity as that reported for the NMDA site (K_i=2μM; Hill slope (nH)=1.0) and at 100μM produced a 24% decrease in the density of ^{3}H-GLY binding sites while not altering the apparent affinity. Agonists at the NMDA receptor (L-GLU, L-homocysteate) did not produce a significant change in ^{3}H-GLY binding but were able to reverse the effect of CPP. Glycine (10μM) produced a 20% increase in the B_{max} of ^{3}H-GLU binding while 10μM 7-chlorokynurenate (7Cl-KYN) produced a 37% decrease in B_{max}. Neither compound significantly changed the apparent K_D. 7Cl-KYN was a selective antagonist at the glycine site (K_i=0.49μM; nH=0.74) relative to the NMDA site (K_i=113μM; nH=0.88). Addition of high concentrations of CPP or L-GLU did not alter the K_i value or the nH for 7Cl-KYN displacement of ^{3}H-GLY binding. These data are consistent with, but do not directly support, the hypothesis that glycine converts a subpopulation of antagonist preferring receptors in the cortex to agonist preferring receptors (Monaghan et al., PNAS 85: 9836, 1988). Supported by DA-02073.

D-CYCLOSERINE: A PARTIAL AGONIST AT THE GLYCINE SITE OF THE RAT N-METHYL-D-ASPARTATE (NMDA) RECEPTOR. T. H. Lanthorn, G. B. Watson, M. P. Baganoff*#, C. L. Deppeler*#, and M. A. Bolanowski*# (SPON: S. D. Hess) CNS Disease Research, G. D. Searle & Company, and #Biological Sciences, Monsanto Company, 700 Chesterfield Village Parkway, St. Louis, MO 63198.

D-cycloserine (DCS) has been reported to exhibit the binding profile of a partial agonist at the glycine modulatory site of the NMDA receptor/channel complex (Hood, *et al.*, 1988). Others have reported that DCS behaves as a full agonist at this site (Johnson, *et al.*, 1988). We have examined the effect of DCS on functional NMDA receptors expressed in *Xenopus laevis* oocytes injected with rat brain mRNA. In voltage clamped oocytes, responses to 100 μM NMDA were potentiated by glycine (EC50=0.60±0.16 μM). NMDA responses were also potentiated by DCS (half-maximal response at 4.8±1.2 μM), however, the amplitude of these responses plateaued at only 40% of that observed in the presence of glycine. Furthermore, in the presence of 3 μM glycine, DCS dose-dependently antagonized NMDA responses to approximately 40% of levels found in glycine alone. From these observations, we conclude that DCS has the characteristics expected for a partial agonist at the glycine site of the NMDA receptor /channel complex.

CYCLOLEUCINE BLOCKS NMDA RESPONSES IN CULTURED HIPPOCAMPAL NEURONS UNDER VOLTAGE CLAMP: ANTAGONISM AT THE STRYCHNINE-INSENSITIVE GLYCINE RECEPTOR. N. Hershkowitz and M.A. Rogawski (SPON: K.L. Kelner). Medical Neurology Branch, NINDS, NIH, Bethesda, MD 20892.

Radioligand binding studies have demonstrated that the neutral amino acid cycloleucine (CL) may act as a competitive antagonist at the glycine modulatory site on the *N*-methyl-D-aspartate (NMDA) receptor complex. In the present study we examined the effects of cycloleucine on NMDA-evoked inward current responses in dissociated hippocampal neuronal cultures using the whole cell voltage-clamp technique. In the presence of 1 μM glycine, CL caused a reversible, dose-dependent inhibition of NMDA responses with an IC_{50} of 24 μM. An increase in glycine to 100 μM resulted in a shift to the right of the CL concentration-effect curve (IC_{50}, 1.4 mM). However, with CL concentrations less than or equal to 100 μM, a fraction of the block could not be overcome by glycine even at concentrations as high as 1 mM. The CL block was unaffected by shifts in the holding potential (-60 to +60 mV), and there was no effect of CL on the reversal potential of the NMDA-evoked current. CL failed to affect kainic acid and quisqualic acid evoked currents at concentrations which inhibited NMDA responses. We conclude that cycloleucine is a potent and selective antagonist of NMDA-receptor mediated responses. Although this effect occurs in part via competitive antagonism at the glycine modulatory site, the CL block cannot be completely reversed by glycine indicating an interaction with an additional site on the receptor-channel complex.

Dr. Hershkowitz was a research associate of the NRC.

GLYCINE ANTAGONISTS CHARACTERIZED AT THE N-METHYL-D-ASPARTATE RECEPTOR COMPLEX. B.A. Meiners, L.M. Pullan, R.A. Keith, M. Britt*, A.B. Klika*, T.J. Mangano*, R.J. Stumpo* and A.I. Salama. Dept. of Pharmacology, ICI Pharmaceuticals Group, ICI Americas Inc., Wilmington, DE 19897.

The antagonism of N-methyl-D-aspartate (NMDA) responses by 7-chlorokynurenic acid (7-Cl-Kyn) and HA-966 (1-hydroxy-3-amino-pyrrolidone-2) has been suggested to occur via the glycine modulatory site of the NMDA receptor complex. We explore here glycine antagonism and the interactions between sites of the receptor complex. HA-966 and 7-Cl-Kyn displace [3H]glycine binding to a strychnine insensitive site. Glycine stimulated [3H]TCP binding is inhibited by 7-Cl-Kyn and HA-966 with potencies greater than on [3H]TCP binding in the absence of added glycine. 7-Cl-Kyn and HA-966 also inhibit NMDA evoked [3H]norepinephrine release from hippocampal slices. The inhibition by 7-Cl-Kyn or HA-966 of glycine stimulated [3H]TCP binding and of NMDA evoked [3H]norepinephrine release is reversible by glycine, D-serine, or L-serine. HA-966 caused an enhancement (up to 2 fold) of the binding of the NMDA antagonist [3H]CPP. The increase in [3H]CPP binding could be reversed by added glycine, suggesting mediation via the glycine recognition site. Thus, 7-Cl-Kyn and HA-966 appear to function as glycine antagonists on the NMDA receptor complex, presumably displacing endogenous glycine and modulating the recognition site for NMDA agonists and antagonists.

87.14

ACTIONS OF GLYCINE ANTAGONISTS ON RAT N-METHYL-D-ASPARTATE (NMDA) RECEPTORS EXPRESSED IN *XENOPUS LAEVIS* OOCYTES. G. B. Watson, M. A. Bolanowski*#, M. P. Baganoff*#, C. L. Deppeler*#, and T. H. Lanthorn, CNS Disease Research, G. D. Searle & Company, and #Biological Sciences, Monsanto Company, 700 Chesterfield Village Parkway, St. Louis, MO 63198.

1-amino-cyclobutyl-1-carboxylate (ACBC) and 1-hydroxy-3-aminopyrrolid-2-one (HA-966) have the binding profile of specific ligands at the glycine modulatory site of the NMDA receptor/channel complex. Additionally, HA-966 has been shown to be a functional glycine antagonist in slice and cultured neuron preparations. We have extended this observation by showing that ACBC and HA-966 antagonize functional NMDA receptors expressed in *Xenopus laevis* oocytes injected with rat brain mRNA. Voltage clamped oocytes responded to NMDA, in the presence of 10 μM glycine, in a dose-dependent manner (EC50=27±2 μM). Responses to NMDA were blocked competitively (EC50 shifted to127±21 μM) by 10 μM D-2-amino-7-phosphonoheptanoate (D-AP7). ACBC and HA-966 noncompetitively blocked responses to 100 μM NMDA, as evidenced by the inability of increasing concentrations of NMDA to overcome antagonism by 300 μM ACBC or 100 μM HA-966. Potentiation of responses to 100 μM NMDA by glycine was dose-dependent (EC50=0.60±0.16 μM). This potentiation was blocked in a competitive manner by 100 μM ACBC (EC50=3.2±0.8 μM) or 100 μM HA-966 (EC50=6.1±2.1 μM). We conclude that ACBC and HA-966 block NMDA mediated responses in a noncompetitive manner through a competitive interaction at the glycine modulatory site of the NMDA receptor complex.

CHARACTERIZATION OF MDL 28,469 AND MDL 29,695 AS SELECTIVE GLYCINE ANTAGONISTS WITH POTENT ANTICONVULSANT ACTIVITY.

B.M. Baron, B.L. Harrison*, D.R. McCarty*, F.P. Miller, C.J. Schmidt*, A.L. Slone* and H.S. White*[1]
(SPON: G. Metcalf) Merrell Dow Research Institute, Cincinnati, Ohio 45215
[1]Univ. of Utah, Salt Lake City, Utah 84112.

HA-966 and 7-Cl kynurenic acid have been described as selective glycine antagonists. IC50 values vs. [^{3}H]CPP were > 100 μM and 75 μM, and vs. [^{3}H]glycine were 18 μM and 0.4 μM, respectively. MDL 28,469 and MDL 29,695 were synthesized as selective glycine antagonists. Respective IC50 values vs. [^{3}H]CPP were 709 μM and 4500 μM and vs. [^{3}H]glycine were 25.1 μM and 16 μM. All compounds inhibited NMDA-stimulated [^{3}H]NE release and cGMP accumulation in rat brain slices. The inhibition was not competitive with respect to NMDA but was reversible with glycine. Upon i.c.v. administration, HA-966, 7-Cl kynurenic acid, MDL 28,469 and MDL 29,695 antagonized quinolinic acid-induced seizures in mice (ED50 values were 276, 13.8, ~ 81, 16.7 nmoles, respectively) and antagonized sound-induced seizures in DBA/2J mice (ED50 values were 43.2, 6.4, 26.6, 13.3 nmoles, respectively). These results demonstrate that the selective glycine antagonists MDL 28,469 and MDL 29,695 may have potential therapeutic value in the treatment of seizure disorders.

GLYCINE ANTAGONISTS AND ZINC INHIBIT [^{3}H]MK-801 BINDING IN RAT BRAIN. S.Y. Sakurai, J.B. Penney and A.B. Young. Neuroscience Program and Dept. Neurology, Univ. Michigan, Ann Arbor, MI 48104-1687.

The N-methyl-D-aspartate (NMDA) receptor-ion channel complex is thought to possess regulatory sites for magnesium, phencyclidine (PCP), glycine and zinc (Zn^{2+}). [^{3}H]MK-801 binds to the PCP site within the associated cation channel. The modulation of [^{3}H]MK-801 binding to the PCP site by ligands which bind to several of these regulatory sites was investigated in rat brain using an in vitro quantitative autoradiographic assay.

[^{3}H]MK-801 binding was inhibited by compounds thought to be acting at the strychnine-insensitive glycine binding site in all brain regions examined. The glycine antagonists, 7-chlorokynurenic acid and kynurenic acid, inhibited [^{3}H]MK-801 binding with IC_{50} values of approximately 10 μM and 100 μM respectively, while HA-966 (1 mM) was not an effective inhibitor of [^{3}H]MK-801 binding. The quinoxalinedione compounds, DNQX and CNQX inhibited [^{3}H]MK-801 binding with IC_{50} values of 10 μM and 30 μM, respectively. The inhibition of [^{3}H]MK-801 binding by CNQX and DNQX was reversed by glycine. Finally, Zn^{2+} inhibited [^{3}H]MK-801 binding with an approximate IC_{50} value of 100 μM in all brain regions examined. Supported by USPHS grants NS 19613 and 15655 and a Merck Faculty Development Award.

87.17

ANTAGONIST ACTIONS OF KYNURENATE AND QUINOXALINE DERIVATIVES AT THE STRYCHNINE-INSENSITIVE GLYCINE SITE OF THE N-METHYL-D-ASPARTATE RECEPTOR. S.L. Pedrotti*, R.A. Zubrowski*, J.W. Ferkany and P.V. Kaplita. Nova Pharmaceutical Corp., Baltimore., MD 21224.

Glycine enhances the actions of glutamate at the N-methyl-D-aspartate (NMDA) receptor, including the induced binding of [^{3}H]N-(1-[2-thienyl]-cyclohexyl)-3,4-piperidine ([^{3}H]TCP) to the phencyclidine (PCP) site, via an interaction with a strychnine-insensitive site. We have evaluated the abilities of several kynurenate and quinoxaline derivatives to inhibit both [^{3}H]glycine binding and glycine-enhanced, NMDA-induced [^{3}H]TCP binding in rat cortical membranes. [^{3}H]Glycine binding was inhibited by 7-chlorokynurenate (7-ClKY, K_i=1.1 μM), 6,7-dichloro-3-hydroxy-2-quinoxaline carboxylic acid (DCHQX, K_i=1.4 μM), 6,7-dinitroquinoxaline-2,3-dione (DNQX, K_i=3.9 μM) and 6,7-dichloroquinoxaline-2,3-dione (DCQX, K_i=6.4 μM). 7-ClKY, DCHQX, DNQX and DCQX also antagonized glycine-enhanced, NMDA-induced [^{3}H]TCP binding (IC_{50}s=30-100 μM). Increasing concentrations of 7-ClKY and DCHQX (1-30 μM) right-shifted the concentration response curves for glycine in enhancing [^{3}H]TCP binding in a parallel fashion, with no effect on the maximum response. DNQX and DCQX (3-100 μM) attenuated the maximum response to glycine. The quinoxalines did, however, exhibit affinity for kainate and quisqualate receptors as well. Thus the data suggest that kynurenate and quinoxaline derivatives are novel, albeit nonselective, antagonists at the NMDA receptor-associated glycine site.

LIGHT INDUCED MEMBRANE CONDUCTANCE CHANGES OF PINEAL PHOTORECEPTORS. P.L.Marchiafava*, C.Kusmic* and E.Strettoi*. (SPON: G. Berlucchi). Dip. Fisiol. e Biochim., Univ. Pisa; Ist. Neurofis. CNR, Pisa, 56100-Italy.

As an initial step to investigate the phototransduction mechanism of pineal photoreceptors we have measured the membrane conductance changes associated with their hyperpolarizing response to a 50 msec flash. A single electrode voltage-clamp technique was used on pineal photoreceptors of the trout Salmo irideus. Current-voltage relations measured at the peak of the photocurrent between +/-40 mV holding potential indicated a decrease of membrane conductance of about 20 per cent relative to the dark values (membrane resistance: 460 MΩ +/- 120 s.d.). The reversal potential of the photocurrent was extrapolated at ca. 50 mV above the dark membrane potential (-19 mV +/- 4 s.d.). These results suggest that an ionic mechanism similar to that in retinal photoreceptors may be involved. The recorded cells were identified at the electron microscope by intracellular injection of Lucifer yellow followed by photoconversion.

EXTRAOCULAR PHOTORECEPTORS IN THE PERIOCELLAR EPITHELIUM OF LOCUSTA MIGRATORIA ?

E. Schlemermeyer [1]*, M. Schuette [2]*, J. Ammermueller [3]*
(SPON: R.L. Chappell) [1]Hunter College, CUNY, NY, NY 10021; [2]NYU Medical Center Dept. Ophthalm. NY, NY 10016; [3]University Munich, Dept. Zoology

The median ocellus of is Locusta migratoria is surrounded by a two-layered epithelium, the periocellar epithelium (POE), which forms two elongated horns reaching to the lateral ocelli. In this POE numerous tiny structures stain intensely with an antiserum against histamine. They have an elongated bean-like shape with a diameter of ca. 0.5 um, length ca. 3 um, and contain a nucleus. They are directed towards the cuticle and connected with finger-like processes to large cells of the inner row. Upon potassium induced depolarisation they release histamine, this is partially blocked in the presence of cobalt. Intraocellarly injected Lucifer yellow is selectively taken up by them which shows a connection between them and the ocellus. Further evidence for a possible role as additional photoreceptors derives from the following: 1. Histamine is also the transmitter of the ocellar photoreceptors, 2. The POE is restricted to areas where the cuticle forms lens-like structures and is transparent, 3. Pigment migration could be observed in the POE.

A MUTATION AT THE DROSOPHILA fused rhabdomeres (fur) LOCUS AFFECTS RHABDOMERE MORPHOLOGY AND PHOTORECEPTOR FUNCTION A. Blake*, P.M. O'Day, T.R. Venkatesh*, Institutes of Neuroscience and Molecular Biology, University of Oregon, Eugene, Oregon 97403

In the Drosophila compound eye the plasma membrane of each photoreceptor cell is elaborately infolded to form the rhabdomeres. These structures are studded with the primary photopigments, run the length of each retinal cell, and are the region in which photo-transduction occurs. We are interested in the development of the rhabdomeres and their role in retinal function. We have characterized fur, a new P element-induced mutation that causes fusion of the rhabdomeres in neighboring photoreceptor cells and compaction of the rhabdomere structure on the longitudinal axis. fur has been localized to the proximal region of the X chromosome by recombination and deficiency mapping. Mutations at fur also produce several distinct physiological abnormalities, including a 10-fold decrease in retinal sensitivity to light relative to wild-type and the absence of a prolonged depolarizing afterpotential. The loss of sensitivity is wavelength-independent. It has been possible to generate partial and complete revertants of fur. Complete revertants show restoration of both structural and functional deficits, suggesting that the mutant phenotype is indeed the result of a P element insertion. We are in the process of cloning the fur locus via its P element tag.

PROPERTIES OF RETINAL GUANYLATE CYCLASE. Y. Horio* and F. Murad** (SPON: R. S. Eisenberg). Dept.of Pharmacology, Northwestern Univ. Med. Sch., Chicago, IL 60011, *Pharmaceutical Division, Abbott Laboratories, Abbott Park, IL 60064.

Light triggers a cascade of reactions in retinal rod cells that leads to the amplified breakdown of cyclic GMP (cGMP) and the generation of a neural impulse. Guanylate cyclase (GC) of bovine rod outer segments (ROS) is entirely a particulate isoenzyme associated with membranes. Previous attempts to solubilize ROS GC have been unsuccessful. We dissociated this enzyme from ROS using high concentrations of KCl and Triton X-100. More than 80 % of total GC activity was recovered in the supernatant fraction after centrifugation (104,000g, 1hr), when ROS GC was treated with 1 M KCl and 0.5% Triton X-100. The dissociation by KCl and Triton X-100 was not observed with lung particulate GC (1) and intestine particulate GC (1). Additionally, atrial natriuretic factor(ANF), E.coli heat stable enterotoxin(ST) and ATPγS that activate lung and intestine particulate GC could not activate ROS GC. These results show that ROS GC is a different isoenzyme from that associated with ANF receptor and ST receptor. When dissociated ROS GC was analyzed by gel filtration TSK SW-4000 column, three peaks (1,200 kD, 1,000 kD and 710 kD) and one minor peak (580 kD) were observed, which indicates that the dissociated ROS GC is part of large complexes with other proteins, sugars and/or lipids.

CYCLIC GMP ANALOGUES BLOCK LIGHT-INDUCED ELONGATION IN ISOLATED TELEOST ROD INNER AND OUTER SEGMENTS. B. A. Liepe* and B. Burnside*(SPON: G. Jacobs). Dept. of Physiology-Anatomy. University of California at Berkeley, Berkeley, California. 94720

Teleost rod photoreceptors change cell length in response to changing light intensities. In the light rods elongate and in the dark they contract. These movements are mediated by the inner segment myoid. To examine intracellular signals that mediate the signal transduction process from light absorption to the onset of motility we are studying mechanically detached rod fragments containing inner and outer segments (RIS-ROS) from retinas of the fish, *Lepomis cyanellus*. RIS-ROS consist of outer segment, ellipsoid, and myoid. When cultured in the light RIS-ROS myoids elongate 16.1 ± 0.9μ (Mean ± SEM, n=12). Dark cultured RIS-ROS myoids elongate only 3.6 ± 0.5μ (n=12). We show light-induced RIS-ROS elongation can be blocked 70-80% by millimolar concentrations of 8-Bromo-cyclic GMP or Dibutyryl-cyclic GMP in the presence of 0.25mM 3-isobutyl-1-methylxanthine (IBMX). In 0.25mM IBMX RIS-ROS elongation was not affected; however at higher dosages (0.5 and 1.0mM) IBMX produced a 40-60% block of light-induced elongation in RIS-ROS. Cyclic GMP analogues and phosphodiesterase inhibitors have been shown to depolarize vertebrate rods. Thus we tested the effects on rod motility of K^+ concentrations shown to block light-induced hyperpolarization in vertebrate rods (27-54mM). These concentrations of K^+ produce a 50-60% block of light-induced RIS-ROS elongation. Our results show that light-induced rod motility is blocked both by agents which prevent light-induced fall in cGMP and by agents which prevent light-induced hyperpolarization. These observations suggest that light-activation of rod motility requires membrane hyperpolarization. (supported by NIH grant EY03575).

CALCIUM/CALMODULIN-DEPENDENT PROTEIN KINASE IN LIMULUS PHOTORECEPTORS. B.G. Calman*, S.C. Edwards, A.C. Wishart*, and B.-A. Battelle, Whitney Laboratory, University of Florida, St Augustine, FL 32086.

A 46 kD protein in Limulus photoreceptors is a substrate for light- and Ca-dependent phosphorylation (Edwards et al., 1989; Wiebe et al., 1989). Here we report that the light-stimulated phosphorylation of this protein is blocked by the calmodulin inhibitor calmidazolium (CZ) at 30 μM, and present an initial characterization of calcium-calmodulin dependent protein kinase (Ca/CAM PK) in Limulus photoreceptors.

^{125}I-calmodulin binds in a Ca-dependent manner to 8 bands in Western blots of photoreceptor proteins. One of these bands, M_r=55 kD, is recognized by a monoclonal anti-body against vertebrate Ca/CAM PK II (from Dr. H.S. LeVine III) and runs in the same position in SDS-PAGE as a Ca-dependent phosphoprotein. Ca/CAM PK activity was assayed in homogenates of lateral eye and ventral photo-receptors using an exogenous peptide substrate, syntide-2. The calmodulin inhibitors CZ (10 μM), mastoparan (3 μM), and CGS 9343B (30 μM) block >90% of Ca/CAM-stimulated activity in this assay. The protein kinase C inhibitor H-7 does not lower activity at concentrations up to 100 μM.

These studies indicate that a Ca/CAM PK is present in Limulus photoreceptors and suggest it may mediate some of the effects of calcium on photoreceptor function. Supported by NSF (BNS 86-07660) and the Whitney Laboratory.

RECOVERY OF BLEACHING ADAPTATION IN PHOTORECEPTORS AND THE cGMP TRANSDUCTION CYCLE. K.N. Leibovic and J. Bandarchi*. Dept. of Biophysics, SUNY/Buffalo, Buffalo, NY 14214.

The objective of this study concerns the mechanisms of bleaching adaptation in vertebrate rods and their effects on response threshold and amplitude. Our method uses isolated rods-in which there is no regeneration of bleached pigment-from the retina of Bufo marinus. The rods are held in a suction electrode and the current responses to flashes of increasing intensity are recorded both in the dark adapted state and after bleaching a fraction of the native rhodopsin. The responses are obtained in Ringer solution and compared with those in a maintainance medium (KNL medium). We have found that the dark adapted responses are the same in Ringer and in medium. After bleaching 30% of the pigment the cell recovers to a steady state in about 45 minutes when in Ringer. Its threshold is elevated by about 1.7 log units above the dark adapted value and its response amplitude is reduced to about 50%. By contrast, after 30% bleaching in medium it takes some 90 minutes to reach a steady state; the response amplitude recovers completely and the threshold is elevated only about 0.7 log units. We have determined the necessary and sufficient components in our medium which produce these effects. They are biotin, pyruvate and elevated dextrose. Our results imply that adaptive metabolic processes exert control at focal points in the transduction cycle, restoring free cGMP after bleaching and increasing sensitivity.

SPECIFICITY AND SELECTIVITY OF POLYCLONAL ANTISERA AGAINST COMPONENTS OF THE NEURAL AND VISUAL TRANSDUCTION PATHWAYS IN RAT AND HUMAN RETINA HISTOLOGIC SECTIONS. J.J. Erdos*, H. Tamir*, C.J. Barnstable*, and J.K. Northup*. (SPON: J.R. Cooper) Depts. of Pharmacology and Opthalmology, Yale Univ. Sch. of Med., New Haven, CT. 06510

Polyclonal antisera were raised in rabbits specific for purified components of the visual and neuronal signal transduction pathways; the α and β/γ subunits of transducin, (G_t-2, G_tβ-11), retinal cyclic GMP phosphodiesterase, (PDE-4), the α subunits of the GTP binding proteins G_o and G_p (G_o-1, G_p-1) and the β/γ subunits common to these proteins, (β-6). Dissected retinas were fixed, sectioned, and preincubated in 5% goat serum before washing and incubation with the above primary antisera at dilutions of 1:500. The retinas were washed and reincubated in secondary antibody as described Hicks, D., and Barnstable, C.J., J. Histochem. Cytochem. 35:1317-1328, 1987.

In rat and human retina Gt-2 specifically labelled the photoreceptor (PR) while β-11 was selectively reactive with the PR and rod outer segments (ROS). In rat PDE-4 only labelled ROS. G_o-1 labelled bipolar cells preferentially while β-6 reacted with cell bodies, axons, synaptic terminals but not ROS. Similarly in rat retina G_p-1 labelled the synaptic layer as well as bipolar cells.

At day three of development rat retinal photoreceptors were reactive for G_t-2 but not β-11 suggesting that in development the α and β subunits of transducin may be differentially expressed. The presence of G_p-1 immunoreactivity in cells of the retinal synaptic layer suggests that the low molecular weight protein G_p is a component of visual neuronal transduction cells and may be involved in the visual transduction process.

EFFECTS OF MILD SYSTEMIC HYPOXIA ON $[H^+]_o$ OUTSIDE ROD PHOTORECEPTORS IN CAT. F. Yamamoto* and R.H. Steinberg. Depts. of Physiol. and Ophthalmol., Univ. of Calif., San Francisco, CA 94143.

Measurements of $[H^+]_o$ by intraretinal microelectrodes showed that pH outside dark-adapted rods (subretinal space) is relatively acidic and is elevated by as much as 0.2 pH units by light (Borgula, G. A., and Steinberg, R. H., Suppl. IOVS, p.289, 1984). We studied the effect of mild systemic hypoxia (P_aO_2 40-90 mmHg) produced by adding N_2 to the inspired gas. In the dark, any measurable drop in P_aO_2 below the normoxic level (range 90-110 mmHg) further decreased subretinal pH. Depth profiles located the maximum decrease to rod inner segments (about 70-85% retinal depth). Its magnitude increased with degree of hypoxia, reaching .06 pH units at a P_aO_2 of 46 mmHg. Light reduced the size of this maximum acidification, and completely blocked it at about 0.5 log units above rod saturation. These data suggest that glycolysis occurs in dark-adapted cat rods, and is increased by any drop in P_aO_2 below the normoxic level, and is decreased by light. The data can be viewed in the context of other evidence indicating that to support the dark current the actively metabolizing rod inner segments exist in an hypoxic environment, even during systemic normoxia (Linsenmeier, R. A. and Steinberg, R. H., J. Gen. Physiol., 84:945, 1984; Linsenmeier, R. A., J. Gen. Physiol., 88:521, 1986).

In the dark, addition of oxygen to the breathing mixture led to an increase in subretinal pH, which was maximal at a hyperoxic P_aO_2 of 150-200 mmHg. This effect is interpreted as an inhibition of glycolysis by the local increase in PO_2 outside rods (Pasteur effect), which has been measured in hyperoxia (Linsenmeier, R.A. and Yancey, C. M., IOVS, 30:612, 1989).

IONIC MECHANISMS OF THE PROLONGED DEPOLARIZATION IN CONES AND RODS. W. B. Thoreson, D. A. Burkhardt, J. Gottesman & S. Zhang. Departments of Physiology & Psychology, Neuroscience Program, Univ. of Minnesota, Minneapolis, MN 55455.

The "prolonged depolarization" is a regenerative, voltage-sensitive response, accompanied by a conductance increase, which can be evoked by the injection of depolarizing current. We have investigated the ionic mechanisms which underlie the prolonged depolarization in intact turtle cones using intracellular recording in the superfused eyecup.

The prolonged depolarization involves activation of a voltage-sensitive Ca channel. It is enhanced by high Ca or Sr, depressed by low Ca, and blocked by Co. The organic Ca channel blockers diltiazem and D600 do not affect the prolonged depolarization. In contrast, D600 blocks Ca-dependent spikes in turtle cones. This suggests that turtle cones possess more than one type of Ca channel.

The prolonged depolarization also requires the presence of intracellular Ca. EGTA (250mM) in the recording electrode abolishes the response, whereas it persists when the electrode contains 100mM CaCl2. TEA, 4-AP, and ion substitution experiments indicate that K and Na fluxes are not responsible for the prolonged depolarization.

The response depends on the chloride gradient. It is enhanced by superfusion with Cl-free media and more evident when using KCl, rather than K methylsulfate or K acetate, as an electrolyte.

Rods in the toad generate a prolonged depolarization which is clearly similar to that of turtle cones. The response may thus reflect conductance mechanisms common to the inner segments of both rods and cones. Our evidence suggests that the prolonged depolarization is initiated by the activation of voltage-sensitive Ca channels, and that the resulting Ca influx activates a long-lasting Cl conductance.

DEVELOPMENT OF CALCIUM CURRENTS IN CULTURED PHOTORECEPTORS. E.L. Gleason, P. Mobbs* and M. Wilson. Dept of Zoology. University of California, Davis, Ca 95616.

Ribbon synapses are the major synapse type found between photoreceptor and second order cells in the vertebrate retina. We have previously shown that cone cells dissociated from embryonic day 8 chick retinae begin to form ribbon synapses by embryonic equivalent (E.E) day 12 (Gleason and Wilson, Soc. Neurosci. Abstr. 14: 1988). In this study, we asked when calcium currents develop in cone cells put in culture on day 8.

Patch clamp recordings obtained from cultured cone cells (E.E. 9 - E.E.18) in the whole-cell configuration showed large outward currents activated positive to -20 mV which were almost completely blocked by an internal solution containing Cs^+ (160 mM) and TEA (5 mM) and were therefore thought to be carried by K^+. These outward K^+ currents were present from E.E. 9 onwards. When outward currents were blocked, a small inward current could be detected between - 30 and +50 mV. The inward current we believed to be a calcium current as it was enhanced in 10 mM $[Ba^{++}]_o$ and blocked completely by 2 mM $[Co^{++}]_o$. The calcium current was extremely rare (2.7% of cells examined) on E.E. 9 and 10 but became more common with time in culture (E.E. 12, 30%; E.E. 14, 64% and E.E. 16, 88%). At all ages, the calcium current activated positive to -30 mV and reached a peak between +7 and +35 mV. Full activation of the current occurred within 8 msec and no inactivation was observed during a 50 msec voltage step. The mean maximum of the subtracted current ($I_{Ba++} - I_{Co++}$) was 31.3 pA but varied greatly from cell to cell (S.D.=15.1 pA). Neither the age nor the size of the cell (on average, capacitance values of cone cells increased with time in culture) was correlated with the magnitude of a cell's peak inward current. We conclude that the full complement of a cell's Ca^{++} channels become functional over a brief period, probably less than one day.

88.12

CRITICAL ANALYSIS OF A KINETIC MODEL FOR PHOTOTRANSDUCTION IN CONES. [1,2]D. Tranchina* and [2]J. Sneyd* (SPON: K. Purpura). [1]Dept. of Biology, [2]Courant Institute, New York University, New York, NY 10012.

We evaluate a recently introduced kinetic model for phototransduction in cones by testing its ability to simulate photoreceptor behavior in several experiments involving manipulation of light input, injected current, and the concentration of free internal calcium, $[Ca^{2+}]_{in}$. In the basic model, light adaptation is mediated through only one site of biochemical feedback: the activity of guanylate cyclase depends sigmoidally on $[Ca^{2+}]_{in}$. The model accounts quantitatively for changes in sensitivity and dynamics of cone responses to light with increasing background level, I_0, and provides a good fit to families of temporal frequency responses measured at 5 mean light levels spanning 4 log units. The model also gives a shift in the stimulus-response function along the log-intensity axis with a change in background light level. However, the fact that injection of depolarizing current in the model does not increase flash sensitivity (as in real cones) suggests that the model be embellished with a voltage-dependent conductance or a voltage dependence of the Na/Ca exchange pump. When $[Ca^{2+}]_{in}$ is frozen at its dark level, sensitivity of the model cone decreases more rapidly with I_0 (compared to the rate of decrease when $[Ca^{2+}]_{in}$ is left free to vary), because [cGMP] decreases more rapidly with I_0 in the absence of guanylate cyclase feedback. Even with fixed $[Ca^{2+}]_{in}$, the time to peak and recovery phase of the model cone's impulse response still shorten with increasing I_0; we believe that both features are mediated by saturation of activated phosphodiesterase. The theoretical behavior of sensitivity and dynamics with fixed $[Ca^{2+}]_{in}$ is similar to that measured by others in rods.

CALCIUM CURRENT IN CONE PHOTORECEPTOR SYNAPTIC TERMINALS. E.M. Lasater and P. Witkovsky. Dept. Physiol., Univ. Utah, Salt Lake City, UT 84108 and Dept. Ophthalmol., NYU Medical Center, New York, NY 10016.

Cone photoreceptors were isolated from the retinas of the turtle, Pseudemys. Whole cell patch clamp recordings were made from cone synaptic terminals. No difference in membrane currents was noted between cone classes. A putative calcium current was isolated with a blocker Ringer, pH 7.6, consisting of (in mM) TEA, 20; $CaCl_2$, 20; 4-AP, 10; NaCl, 130; KCl 2.9; $MgCl_2$, 1.2; HEPES, 8.4; glucose, 10. The electrode contained CsCl, 120; NaCl, 4; EGTA, 5, HEPES, 84; $CaCl_2$, 0.5, trace Mg-ATP. The average calcium current (N=38) activated near -40 mV, reached its peak value of -70 pA near +10 mV and reversed near +80 mV. The calculated reversal potential for i_{Ca} is +200 mV. The measured current reversed at a more hyperpolarized potential, a finding attributed to residual outward currents. The time constant of activation was about 4 msec. The current relaxed to about 90% peak value with tau=1 sec and was sustained thereafter (longest test step 16 sec). In 20 mM $[Ca]_o$ the calcium current was blocked partially by 4 mM Co and completely by 20 mM Co (N=5). It was reduced 50% by 10 uM nifedipine (N=5), unaffected by the nifedipine carrier solution (N=2) and enhanced 2x by 10 uM Bay K 8644 (N=4). The current was unaltered by the $GABA_b$ agonist baclofen (10 uM, N=4) or by dopamine (10 uM, N=2) or serotonin (10 uM, N=2). Supported by EY05972 (E.M.L.) and EY03570 (P.W.).

PHARMACOLOGICAL CHARACTERIZATION OF CALCIUM CHANNELS MEDIATING SYNAPTIC TRANSMISSION FROM PHOTORECEPTORS TO HORIZONTAL CELLS. J. Kleinschmidt, Dept. of Ophthal., New York Univ. Med. Ctr., New York, NY 10016.

An L-type Ca current has been described in amphibian rods and cones and in turtle cones. The properties of this current raise doubts about its involvement in photoreceptor transmitter release. To characterize the Ca channels which support transmitter release, I have examined the effect of agents which modify Ca currents on horizontal cell membrane potential and light-evoked responses in the isolated superfused salamander retina. Synaptic transmission was functional in nominally Ca-free medium (0 Ca) as well as in 0 Ca medium containing 1 mM Sr or Ba. The potency of inorganic Ca channel blockers in hyperpolarizing H cells and blocking their responses decreased in the following order: La > Cd > Ni = Zn > Co > Mn > Mg. Omega-conotoxin (10-100 uM) had no effect in either salamander or goldfish retina. At very high concentrations (10-100 uM), nifedipine reduced but did not block H cell responses. Bay K 8644 (5 uM) had complex effects on H cells, reducing responses and eventually inducing prolonged regenerative responses, presumably Ca spikes. D600 at 40 uM had no effect. These results will be discussed in relation to the 6 or 7 distinct types of Ca channels so far identified in other cell types.

DO RODS AND CONES ACTIVATE DIFFERENT EXCITATORY AMINO ACID (EAA) RECEPTORS? H. G. Kim and R. F. Miller. Washington Univ. Sch. of Med., St. Louis, MO 63110 and Dept. of Physiology, Univ. of Minnesota, Mpls, MN 55455.

We have studied rod and cone neurotransmission onto 2nd-order neurons, by dual whole-cell recordings from synaptically coupled pairs, using direct visualization in a perfused slice preparation of the mudpuppy retina. In addition, we examined rod- and cone-mediated synaptic responses in the superfused retina-eyecup preparation of the same species, using cone-matched stimuli to determine the relative rod and cone inputs into horizontal cells (HCs). Both experimental paradigms were used to evaluate the sensitivity of rod- and cone-mediated transmission to a variety of known EAA antagonists.

In the presence of comparatively weak concentrations of EAA antagonists (kynurenic acid, CB-PzDA, BB-PzDA, CNQX, and D-O-Phosphoserine), HC recordings revealed that cone-mediated responses were significantly more attenuated than rod-mediated ones. This distinction was made by comparing the antagonist action on high vs. low-intensity stimuli, response waveform, response to flickering light and synaptic responses evoked by current injection into rods and cones. These observations suggest that the postsynaptic receptors on the HCs are different for rods vs. cones. (Supported by NEI grant R01EY03014, and R01EY07376)

WAVELENGTH-RELATED SYNAPTIC MULTIPLICITY IN THE TRANSMISSION FROM CONE PHOTORECEPTORS TO H1 HORIZONTAL CELLS M. Yamada*, S. Yasui* and M.B.A. Djamgoz*. (SPON: M. Murakami). Imperial College of Science, Tech. and Med., London, UK.

Horizontal cells of the H1 type as well as vertebrate photoreceptors of every kind respond with graded hyperpolarization to all visible lights. This sign-conserving synaptic transmission has been accounted for by assuming that the light-induced presynaptic hyperpolarization reduces the secretion of an excitatory neurotransmitter from photoreceptor terminals. Recently, however, we have demonstrated that short- and long-wavelength (λ) signals are transmmited differently to H1 cells in the carp retina (Yasui, S. & Yamada, M. *Exp. Brain. Res.*, **74:256**, 1989). Such spectrally segregated synaptic multiplicity was further examined here. Application of 5 μM dopamine to the retina enhanced preferentially the responses to long-λ stimuli, whereas application of 1mM 2-amino-4-phosphonobutyrate (APB) potentiated preferentially the short-λ responses. Also, dopamine depolarized and APB hyperpolarized the resting membrane potential in the dark. These effects are consistent with the idea that the short-λ specific synaptic mechanism is of a conductance (g_m)-decreasing and sign-reversing type, as opposed to the classical g_m-increasing paradigm of excitatory synapse mediating mainly long-λ signals; probablly APB acts as an agonist of the g_m-decreasing endogenuos transmitter (as in the transmission from rod photoreceptors to ON-center bipolar cells), whereas dopamine potentiates the postsynaptic chemosensitivity to the g_m-increasing excitatory transmitter which may be glutamic acid (*cf.* Knapp, A.G. & Dowling, J.E., *Nature*, **325:437**, 1987).

ELECTROPHYSIOLOGICAL EVIDENCE OF CONE INHIBITION OF RODS IN NORMALS-VS-ACHROMATS. K.W. Wright* and B.E.S. Fox. Childrens Hospital Los Angeles & Univ. Southern California Sch. of Med., Dept. of Ophthalmology, Los Angeles, CA, 90027.

Previous psychophysical experiments have indicated a probable cone inhibition of rods under photopic conditions. This cone-rod interaction, however, has not been verified electrophysiologically. This study examines cone-rod interaction using standard ERG under special conditions in normal humans and patients with congenital absence of cones (ie, complete achromatopsia). All subjects were dark adapted for 15 minutes. A blue (467nm) flash (23 ft-L) ERG was obtained in the dark adapted state. The blue flash ERG was repeated with red ambient illumination (660nm, 550 ft-L). Dark adapted blue flash ERGs, which evoke primarily rod responses, showed robust responses in both normals and achromats. Ambient red illumination, which primarily activates the cone photoreceptors, caused an approximate 2/3 reduction in the blue flash ERG in normals. Achromats however, showed no reduction in blue flash ERG under red ambient illumination.

These results suggest active inhibition of rods by cones when cones are stimulated in normals. The blue flash responses were not decreased in achromats, who have normal rod function, which indicates that the red ambient light did not bleach the rod photopigment. Blue flash responses in achromats were not decreased because achromats do not have cones. Thus, this mechanism is different from the inactivation of rods by bleaching of rhodopsin and may help explain why patients with cone dysfunction (eg. achromatopsia) are photophobic.

ELECTROPHORETIC ANALYSIS OF PROTEINS OF THE TROUT SACCULAR OTOLITHIC MEMBRANE. K.M. Khan* and D.G. Drescher. (SPON: J.A. Kaltenbach) Lab. of Bio-otology, Wayne State Univ. Sch. of Med., Detroit, MI 48201.

The ultrastructure of the otolithic membrane has been described for various vertebrate species. However, the chemical composition and properties of this entity are virtually unknown. We have analyzed proteins of the otolithic membrane of the trout saccule (considered to be an organ of hearing in fish) by SDS-PAGE. Endolymphatic sacs were dissected and placed in cold trout saline. The lateral saccular walls were excised, the otoliths removed, and the otolithic membranes carefully peeled from the sensory epithelium. Ten membranes were pooled and homogenized in 100 μl SDS buffer (62.5 mM Tris chloride, 2.3% SDS, 12.5% glycerol, 5% 2-mercaptoethanol, pH 7.0). Nine major proteins were detected in the homogenate, with molecular weights ranging from 35 to >300 kDa. Periodic acid-Schiff staining of gels indicated that the 43, 94, 100, and 160 kDa bands were glycoproteins. Lectin binding on western blots further suggested that the 53 and 65 kDa bands may be glycoproteins. Incubation of blots with collagen type II antibodies suggested that the 94 kDa band was collagen type II or a related protein. The general similarites in chemical composition of the trout saccular otolithic membrane and the mammalian tectorial membrane are consistent with the theory that the two structures may perform similar functions. Supported by NIH Grant NS 16166 to DGD.

MEMBRANE CURRENTS IN DISSOCIATED HAIR CELLS FROM THE INNER EAR OF *RANA PIPIENS*. E.E.Serrano and P.M. Narins. Dept. of Physiology and Dept. of Biology, University of California, Los Angeles, CA 90024.

We are interested in the effects of temperature on membrane properties of hair cells from the frog, *Rana pipiens*. In these ectothermic animals, changes in daily core temperature of 20°C are not uncommon. We have used the patch clamp technique in the whole cell configuration to characterize the membrane currents normally present in these cells. Hair cells were mechanically dissociated from the sacculus after sequential treatment with a)0.05% papain in low-divalent saline (LDS) for 5 min b)0.1% bovine serum albumin in LDS for 1 hour. Standard patch clamp technique was used to obtain recordings from dissociated hair cells at 12°C. We observed the following currents under voltage clamp in the saccular hair cells: inward current at potentials more positive than -30 mV; a fast transient outward current; delayed outward current; delayed inward current at potentials more negative than -70 mV. We noted that while all cells contained the inward and delayed outward current, the delayed inward and fast transient outward current were present in a subpopulation of hair cells. We examined the effect of temperature on the delayed outward current. Outward current magnitude increased with temperature with a Q_{10} of 2.0 to 2.5 in the temperature range 12-24°C. COCHLEAR CYTOGENESIS AND MIGRATION VISUALIZED THROUGH PULSE LABELING OF CHICK EMBRYOS IN CULTURE. A. Katayama and J.T. Corwin. Depts. of Neuroscience and Otolaryngology, University of Virginia Med. Ctr., Charlottesville, VA 22908.

Cytogenesis in the cochlear sensory epithelium in chickens was investigated through pulsed ^{3}H-thymidine (^{3}H-TdR). Embryos were removed from their shells at E3, and cultured in petri dishes until E7, when ^{3}H-TdR was injected i.v. via a glass micropipette. This method resulted in a fast systemic delivery and clearance of the DNA precursor as shown by measurements of total tritium and ^{3}H-TdR in plasma. Many progenitor cells in this organ are in the synthesis (S) phase at E7. The fates of those cells were determined by examining cochleae from embryos fixed for autoradiography after progressively longer survival periods (between 0.5 and 192 hr) following the pulse.

Preliminary results indicate that heavily labeled nuclei are mainly in the basal two thirds of the thickness of the sensory epithelium 30 min. after ^{3}H-TdR injection. These cells incorporated ^{3}H-TdR in S phase, and remained in S phase or proceeded to the G2 phase by the time of fixation. Longer survival periods allowed the cells to proceed further in the cell cycle; label started to appear in the nuclei at the luminal surface, where mitotic figures were occasionally observed. These observations suggest that the nuclei of proliferating cells synthesize DNA while in the basal strata, then migrate through the thickness of the sensory epithelium toward the luminal surface and divide. This intermitotic migration of the cell nuclei is similar to that observed in cytogenesis in the neural tube.

Across the basilar papilla, the spatial pattern of unlabeled cells observed minutes and hours after pulse labeling at E7 is very similar to the pattern observed after cumulative labeling of mitotic cells from E7 to E15 (Katayama, A and Corwin, J. T., J. Comp. Neurol., 281:129, 1989). New hair cells and supporting cells do not invade the space already occupied by older postmitotic cells, instead they differentiated in the same areas where they were produced.

REGENERATED HAIR CELLS CAN ORIGINATE FROM SUPPORTING CELL PROGENY: EVIDENCE FROM LASER ABLATIONS, ACOUSTIC TRAUMA, AND DNA LABELING. J.T. Corwin, J.E. Jones, K.J. Balak, and D.A. Cotanche. Depts. of Neuroscience and Otolaryngology, Univ. of Virginia Med. Ctr., Charlottesville, VA 22908.

We have reported that supporting cell mitoses can give rise to new cells that differentiate as hair cells during regeneration, but that has been challenged. Here we present additional evidence.

In one series of experiments, chickens were exposed to 40 hrs of acoustic overstimulation followed by a varied length of recovery and administration of ^{3}H-thymidine shortly before fixation. The earliest thymidine labeling of nuclei was found at the sites of acoustic lesions in cells beneath the basilar membrane, in cells at the inferior edge of the epithelium, and in the supporting cells. Later labeling involved both supporting cells and hair cells at those sites. In some lesions early labeling was clearly restricted to the supporting cell strata.

In another series of experiments, a laser microbeam was used to cleanly and individually kill all of the hair cells in identified lateral line epithelia in the tails of anesthetized axolotl salamander larvae. Individual 3 ns pulses of 355 nm (UV) wavelength from a neodymium-YAG laser were sufficient to kill hair cells without causing noticeable damage to surrounding cells. After the laser ablation these epithelia contained only supporting cells, but they still regenerated hair cells. Regeneration was monitored by a series of procedures, which included nearly continuous time-lapse video microscopy from the time of ablation through to the time of new hair cell formation.

We conclude that epithelia that are capable of regenerating hair cells contain differentiated cells that respond to trauma-induced changes in the sensory epithelia by reentering the mitotic cycle. Supporting cells are one of the cell types that can serve as multipotent progenitors producing progeny that can differentiate as replacement hair cells.

THE FORMATION OF MATURE KINOCILIA IN AMPHIBIAN HAIR CELLS. C.K.Ochiai*, M.W.Kelley* and J.T.Corwin. (SPON: N. Lenn) Depts. of Otolaryngology and Neuroscience, Univ. of Virginia Med. Ctr., Charlottesville, VA 22908.

In the bullfrog sacculus, new hair cells are added at the edge of the sensory epithelium. The cilia bundles of cells in this region differ from more centrally located cells in the size, spacing and length of their stereocilia and in the size of their kinocilia. Over time, these immature cells develop the morphology of the central, mature cells. Two of the morphometric changes that occur during this development are growth of the kinocilium and the formation of a kinociliary bulb. We have hypothesized that kinocilium growth is followed by kinocilium shortening, and that the kinociliary bulb forms as a result of depolymerization of microtubules at the apical end of the kinocilium during this (shortening) phase of maturation.

In order to investigate this hypothesis, sacculi from adult bullfrogs were removed and prepared for scanning electron microscopy. The length of the kinocilium and the width of the bulb were measured and plotted against the length of the longest stereocilia for 82 cells.

The results indicate that kinocilium length changes biphasically. An initial, apparently rapid, growth phase is followed by shortening of the kinocilium. Increase in kinocilium bulb width correlates with shortening of the kinocilium length. A linear relationship exists between increasing bulb width and increasing stereocilia length.

These findings indicate that kinocilia develop biphasically. They are consistent with the hypothesis that increasing bulb width results from an accumulation of cytoskeletal elements during the kinocilium shortening phase. It seems likely that this shortening results from depolymerization of microtubules at the apical end of the kinocilium.

89.6

HAIR CELL STEREOCILIA BEND AT THEIR BASES AND TOUCH AT THEIR TIPS. D.P. Corey, N.Hacohen*, P.L. Huang and J.A. Assad. Massachusetts General Hospital Dept of Neurology, Harvard Medical School, and Howard Hughes Medical Institute, Boston, MA 02114

If the tip-links hypothesis for hair cell transduction is correct, then a detailed description of the mechanics of the transduction elements requires a good understanding of the geometry of bundle motion. Two consistent but qualitative observations from direct visualization of moving hair bundles are that the stereocilia move as rigid rods that pivot at their bases, and that the bundle moves as a unit--*i.e.*, the stereocilia seem to stick together (Flock *et al*, 1977; Hudspeth, 1983).

We have used high-resolution video imaging of single bundles on dissociated bullfrog hair cells to quantify the relative movement of parts of the bundle, at a sensitivity of about 10 nm. These measurements are consistent with a geometrical model that follows from two assumptions: moving stereocilia bend at their bases and touch at their tips. The measurements are inconsistent with any appreciable degree of spreading or splay with displacement.

The geometrical model then makes two predictions: First, the tip links are mechanically in parallel and not in series, so they act as independent elements when the bundle is driven. Second, for a given displacement, the stretch on the tip link is nearly the same for all links, so they receive identical stimuli. These consequences greatly simplify biophysical analyses.

The model also provides a geometry factor, γ, relating tip-link stretch to bundle displacement, which is 0.1 relative to the tip of the bundle or about 0.14 relative to the bulb of the kinocilium, confirming the calculation of Howard *et al.* (1988) from a similar model.

89.7

MECHANICAL AND ANATOMICAL CORRELATES OF OUTER HAIR CELL VULNERABILITY. B.N.Evans * (SPON:P.Dallos). Dept. of Neurobio. and Physiol., Northwestern U., Evanston Il, 60201.

A hallmark of outer hair cell (OHC) morphology is the prominent cisternal complex associated with its plasma membrane. When "whole-organ" tissue is examined by conventional fixation techniques, the subsurface cisternae have a fenestrated appearance. As part of an on-going study of the structure/function relationships involved in hair cell motility, OHCs were isolated from guinea pig cochleae with mild enzymatic and mechanical treatments (Brownell et al., Science:1984, 227, pp.194-196). The cells were fixed and prepared for electron microscopy. An unexpected finding was the occasional occurrance of multiple, non-fenestrated cisternae lining the perimeter of the cytoplasmic compartment.

To examine whether the non-fenestrated form more closely represents the morphology of this complex under in-vivo conditions, individual cells were recovered following mechanical challenges induced by transmembranous application of electrical current waveforms. Peak displacements greater than 500 nm led to a slow decrease in the resting length (10-20%) of cells and as well as a loss in movement threshold sensitivity and response asymmetry. The ultrastructural correlates of recovered cells revealed vesiculation patterns which were graded with the magnitude of the change in their resting length. Such findings suggest that the "fenestrated" system may be an artifactual remnant of a more highly organized and non-fenestrated network in-vivo.

GADOLINIUM IONS REVERSIBLY BLOCK VOLTAGE DEPENDENT MOVEMENTS OF ISOLATED OUTER HAIR CELLS. J. Santos-Sacchi* (SPON:H. Sapru), Laboratory of Otolaryngology, UMDNJ - New Jersey Medical School, Newark, NJ, 07103.

Whole cell voltage clamp was used to study the voltage dependent changes in the length of outer hair cells (OHC). OHCs were non-enzymatically isolated from the the guinea pig organ of Corti, and were placed in a chamber containing modified Leibovitz medium (NaCl 137 mM, KCl 5.37 mM, $MgCl_2$ 1.8 mM, $CaCl_2$ 1.25 mM, glucose 5 mM, HEPES 5 mM, pH 7.0-7.2). In Ca++-free media EGTA (1 mM) replaced Ca++. Cells were perfused via a multi-barreled pipette with various test solutions. Patch electrodes contained 140 mM KCl or CsCl, 2 mM $MgCl_2$, 1, 5, or 10 mM EGTA, and 5 mM HEPES pH 7.0- 7.2. Giga-ohm seals were made at the nuclear level on OHCs prior to cell entry. Under voltage clamp, cells were held near -70 n.V and stepped to hyperpolarized and depolarized potentials for 200 msec, and current records saved for analysis. Simultaneous video recordings at 2000x were made and the mechanical movements of the cuticular plate were subsequently measured with a differential optoresistor off the monitor.

OHCs exhibit an outward rectification upon depolarization which is carried by K+. The outward current can be blocked by a variety of treatments, including intracellular Cs, or extracellular 20 mM TEA, 20 mM 4- AP, 10 mM Ba++, 1 mM Cd++, or 0.5 mM Gd+3. Intracellular CsCl unmasks an inward Ca++ current which peaks at potentials of + 30 to +40 mV. Although 200 nM ChTX blocks some of the outward K+ current, Ca++ - free media is ineffective. This suggests that an intracellular store of Ca++ is responsible for the activation of Ca++ - activated K currents.

OHCs contract when depolarized from the holding potential. Responses as large as 29 nm/ mV have been observed. The average response is 15 nm/ mV in the depolarizing direction, but hyperpolarization causes an elongation which rapidly saturates above the holding potential; above -70 mV the response is about 2 nm/mV. All treatments which block the various currents in OHCs do not interfere with the mechanical responses, except Gd+3. Gadolinium rapidly and reversibly reduces or abolishes OHC contractions due to depolarization, and its effect is probably not due to an ionic current block as none of the other blocking agents were effective. It is interesting to note that gadolinium is a potent blocker of stretch activated channels which also are voltage activated, and that recent evidence indicates that stretch activated channels exist in the OHC lateral membrane.

EVIDENCE FOR KAINIC ACID RECEPTOR ON NON-NEURONAL CELLS IN THE FROG LABYRINTH. C.J. Dechesne, D.R. Hampson, G. Goping*, K. Wheaton* and R.J. Wenthold Lab. Mol. Otology, NIDCD, NIH, Bethesda, MD 20892.

In previous studies, we examined the presence of kainic acid (KA) receptor (KAR) in the frog utricle using monoclonal and polyclonal antibodies against purified KAR isolated from frog brain (Hampson et al, in prep). The results (Neurosci Abst, 321.10, 1988) showed immunostaining of afferent terminals making synapses with hair cells. In addition, oblong fibroblast-like (Flo) cells, situated in the inner ear connective tissue, were intensely stained on their cytoplasmic membranes. Here, we further investigate the presence of KAR in these cells.

Three sets of experiments were performed on frog inner ear. 1) Immunoblots of 1- and 2-dimensional gels, with monoclonal and polyclonal antibodies, 2) 3H-KA binding studies with in vitro autoradiography 3) Neurotoxic effects of in situ injections of KA.

On immunoblots, immunoreactive proteins were detected, with both types of antibody, at the same isoelectric point but slightly different molecular weight than the purified KAR. High density of 3H-KA binding was observed in connective tissue of the inner ear. Flo cells showed signs of degeneration after injections of 10μM KA. The presence of KAR on Flo cells is then confirmed but its role at this location remains hypothetical.

LASER DOPPLER VIBROMETER MEASUREMENTS OF BASILAR MEMBRANE MOTION IN THE GUINEA PIG. Alfred L. Nuttall, David F. Dolan, and Gopal Avinash, Kresge Hearing Research Institute, The University of Michigan Medical School, Ann Arbor, MI 48109.

Basilar membrane (BM) motion has previously been studied using five different methods; Optical microscopy, Mössbaurer velocimetry, capacative probe, laser speckle, and laser interferometry. Each of these methods had major drawbacks concerning the difficulty of placing objects on the basilar membrane (their areal size, mass, or toxicity), keeping the analysis area small, or maintaining cochlear hydromechanical integrity. We present here a new approach which solves most of these problems. Using an optical compound-microscope, the laser beam of a laser Doppler vibrometer (Polytec OVF1000) was focused to a diffraction limited spot. The focused beam was directed onto a 10-15 micrometer solid glass bead which was previously gently placed on, and sticks to, the basilar membrane. Placement of the microbead and visual observation to focus the laser beam are done through a 0.5 mm diameter hole made in the bony wall of the cochlea. The hole in the cochlea and the microbead do not cause obvious inner ear sensitivity change. Isodisplacement functions at 0.5 nanometer were obtained for the frequency variable. These functions showed appropriate frequency tuning as has been shown by previous studies. Intensity functions of displacement vs. sound level showed compressive-type nonlinear behavior at frequencies near the best or characteristic frequency for the measured location on BM (about 17 kHz). Qualitative observations of both propagated intermodulation traveling waves and an apparent slow shift in BM position during sound stimulation were made. The method offers the important advantage of multiple point measurements of basilar membrane vibration. *(Supported by NIH grant #NS15107)*

SPONTANEOUS OTOACOUSTIC EMISSION INCIDENCE IN HUMAN EARS: GENDER DIFFERENCES AND BILATERAL SYMMETRY. M.L. Whitehead* (SPON: G.K. Martin). Dept. of Otolaryngol. and Communicative Sci., Baylor Col. of Med., Houston, TX 77030.

Strickland et al. (*J. Acoust. Soc. Am.*, 78:931-935, 1985), in a survey of both ears of 50 prepubescent children, found a similar incidence of spontaneous otoacoustic emissions (31% of ears possessed SOAEs) to that previously reported for adults using similar microphones. They also reported that significantly more female than male children possessed SOAEs (52% vs. 24%, a ratio of 2.2:1). Their data further demonstrates a clear correlation of the number of SOAEs detected in the two ears of each emitting subject ($r=0.76$, $p<0.001$). These findings may be interpreted as evidence for a genetic involvement in the determination of SOAE incidence. To explore this possibility further, both ears of 38 normally hearing adults (mean age 24.7 yrs) were surveyed for SOAEs with a custom-modified, low-noise microphone (Wilson, J.P. *J. Physiol.*, London, 298:8-9P, 1980). A mean of 3.7 SOAEs per emitting ear were found in 50% of ears. This incidence is significantly greater than that reported by Strickland et al. However, there was no significant difference between the two studies after correction for the lower noise-floor of the present microphone system. Significantly more female than male subjects possessed SOAEs (77% vs. 38%, a ratio of 2.0:1). There was a clear correlation of the number of SOAEs detected in the two ears of each emitting subject ($r=0.63$, $p<0.005$). These findings provide further support for the hypothesis of a genetic involvement in the determination of SOAE incidence by corroborating in adults the gender difference and between ear correlation of SOAE incidence described in prepubescent children.

90.3

RESPONSES OF THE MAMMALIAN COCHLEA TO WAVEFORM SINGULARITIES. E.R.Lewis and K.R.Henry*. Electronics Research Lab., Univ. of Calif., Berkeley, CA 94720 and Dept. of Psychology, Univ. of Calif., Davis, CA 95616.

Whenever an acoustic waveform either begins or changes its trajectory, there will be an abrupt change either in sound pressure or in one or more of the time derivatives of sound pressure. The resulting singularity in the acoustic waveform has the potential of being a precise timing cue for acoustic image processing. Waveform singularities are ubiquitous among biologically significant sounds, such as footfalls and vocalizations. Appropriate filters, with high-order dynamics, can respond selectively to singularities; and over a bank of such filters, variously tuned, different singularities will produce different signatures (Lewis, E.R. and Henry, K.R., *Hearing Res.* 37:219, 1989). The typical mid- and low-frequency filter channels of the cochlea are especially well suited to this task. In an experimental study to determine whether or not the cochlea of the gerbil (*Meriones unguiculatus*) is selectively responsive to singularities, we employed ramp-modulated sine waves with stepwise changes in the first or second time derivatives of sound pressure. We report that these singularities can trigger nearly synchronous spikes over substantial populations of afferent axons, and that markedly different populations are excited by different singularities. Thus, in addition to its celebrated role as frequency analyzer, the cochlea is an excellent analyzer of temporal events.

ALDOSTERONE MEDIATES AN INCREASE OF INNER-EAR OUABAIN BINDING SITES. T.P. Kerr*, D.Z. Pitovski* and D.G. Drescher. Lab. of Bio-otology, Dept. of Otolaryngology, Wayne State Univ. Sch. of Med., Detroit, MI 48201

The various chambers of the membranous labyrinth contain endolymph, an extracellular fluid with high $[K^+]$, low $[Na^+]$, and a positive DC potential. These properties are thought to be maintained by active transport mechanisms in which the enzyme Na^+, K^+-ATPase participates. We have isolated inner-ear tissues of Hartley guinea pigs by microdissection. The specimens were then incubated with ^3H-ouabain (a specific Na^+, K^+-ATPase inhibitor), and binding was normalized to tissue dry weight. Scatchard analysis of cochlear lateral wall from normal animals revealed a single population of ouabain binding sites, with K_d of 2.82 uM. We hypothesized that aldosterone ("aldo," a mineralocorticoid hormone) might increase the population of Na^+, K^+-ATPase sites. Therefore, guinea pigs were maintained on a high Na^+/low K^+ diet for 4-5 days (to suppress endogenous aldo secretion). Twenty-two hours prior to sacrifice, the experimental group received an aldo injection (10 ugm/100 gm); paired controls were sham-injected. At 5 uM ^3H-ouabain concentration, binding in ampullae from the aldo group was 171% higher than controls (but failed to attain statistical significance with the sample size employed). Binding in lateral wall of the basal cochlear turn from the aldo group was 127% higher than controls (p .05 by two-tailed t-test). EFFECTS OF ARGININE VASOPRESSIN ON COCHLEAR BLOOD FLOW IN THE NORMOTENSIVE RAT. Grant M. McLaren*, H.A. Dengerink, and John W. Wright.(SPON: J. Wright). Washington State University, Pullman, WA.,99164. Previous studies in our laboratory have revealed modifications of cochlear blood flow (CoBF) measurements via laser Doppler flow meter following both intra-arterial and local infusion of the neuroactive hormone arginine vasopressin (AVP)(Laugel et al.,1988). To test the hypothesis that AVP would yield dose-dependent alterations in CoBF, ten minute intra-arter-ial infusions of 0, 0.1, 1, 10, and 100 pmol/50µl 0.15 M NaCl/ min were utilized in anesthetized male adult Sprague-Dawley (SD) rats. Results indicate that systemic blood pressure (BP) responds to AVP in a dose-dependent fashion. Significant changes in CoBF were observed only in animals that received the 100 pmol/min AVP infusion while animals that received doses at and below 10 pmol/min evidenced significant elevations in BP but no alterations in CoBF. Laser Doppler measurements of skin blood flow (SBF) were conducted in eight additional SD rats that received the intra-arterial infusions of AVP (10 pmol/min for ten min). Significant elevations in BP and decreases in SBF were observed under these experimental conditions.

Dose (pmol AVP)	ΔBP(mm Hg)	ΔCoBF(%)	ΔSBF(%)

DISTRIBUTION OF FIBRONECTIN IN THE RAT COCHLEA DURING INNER EAR DEVELOPMENT. N. K. Woolf, F. J. Koehrn* and A. F. Ryan. Division of Otolaryngology, UCSD Medical School and Veterans Administration Medical Center, La Jolla, CA 92161.

Fibronectin stimulates the growth of neuronal processes in many neural systems by altering cell surface adhesive properties. Immunocytochemistry was employed to document the distribution of fibronectin in the inner ear of Sprague-Dawley rats from embryonic day 8 (E-8) to post-natal day 120 (P-120).

From E-20 to P-4, dense fibronectin immunoreactivity was observed immediately beneath the cochlear hair cells. At E-20, this reactivity was restricted primarily to the region beneath the inner hair cells. At P-0 to P-4, reactivity was observed beneath both outer and inner hair cells. Immunoreactivity beneath hair cells was not present or was much less intense at other ages. During the developmental period from E-20 to P-4, the region beneath the cochlear hair cells is being actively innervated by both afferent and efferent nerve fibers. The results of the present study suggest that fibronectin is positioned to play a role in guiding and regulating neural outgrowth within the developing organ of Corti.

NIMODIPINE, A CALCIUM CHANNEL ANTAGONIST, REVERSES THE SUMMATING POTENTIAL. R.P. Bobbin, P.J. Jastreboff, M. Fallon* and T. Littman*. Kresge Hearing Res. Lab., LSU Med. Cntr., New Orleans, LA 70112; Dept. of Surgery, Yale Univ., New Haven, CT 06510.

This study examined the effect of nimodipine (BAY E 9736; Miles), an L-type of calcium channel antagonist on cochlear potentials recorded from anesthetized guinea pigs. Perilymph spaces of guinea pig cochleae were perfused with Ringer solutions containing up to 10 µM concentrations of nimodipine at a rate of 2.5 µl/min for 10 min. Immediately after each period of perfusion the compound action potential of the auditory nerve (CAP), cochlear microphonics (CM) and the summating potential (SP) evoked by 10 kHz tone bursts of varying intensities were recorded from a wire inserted in the basal turn scala vestibuli. Nimodipine suppressed the CAP at about 0.1 µM and the CM and SP at 0.3 µM. SP evoked by low intensity tone bursts (62 dB SPL) changed from negative to positive at 3 µM nimodipine. At higher intensity (98 dB SPL) the positive SP induced by nimodipine remained while a negative SP reappeared during the positive SP. L-type calcium channels appear to be involved in hair cell function and generation of the negative SP.

SENSORINEURAL HEARING LOSS AND TEMPORARY THRESHOLD SHIFTS IN AN ANIMAL MODEL OF CALCITONIN INDUCED HYPOCALCEMIA, HYPERMAGNESEMIA AND HYPERPHOSPHATEMIA. A.M. Shapiro*, C.L. Campese*, A.T. Cacace* S.M. Parnes* and N.L. Strominger (SPON: L. Nelson). Depts. of Surgery and Anatomy, Albany Medical College, Albany, N.Y. 12208.

Hypocalcemia induced sensorineural hearing loss is thought to involve active processing at the cellular level. Immunoreactive synthetic salmon calcitonin (iCT) was used to produce temporary threshold shifts (TTS) in the New Zealand white rabbit which correlated with maximal decreases in serum calcium (Shapiro et al., Assoc. Res. Otolaryn., 98, 1989). We have now studied this effect prospectively in four macaque monkeys utilizing intravenous iCT. Similar to the rabbit, decreases in serum calcium correlated with increases in auditory thresholds during the first 14 days post-iCT administration determined by brainstem auditory evoked potentials (BAEPs). Temporary threshold shifts, approx 28 dB, were maximal between one and two hrs post-iCT infusion. Increases in phosphate and magnesium were consecutive with the observed calcium decreases, supporting a possible role for these divalent ions.

DOSE-DEPENDENT SERUM CALCIUM DECREASE AFTER SALICYLATE. P. J. Jastreboff, R. Hansen* and C. T. Sasaki. Dept. of Surgery, Yale Univ. Sch. of Med., New Haven, CT 06510.

Salicylate administration results in increased hearing threshold and tinnitus but mechanisms of its action remain unknown. After salicylate, used to induce tinnitus in rats, decreased serum and CSF calcium levels were observed. Since modification of cochlear calcium might cause changes in auditory nerve activity, salicylate's effect on calcium in serum was investigated initially. Pigmented rats were injected i.p. with sodium salicylate in doses 57-350 mg/kg. Blood was taken from the tail just before and 2 h after injection, and salicylate and total calcium were evaluated.

Salicylate level was linearly dependent on the dose injected and ranged from 15 to 60 mg/dL. Salicylate resulted in a significant decrease of calcium ($p<0.01$) to about 90% of control values for the highest doses used. Nonlinear regression analysis revealed that this decrease was significantly related to the dose injected and to salicylate level in serum. Interestingly, calcium levels exhibited rapid decrease once serum salicylate levels rose above 20 mg/dL, corresponding to the threshold level for evoking tinnitus in humans, followed by a plateau reached for salicylate levels of about 40 mg/dL. The results suggest the possibility of calcium-related mechanisms of salicylate action on the cochlea, since a correlation between changes of calcium level in serum and in CSF has been reported. (Supported by NIH Grant NS22024)

THE LATERAL OLIVOCOCHLEAR SYSTEM IN RATS AS REVEALED BY CHOLERA TOXIN-HRP. D.E. Vetter and E. Mugnaini, Lab. of Neuromorphology, Univ. of Conn., Storrs, CT. 06269-4154.

HRP conjugated to cholera toxin B chain (CT-HRP) is an excellent neuroanatomical tract tracer that produces distinct delineation of the dendritic arbors of retrogradely labelled neurons. Using CT-HRP, we have re-examined the olivocochlear (OC) system in adult rats and found that the lateral OC system is more complex than originally presumed. There are at least two lateral OC neuron groups that differ in the size and location of the cell bodies and in dendritic features. Small spherical cells, 12-13um in diameter, are located primarily in the body of the lateral superior olive (LSO). Large fusiform cells, 20um in long diameter, are located in the fiber capsule surrounding LSO, and rostrally they merge into RPO. Small OC cells generally have dendritic arbors perpendicular to the LSO turns, but in the tips of the LSO limbs, the cells exhibit curving dendrites. The dendrites of small cells do not extend beyond LSO borders. The large OC neurons have straight, long, and thick dendrites, some of which project into LSO. CT-HRP intracochlear injections consistently reveal over 400 lateral OC neurons in the superior olive ipsilateral to the injected cochlea. Few medial OC cells are revealed after intracochlear CT-HRP injections, possibly reflecting a paucity of binding sites for the CT B-subunit on the medial system OC terminals.

90.11

INNERVATION OF THE DEVELOPING COCHLEA *IN VIVO AND IN VITRO* AS REVEALED BY GAP-43. H.M. Sobkowicz, M.R. Emmerling*, and D.J. Schreyer. Dept of Neurology, Univ. of Wisconsin, Madison, WI 53706 and Dept of Neurobiology, Stanford Univ. School of Medicine, Stanford, CA 94305.

Monoclonal antibody to GAP-43, a protein associated with growing nerve fibers, was used to study immunocytochemically the innervation of the intact and cultured cochlea from ICR mice. GAP-43-like immunoreactivity *in vivo* is present in the spiral ganglion cells and their growth cones on embryonic day 13 (E13); on E16 in radial bundles; and on E18 in radial bundles, in neurofibrillar cups on inner and outer hair cells, in inner spiral plexus and bundle, in tunnel fibers, and in three outer spiral bundles. The staining in the 1-day old fades away, but reappears in the 2 to 3-day old in endings around the inner hair cells and the inner spiral bundle. From 4 to 10 days, GAP-43 in the inner spiral bundle disappears and is expressed mainly in neurofibrillar cups on the outer hair cells of the 1st and 2nd rows, and finally of the 3rd row. By 10 days, GAP-43 is re-expressed in part of the inner spiral bundle, the only structure that stains in the adult. Comparing GAP-43 stainings with that of efferents by AChE and of afferents by neurofilament antibody suggests that GAP-43 is transiently expressed in the afferents mostly prenatally and in the efferents early postnatally. The apparent perinatal loss of GAP-43 staining in the afferents may be reversed in culture. GAP-43 may be induced by mechanical injury or by treatment with the ototoxic drug gentamicin both in free-growing and synaptically engaged fibers. The free growing fibers express GAP-43 distally, but in synaptically engaged fibers, growing by elongation, GAP-43 is expressed proximally. Thus early postnatally, spiral ganglion cells are able to synthesize GAP-43 for growth and repair. (NSF Grant BNS-8719716 and NIH-NINCDS NS26513-01)

90.12

DEGENERATION OF EFFERENT TERMINALS IN THE CHINCHILLA COCHLEA BY A CHOLINERGIC NEUROTOXIN. Barbara J. Morley, Kevin Spangler, Bobbie L. Schneider*, and Eric Javel. Boys Town National Institute, Omaha, NE 68131 and the Department of Anatomy, Creighton University Medical School, Omaha, NE 68178.

Ethylcholine aziridinium ion (AF64) is a choline analog that blocks high-affinity choline transport in cholinergic neurons and produces specific degeneration of cholinergic terminals and axons. The effects of AF64 are biphasic, producing specific effects on cholinergic terminals at low concentrations (<22 μM) and non-specific effects at higher concentrations (Amir, A. et al., *Brain Res.* 454:298, 1988).

For these studies, chinchillas were anesthesized and the cochlear fenestrae were exposed. A solution of 1 μM of AF64 diluted in artificial perilymph was infused through the cochlear scalae. Control animals were injected with artificial perilymph only. Seven days after the infusion the animals were anesthesized and perfused with mixed aldehyde fixative. The cochleas were removed and processed for transmission electron microscopy.

Organs of Corti in AF64-treated animals exhibited loss of synaptic terminals in the region of the inner spiral bundle while many thin, presumably efferent axons remained in both the inner and tunnel spiral bundles. Preliminary observations indicate that only lateral efferent terminals degenerated. These results indicate that AF64 could be a useful pharmacological agent in studying cholinergic efferent terminals in the cochlea.

This research was supported by grants from the Deafness Research Foundation (KS), State of Nebraska (BJM), and NIH (EJ).

EFFECTS OF PURE TONE ACOUSTIC TRAUMA ON COCHLEAR WHOLE-NERVE RESPONSES TO ELECTRICAL STIMULATION OF THE CROSSED OLIVOCOCHLEAR BUNDLE. D.F. Dolan* and A.L. Nuttall, (SPON: S. Shore). Kresge Hearing Research Hearing Institute, Univ. of Mich. Med Sch., Ann Arbor, MI 48109.

Acoustic overstimulation is known to produce either temporary (TTS) or permanent threshold shift (PTS). The acoustic overstimulation has differential effects on the inner (IHC) and outer hair cells (OHCs) depending on stimulus duration and intensity. Electrical stimulation of the crossed olivocochlear bundle (COCB) reduces the cochlear whole-nerve response (CAP) to low to moderate acoustic stimuli also by differential effects on hair cells. In this study we present data on the effects of electrical stimulation of the COCB on the CAP to tone bursts after acoustic trauma.

Anesthetized guinea pigs were surgically prepared for placement of a round window (RW) recording electrode and stereotaxic placement of a bipolar stimulating electrode at the floor of the 4th ventricle. Acoustic overstimulation, in the form of pure tones, were presented from 90 - 120 dB SPL for 1.0 to 10.0 minutes. When overstimulation produced only small changes in sensitivity less than 20dB (3-15 dB), there was either a similar (proportional) change in the effects of COCB activity or an increase in CAP reduction amounting to 3-8 dB in excess of control levels. Similarly short, intense overstimulation, producing changes in sensitivity greater than 20dB, tended to cause little or no effect on COCB action. Long duration, less intense overstimulation producing changes in sensitivity greater than 20dB tended to reduce the effect of COCB activation. The results will be discussed in terms of possible anatomical cites of damage. (Supported by NIH grant #NS15107).

90.14

DEVELOPMENTAL CHANGES IN THE CHARACTERISTIC FREQUENCY OF SINGLE SPIRAL GANGLION NEURONS AT A FIXED LOCATION WITHIN THE MAMMALIAN COCHLEA. S.M. Echteler, E.M. Arjmand* and P. Dallos. Auditory Physiology Lab. and Dept. of Neurobiol. and Physiol. Northwestern Univer., Evanston, IL 60208.

To ascertain the process by which the mammalian cochlear frequency-place map develops, we have examined the emergence of frequency tuning in single spiral ganglion neurons. Recordings were made at a constant location within the basal cochlea in an age-graded series of anesthetized Mongolian gerbils.

Our surgical approach to the spiral ganglion was patterned after that of Robertson and Manley (J. Comp. Physiol. 91:363, 1974). Frequency tuning curves were obtained from individual spiral ganglion neurons with a computer-automated paradigm. Following electrophysiological characterization, neural recording sites were marked by iontophoretic injection of horseradish peroxidase.

We find that between postnatal days 14 and 17, neural tuning curves measured from gerbil cochlear neurons supplying the same region of the organ of Corti (3.0 mm $\pm$ 200 μm from the basal end of the basilar membrane) undergo a systematic increase in characteristic frequency (CF) from 7.3 to 16.5 kHz. During this same time period, neural threshold at CF decreases by 80 dB. As cochlear length is fully developed in the gerbil by postnatal day 12 and functional maturation of the gerbil middle ear is essentially complete by postnatal day 14 (Woolf and Ryan, Hearing Res. 35:131, 1988), our findings provide direct support for the hypothesis that mature tonotopy arises within the inner ear through changes in the spatial encoding of frequency along the cochlear duct (Rubel and Ryals, Science, 219:512, 1983; Harris and Dallos, Science, 225:741, 1984). (Supported by NIH grant NS08635).

90.15

ACOUSTIC NEURONS AND THEIR PAPILLAR INNERVATION PATTERNS IN THE FROG: AN HRP STUDY. D. D. Simmons[1] and P. M. Narins[2]. [1]Natural Science Division, Pepperdine University, Malibu, CA and [2]Dept. of Biology, UCLA, Los Angeles, CA.

Horseradish peroxidase injections were made into the eighth nerve of the frog *Rana pipiens*. These injections retrogradely labeled ganglion neurons in both divisions of the eighth nerve. The anterior branch of the nerve innervated vestibular organs and the posterior branch innervated two distinct acoustic organs: the amphibian papilla (AP) and the basilar papilla (BP).

In the ganglion, all labeled neuronal somas had bipolar cell shapes. Acoustic GCs had the smallest average soma areas (roughly 120 μm^2) and, near the cell body, had dendritic (Dp) fibers that were much thinner than axonal (Dc) fibers (Dc/Dp ratio > 2). Vestibular GCs had larger average soma areas (> 250 μm^2) and roughly equal diameter dendritic and axonal fibers.

In the AP and BP, labeled fibers demonstrated different patterns of innervation. Labeled fibers terminating in the caudal-most region of the AP were thin (< 0.7 μm in diameter), and traveled long distances (> 1 mm) whereas fibers terminating in the rostral-most region tended to be thicker (up to 1 μm), traveled shorter distances, and were more highly branched. Fibers in the BP were more homogeneous: they traveled relatively short distances (< 0.5 μm) underneath the supporting cells before rising to terminate directly on single hair cells. As of yet, no branching has been observed within the BP. Possible functional significance of these anatomical features will be discussed.

This research was supported by grants [1]BNS 8719610 (NSF), a grant from the Ralph M. Parson's Foundation, and [2]NS 19725 (NIH).

ISOINTENSITY TONAL RESPONSES OF AUDITORY FIBERS IN THE GREEN TREEFROG (*Hyla cinerea*) AS A MEASURE OF SELECTIVITY TO COMPLEX SOUNDS. D.Lim* and R.Capranica. Section of Neurobiology and Behavior and School of Electrical Engineering, Cornell University, Ithaca, NY 14853.

At a fixed sound intensity, the firing rate in spikes/sec of a single auditory nerve fiber was measured as the tonal frequency was varied incrementally across the entire extent of the excitatory tuning curve, thus generating a spike rate contour as a function of frequency. A family of such isointensity contours was compiled at several different intensities within each fiber's tuning curve.

The isointensity contours fall into three distinct classes: (1) single-peaked profiles, (2) flat-shaped profiles, and (3) multipeaked profiles. For a single fiber, it's family of profiles represents a set of tonal response transfer functions from which a transfer matrix can be constructed. This matrix is characterized by a singular value decomposition method in which the fiber's selectivity in complex signal space can be predicted, namely it is most sensitive to signal components containing the highest singular values. Preliminary results using this approach to studies of encoding of complex sounds in the green treefrog's peripheral auditory system will be discussed. (Supported by NIH grant NS-09244.)

COCHLEAR DYSFUNCTION IN A TRANSGENIC MOUSE FAMILY. C.D. Katz*[1], S.J. Madors*[1], C.M. Henley*[1], P.A. Overbeek*[2], M. Kovak*[2], G.K. Martin[1], and B.L. Lonsbury-Martin[1] (SPON. A.C. COATS). [1]Dept. of Otolaryngol. Commun. Sci. and [2]Dept. of Cell Biol. and Howard Hughes Med. Inst., Baylor Col. of Med., Houston, TX 77030.

Transgenic mice were generated by microinjection of one-cell stage FVB/N mouse embryos with a construct containing the human beta-actin promoter and the bacterial neomycin resistance gene. When F1 mice from one (OVE7) of three transgenic families were inbred, nearly 1/4 of the offspring showed pronounced hyperactivity, head-bobbing, and circling. Further studies indicated that homozygous transgenic mice exhibited head-bobbing, while some heterozygotes were hyperactive and others were behaviorally normal. Cochlear activity was tested in control and heterozygous and homozygous OVE7 mice using response-growth functions (2-8 kHz, 30-85 dB SPL, 5-dB steps) of $2f_1$-f_2 distortion-product emissions (DPEs). Control mice showed normal DPE thresholds of ~37 dB SPL and maximum amplitudes in response to 75-dB SPL primaries of ~35 dB SPL at 6 and 8 kHz. In general, heterozygous mice displayed either normal or poor (thresholds >45, amplitudes ~20 dB SPL) DPEs that were relatively independent of their behavioral phenotype, while homozygous subjects had essentially no DPEs. For these latter mice, histologic examination of the cochlea indicated that inner-ear development was arrested at an early embryologic stage. Follow-up experiments are attempting to clone the transgenic insert from a genomic library so that the molecular basis of the suppression of inner-ear development in transgenic mutants can be established. RESISTANCE TO REPEATED PURE-TONE EXPOSURE IN ANESTHETIZED RABBIT. B.D. Mensh*[1,2], B.L. Lonsbury-Martin[1,3] and G.K. Martin[3]. [1]Div. of Neurosci., [2]Med. Sci. Tr. Prog. and [3]Dept. of Otolaryngol. Commun. Sci., Baylor Col. of Med., Houston, TX 77030.

Previous findings in our laboratory (Lonsbury-Martin et al., *Soc. Neurosci. Abstr.*, 18:1099, 1988) showed that repeated exposure of awake rabbits to moderate sounds resulted in reduced susceptibility to cochlear dysfunction that was measured physiologically using distortion product emissions (DPEs). The primary goal of the present work was to develop a "resistance" model in anesthetized rabbit so that experiments investigating the role of the cochlear efferent system could be performed acutely. The paradigm consisted of: (1) establishing baseline 2f1-f2 DPEs at the geometric-mean frequency (2.3 kHz) 1/2-octave above exposure, in response to 50-dB SPL primaries, (2) exposing the ear to 1.7 kHz at 100-dB SPL until 10-20 dB reductions in DPEs occurred, and (3) tracking recovery to within 2 dB of control DPE levels. For each animal, after the first exposure, the paradigm was repeated at regular intervals for 8-11 days. Exposing four rabbits demonstrated that repeated exposure initially decreased the susceptibility of the cochlea to the effects of loud sound. That is, the duration of the exposure needed to reach the criterion reduction in DPE magnitude increased. Further exposures eventually reversed this trend, probably due to cochlear damage. Future experiments in the acute "resistance" model will use pharmacologic, contralateral acoustic stimulation, and lesioning techniques to define the contribution that cochlear efferents make to the reduced susceptibility process. [EY02520, ES03500, DRF].

PEPTIDES: PHYSIOLOGICAL EFFECTS I

91.1

EFFECTS OF CHOLECYSTOKININ ON NEURONS OF CAT PANCREATIC GANGLIA. R. C. Ma* and J. H. Szurszewski. Dept. of Physiology and Biophysics, Mayo Medical School, Rochester, MN 55905.

Immunocytochemical studies have shown that cholecystokinin-like material is present in pancreatic ganglia. To study the effects of cholecystokinin octapeptide (CCK), intrapancreatic ganglia were pinned out in vitro and perfused with oxygenated Krebs solution (35°C). During intracellular recordings, CCK (10^{-4} M) was applied extracellularly by pressure ejection. Sulfated and desulfated CCK evoked a slow depolarization in 76 of 94 and in 29 of 36 cells, respectively. The mean (± SEM) depolarization was 6.5±0.5 mV and 6.8±0.8 mV, respectively. In 23 of 30 cells, both forms of CCK evoked similar changes in membrane potential. During depolarization evoked by both forms of CCK, membrane input resistance increased in 28 cells and decreased in 7. No change occurred in 13 cells. Hexamethonium and a low Ca^{2+} solution did not effect CCK induced changes in membrane potential and input resistance indicating a post-synaptic action. In 20 of 105 cells, both forms of CCK evoked periods (10 to 120 min long) of spontaneous activity which consisted of fast excitatory postsynaptic potentials and action potentials indicating CCK can also affect some neurons through presynaptic cholinergic terminals. In summary, sulfated and desulfated CCK can act at presynaptic and postsynaptic sites. (DK 17632.)

91.2

ELECTROPHYSIOLOGICAL EFFECTS OF CHOLECYSTOKININ ON AMYGDALA NEURONS. C. ROUILLARD, L.A. CHIODO and A.S. FREEMAN. Lab. of Neurophysiology, Center for Cell Biology, Sinai Research Institute and the Cell. & Clin. Neurobiology Prog., Wayne State Univ., Detroit, MI 48235.

Cholecystokinin (CCK) is found in high concentrations in the limbic system of mammalian CNS. Large numbers of CCK cell bodies and CCK-containing fibres are located throughout the amygdaloid complex. The effects of CCK-8S on amygdala neurons were studied using standard extracellular single-unit and iontophoretic recording techniques in locally anesthetized, gallamine-immobilized, artificially respired rats. Intravenous injection of CCK-8S (cumulative dose: 2-32 ug/kg) excited most of the amygdala neurons tested (8/10). In some of these neurons (n=4), the excitatory effect of CCK progressed to apparent depolarization inactivation as indicated by the widening of the wave form and the decrease of its amplitude even with relatively modest firing rates increases. CCK exerted an inhibitory effect on one cell and the last cell was not affected by the peptide. Iontophoretic application of CCK-8S produced similar results: the peptide excited 3 of the 6 cells tested, partially inhibited one and had no effect on the two other cells. These results strongly suggest that CCK acts as a neurotransmitter or a neuromodulator in the amygdaloid complex.

Supported by grants MH42136 (ASF), MH41557 (LAC) and Sinai Res. Inst.; CR is a FRSQ postdoctoral fellow.

91.3

CHRONIC INTRAVENTRICULAR ADMINISTRATION OF CHOLECYSTOKININ MARKEDLY REDUCES THE NUMBER OF SPONTANEOUSLY ACTIVE MIDBRAIN DOPAMINE NEURONS. L.H. Jiang and R.Y. Wang. Department of Psychiatry and Behavioral Sciences, SUNY Stony Brook, Stony Brook, NY 11794-8790.

Ample evidence suggests that cholecystokinin (CCK) functionally opposes dopamine (DA). The aim of the present study was to decide whether chronic CCK mimics the effect of antipsychotic drugs on midbrain DA cells. Since CCK does not readily cross the blood brain barrier, it was administered directly to the lateral ventricle (icv) of Sprague-Dawley rats via a cannula connected to an osmotic minipump with a polyethylene tubing. CCK was delivered continuously by the minipump (132 ng/day) for 2 to 3 weeks. Standard extracellular single cell recording techniques was used to determine the number of spontaneously active DA cells/electrode track in anatomically defined A9 and A10 areas. Acute icv administration of CCK-8S (252.1 ± 49 ng in 2-4 µl, n=7) decreased the number of spontaneously active DA cells in both the A9 (0.46 ± 0.1, n=7) and A10 (0.8 ± 0.2, n=7) regions as compared to the control values (A10. 1.33 ± 0 .1; A9, 0.71 ± 0.1). Intravenous (i.v.) administration of the CCK-A antagonist lorglumide (4.8 µg/kg) reversed CCK-induced effects (n=3). Similarly, chronic icv administration of CCK, but not saline, also significantly reduced the number of spontaneously active A9 (0.33 ± 0.03, n=8) and A10 (0.53 ± 0.06, n=8) DA cells. The CCK-A receptor antagonist L-364,718 (40 ng/kg, i.v.) but not CCK-B receptor antagonist L-365,260 (40 ng/ng, i.v., n=4) reversed the chronic CCK-induced effects, returning the number of A9 and A10 DA cells to control values (A9, 0.8 ± 0.09; A10, 1.16 ± 0.1, n=5). These results suggest that chronic CCK mimics the actions of antipsychotic drugs and this effect is mediated by CCK-A receptors in the rat brain. (Supported by USPHS Grants MH-41440 and MH-00378)

91.4

CHOLECYSTOKININ (CCK) EVOKES OXYTOCIN AND VASOPRESSIN RELEASE FROM PERFUSED EXPLANTS OF RAT HYPOTHALAMUS. C.R. Jarvis, B.J.M. van de Heijning*, and L.P. Renaud, Centre for Research in Neuroscience, Montreal General Hospital and McGill University, Montreal, Canada H3G 1A4.

The supraoptic nucleus displays both CCK-immunoreactive cells and high affinity CCK-binding. The observation that CCK also induces a receptor-mediated depolarization of rat supraoptic neurons prompted an in vitro study of the ability of CCK to evoke the release of vasopressin (VP) and/or oxytocin (OT) from the neurointermediate lobe of hypothalamic explants. Explants (with the anterior pituitary removed) were perfused with oxygenated artificial cerebrospinal fluid via the internal carotid arteries. Perfusate was collected by a suction pipette positioned over the neurointermediate lobe and levels of OT and VP were assessed by RIA. Three minute infusions of 0.1-1.0 µM sulfated CCK-8 evoked a two to three-fold increase in the basal levels of both OT and VP. Test pulses of norepinephrine (60 µM), which induce VP release, verified the viability of the explant. These data suggest a role for CCK in OT and VP secretion.

Supported by FCAR, FRSQ, and MRC.

91.5

CHRONIC CHOLECYSTOKININ OCTAPEPTIDE (CCK8) ALTERS THE NUMBER OF SPONTANEOUSLY ACTIVE DOPAMINE NEURONS IN THE MESENCEPHALON OF THE RAT. J.D. Stittsworth, Jr.[1] and A.L. Mueller[2] 1)Neurosci. Res. Div., Abbott Labs., Abbott Park, IL 60064 and 2)Natural Product Sciences,Inc.,420 Chipeta Way,Salt Lake City,Utah 84108

Chronic administration of antipsychotic drugs results in a time dependent depolarization inactivation of dopamine (DA)-containing neurons in the ventral tegmental area (VTA, A10) and/or the substantia nigra (SN, A9). This phenomenon can be observed electrophysiologically as a decrease in the number of DA-containing neurons encountered with extracellular recording. Since previous experiments have demonstrated that CCK8 might modulate DA actions in the VTA and the SN, we decided to investigate CCK8's antipsychotic potential utilizing this in vivo model. Recordings were made in chloral hydrate anesthetized, male Sprague-Dawley rats. The recording electrodes were passed through stereotaxically defined areas of the SN and the VTA and the number of spontaneously active DA-containing neurons were counted and averaged per track (10 tracks/area). The number of DA-containing neurons encountered in vehicle treated animals were 0.70 +/-0.07 for the VTA (n=!8) and 0.71 +/-0.05 for the SN (n=18). After 21 days of daily subcutaneous administration of either haloperidol(HAL, 0.5 mg/kg), clozapine (CLOZ, 20 mg/kg) or CCK8 (0.03 mg/kg or 0.1 mg/kg), reductions in number of spontaneously active DA-containing neurons were observed. The reductions seen with HAL and CLOZ were consistent with previous reports. CCK8 reduced the number of neurons in both SN (0.03 mg/kg: 0.28 +/-0.07, n=8 and 0.1 mg/kg: 0.33 +/-0.08, n=11) and VTA (0.03 mg/kg: 0.43 +/-0.11, n=7 and 0.1 mg/kg: 0.36 +/-0.14 n=9).

OPIOID-LIKE ACTIONS IN VITRO AND IN VIVO OF A NOVEL CHOLECYSTOKININ ANALOG WITH HIGH SELECTIVITY FOR BRAIN CCK RECEPTORS. T.H. Kramer*, S.N. Fang*, P. Davis*, E.A. Ayres*, P.K. Lemcke*, V.J. Hruby*, and T.F. Burks. Depts. of Pharmacology and Chemistry, University of Arizona, Tucson AZ 85724.

$[CH_3\text{-}Nle^{28},CH_3\text{-}Nle^{31}]CCK_{26\text{-}33}$ (F8702), an analog of sulfated $CCK_{26\text{-}33}$ (CCK) synthesized in our laboratories, has high affinity for brain CCK receptors and low affinity for pancreatic (peripheral) CCK sites. We have studied F8702 and CCK actions in guinea pig ileum (GPI) whole segment (GPI-WS), longitudinal muscle/myenteric plexus (GPI-LM), and mouse vas deferens (MVD) bioassays, as well as hotplate analgesia (HP) and gastrointestinal transit (GIT) tests in mice. Whereas CCK was a full agonist in GPI-WS (A_{50}=2.56nM), F8702 had no (contractile) activity. In GPI-LM, F8702 was a partial (inhibitory) agonist (IC_{50}=10μM), sensitive to naloxone (NLX) and the μ antagonist CTAP. In MVD, F8702 was a full agonist (IC_{50}=1μM), with measurable but low sensitivity to the antagonists NLX, CTAP, ICI 174864, and nor-BNI. CCK was devoid of opioid actions in both GPI-LM and MVD. After i.c.v. injection in mice, F8702 caused analgesia (A_{50}=3μg) which was blocked by high dose (10 mg/kg) NLX, and inhibited GIT (A_{50}=2μg); CCK had minimal activity in both tests. F8702 may stimulate endogenous opioid release or nonselectively act at opioid as well as brain-type CCK receptors. (Supported by USPHS grants DA04248 and DK36289.)

91.7

PHARMACOLOGICAL AND FOOD INTAKE SUPPRESSING ACTIONS OF A-68552, A CONFORMATIONALLY-CONSTRAINED ANALOG OF CCK7. A.M. Nadzan*, M.D. Tufano*, C.W. Lin*, K. Asin, T. Miller*, D. Witte*, L. Bednarz*, M.J. Cullen*, W. Montana (SPON: W. Giardina). Neuroscience Research Division, Pharmaceutical Discovery, D-47H, Abbott Laboratories, Abbott Park, IL 60064.

A metabolically-stable and conformationally-constrained analog of CCK7, A-68552, was compared with CCK8 for its ability to bind to type A and B CCK receptors, stimulate phosphoinositol turnover and amylase release from pancreatic acinar cells and suppress food intake. A-68552 exhibited high affinity binding to pancreatic acinar cells (type A, IC50 = 4 nM) and to cortical receptors (type B, IC50 = 0.3 nM). In studies of phosphoinositol turnover in pancreatic acinar cells, A-68552 stimulated only 79% that of CCK8: however, it proved to be a full angonist in the stimulation of amylase release (EC50 = 1 nM). Both actions were blocked by the type A CCK antagonists, A-65186 and L-364,718. In food-deprived rats, A-68552 suppressed feeding in a dose dependent manner (ED50 = 3 ug/kg) and exhibited a prolonged duration of action over that of CCK8. This analog represents a valuable probe for the study of CCK's involvement in pancreatic function and in feeding.

91.8

COMPARISON OF MICRODIALYSIS AND PUSH-PULL PERFUSION TECHNIQUES FOR IN VIVO STUDIES OF NEUROPEPTIDE RELEASE. S.DeMesquita[1], K.Laitinen*, M.Beinfeld[2], A.Rokaeus*[3], J.N.Crawley. Clinical Neuroscience Branch, NIMH, Bethesda, MD 20892; [1]Dept. of Physiology, Marshall Univ., Huntington, WV 25755; [2]Dept. of Pharmacology, St. Louis Univ., St. Louis, MO 63104; [3]Dept. of Biochemistry, Karolinska Institutet, Stockholm, Sweden.

The release of neuropeptides was studied using intracerebral microdialysis and push-pull perfusion techniques. The coexistences of cholecystokinin (CCK) and dopamine in the mesolimbic pathway, and of galanin (GAL) and acetylcholine in the septohippocampal pathway, provide model systems for investigating peptide release in vivo. Microdialysis and push-pull perfusion experiments were compared for sensitivity and accuracy in sampling CCK from the posterior nucleus accumbens and GAL from the ventral hippocampus. Dialysis probes (3mm) or concentric push-pull cannulae (1mm) were perfused with aCSF or bovine serum albumin and bacitracin in aCSF at flow rates of 1 or 10 μL/min respectively. RIA was performed on samples obtained before and during perfusion with 100 mM KCl or 150 μM veratridine. Push-pull perfusion yielded a much greater percent recovery in vitro for both peptides as compared to microdialysis.

91.9

NEUROPEPTIDES MICROINJECTED INTO THE VENTRAL TEGMENTUM MODULATE DOPAMINE AND METABOLITES IN THE NUCLEUS ACCUMBENS AS MEASURED BY IN VIVO MICRODIALYSIS. K.Laitinen*, S.DeMesquita, J.N.Crawley (SPON: L.R.Skirboll). Unit on Behavioral Neuropharmacology, Clinical Neuroscience Branch, NIMH, Bethesda, MD 20892.

Microinjection of neuropeptides, including neurotensin, cholecystokinin, substance P, substance K, and oxytocin, into the ventral tegmental area (VTA), produce behavioral effects such as locomotion and grooming in the rat. The relative importance of each peptide on its receptors in the VTA in regulating postsynaptic dopamine (DA) release is unknown. In vivo microdialysis was employed to quantitate DA and its metabolites from the posterior nucleus accumbens (NA) before and after neuropeptide administration into the VTA. Anesthetized male Sprague-Dawley rats were unilaterally infused with each of the above neuropeptides at 1 nmole or 1 pmole/0.5 ul saline, over a one minute period, at 5.8 mm posterior and 0.5 mm lateral to bregma, 8.3 mm ventral to the surface of the skull (VTA). A Carnegie Medicine microdialysis probe, 2 mm length, was positioned ipsilaterally at 1.2 mm anterior and 1.2 mm lateral to bregma, 8.5 mm from the surface of the skull (NA), perfused with Ringers's solution at a flow rate of 1.0 ul/min. Perfusate was analyzed by HPLC with electrochemical detection for DA, DOPAC, and HVA. Neurotensin, which increases locomotion, increased DA, DOPAC and HVA. Cholecystokinin, substance P and substance K, which have complex behavioral actions on locomotion and grooming, produced small increases in DOPAC. These data suggest a correlation between behavioral effects of neuropeptides and their actions on mesolimbic dopamine release.

91.10

VENTRAL SEPTAL NEURONS MAY MEDIATE VASOPRESSIN ANTIPYRESIS BY ALTERING ACTIVITY OF ARCUATE AND DORSOMEDIAL HYPOTHALAMIC NEURONS. W.B. Mathieson, Q.J. Pittman and W.L. Veale. Dept. Med. Physiol., Univ. Calgary, Alberta T2N 4N1.

During fever, arginine vasopressin (AVP) is released from nerve terminals in the ventral septum to limit the magnitude of the hyperthermic response. To investigate potential pathways which may mediate AVP's antipyretic effects, a retrograde neuronal tracer, Fluorogold, was iontophoretically injected into hypothalamic sites suspected to receive efferent projections from the ventral septum. Following Fluorogold injections in the arcuate and dorsomedial hypothalamic nuclei, retrogradely labeled neurons were visualized in septal sites previously associated with AVP release and highly sensitive to microinfusion of AVP during fever. In separate experiments, single unit recordings in the arcuate and dorsomedial hypothalamic nuclei demonstrated both excitatory and inhibitory synaptic potentials following electrical stimulation of the ventral septal area. Since the arcuate nucleus contains a-MSH synthesizing neurons which may regulate the early phase of fever (Samson et al., Peptides 2:419, 1981) and the dorsomedial hypothalamic may activate heat production in brown adipose tissue (Freeman and Wellman, Br.Res.Bull.18:7, 1987), these results suggest two pathways by which AVP release in the ventral septum could initiate antipyresis.

91.11

LIGHT-DARK RHYTHMS OF VASOPRESSIN (AVP) IN DISCRETE HYPOTHALAMIC NUCLEI: RELATIONSHIP TO FEEDING. M.Jhanwar-Uniyal, M. Chapleur, A.J.Burlet and S.F.Leibowitz. The Rockefeller Univ., N.Y., and Laboratoire de Biologie Cellulaire, Faculte de Medecine, INSERM U 308, Nancy, France.

The present study examined AVP content in discrete hypothalamic areas at 5 different times of the 12/12 hr light/dark cycle (0700, 1300, 1800, 2000, 0100), with lights out at 1900 hr. Nine nuclei, namely, paraventricular (magnocellular PVN-M or parvocellular PVN-P), dorsomedial (DMN), median eminence (ME), arcuate (ARC), perifornical lateral (PLH), supraoptic (SON), suprachiasmatic (SCN), and ventromedial (VMN), were assayed for AVP content via RIA.

The results revealed a significant shift in AVP content across the light/dark cycle, in 5 hypothalamic nuclei. In the PVN-P and PVN-M, opposite temporal patterns were observed. The PVN-P exhibited lowest AVP levels (4.2 ng/mg P) 1 hr after dark onset and peak AVP content (9.6 ng/mg P) at light onset. In contrast, AVP in the PVN-M peaked in the early dark period (21.0 ng/mg P) and declined towards light onset (7.1 ng/mg P). Moreover, peptide levels in the SCN shifted in a similar manner to those in the PVN-M, whereas the ARC and PLH responded similarly, but not identically, to the PVN-P. The AVP content of the PVN-P showed a sharp decline from 1 hr prior to dark onset to 1 hr after dark onset. This may be related to the onset of natural feeding at this time, since our previous studies have shown a similar change after refeeding in food-deprived rats.

91.12

ARGININE VASOPRESSIN AND ATRIAL NATRIURETIC FACTOR: EVIDENCE FOR A HOMEOSTATIC SYSTEM SET AT THE THRESHOLD OF VOLUME-MEDIATED NATRIURESIS. P.A. Mason, K.M. Chu*, D. Bhaskaran, L.G. Ganousis*, A.S. Nies*, C.R. Freed, and J.A. Durr*. Depts. of Med. and Pharm., Univ. of Colo. Health Sci. Ctr. Denver, CO 80262.

Arginine vasopressin (AVP) and atrial natriuretic factor (ANF) have opposite vascular and renal effects and are reciprocally controlled by blood volume (BV). The influences of BV and plasma osmolality (Posm) on the plasma concentrations of AVP and ANF were investigated using rats. Chronic changes in BV and Posm were produced by fluid deprivation. Acute changes in BV and Posm were produced by intraperitoneal injections of 35% polyethylene glycol and/or saline solutions (200, 600, 1000 mOsm/kg). Regression analysis showed that AVP correlated directly with Posm and inversely with BV. Posm was the major predictor of baseline AVP. Conversely, ANF correlated directly with BV and inversely with Posm. BV was the major predictor of baseline ANF. A 25% decrease in BV would be required for complete ANF suppression. Increasing BV by only 2% stimulates ANF release and natriuresis until BV normalizes and the ANF returns to its basal level. Since the ANF release threshold is 25% below normal BV and ANF secretion is not suppressible without AVP stimulation, natriuresis appears to be continuously used to maintain circulating volume. These results suggest that sodium conservation is not the primary regulator of circulating volume.

91.13

VASOPRESSIN PRODUCES A CHOLINERGICALLY-MEDIATED AROUSAL (ANALEPTIC) EFFECT IN PENTOBARBITALIZED RATS. A. Horita and M.A. Carino (SPON: H. Lai). Depts. of Pharmacology and Psychiatry, Univ. Wash. Sch. of Med., Seattle, WA 98195.

Arginine vasopressin (AVP), in addition to possessing antidiuretic and vasopressor activities, may play a role in behavioral, memory and temperature regulatory processes. We now describe a cholinergically-mediated analeptic effect of AVP that is produced in pentobarbital (PB)-narcotized rats. Icv doses of 100 ng, but not 50 ng, of AVP significantly shortened the duration of loss of righting reflex produced by PB. Atropine, but not methylatropine, completely blocked the analeptic effect, indicating the cholinergic nature of the response. Sodium dependent, high affinity choline uptake (HACU) activity was reduced in cortical and hippocampal synaptosomes prepared from PB-treated rat brains (as compared to conscious controls). AVP (100 ng, icv) restored HACU activity to normal in hippocampus, but not in cortex. The desglycinamide analog of AVP was devoid of analeptic activity. [Mcp^1,Tyr(OMe)^2]-AVP (10 ug, icv), the vasopressor antagonist, produced complete and specific block of the AVP-induced analeptic response. [d(CH$_2$)^5, D-Ile^2,Ile^4]-AVP, an antagonist of the antidiuretic effect of AVP, only partially blocked the AVP response at 10 ug, icv. (Supported by Rehabilitation Research and Training Grant, H133B80081).

91.14

HIPPOCAMPAL INHIBITION PRODUCED BY STIMULATING VASOPRESSIN CELLS IN THE MEDIAL AMYGDALA. D. Albeck*, T. Smock, P. McMechen*, D. Purves* and L. Floyd*. (SPON: Herbert P. Alpern). Center for Neurosciences, Dept. of Psychology, Univ. Colorado, Boulder, CO 80309.

Arginine vasopressin (AVP) acts directly on two target cell types in the rat hippocampus; inhibitory interneurons and small blood vessels. Excitation of the interneurons produces secondary inhibition of pyramidal cells (Albeck and Smock, 1988, Brain Res. 463:394). Recently the source of hippocampal AVP-like peptide has been located in the medial amygdala (Caffé et al., 1987, J. Comp. Neurol. 261:237). Here we report that electrical stimulation of this nucleus produces inhibition of pyramidal cells that is indistinguishable from the action of applied AVP.

Experiments were performed on 44 male Sprague-Dawley rats acutely anesthetized with urethane. When 100-700 ng AVP was applied to the central ventricle, a large and reversible inhibition of the evoked field population spike in CA$_1$ was observed (n = 6). The characteristics of the inhibition were the same as that obtained with 1 μM AVP in the hippocampal slice preparation. Furthermore, when brief trains of electrical stimuli (5-15 v, 0.5 msec at 100 Hz for 100 msec) were applied to the medial amygdaloid nucleus, presumably releasing endogenous AVP, a reversible inhibition of the hippocampal population spike was also obtained (n = 32). Histology showed that the inhibition could only be obtained from electrode positions in the medial amygdaloid nucleus, shown by immunocytochemistry and tract-tracing techniques to be the source of hippocampal AVP. Like peptidergic potentials in simple preparations, the response to amygdala stimulation was slow to develop (15 sec) and lasted a long time (10-15 min).

Since AVP applied to the slice preparation, applied to the ventricle in the whole animal, or presumably released endogenously by stimulation of the medial amygdala has in each case the same impact on pyramidal cells in the hippocampus, we propose that each result is a reflection of a common peptidergic mechanism in the mammalian brain. Since specific structural antagonists can be used to block the action of AVP in the hippocampus, the results present the prospect that the nature of the native transmitter can be determined based on susceptibility to antagonist blockade.

91.15

HIPPOCAMPAL INHIBITION BLOCKED BY A VASOPRESSIN/OXYTOCIN ANTAGONIST. T. Smock, D. Albeck*, P. McMechen*, and D. Purves*. Center for Neurosciences, Department of Psychology, University of Colorado, Boulder, CO 80309.

Stimulation of the source of hippocampal vasopressin-like peptide produces an inhibition of pyramidal cells that is identical to that obtained by application of vasopressin in the slice preparation or the whole animal (Albeck et al., this meeting). Here we show that the action of the endogenously released peptide can be blocked by an antagonist specific to brain vasopressin/oxytocin receptors. Taken together, the results constitute strong evidence for peptidergic transmission in the rat hippocampus.

Experiments were done on 17 male Sprague-Dawley rats. As for the action of vasopressin in the slice, the action of i.c.v. vasopressin (100-500 ng) was blocked by the structural analog d(CH$_2$)$_5$ Tyr (Me) AVP (4 of 5 trials). The fact that the hippocampal response to stimulation of peptidergic fibers from the amygdala is repeatable within animals was exploited to test for vasopressin mediation in an internally controlled paradigm. In ten trials, the specific V$_1$ pressor antagonist was ineffective in blocking the action of the endogenous peptide.

However, when the experiments were repeated with the oxytocin/vasopressin analog [des-Gly-NH$_2$ d(CH$_2$)$_5$ Tyr (Me)^2 Thr^4] OVT, the action of the endogenously released peptide was invariably blocked (n = 4).

The resemblance of the endogenous signal to the action of exogenous vasopressin, together with evidence for synthesis, transport and secretion of vasopressin-like material by neurons in the medial amygdala constitute evidence for peptidergic transmission mediated by a vasopressin-like peptide. The evidence, presented here, for blockade of the action of the native peptide with a specific antagonist for the brain vasopressin/oxytocin receptor makes the case very strong. The additional fact that an antagonist that blocks the action of exogenous vasopressin fails to block the action of the endogenously released substance suggests that this endogenous substance may be similar, but not identical, to pituitary vasopressin.

Supported by NSF BNS 8520622 and a gift of antagonists from Dr. Maurice Manning.

Atrial natriuretic peptide (ANP) decreases glucose utilization in the subfornical organ (SFO). E. Nermo-Lindquist*, M.L. Terrell, J. Nassar*, H. Lekan, S. Freeman* and M. Kadekaro. Div.of Neurosurgery, Univ. of Texas Med.Branch, Galveston, Tx. 77550.

Previous studies have shown that glucose utilization in the SFO is increased in several rat models in which angiotensin II (AII) levels are elevated. The objective of this study was to investigate with the deoxyglucose method if ANP acts at the SFO to antagonize the effects of AII. Male adult homozygous Brattleboro (DI) and Sprague-Dawley (SD) rats were used. DI rats, who are characterized by high plasma levels of AII, were infused intravenously with saline (n=12) or ANP (0.1 ug/ min) (n=12) for 30 min. ANP decreased blood pressure but did not change glucose utilization in the SFO or neural lobe (NL). Because hypotension could mask the effect of ANP, DI rats were infused with albumin (n=6), or with albumin+ANP (n=6) to prevent hypotension. Glucose utilization tended to decrease in the SFO (p=0.08) but did not change in the NL. SD rats were infused intravenously with saline (n=8), AII (2.5 ug/ min) (n=8) or AII (2.5 ug/ min)+ANP (0.15 ug/min) (n=8) for 45 min. AII stimulated water intake and increased glucose utilization in the SFO and NL. ANP reduced the drinking response to AII and decreased glucose utilization in the SFO (p=0.003), but did not in the NL. The results suggest that ANP acts at the SFO to antagonize the effects of AII.

91.17

INTRACEREBROVENTRICULAR CORTICOTROPIN-RELEASING FACTOR INCREASES BRAIN CONCENTRATIONS OF PRO-OPIOMELANOCORTIN-RELATED PEPTIDES L.P. Kapcala, C.F. Weng* and R.L. Hauger. University of Maryland School of Medicine, Dept. Med., Baltimore, MD 21201 and VAMC and UCSD School of Medicine, Dept. Psych., La Jolla, CA 92093

Corticotropin-releasing factor (CRF) is considered an important brain neuroregulator in view of its widespread brain distribution and its diverse biochemical and behavioral effects on brain. Despite sugggestions that CRF stimulates hypothalamic secretion of pro-opiomelanocortin (POMC)-related peptides in vitro, effects of CRF on brain levels of POMC-derivatives are not known. We tested the hypothesis that central administration of CRF alters brain concentrations of POMC-related peptides. CRF (1μg) or placebo was administered into the lateral ventricle of adult rats and brain concentrations of IR-POMC peptides were measured after 60 min. IR-α-MSH was measurable only in hypothalamus. Concentration changes are shown below.

* $p<0.05$ ** $p<0.01$

Region	IR-	% Change Relative to Control ACTH	β-endorphin	α-MSH
Hypothalamus		+ 42	+ 51*	+376**
Hippocampus		+128	+300*	-
Amygdala		+ 25	+ 91**	-
Cortex		+463**	+692**	-

CRF also produced significant decrements in molar ratios of IR-ACTH/IR-β-endorphin in amygdala and hippocampus and an increment of hypothalamic IR-α-MSH/IR-β-endorphin.

CONCLUSIONS: 1) Intracerebroventricular CRF produces potent behavioral effects and increases brain concentrations of POMC-related peptides particularly in cortex which contains highest CRF receptor concentrations. 2) Changes in molar ratios of POMC-related peptides suggest a possible differential regulation of different POMC derivatives. 3) Some of CRF's behavioral effects may be mediated via changes in brain POMC-related peptides.

91.18

PARTICIPATION OF AMYGDALOID CENTRAL NUCLEUS (ACE) IN CRF INDUCED INCREASES IN IN VITRO TRYPTOPHAN HYDROXYLASE ACTIVITY (TrpH). **V.B.Singh, T-H.Phan and Margaret Boadle-Biber. Dept. of Physiology, Medical Coll. of Virginia, Virginia Commonwealth University, Richmond, Va-23298-0551.**

Corticotropin-releasing-factor (CRF) may regulate behavioral, visceral and neuroendocrine responses to stress. We reported that ICV infusions of CRF (3 ug total in 6 uL vehicle or vehicle alone given over 30 sec) into awake male Sprague Dawley rats, increase in vitro cortical and midbrain TrpH activity by 50-60% over that of vehicle infused control rats (Singh et al. Faseb J. 3: A729. 1989). We have now examined whether CRF infusion into amygdaloid central nucleus (ACE) or dorsal raphe nucleus (DR) also increases the in vitro activity of cortical and midbrain TrpH. CRF (3 ug/6 u L vehicle) or vehicle (6 u L) alone was infused into ACE or DR over 30 sec via guide cannulae implanted 3-4 days earlier under surgical anesthesia. Rats were killed by decapitation at different time intervals after infusion and cortex and midbrain were carefully removed on ice and stored at -70°C until assayed for TrpH activity (Boadle-Biber et al. Brain Res. 482: 306, 1989). A rapid (within 15 min) increase in TrpH activity was noticed with CRF infused into ACE and a slow increase (over 45 min) with CRF infusion to DR. This increase in TrpH activity was comparable with that of sound-stress-induced changes and direct electrical stimulation to dorsal raphe nucleus. It was reversed by alkaline phosphatase treatment and was nonadditive with the increase in the activity obtained under phosphorylating condition. The above findings suggest a direct role of ACE in stress induced changes in TrpH activity. Supported by NIH GRANT NS14090 to MCB-B.

CORTICOTROPIN RELEASING FACTOR (CRF) DECREASES A MEDIUM/SLOW AFTERHYPERPOLARISATION (m/sAHP) AND EVOKES A HYPERPOLARISATION IN AMYGDALOID NEURONES. **D.G. Rainnie*, B.J.H. Fernhout*, M.E. Abreu and P. Shinnick-Gallagher** (SPON: O.S. Steinsland). Dept. of Pharmacology, Univ. of Texas Medical Branch, Galveston, TX 77550.

The amygdaloid complex has been shown to contain a high density of CRF receptors and CRF-immunoreactive neurones. In the present in vitro study we examined the effect of superfusing CRF (10-250nM) on neuronal firing activity in the basolateral (BLA) and central (ACe) amygdala of the rat by conventional intracellular recording techniques. In those BLA neurones that showed a m/sAHP CRF (250nM) caused a voltage independent reduction (33-90%) in the m/sAHP amplitude observed following evoked burst firing activity (6/6 cells tested). In ACe neurones CRF (10-250nM) caused a similar reduction (41-77%) in 4/6 cells tested. Additionally in ACe neurones CRF evoked a 2-14mV hyperpolarisation (6/6 cells tested) which was associated with an increase in membrane input resistance (R_m) (3/6 cells) and a reduction in anomalous rectification. Conversely in the BLA CRF caused no apparent change in the membrane potential but decreased R_m in 4/7 cells tested. Hence CRF has differential effects in individual nuclei of the amygdaloid complex which may reflect their physiological requirements during times of stress. (Supported in part by NS24643).

ACTIVATION OF RAT RETINA ADENYLATE CYCLASE BY CORTICOTROPIN-RELEASING FACTOR. P. Onali and M. C. Olianas. Dept. of Neurosciences, Univ. of Cagliari, Italy.

Corticotropin-releasing factor (CRF), a peptide widely distributed in the CNS, has also been detected in the retina of different animal species, where it may act as a neurotransmitter. In the present study we report that human-rat CRF stimulates adenylate cyclase activity of rat retina homogenate. The CRF stimulation is concentration-dependent with an EC50 value of 50 nM. Maximal stimulation corresponds to 90% increase of basal enzyme activity. The CRF effect is counteracted by the CRF antagonist α-helical CRF 9-41 with a Ki value of 40 nM. Other CRF-like peptides such as sauvagine (Sauv) and urotensin I (Urot) are as effective as CRF with the rank order of potency: Urot ≥ Sauv > CRF. The Sauv and Urot stimulations are not additive with that elicited by CRF. The CRF effect is independent of the concentration of Ca^{++}, is enhanced by increasing the Mg^{++}concentration up to 5-10 mM and requires GTP. These results indicate that in rat retina CRF and CRF-like peptides may increase cyclic AMP formation by activating a receptor site linked to adenylate cyclase. This biochemical response may constitute an important mechanism for the action of CRF in the retina.

91.21

Ca^{++}-DEPENDENT ACTIVATION OF STRIATAL TYROSINE HYDROXYLASE BY CRF : INHIBITION BY PRESYNAPTIC DOPAMINE AUTORECEPTORS. M.C. Olianas and P. Onali. Department of Neurosciences, University of Cagliari, Italy.

In mouse striatal synaptosomes corticotropin- releasing factor (CRF), a putative neurotransmitter in the CNS, stimulated dopamine (DA) synthesis by activating tyrosine hydroxylase (TH). TH activity was assayed in extracts prepared by centrifugation and sonication of mouse striatal synaptosomes preincubated with the test agents. CRF maximally increased TH activity by 60% with an EC50 value of 15 nM. The CRF stimulation was antagonized by α-helical CRF 9-41 (Ki 100 nM) and was mimicked by sauvagine and urotensin I, two peptides homologous to CRF. The stimulation of TH activity was not associated with a stimulation of cyclic AMP production by CRF in striatal homogenates. The CRF stimulation was strictly dependent on the concentration of Ca^{++}in the incubation medium. Quinpirole (1 μM), a selective D2 DA receptor agonist, reduced the maximal CRF stimulation by 47% without changing the EC50 of the peptide. These results indicate that striatal dopaminergic terminals contain a receptor system for CRF that activates TH via a Ca^{++}-dependent pathway which is sensitive to modulation by presynaptic DA autoreceptors.

92.1

A NOVEL ANTAGONIST TO VASOACTIVE INTESTINAL PEPTIDE.
I. Gozes, M. Fridkin* and D.E. Brenneman. Depts. Hormone Res. & Organic Chem., Weizmann Inst. Rehovot, Israel. Lab. Mol. Genetics and Dev. Neurobiol. NICHD, NIH Bethesda, MD, 20892.

To better understand the interactions of vasoactive intestinal peptide (VIP) with its receptor, we have devised a novel VIP antagonist by a hybrid peptide strategy. A molecule was synthesized that combines a portion of VIP with a portion of neurotensin, peptides of opposite pharmacological action. The antagonistic nature of the new molecule was tested in cell cultures derived from the central nervous system. The hybrid antagonist displaced 85-90% of VIP binding to glial cell cultures. This displacement had a biphasic nature indicating two binding sites, one with an IC50 of 30 pM and another with an IC50 of 0.1 μM. Moreover, the formation of VIP-stimulated cAMP in these cell cultures was decreased by the peptide with an IC50 of 0.08 μM. The inhibition in all assays was more effective than that achieved in the presence of other putative VIP antagonists. The hybrid antagonist (10 μM) did not stimulate cAMP formation. Finally, previous studies have shown that nonneuronal cells stimulated by VIP secrete neuronal survival factors. Indeed, the addition 1 nM hybrid antagonist to dissociated spinal cord cultures resulted in neuronal cell death (42% decrease from controls). The availability of highly potent VIP antagonists may offer a route to study the molecular characteristics of the multiple VIP receptors as well as help delineate other biological activities attributable to VIP. (IG is on sabbatical from the Weizmann Inst.)

92.2

VAGINOCERVICAL STIMULATION RELEASES VASOACTIVE INTESTINAL PEPTIDE-LIKE IMMUNOREACTIVITY (VIP) INTO SPINAL CORD SUPERFUSATES IN RATS.
B.R. Komisaruk[1], A.R. Gintzler[2], C. Banas[1*] and M.A. Blank[3*] Institute of Animal Behavior, Rutgers Univ., Newark, NJ 07102[1], Depts. Biochem.[2] and Surgery[3], SUNY Medical Center Brooklyn, NY 11203

It has been shown previously that vaginocervical mechanostimulation (VS) produces analgesia and elicits afferent activity in the pelvic nerve, transection of which significantly reduces VS-produced analgesia. Other laboratories provide evidence that the primary afferent terminals of the pelvic nerve contain VIP, and electrical stimulation of the pelvic nerve releases VIP. VIP administration to the spinal cord produces analgesia. The present study ascertained whether VS releases VIP into superfusates of the lumbosacral spinal cord. Samples (2.5 min each) were collected on ice and frozen at -70°C immediately. VIP was assayed by RIA before, during and after VS or foot pinch (FP). The peak level of VIP in the baseline period was compared with that in the stimulation period. Mean ± sem level of VIP (fmol/ml superfusate) was 12.1 ± 2.4. This was significantly greater ($p<0.03, n=10$) than the prestimulation baseline (7.6 ± 1.2) or the FP (6.8 ± 1.1) control levels, which did not differ significantly from each other. These data support our hypothesis that VIP released from pelvic nerve primary afferent terminals in the spinal cord may mediate, at least in part, VS-produced analgesia.

92.3

VAGINO-CERVICAL STIMULATION (VS) REDUCES SUBSTANCE P RELEASE INTO SPINAL CORD SUPERFUSATES IN RATS.
JL Steinman, C Banas*, SW Hoffman* & BR Komisaruk, Institute of Animal Behavior, Rutgers Univ., Newark, NJ 07102.

In the present study, levels of substance P (sP) measured in superfusates of the lumbosacral region of the spinal cord were significantly reduced to 61.6% below basal levels during and immediately after VS. Superfusate samples, collected on ice and frozen at -70C, were analyzed by RIA. Six basal samples (3 min ea.) were collected before and after VS trials. Electric shock to the hindpaw evoked a 64.2% increase in sP levels. In 4 experiments, the levels of sP were significantly lower after VS plus shock (52%) than basal levels or than levels measured after shock alone ($p<.04$ Mann-Whitney U test).

These results indicate that VS, which produces analgesia in rats, reduces the basal release of sP and attenuates hindpaw shock-induced sP release from the spinal cord.

LHRH Modulates Nociceptive Responses in Female Rats.
A. Ratka* and J.W. Simpkins. Dept. of Pharmacodynamics, U. of Florida, Gainesville, FL 32610.

We have shown that responsiveness to painful stimuli changes during the estrous cycle (Neuroendocrinol. 48:394, 1988). In the present study, we evaluated the role of LHRH in modulating nociceptive responses in female rats. In ovariectomized (OVX) rats, an LHRH agonist ([Des-Gly10]LHRH Ethyl Amide; 1 ng/rat/μl) given icv at either 90, 60, 30 min before the hot-plate test caused a time-dependent, four-fold, increase in pain perception (hyperalgesia) vs. saline treated controls. Further, the LHRH agonist (1 ng/rat/μl; icv) attenuated morphine (5 mg/Kg, sc)-induced antinociception. The injection of an LHRH antagonist ([D-Phe2,Pro3,D-Phe6]LHRH) to OVX rats in doses of 0.1, 1 or 10 ng/rat 30 min prior to morphine, potentiated and prolonged morphine-induced antinociception in a dose-dependent manner. Moreover, the potent hyperalgesia observed in OVX rats treated with naloxone (1 mg/kg, sc) was reversed by pre-injection of the LHRH antagonist (0.1 ng/rat, icv). OVX rats primed with estradiol (EB) and progesterone (P) were less sensitive to the antinociceptive effect of morphine than OVX rats. When EBP treated rats received the LHRH antagonist prior to morphine, a two-fold increase in morphine-induced antinociception was observed. In conclusion, LHRH may interact with central opioid systems causing an increased sensitivity to pain (hyperalgesia) and a reduction of the antinociceptive effect of morphine. Response of the Normal and Arreflexic Bladder to Spinally Administered Primary Afferent Neurotransmitters in the Intact and Chronic Spinal Rat.
Paul J. Tiseo, and Tony L. Yaksh*. (Spon. L.-Y. Liu-Chen)*
Univ. of California, San Diego Medical Center, Dept. of Anesthesiology.

Following spinal cord lesion, there is a reliable loss of the ability of the bladder to store and efficiently expel urine. Normally, information relevant to communicating the state of bladder distention is part of a supraspinally mediated reflex and is carried by large afferent fibers. Following spinal trauma, it appears that smaller (type C) afferents may play a more dominant role. As the identity of many C-fiber transmitters is well documented and known to include amino acids (glutamate) as well as neuropeptides (SP, CCK, VIP, CGRP and SST), the present study systematically examined the effect of these agents and several selective antagonists administered into the lumbar intrathecal space on the volume-evoked micturition reflex (VEMR) of intact and spinally transected rats. Male S-D rats were surgically implanted with chronic catheters in the urinary bladder (PE-90) and the lumbar intrathecal space (PE-10). At the time of testing, the VEMR was studied during a constant infusion of saline (200 µl/min) into the bladder before and after intrathecal (i.t.) injection of an agent. In the intact animal, i.t. administration of glutamate, SP, CCK, VIP, or SST produced *no* alterations in the VEMR. However, administration of antagonists for glutamate (MK-801), and VIP ([4-Cl-D-Phe^6, Leu^{17}]-VIP), but *not* CCK(L-364, 718-000), produced a dose-dependent increase in frequency of detrusor muscle contraction and sphincter opening pressure with a corresponding decrease in volume to VEMR. Preliminary studies in transected animals (T-12) have shown that both glutamate and VIP can generate detrusor muscle contractions and VEMR's in arreflexic bladders beginning 5-10 days post-transection. These studies suggest that it may be possible to pharmacologically drive several systems mediating the VEMR, following the loss of this reflex in transected animals.

PARAVENTRICULAR NUCLEUS INJECTION OF TACHYKININS CAUSES HYPERTENSION AND TACHYCARDIA VIA AVP DESCENDING PATHWAY.
D-P. Tan* and K. Tsou. (SPON: G.D. Trisler). Dept. Pharmacol. III, Shanghai Inst. of Materia Medica, Academica Sinica, Shanghai 200031.

Our previous studies have shown that small amounts of intrathecal vasopressin or oxytocin elicited significant hypertension mediated via excitation of the spinal sympathetic system (*Peptides* 6:1191 and 7:569). We sought to determine whether stimulating the hypothalamic paraventricular nucleus (PVN) by tachykinins can regulate cardiovascular function and whether such regulation is modulated by the descending vasopressinergic pathway from the PVN to the spinal cord. In sino-aortic denervated rats, PVN injection of tachykinins elicited hypertension and tachycardia:

	Max. Δ Mean Arterial Pressure (mm Hg)		Max. Δ HR (beats/min)	
	1 µg	3 µg	3 µg	
Saline (1 µl)	-2 ± 2		-4 ± 6	
Substance P	9 ± 3*	18 ± 2**	14 ± 4*	
Physalaemin	n.t.	18 ± 1**	n.t.	
Kassinin	18 ± 3**	36 ± 3**	19 ± 4*	* P<0.05
Eledoisin	24 ± 3**	46 ± 6**	25 ± 4*	**P<0.01

The hypertensive effect began within 2 min after tachykinin injection and lasted 10-20 min. The potency order was eledoisin > kassinin > substance P = physalaemin. Tachycardia began within 4 min after injection and lasted ≥12 min. The potency order was eledoisin > kassinin > substance P. Intrathecal injection of a vasopressin antagonist Pmp^1-O-Me-Tyr^2-Arg^8-vasopressin (but not saline) greatly attenuated the two cardiovascular effects of PVN injection of eledoisin (ΔMAP 46 ±6 vs. 8 ± 2 ($P<0.001$); ΔHR 25 ± 4 vs. -2 ± 2, $P<0.01$)).

These data suggest that (1) tachykinins can stimulate the PVN to elicit significant cardiovascular effects; (2) these effects mostly were via NK-3 receptors in the PVN; and (3) the AVP descending pathway from PVN to spinal cord may be involved in the tachykinin-induced cardiovascular effects.

92.7

SOMATOSTATIN-14 (SOM-14) AND SOMATOSTATIN-28 (SOM-28) INHIBIT CA CURRENTS IN RAT NEOCORTICAL NEURONS. H.L. Wang, T. Reisine, M. Dichter, Departments of Pharmacology and Neurology, University of Pennsylvania School of Medicine and Graduate Hospital, Philadelphia, PA 19104.

The prosomatostatin-derived peptides, SOM-14 and SOM-28, are believed to function as neurotransmitters or neuromodulators in the cerebral cortex. We have examined the effects of these two peptides on ionic conductances in cultured rat neocortical neurons. These cultured neurons express SOM receptors and release both immunoreactive SOM-14 and SOM-28. We previously showed that SOM-14 and SOM-28 differentially regulate delayed rectifier K currents in these neurons. As SOM peptides have also been reported to block voltage-dependent Ca currents in pituitary cell lines and sympathetic ganglionic neurons, we examined their effects on Ca currents in neocortical neurons.

Voltage-dependent Ca currents of rat neocortical neurons were recorded using whole-cell patch clamp techniques under conditions in which K and Na currents were blocked. SOM-14 (100 nM) and SOM-28 (100 nM) did not effect the low voltage activated Ca current, but both peptides reversibly blocked the high voltage activated Ca current and slowed the activation of this current. When patch pipettes contained 100 uM cAMP and 0.5 mM IBMX, SOM-14 and SOM-28 still inhibited Ca currents. Inclusion of the non-hydrolysable GTP analog, GTP-γ-S (500 uM), in the recording electrode produced effects similar to those produced by SOM-14 and SOM-28. Pretreating neurons with pertussis toxin (PTX) prevented the inhibition of Ca currents by SOM-14 and SOM-28. Our results suggest that SOM-14 and SOM-28 inhibit Ca currents of rat neocortical neurons through a cAMP-independent mechanism involving PTX-sensitive G-proteins. Further studies are needed to determine whether SOM-14 and SOM-28 regulate Ca currents through the same population of receptors and/or G-proteins.

BRADYKININ-INDUCED CURRENTS IN RAT DRG NEURONS AND F-11 CELLS ARE INSENSITIVE TO PERTUSSIS TOXIN. D.S.McGehee* and G.S. Oxford, Dept of Physiology, University of North Carolina, Chapel Hill, NC 27599

Cultured rat DRG neurons will respond to bradykinin (BK) with a transient inward cation current (10-60pA) which desensitizes markedly. Whole cell patch clamp techniques were used to measure BK responses from DRG neurons dissociated from rat pups aged E15 to day 1 postnatal. A subpopulation of these cells responded to BK (10-1000nM), while the age of the animals used had no remarkable influence on either the character of the response or the % of cells responding. Ion replacement studies have shown that the BK-induced current can be carried by Na^+, Li^+ or Cs^+, but not by large impermeant species such as NMG^+ or TMA^+. Varying the chloride reversal potential had no effect on the response. In standard recording solutions ramp voltage clamp analyses have shown that the BK current reverses near 0mV, indicating a non-selective cation conductance. The mouse neuroblastoma x rat DRG hybrid cell line, F-11 responds to BK with a biphasic response, a strong outward current followed by a slow inward current, much like the BK response of the NG108-15 cell line reported by Brown et al. (1987). The responses differ, however, in that the second phase in NG108-15 represents a conductance decrease, whereas the response of DRG and F-11 neurons results from a conductance increase which reverses near 0mV. Overnight pretreatment with *Pertussis* toxin (350ng/ml) had no obvious effect on BK responses in DRG or F-11 cells. We are currently undertaking experiments to determine the role of GTP-binding proteins and second messenger candidates in these responses. Supported by NIH Grant NS23804.

92.9

SUBSTANCE P-MEDIATED SYNAPTIC INTERACTIONS BETWEEN RAT MYENTERIC NEURONS IN CELL CULTURE. A.L. Willard, Dept. of Physiology, University of North Carolina, Chapel Hill, NC 27599-7545.

Subsets of rat myenteric neurons in cell culture evoke slow depolarizations (slow EPSPs) in other myenteric neurons without causing detectable fast EPSPs (Willard & Nishi, *Neuroscience* 16:213, 1985). I have tested the hypothesis that Substance P (SP) mediates these slow EPSPs.

Experiments were performed on 3 to 5 week old cultures. Intracellular recordings were made from individual myenteric neurons while other neurons were stimulated with either a loosely sealed (R_{seal} < 200 MΩ) extracellular patch pipet or with an intracellular electrode.

The following data support the hypothesis that SP mediates a subset of slow EPSPs between cultured myenteric neurons. i. Seventeen of 28 neurons that evoked slow EPSPs contained immunohistochemically detectable SP-LIR. ii. The slow EPSPs, which appear to be due to decreased resting K^+ conductance, were mimicked by synthetic SP or by an analog, [pGlu^6, Pro^9]-Substance P 6-11 (septide), which is reported to be specific for NK-1 tachykinin receptors (Laufer et al, *J. Pharm. Exp. Ther.* 245:639, 1988). iii. Prior application of SP or septide reduced or prevented the slow EPSPs. iv. Specific antisera against SP reduced or blocked the slow EPSPs caused by 8 of 13 neurons. All 8 of the neurons whose postsynaptic actions were affected by anti-SP were found to be SP-positive in the immunohistochemical assay, while 0/4 neurons whose actions were unaffected by anti-SP were SP-positive.

I conclude that a subset of the slow EPSPs are mediated by a Substance P-like molecule. The mediator of the slow EPSPs caused by neurons that lack immunohistochemically detectable SP remains to be determined. Supported by NIH grant NS24362.

92.10

EFFECT OF CENTRALLY ACTIVE NEUROPEPTIDES ON GASTRIC LUMINAL ACID (H^+), SEROTONIN (5-HT) AND HISTAMINE (HIST) RELEASE IN THE RAT. **R.L. Stephens, Jr. and Y. Tache' Department of Physiology, The Ohio State Univ., Columbus, Ohio 43210 and CURE, VA Wadsworth Medical Center, UCLA, Los Angeles, CA 90073.**

Intracisternal (ic) injection of TRH analogue RX 77368 stimulates gastric H^+ and 5-HT secretion into the gastric lumen (Amer. J. Physiol. 256; G377-383, 1989). This study was designed to assess the effect of ic injection of other centrally active neuropeptides on H^+, 5-HT, and HIST secretion into the gastric lumen of 2-hr pylorus ligated rats. 5-HT and HIST were measured by HPLC methodology. Bombesin (500ng) and CRF (5 μg) produced marked (>95%) reduction in H^+ and 5-HT secretion. However, vagal stimulants RX 77368 (100ng) and somatostatin analogue ODT8-SS (1μg), while increasing H^+ secretion, produced stimulation and inhibition, respectively of luminal 5-HT and HIST secretion:

Treatment	N	H^+ Output (μmol/2 hr)	5-HT (ng/2hr)	HIST (ng/2hr)
vehicle	5	189 ± 63	159 ± 33	2.8 ± 1.4
RX 77368	5	348 ± 55[a]	568 ± 65[a]	15.9 ± 6.6[a]
ODT8-SS	5	395 ± 67[a]	14 ± 4[b]	0.4 ± 0.1[b]

[a]: sign. increase $p<0.05$; [b]: sign. decrease $p<0.05$

The data reveals central peptidergic pathways which influence gastric 5-HT and HIST release, and suggests a dissociation between mechanisms of central regulation of gastric H^+ output and luminal 5-HT and HIST release. Supported by Ohio State University Seed Grant 221192.

92.11

OXYTOCIN AGONIST ADMINISTERED CENTRALLY DECREASES FOOD INTAKE IN RATS. B.R. Olson*, M.D. Drutarosky*, M.S. Chow*, V.J. Hruby*, E.M. Stricker, and J.G. Verbalis (SPON: A. Robinson). University of Pittsburgh, Pittsburgh, PA and University of Arizona, Tuscon, AZ.

Activation of central oxytocinergic (OT) pathways is frequently correlated with inhibition of gastric motility (GM) and food intake (FI) in rats. Although systemically administered OT does not decrease GM or FI, OT projections from the paraventricular nucleus to the brainstem have been shown to participate in vagally-mediated inhibition of GM (Rogers et al, Peptides, 8:505, 1987). To ascertain whether central OT projections similarly mediate inhibition of FI, we evaluated the effect of acute icv injections of an OT agonist (MSC(11)51; OTAg) on FI in male rats trained to eat pelleted chow on a twice daily feeding schedule. Various doses of OTAg dissolved in 5 ul of artificial CSF (aCSF) were administered through indwelling lateral ventricular cannulae 30 min before a 1h morning feeding session. Significant inhibition of FI was found with increasing doses of OTAg as compared to each animal's FI after aCSF icv (*$p < 0.001$):

OTAg dose (pmol)	10	25	50	500
FI (% of baseline)	82 ± 33 (n=4)	55 ± 19* (n=4)	53 ± 6* (n=8)	41 ± 12* (n=5)

Our results demonstrate that central injection of an OT agonist decreases food intake in rats, and support the hypothesis that central OT projections may act to inhibit food intake in addition to their already established role of inhibiting gastric motility.

92.12

OXYTOCIN-INDUCED PENILE ERECTION AND YAWNING: ROLE OF CALCIUM AND PROSTAGLANDINS. A. Argiolas and M.R. Melis, Department of Neurosciences, University of Cagliari, Via Porcell 4, 09124 Cagliari (Italy).

The effect of inhibitors of calcium channels verapamil, flunarizine, nimodipine, nicardipine, and nifedipine, and of prostaglandin synthesis indomethacin and aspirin, on penile erection and yawning induced by oxytocin was studied in male rats. All calcium channel inhibitors given i.p. 60 min before i.c.v. oxytocin (30 ng) prevented in a dose-dependent manner oxytocin effect. Nimodipine and nicardipine were the most effective being active at doses between 5 and 20 mg/kg, while nifedipine, verapamil and flunarizine were active at doses higher than 15 mg/kg. Unlike calcium channel inhibitors, indomethacin (10 and 50 mg/kg i.p.) and aspirin (100 mg/kg i.p.) were ineffective. Microinjection of calcium, but not of prostaglandin E_2 and prostaglandin F_2 in the paraventricular nucleus of the hypothalamus, the brain area most sensitive for the induction of the above behavioral responses by oxytocin, induced a symptomatology similar to that induced by oxytocin. The present results suggest that calcium might be the second messanger which mediates the expression of penile erection and yawning induced by oxytocin.

92.13

ANGIOTENSIN II INDUCES OXYTOCIN AND VASOPRESSIN RELEASE FROM PERFUSED HYPOTHALAMIC EXPLANTS. M. J. Sullivan, B. J. M. van de Heijning* and L. P. Renaud. Centre for Research in Neuroscience, Montreal General Hospital and McGill University, Montreal, Quebec, Canada. H3G 1A4.

Intracerebroventricular injections of angiotensin II (Ang II) have been demonstrated to produce increases in circulating levels of vasopressin (VP) and oxytocin (OX) in the rat. Electrophysiological evidence implicates angiotensin in depolarization of putative OX and VP neurosecretory neurons of the supraoptic nucleus. These studies suggest a role for the central angiotensin system in mediating the release of both OX and VP from the neural lobe of the pituitary.

This study examined the effect of Ang II on release of OX and VP from hypothalamic explants prepared from rat brain. Explants were perfused via the internal carotid arteries with approximately 1.5 ml/min oxygenated, warmed artificial cerebrospinal fluid and the anterior pituitary removed. The perfusate was continuously sampled via a suction tube positioned near the neural lobe. Addition of 100 µM Ang II (200 µl/min for 2 min) to the perfusate resulted in increased release of both OX and VP. Attenuation of the angiotensin-induced responses by application of the angiotensin antagonist Sar^1, Thr^8 angiotensin II (1 mM) and by electrolytic lesion of the SON were investigated. The results demonstrate hypothalamic angiotensin is involved in modulation of OX and VP release from the pituitary.

ANGIOTENSIN II (AII) BUT NOT CARBACHOL DIPSOGENESIS IS RESISTANT TO PERTUSSIS TOXIN (PTX) TREATMENT. R.C. Speth and K.L. Grove* (SPON: R.E. Hruska). Dept. of VCAPP, Washington State University, Pullman, WA 99164-6520.

AII receptor stimulation is transduced via two or more different GTP binding (G) proteins. AII inhibits adenylate cyclase activity via the PTX sensitive G_i, and stimulates phospholipase C activity via PTX sensitive, and insensitive mechanisms. There is little information regarding G protein coupling of brain AII receptors, therefore this study examined whether a PTX sensitive G protein mediates the dipsogenic actions of AII in the brain. Rats were implanted with a stainless steel guide cannula positioned 2 mm above the lateral ventricles (LV). 200 pmol of AII was administered into the LV with an injector cannula to determine the dipsogenic response to AII, after which 0.5-1.0 ug of PTX was administered into the LV. 2-3 days later the dipsogenic response to 200 pmol of AII in the LV was again determined. The same protocol was used to test the effect of PTX on the dipsogenic response to 1.64 nmol of carbachol.

DIPSOGEN	(n)	CONTROL PERIOD	2-3 DAYS post-PTX
AII	(6)	9.2 +/- 2.6	10.0 +/- 2.4
Carbachol	(10)	4.1 +/- 2.1	1.8 +/- 2.2†

† $p = 0.0022$, less than control carbachol response.

These results suggests that the dipsogenic actions of AII in the brain are not mediated by a PTX sensitive G protein, while the muscarinic cholinergic dipsogenic response is mediated by a PTX sensitive G protein.

EXCITATION OF RAT SPINAL MOTONEURONES BY TRH. G. Lacey* and A. Nistri. Pharmacology Dept., St. Bartholomew's Hosp. Med. Coll., London EC1M 6BQ., England.

The endogenously occurring tripeptide TRH can excite a number of central neurones. We examined the effect of TRH on spinal motoneurones in vitro. Intracellular recordings were obtained from lumbar motoneurones of the isolated spinal cord of 5-6 day old rats. Preparations were continuously superfused at 25°C with Krebs solution. Motoneurones had average membrane potentials of -65 mV and input resistance of 40 MΩ. Bath-applied TRH (protirelin tartrate; 50 µM) elicited slowly developing membrane depolarizations (on average 25 mV) with slow recoveries on washout. During TRH application neurones fired repetitively and displayed intense synaptic activity. In contrast, the putative transmitter glutamate (1 mM) induced rapid depolarizations of smaller amplitude (15 mV on average) with fast recovery. Cell input resistance was consistently increased by TRH, a phenomenon not due to membrane rectification. In the presence of TTX (1 µM) to block fast regenerative activity, 80% of motoneurones were depolarized by TRH and largely increased their input resistance; the latter change was not mimicked by raising extracellular K^+ or by steady depolarizing currents. Our results suggest that TRH produced a long-lasting period of increased motoneuronal excitability during which repetitive spike discharges were observed.

THE EFFECTS OF INTRATHECAL INJECTION OF NPY ON RENAL SYMPATHETIC NERVE ACTIVITY AND THE INTERACTION WITH OTHER VASOACTIVE AGENTS. X. Chen, M.M. Knuepfer and T.C. Westfall (Spon: M.A. Walz). Dept. of Pharmacology, St. Louis Univ. Med. Ctr., St. Louis, MO 63104

The intrathecal (Int) injection of NPY produces a decrease in BP. In the present study we examined the effect of Int injections of NPY on renal sympathetic nerve and baroreflex activity, and the interaction between NPY and norepinephrine (NE) and vasopressin (AVP). For Int injections, one polyethylene catheter (PE10) was inserted down the spinal subarachnoid space (about T10) through a puncture of the atlantoocipital membrane of anesthetized rats. Drugs were dissolved in saline and slowly injected at a volume of 10 µl-15 µl. A branch of the renal nerve was dissected for recording of renal sympathetic nerve activity. The left femoral (or carotid) artery and vein were cannulated for (BP) measurement and drug infusion, respectively. The Int injection of NPY (4 nmol/kg) significantly decreased renal sympathetic nerve activity (38± 3.6%, $p < .05$) and decreased BP (12± 1.5%, $p < .05$), but did not change the baroreflex sensitivity significantly. The Int injection of NE (5 nmol) significantly decreased BP and heart rate ($p < .05$). Pretreatment with a subthreshold dose of NPY prevented the depressor effect of Int NE ($p < .05$). The Int injection of AVP produced an increase in BP with a peak response at 3 min. A 2nd injection of AVP resulted in attenuation of the peak response. NPY (.01 nmol) 30 min previously did not alter the second AVP response (Supported by HL26319 and 35202).

INTRAPORTAL INFUSIONS OF NEUROPEPTIDE Y INHIBIT GLUCOSE OUTPUT BY THE LIVER. L. Goehler, L. O'Farrell, G. Boublick*, J. Rivier*, and D. Novin. Dept. Cell. and Struct. Biol., U. of Colorado, Denver, CO, Dept. of Psych., UCLA, Los Angeles, CA, and Salk Institute, La Jolla, CA.

Neuropeptide Y (NPY), the neuronal component of the pancreatic polypeptide family of regulatory peptides, colocalizes with tyrosine hydroxylase in sympathetic nerves innervating the livers of rabbits and guinea pigs. Sympathetic nerves innervating the liver regulate liver glucose production, particularly during stress. To investigate whether NPY modulates stress-induced hyperglycemia, NPY (200 ug/kg) was infused intraportally into the livers of anesthetized, surgically stressed rabbits, and unstressed chronically catheterized rabbits alone or in combination with the hyperglycemic hormones glucagon or norepinephrine (NE).

NPY infusions significantly reduced hyperglycemia compared to vehicle infused controls in surgically stressed animals. In unstressed rabbits, NPY had a mild but significant hypoglycemic effect when infused alone, and attenuated the actions of glucagon and NE by 35% and 60%, respectively, supporting role for NPY in the regulation of liver glucose production.

92.18

Neuropeptide Y (NPY) *does not* inhibit the perforant path-dentate granule cell synapse in rat hippocampal slice. **William F. Colmers and Gloria J. Klapstein* Dept. Pharmacology, Univ. of Alberta, Edmonton, Alberta, T6G 2H7, Canada.**

NPY potently inhibits excitatory synaptic transmission at the stratum radiatum-CA1 and mossy fiber-CA3 synapses in rat hippocampus. The action of NPY was therefore assessed on the perforant path (PP) to dentate granule cell (DGC) synapse, the first major input to the hippocampal formation.

Hippocampal slices (500 µm) were prepared using standard techniques, and held submerged in oxygenated buffer at 35°C. DGC's were impaled with 2M K^+-acetate filled microelectrodes (100-150 MΩ); field potentials were recorded with 2M NaCl-filled pipettes. Drugs were applied via the bath.

DGC's were characterized by their position, resting potential and action potential waveform. Stimulation of PP elicited a short-latency EPSP which could be abolished by application of the (Q/K) glutamate receptor antagonist CNQX (10 µM). Application of 1 µM NPY only caused a reversible reduction (of 20%) in the PP EPSP amplitude in 1 of 6 neurons. Resting and active membrane properties were not affected. 1 µM NPY only reduced (by 16%) the PP-evoked extracellular population spike (PS) recorded in the granule cell layer in 1 of 4 experiments. However, the presynaptic inhibitors baclofen (30 µM), muscarine (10 µM) and 2-chloroadenosine (2-CA; 3 µM) caused large (>60%), reversible reductions in the intracellularly recorded EPSP, and reversibly abolished the PS in all preparations.

The results indicate that NPY does not significantly affect synaptic transmission between PP and DGC's. Because NPY potently inhibits several other major excitatory synapses in hippocampus, NPY's function may be to modulate excitatory transmission only within the hippocampus proper.

TRH STIMULATES INOSITOL PHOSPHATE (IP_X) RELEASE IN RAT HIPPOCAMPAL (HC) SLICES. A. Sattin, N.D. Means*, and M.J. Kubek. Depts. of Psychiatry and Anatomy, VA and Indiana Univ. Med. Centers, Indianapolis, IN 46202.

Our previous work has suggested that HC contains both extrinsic and intrinsic TRH and the latter may be augmented 5-fold following seizures. Our histochemical observations have localized the TRH in cell bodies and dendrites of CA and granule cells. Since HC contains TRH receptors, and since TRH is a potent stimulus of IP_X release in pituitary-derived GH_3 tumor cells, we incubated HC slices (0.3 mm) in an oxygenated artificial CSF (37°). After a 1 h. load-up with myo-(2-^{3}H) inositol followed by a 20 min. chase with cold myo-inositol, and then a 15 min. preincubation (with or without 10 mM Li^+), we exposed the slices to agonists. Following extraction of the ^{3}H-IP_X by grinding the slices in chloroform/methanol, the aqueous IP_X was isolated chromatographically. Results were expressed as the ratio of aqueous soluble dpm (^{3}H-IP_X) vs. the total radioactivity present in the sample (sum of the dpm in both the aqueous and organic phases). A 2 min. exposure to 10 nM TRH in the absence of Li^+ increased the formation of IP_X 18% over baseline (p .02) which was less than the 29% increase observed after exposure to 10 mM L-glutamic acid. In 10 mM Li^+, TRH gave a 5%-25% increase at 10 min. and a 32%-53% increase at 30 min., compared to 33%-82% and 142%-176%, respectively, for 100 uM NE. Results with higher doses of TRH will also be presented. Supported by VA Res. Svc.

BETHANECHOL AND GALANIN INITIATE HYPERPOLARIZATION OF MUDPUPPY ATRIAL MUSCLE CELLS BY DIFFERENT MECHANISMS. L. A. Merriam, L. M. Konopka and R. L. Parsons. Dept. of Anat. & Neurobiol., Univ. of Vt., Burlington, VT 05405.

Vagal stimulation produces cholinergic and non-cholinergic inhibition of cardiac output in mudpuppy heart (Axelsson and Nilsson, Exp. Biol. 44:229, 1985). A neuropeptide, similar to mammalian galanin, is co-localized with ACh in the postganglionic parasympathetic neurons innervating the heart. ACh and galanin inhibit twitch tension in isolated cardiac muscle preparations (Parsons et al., Neuroscience, 1989). We demonstrate here that enzymatically dissociated mudpuppy atrial muscle cells can be hyperpolarized by both bethanechol and galanin. The onset of hypolarization is much slower and the duration longer with galanin than with bethanechol. The hyperpolarizations by both agonists are voltage dependent, increasing with depolarization and reversing at ~-100mV. Atropine (5uM) blocks the bethanecol hyperpolarization but not the galanin hyperpolarization. Following substitution of Mg^{2+} for extracellular Ca^{2+}, the galanin hyperpolarization is markedly reduced without a significant change in the bethanechol response. We suggest that both agonists initiate hyperpolariation by activating a K^+ conductance, but the membrane receptors and the class of K^+ channels involved appear to be different. Supported by Grants NS 23978 and NS 25973.

GALANIN STIMULATES PHOSPHATIDYLINOSITOL TURNOVER IN CARDIAC TISSUE OF NECTURUS. J.C. Hardwick, T.W. McKeon, R.E. Carraway*, L. Konopka, and R.L. Parsons. Department of Anatomy and Neurobiology, University of Vermont, Burlington, VT 05405 and Department of Physiology, University of Massachusetts Medical Center, Worcester, MA 01605.

Application of either galanin or bethanechol, a muscarinic agonist, causes hyperpolarization of cardiac muscle cells in Necturus maculosus (mudpuppy). Biochemical and immunohistochemical studies were undertaken to investigate the effects and location of galanin-like peptide in mudpuppy cardiac tissue. Galanin-like peptide is present in high concentration in cardiac tissue as compared to other tissues known to contain substantial amounts of galanin across species. Galanin-immunoreactive processes of postganglionic parasympathetic neurons are present in atrial and ventricular tissue in close association with cardiac muscle fibers. In addition, galanin, but not bethanechol, stimulates phosphatidylinositol (PI) turnover in both atrial and ventricular preparations. A dose-response curve for the galanin-induced stimulation of PI turnover in atrial muscle showed maximal stimulation at a concentration of 10^{-6} M, and an apparent EC_{50} of 7.5 nM. Preincubation with pertussis toxin (50 ng/mL) had no effect on galanin stimulation of PI turnover. From these data, we conclude that a galanin-like peptide is present in fibers innervating cardiac muscle of the mudpuppy. Galanin can then act as a modulator of cardiac muscle via stimulation of the phosphatidylinositol second messenger system. Supported by PHS grants NS 23978 and NS 25973.

EFFECT OF NEUROTENSIN ON IN VIVO RELEASE OF ACETYLCHOLINE FROM THE RAT STRIATUM. M. Shimoyama and S. Kito. Third Department of Internal Medicine, Hiroshima University School of Medicine, Hiroshima, 734. Japan.

Interaction between neuropeptides and dopamine (DA) has been well documented in certain brain regions. Nevertheless, there have been few papers on neurotensin(NT)'s effect on acetylcholine (ACh) in the central nervous system. We examined the effect of NT on in vivo release of ACh and DA from the rat striatrum using intracerebral dialysis. A dialysis probe (3 mm in length) was implanted into the rat striatum and perfused with a Ringer solution (DA release experiments) or that containing 10 μM physostigmine (ACh release experiments). ACh and DA in the perfusates were measured by HPLC with electrochemical detector. Local administration of NT(10^{-6} M - 10^{-4} M) into the rat striatum stimulated both DA and ACh release. Intraperitoneal administration of NT(25-100 μg/kg) also enhanced spontaneous release of ACh and DA, though less effective than intrastriatal administration. These results demonstrated that intrastriatal and systemic administration of NT caused increases of striatal ACh and DA release. The action of NT resembled the effect of a DA receptor antagosist.

SEROTONIN RECEPTORS I

93.1

TEMPERATURE DEPENDENCY OF QUIPAZINE'S AGONISTIC/ ANTAGONISTIC INTERACTION AT SEROTONIN AUTORECEPTORS. G.M. Williams, D.L. Smith* and D.J. Smith. Anesth. & Pharmac., WVU Health Sci. Ctr., Morgantown, WV 26506.

Some investigators (Neuropharmacol 27:37, 1988) show that quipazine acts as an agonist at autoreceptors, while others (Neuropharmacol 21, 445, 1982; J. Neurochem. 45:1886, 1985) only report an antagonistic action at ≥ 1μM. In the present study, several experimental conditions were tested for their ability to influence quipazine's action. Initially, synaptosomes isolated from rat spinal cord tissue were superfused at 25°C with a Tris-buffered Krebs solution containing 1μM fluoxetine. They were preloaded with ^{3}H-5HT, and release was induced by elevating K^+ to 15mM. Under this condition 1μM quipazine was only antagonistic to autoreceptor function. The addition of 10μM pargyline and/or 5.7mM ascorbic acid to the medium failed to alter this effect. Likewise, an agonistic action was not observed when fluoxetine was removed. In contrast, elevating the temperature of the superfusion medium to 37°C allowed a dose related agonistic action, with 10nM-1μM quipazine reducing the release of ^{3}H-5HT from 90-67% of control. Also, the K^+-induced release of ^{3}H-5HT was doubled and the agonist potencies of 5HT and RU24969 were 1.5 times greater. These data suggest that the processes occurring in response to the interaction of agonists at autoreceptors are sensitive to temperature changes. Supported by NIH 5-T32-GM07039 and the Dept. of Anesth.

CHARACTERISTICS OF 5-HT_3 RECEPTOR-EVOKED DOPAMINE RELEASE FROM RAT BRAIN. P.Blandina*,J.Goldfarb, B. Craddock-Royal* and J.P.Green. Department of Pharmacology, Mount Sinai School of Medicine, C.U.N.Y., New York, NY 10029.

5-HT3-receptor activation releases dopamine (DA) from superfused rat striatal slices (P.Blandina,J.Goldfarb, and J.P.Green.Eur.J.Pharmacol. 155:349,1988). We now report that the process is Ca^{++}-dependent, sensitive to tetrodotoxin (TTX) and enhances the K^+-evoked DA release. Rat striatal slices were superfused and DA was measured (P.Blandina et al.Eur.J.Pharmacol. 155:349,1988). When the slices were prepared in and superfused with Ca^{++}-free, EGTA-containing medium,5-HT-evoked DA release was completely abolished. A similar result was obtained with 3 min preincubation in Ca^{++}-free,EGTA-containing medium, thus suggesting that 5-HT releases DA by promoting the entrance of Ca^{++} ions into the nerve terminals. Superfusion of the slices with 0.5 μM or 1 μM TTX reduced the 5-HT-evoked release by 40%,implying multiple mechanisms for the 5-HT action. Both 5-HT and the 5-HT3 agonist,2-CH3-5-HT,enhance the K^+-induced DA release by 30%. Activation of 5-HT3 receptor could be the mechanism by which the serotonergic raphé projections modulate striatal dopaminergic activity independently of control of firing of dopaminergic cell bodies in the substantia nigra. Supported by a grant (DA 01875) from the National Institute on Drug Abuse.

RU 24969-INDUCED EMESIS IN THE CAT: SEROTONIN-1D SITES IMPLICATED. J.B. Lucot. Dept. Pharmacol., Wright State University, Dayton, OH 45435.

This study was part of a series of experiments designed to characterize the role of serotonin (5-HT) receptor subtypes in emetic syndromes. 5-HT agonists were administered subcutaneously and the cats observed for 45 min or for 15 min after the last emetic event, whichever occurred later. RU 24969 elicited emesis with a maximally effective dose of 1.0 mg/kg. 5-Methoxytryptamine was found to have lower efficacy and more nonspecific effects. TFMPP was devoid of emetic effects. Emesis elicited by 1.0 mg/kg of RU 24969 was unaltered by pretreatment with phentolamine, yohimbine, (-)propranolol and haloperidol, suggesting that catecholamines played no role. Emesis was prevented by metergoline but not by ICS 205 930, ketanserin, cyproheptadine, mesulergine or BMY 7378. Evaluation of the results implicates 5-HT_{1D} sites in the emetic response. This conclusion will have to be verified when drugs selective for this site become available. The emesis was also prevented by 8-OH-DPAT, confirming that it has a general antiemetic effect in cats.

93.4

NEURONAL AND MUSCULAR 5-HT RECEPTORS OF THE GUINEA PIG LONGITUDINAL MUSCLE-MYENTERIC PLEXUS (LM-MP). J. Coupet, H. Park, C. E. Rauh, F. Arnold and L.R. Meyerson. American Cyanamid Co., Med. Res. Div., Ramapo College, Mahwah, NJ 07430

Multiple 5-HT receptor subtypes have been implicated in the excitatory and inhibitory responses evoked by 5-HT when applied to ileal preparations. The present study shows that 5-HT_{1A}, 5-HT_2 and 5-HT_3 receptors are functionally involved in these responses based upon electrophysiological and biochemical experiments with LM-MP. Muscle tension in LM-MP strips was monitored in the presence of various agonists and antagonists. Tetrodotoxin (TTX) at 0.2 µM was used to differentiate between direct muscular and neuronal mediated contractile components. Neuronally mediated contractions were completely attenuated by TTX and by the 5-HT_3 antagonists ICS 205-930, GR-38032F or zacopride. Those contractions due to direct stimulation of 5-HT receptors on the smooth muscle were neither affected by TTX nor by 5-HT_3 antagonists but were completely inhibited by ketanserin or cinanserin (200 nM). The binding of [^{3}H]-ketanserin to ileal membranes revealed high and low affinity components with Kd values of 0.5 and 20 nM, respectively. In myenteric plexus synaptosomes, 8-OH-DPAT prevented the evoked release of [^{3}H] acetylcholine and inhibited forskolin-stimulated adenylate cyclase with IC_{50} values of 0.5 and 1.0 µM, respectively. Collectively, the results of these experiments indicate that in the guinea pig ileum, at least three separate 5-HT receptor subtypes are functionally involved in the excitatory and inhibitory responses to 5-HT. An excitatory 5-HT_2 receptor resides directly on the smooth muscle while an excitatory 5-HT_3 as well as an inhibitory 5-HT_{1A} receptor is located on the neuronal network of the LM-MP.

93.5

IMPORTANCE OF 5-HT_{1A} AND 5-HT_2 RECEPTORS IN THE EXPRESSION OF FOREPAW TREADING AND HEAD TWITCHES IN RATS. J. Arnt and J. Hyttel*. H. Lundbeck A/S, Ottiliavej 7-9, DK-2500 Copenhagen-Valby, Denmark.

Serotonin$_{1A}$ (5-HT_{1A}) receptors are considered to mediate the forepaw treading syndrome in rodents, whereas 5-HT_2 receptors are considered to mediate head twitch behaviour (Tricklebank, M., Trends Pharmacol. Sci. 6, 403, 1985). In this study an interaction between these sites in the expression of both behaviours is suggested. The 5-HT_{1A} agonist 8-OHDPAT induced a maximum score of forepaw treading (ED_{50} 8.0 µmol/kg, s.c.). After combination with the 5-HT_2 agonist DOI, which does not induce forepaw treading per se, the potency was increased 20 times. In contrast, 8-OHDPAT inhibited the head twitches induced by DOI. This suggests an opposite interaction between 5-HT_{1A} and 5-HT_2 receptors in expression of these 2 behaviours. In contrast, forepaw treading induced by the mixed $5\text{-HT}_{1A}/5\text{-HT}_2$ agonist 5-methoxy-N,N-dimethyltryptamine was unchanged by DOI. The partial 5-HT_{1A} agonists buspirone, ipsapirone and gepirone did not induce forepaw treading when given alone or in combination with DOI, whereas all inhibited DOI-induced head twitches. The combined effect of 8-OHDPAT and DOI on forepaw treading was inhibited by (-)-alprenolol (a mixed 5-HT_{1A}/β-adrenoceptor antagonist) and also by the 5-HT_2 antagonists ritanserin or ketanserin. These results support the hypothesis that 5-HT_{1A} receptors mediate forepaw treading, but that activation of 5-HT_2 receptors is necessary for expression of the maximum resonse and sensitivity. Further, the results indicate that high 5-HT_{1A} efficacy is necessary for expression of forepaw treading.

93.6

1-(2,5-DIMETHOXY-4-IODOPHENYL)-2-AMINOPROPANE (DOI) ACTIVATION OF THE 5-HT_2 RECEPTOR SUBTYPE INCREASES RAT PLASMA ACTH CONCENTRATION.

B. H. King*, C. Brazell*, C.T. Dourish, and D.N. Middlemiss*. *UCLA Neuropsychiatric Institute, Los Angeles, and the Neuroscience Research Centre, Merck Sharp and Dohme, Terlings Park, Eastwick Road, Harlow, Essex, England.*

We have investigated the plasma ACTH response to 1-(2,5-Dimethoxy-4-iodophenyl)-2-aminopropane (DOI) in the rat, with the aim of distinguishing the role of 5-HT_2 from 5-HT_{1C} receptors in the mediation of measured changes. Male Sprague-Dawley rats received s.c. antagonist or vehicle at time zero, followed by DOI, 0.8 mg/kg s.c. at 30 minutes, and cardiac puncture under halothane anesthesia at 60 minutes. Plasma ACTH was measured by two-site immunoradiometric assay (Euro-Diagnostics BV, Apeldoorn, Holland). The ACTH response to DOI was blocked by the 5-HT_2 receptor antagonists ICI 170,809, mesulergine, spiperone, and ketanserin, whilst the $5\text{-HT}_{1A}/5\text{-HT}_{1B}$ receptor antagonist, (-)-pindolol, had no effect.

The lack of demonstrable inhibition by (-)-pindolol, a drug with high affinity at $5\text{-HT}_{1A}/5\text{-HT}_{1B}$ sites but not $5\text{-HT}_{1C}/5\text{-HT}_2$ sites effectively minimizes the former receptor subtypes' importance, as well as beta-receptor involvement in the mediation of the DOI effect on ACTH. Additionally, spiperone has approximately 600-fold greater affinity for the 5-HT_2 than for the 5-HT_{1C} site (Hoyer, D, *J. Recept. Res.*, 8:59-81, 1988), and ketanserin, which shares nanomolar affinity at the 5-HT_2 site but not at dopaminergic sites, also inhibited the DOI-mediated ACTH increase. Thus it appears that 5-HT_2 receptor stimulation is more important than that of the 5-HT_{1C} receptor in the production of the DOI-induced ACTH response.

ESTROGEN EFFECTS ON 5-HT_{1A} BINDING SITES AND INHIBITION OF FORSKOLIN STIMULATED ADENYLYL CYCLASE ACTIVITY IN HIPPOCAMPUS OF OVARIECTOMIZED RATS. William P. Clarke[1], Saul Maayani[1,2] and Joseph Goldfarb[1]. Depts. of Pharmacology[1] and Anesthesiology[2], Mount Sinai School of Medicine, CUNY, New York, NY 10029.

Activation of the serotonin$_{1A}$ (5-HT_{1A}) receptor elicits two independent effects in rat hippocampal preparations: 1) an increase in K^+ conductance of pyramidal cells, resulting in hyperpolarization and decrease in population spike amplitude, and 2) inhibition of forskolin stimulated adenylyl cyclase (FSAC) activity. Chronic treatment of ovariectomized (OVX) rats with estrogen (3-6 days) enhances 5-HT_{1A} agonist induced decrease in population spike amplitude and hyperpolarization (Clarke and Goldfarb, Eur. J. Pharm. 160:195, 1989; Clarke et al., Neurosci. Abstr 14:553, 1988).

Female Sprague Dawley rats were OVX and two weeks later received silastic capsule implants sc containing either estradiol-17β (ES, 10% or 20% in cholesterol) or cholesterol (CHOL) alone. Rats were sacrificed 4 days later. For 5-HT inhibition of FSAC activity, mean (±SEM) pEC_{50} and E_{max} values for CHOL rats (n=5) were 7.23 ± 0.13 and 21.7% ± 2.08 and for ES (n=5) rats were 7.75 ± 0.24 and 24.1% ± 1.59, respectively. For [^{3}H]8-OH-DPAT binding mean (±SEM) pK_d and B_{max} (fmols/mg protein) values for CHOL rats (n=3) were 8.84 ± 0.07 and 650 ± 49 and for ES rats (n=3) were 9.03 ± 0.08 and 639 ± 48, respectively. Based on these preliminary data, the magnitude of estrogen induced leftward shift in the concentration response curve (CRC) for inhibition of FSAC by 5-HT appears similar to the estrogen induced shift in the CRC for 5-HT_{1A} induced decrease in population spike amplitude.

Ca^{++} MOBILIZATION MEDIATED BY 5-HT_2 RECEPTORS IN FURA-2-LOADED HUMAN PLATELETS.

A.Kagaya*,M.Mikuni,H.Yamamoto*,Y.Kuroda* and K.Takahashi* (SPON:M.Watanabe).Div. of Mental Disorder Res., National Institute of Neuroscience,NCNP,Kodaira,Tokyo 187,Japan.

Recent studies suggest that the activation of 5-HT_2 receptors increases phosphatidylinositol hydrolysis in the CNS and human platelets. It has also been shown that inositol-trisphosphate can mobilize intracellular Ca^{++}. To know the precise relationship between 5-HT_2 receptors and cytoplasmic Ca^{++} mobilization, we have investigated the effects of serotonergic agents on intracellular Ca^{++} concentration in fura-2-loaded human platelets. 5-HT increased intracellular Ca^{++} concentration in a dose dependent manner. A maximal increase in Ca^{++} concentration, which was observed at 10uM 5-HT, was 116±21nM with 5-HT's EC_{50} value of 0.2uM. Ketanserin, a selective 5-HT_2 antagonist, inhibited 5-HT-induced Ca^{++} increase dose-dependently with IC_{50} value of 2nM. DOI, a 5-HT_2 agonist, increased Ca^{++} concentration in a ketanserin-reversible fashion. Since DOI, however, partially antagonized the ability of 5-HT to elevate intracellular Ca^{++} control, DOI may act as a partial agonist at 5-HT_2 receptor. These results indicate that the stimulation of 5-HT_2 receptors increases intracellular Ca^{++} concentration in human platelets, suggesting that platelets can be useful means to investigate 5-HT_2 receptor functions in the CNS.

SEROTONIN 5-HT$_2$ RECEPTORS ON A CLONAL CELL LINE ARE COUPLED TO PHOSPHOINOSITIDE HYDROLYSIS. K. J. Nicklaus and P. B. Molinoff. Dept. of Pharmacology, Univ. of Penn., Phila., PA 19104.

A clonal cell line was established from the transplantable rat pituitary tumor 7315a. Results of radioligand binding studies indicate that P11 cells express 5-HT$_2$ receptors. Analysis of the binding of [^{125}I]LSD to membranes from P11 cells revealed the presence of a single class of high-affinity sites (K_d=1.6 nM, B_{max}=211 fmol/mg protein). The pharmacological profile of the inhibition of the binding of [^{125}I]LSD by a panel of drugs was consistent with the expected profile of these drugs at 5-HT$_2$ receptors. The affinity of the site for serotonin was in the low micromolar range and was decreased by GTP. Serotonin stimulates phosphoinositide hydrolysis in P11 cells. Increasing concentrations of the 5-HT$_2$ selective antagonist ketanserin block phosphoinositide hydrolysis stimulated by serotonin, and Schild analysis suggests simple competitive inhibition. The K_i for ketanserin derived from Schild analysis is comparable to the K_i for ketanserin measured in binding assays with [^{125}I]LSD. These results suggest that stimulation of phosphoinositide hydrolysis in P11 cells by serotonin is mediated by 5-HT$_2$ receptors. Pretreatment of P11 cells with pertussis toxin resulted in ADP-ribosylation of G_i and G_o, but did not affect the ability of serotonin to stimulate phosphoinositide hydrolysis. Therefore the G protein that couples 5-HT$_2$ receptors in P11 cells to phospholipase C is unlikely to be G_i or G_o. P11 cells will be a useful model system for future studies of the regulation and function of 5-HT$_2$ receptors on cultured cells. *Supported by NS18591 and a N.S.F. fellowship to K.J.N.*

BLOCKADE OF AN ATYPICAL CENTRAL 5-HT RECEPTOR BY BRL 24924 IN THE RAT HIPPOCAMPUS. Y. CHAPUT, R.C. ARANEDA* AND R. ANDRADE. Dept. of Pharmacology, St. Louis Univ. School of Med., St. Louis, MO 63104.

It has been shown previously that the superfusion of serotonin (5-HT) onto CA1 cells in hippocampal slices elicits a hyperpolarization which is accompanied by a marked reduction of the calcium-activated after-hyperpolarization (AHP). Since this potential is the primary determinant of spike-frequency adaptation in these neurons, this second effect functions to modulate the inhibitory actions of the 5-HT induced hyperpolarization. While the ability of 5-HT to hyperpolarize these cells is known to be mediated via a 5-HT$_{1A}$ receptor, the effects on the AHP are mediated by a different as yet unidentified receptor. Therefore, CA1 pyramidal neurons were recorded intracellularly using an in vitro slice preparation, in order to determine the effectiveness of a series of 5-HT receptor antagonists in blocking this second response to 5-HT.

Calcium spikes and their associated AHPs were recorded in the presence of TTX (0.3 μM) and TEA (5 mM). As previously reported, bath administration of 5-HT (10 μM) reduced the AHP without affecting the calcium spike. BRL 24924 (1 to 30 μM), markedly reduced this effect of 5-HT (10 μM) on the AHP, without either altering the AHP itself or reducing the 5-HT$_{1A}$-mediated hyperpolarization. The ability of 5-HT to reduce spike-frequency adaptation was also blocked by BRL 24924. In contrast to these results, bath administration of the non-selective 5-HT$_1$/5-HT$_2$ receptor antagonists methysergide (30 μM) and metergoline (30 μM), or of the 5-HT$_3$ receptor antagonist ICS 205-930 (up to 50 μM), had little effect on the ability of 5-HT to reduce the AHP.

These data further strengthen the suggestion that the 5-HT receptor mediating the decrease in the AHP of rat CA1 hippocampus pyramidal neurons does not conform to any of the 5-HT receptors defined by binding studies. Moreover, its selective blockade by BRL 24924 indicates that this receptor may resemble the atypical 5-HT receptor present on enteric neurons. This work was supported by the Pharmaceutical Manufacturers Association Foundation and USPHS Grant MH 43985 to R.A., and, by an MRC postdoctoral Fellowship to Y.C.

THE IDENTIFICATION OF 5-HT$_2$ AND 5-HT$_3$ RECEPTORS IN RAT DORSAL ROOT GANGLION (DRG) CELLS. **S. Todorovic* and E.G. Anderson. Dept. Pharmacology, University of Illinois at Chicago, Chicago, IL 60612.**

The effects of 5-HT on the transmembrane potential of rat DRG somata was studied in 150 A type, 16 C type and 22 unidentified neurons. 5-HT produced a concentration dependant depolarization in 88% of these neurons. Current-voltage curves were used to determine membrane input resistance (Rin) in these cells. In 51% of the responding cells, 5-HT increased Rin, in 41% 5-HT decreased Rin, while in 8% both responses were observed on the same cell. A and C type cells responded similarly. In cells showing an increase Rin, 1-10nM of ketanserin (5-HT 2 and alpha-1 antagonist) shifted the dose response of 5-HT to the right (pA2 =9.5 $\pm$0.26). Alpha-methyl serotonin (a 5-HT 2 agonist) mimicked 5-HT in this action. Norepinephrine (NE) also depolarized many of these cells (77%, N=20) while increasing Rin, an action blocked by 10nM ketanserin or prazosin (a selective alpha-1 antagonist). However, prazosin had no effect on the 5-HT response.

Cells showing depolarization to 5-HT with decreased Rin were unaffected by ketanserin. However, ICS 205-930 and MDL 72222 (selective 5-HT3 antagonists) strongly shifted this dose response curve to the right (pA2 = 10.4 $\pm$ 0.4 and 8 $\pm$0.27, respectively). 2-Methyl 5-HT acted as agonist on this response.

Neither depolarizing response showed desensitisation when exposed to supramaximal concentrations of 5-HT for up to 15 min. Quipazine and MK-212 mimicked the depolarizing response with increased Rin, but antagonized (10 - 100 nM) the depolarizing response with decreased Rin.

These data indicate that 5-HT induced depolarization with increased Rin is mediated by 5-HT 2 receptor and the depolarization with decreased Rin is mediated by 5-HT 3 receptor. Supported by PHS NS 17834-04.

PROTEIN KINASE C INHIBITORS POTENTIATE SEROTONIN-INDUCED DEPOLARIZATIONS IN PYRAMIDAL LAYER CELLS OF PIRIFORM CORTEX P.W. Sheldon* and G.K. Aghajanian. Departments of Pharmacology and Psychiatry, Yale University, New Haven, CT 06510.

Previously we found that serotonin (5-HT) causes a small depolarization (2-6 mV) in a subpopulation of pyramidal layer cells of the rat piriform cortex. This depolarization is mediated by a 5-HT-2 receptor. It is known that the 5-HT-2 receptor stimulates phosphoinositide (PI) turnover, which can lead to an activation of protein kinase C (PKC). This study explores the effects of PKC inhibitors on 5-HT-2-mediated depolarizations in piriform pyramidal cells.

In intracellular recordings in brain slices of rat piriform cortex, bath application of the isoquinoline sulfonylamide protein kinase C inhibitor H-7 (100μM) had no effect alone but increased the magnitude of the depolarizing effect of 5-HT (100μM) approximately 100% and prolonged the duration of the 5-HT response in all cells tested. Another protein kinase C inhibitor, sphingosine (10μM), had similar effects. In cells which were not depolarized by 5-HT, H-7 produced no effect alone or in the presence of 5-HT. In piriform interneurons which are induced to fire via 5-HT-2 receptors, H-7 also increased the effect of 5-HT. We conclude that inhibition of PKC potentiates 5-HT-2-mediated excitation. Furthermore, we propose that 5-HT activation of PI turnover, by leading to an activation of PKC, could act as a negative feedback loop to regulate 5-HT-induced excitation.

A 5-HT MEDIATED IPSP IN THE NUCLEUS PREPOSITUS HYPOGLOSSI AND PRESYNAPTIC INHIBITION BY 5-HT$_{1D}$ RECEPTOR AGONISTS. D.H. Bobker* and J.T. Williams (SPON: E.A. Zimmerman). Vollum Institute, OHSU, Portland OR 97201

Intracellular recordings were made from guinea pig prepositus hypoglossi (PH) neurons in vitro. Focal stimulation of the brain slice evoked a slow, inhibitory synaptic potential (IPSP) that was typically 10-30 mV in amplitude. The IPSP reversal potential was -111 $\pm$ 1.4 mV (2.5 mM K^+) and showed a Nernstian dependence on $[K^+]_o$. Spiperone blocked the IPSP with an IC_{50} of 40 nM, while ketanserin (1 μM) and sulpiride (1 μM) had no effect. 5-HT hyperpolarized PH cells with an EC_{50} of 8.5 μM in control, and 135 nM in 10 μM cocaine. Spiperone produced a parallel, right-shift of the 5-HT concentration response curve; Schild analysis yielded a K_d of 10 nM. These results suggest that this IPSP was mediated by an increased conductance to potassium resulting from synaptically released 5-HT acting upon 5-HT$_{1A}$ receptors.

The amplitude of the IPSP was reversibly decreased by TFMPP. The EC_{50} value for TFMPP was 50 nM, with a maximal inhibition of 90% at 300 nM. TFMPP (1 μM) had no effect on the membrane potential and did not change the hyperpolarization induced by 5-HT (10 μM). Quipizine acted as a competitive antagonist, and had an estimated K_d of 164 nM. These data are compatible with the presence of a presynaptic 5-HT$_{1D}$ receptor which modulates 5-HT release. Supported by USDHHS DA 04523 & NIH HL 07596

EFFECTS OF TYPICAL AND ATYPICAL ANTIPSYCHOTIC DRUGS ON MEDIAL PREFRONTAL CORTEX 5-HT$_2$ RECEPTORS: A MICROIONTOPHORETIC STUDY. C.R.Ashby, Jr., and R.Y.Wang. Department of Psychiatry and Behavioral Sciences, SUNY Stony Brook, Stony Brook, NY 11794-8790.

Previously, we have reported (Neurosci. Abstr., 1988, 14:645) that iontophoresis (ionto) of the 5-HT$_2$ (S2) agonist (±)-1-(2,5-dimethoxy-4-iodophenyl)-2-aminopropane (DOI) suppresses medial prefrontal cortex (mPFc) cell firing and this effect can be reversed by ionto of various putative S2 antagonists. DOI's suppressant effect is not blocked by the selective S3 antagonists BRL 43694 or the 5-HT$_{1a,1b}$,ß antagonist (±)-pindolol, suggesting that DOI's action is relatively selective for the S2 receptor. In this abstract, we report the effects of the typical antipsychotic drugs (APDs) l-sulpiride (SUL), spiperone (SPIP) and haloperidol (HAL) and the atypical APD clozapine (CLOZ) on DOI's action in the mPFc. Male -Sprague Dawley rats (200-300g) were anesthetized with chloral hydrate (400mg/kg,i.p.), placed in a stereotaxic instrument and a small burr hole drilled over the mPFc. (±)DOI produced a significant dose-dependent suppression ($p < 0.001$, analysis of variance) of mPFc cell firing. CLOZ (10nA) significantly blocked DOI's effect at 20,40 and 80 nA ($p < 0.01$, paired t-test). HAL (10nA) significantly potentiated DOI's action at 20nA ($p < 0.01$, paired t-test) and had no effect at the other currents. SPIP (10nA) only blocked DOI's suppressant effect at 80nA ($p < 0.01$), whereas SUL did not alter DOI's action. Overall, these results suggest that there is an apparent difference between typical and atypical APDs in blocking DOI's effect. Further studies are needed to determine whether the differential actions between typical and atypical APDs can be explained by their differences in in vivo affinity for S2 receptors or differences in S2/D2 ratios. (Supported by USPHS Grants MH-41440, 00378 to RYW; NRSA 09791 to CRA).

DIFFERENTIAL EFFECTS OF HALOPERIDOL AND CLOZAPINE IN ANTAGONIZING THE SUPPRESSANT ACTION OF THE 5-HT_3 AGONIST 2-METHYLSEROTONIN ON MEDIAL PREFRONTAL CORTICAL CELLS. R.J. Kasser, C.R. Ashby, Jr. and R.Y. Wang. Department of Psychiatry and Behavioral Sciences, SUNY Stony Brook, Stony Brook, NY 11794-8790.

We have previously reported that the selective 5-HT_3 (S3) agonist 2-methylserotonin (2-Me-5HT) dose-dependently suppresses medial prefrontal cortical (mPFc) cell firing. This effect is antagonized by the S3 antagonist BRL 43694 but not by metergoline (5-$HT_{1a,1b,1c}$, 5-HT_2 antagonist) or (±)-pindolol (5-$HT_{1a,1b}$,ß antagonist). Radioligand binding data indicates that the typical antipsychotic drugs (APDs) fluphenazine, sulpiride and haloperidol (HAL) fail to inhibit ^{3}H-zacopride binding in rat cortical membranes. However, there have been no studies reporting the effects of atypical APDs on S3-mediated functions. We examined the effects of HAL and clozapine (CLOZ) on 2-Me-5HT-induced suppression of mPFc cells using single cell recording and iontophoresis (ionto). Male Sprague-Dawley rats (200-300g) were anesthetized with chloral hydrate (400 mg/kg, i.p.), placed in a stereotaxic instrument and a small burr hole drilled over the mPFc. The concentration of the drugs in the six barrel micropipettes was 10mM. 2-Me-5HT dose-dependently suppressed (ANOVA, $p < 0.001$) mPFc cell firing. Ionto-CLOZ (10nA,) but not HAL (10nA) blocked 2-Me-5HT's suppressant effect at 20, 40 and 80 nA ($p < 0.01$, paired t-test). Overall, these results suggest that APDs may interact with S3 binding sites in the brain. Whether their action on S3 sites is correlated with therapeutic efficacy or side effects remains to be determined. (Supported by USPHS Grants MH-41440 and MH-00378 to RYW, NRSA 09791 to CRA).

INTRAVENTRICULAR ADMINISTRATION OF THE 5-HT_3 RECEPTOR AGONIST 2-METHYL-5HT RELEASES DOPAMINE IN THE NUCLEUS ACCUMBENS: CHRONOCOULOMETRIC STUDIES. R.Y. Wang, L.H. Jiang, R.J. Kasser and C.R. Ashby, Jr. Department of Psychiatry and Behavioral Sciences, SUNY Stony Brook, Stony Brook, NY 11794-8790.

A high density of 5-HT_3 (S3) sites have been shown to be present in the mesocorticolimbic system. The functional role of (S3) receptors in the CNS remains unclear. It has been reported that activation of S3 receptors causes release of dopamine (DA) from rat striatal slices. The aim of the present study was to determine whether intraventricular administration of the S3 receptor agonist 2-methylserotonin (2-Me-5HT) releases DA in the nucleus accumbens (NAc). Sprague-Dawley rats were anesthetized with chloral hydrate. A nafion coated carbon-fiber electrode was calibrated in vitro and then was implanted in the NAc. A computer-aided in vivo electrochemical recording system was used to monitor the release of DA. Intraventricular (icv) injection of 2-Me-5HT (0.7 ± 0.02 nmole, n=8) significantly enhanced DA release (0.117 ± 0.016 µM). ICV administration of saline, 8-OHDPAT (5-HT_{1a} agonist) or (±)DOI (5-$HT_{1c,2}$ agonist) was without effect. 2-Me-5HT-induced release of DA in NAc was prevented by icv injection of the S3 antagonist BRL 43694 (86 ± 25 nmole), which by itself did not alter the release of DA in the NAc. 6-OHDA injected into the medial forebrain bundle (n=3) abolished 2-Me-5HT-induced effect. These results suggest that 2-Me-5HT activates DA neuronal activity and S3 antagonist reverses the DA hyperactivity; they are in line with the view that S3 antagonists have antipsychotic potential. (Supported by USPHS Grants MH-41440 and MH-00378 to RYW, NRSA 09791 to CRA and MH-43893 to RJK).

SEROTONERGIC AGENTS REVERSE DECISION-MAKING DEFICITS INDUCED BY A DOPAMINE AGONIST IN NEONATAL RATS. P.M. Whitaker-Azmitia, L. Molino, J. Caruso and A.V. Shemer. Dept. of Psychiatry and Behavioral Science, SUNY, Stony Brook, NY 11794.

Serotonin and dopamine interact in regulating some motor functions, however, an interaction in cognitive behaviors has not been examined.

15D rat pups were injected with 0.3 mg/kg SKF 38393 (a selective D_1 agonist, shown to produce decision-making deficits) or SKF 38393 with the following drugs: SCH 23390 (.075-.5mg/kg), ipsaperone (5-20mg/kg), chlomipramine (6-25mg/kg), buspirone (2-10mg/kg), or diazepam (1-5mg/kg). SKF 38393-induced behaviors were completely reversed in animals injected with the D1 antagonist SCH 23390, the selective 5-HT_{1a} agonists ipsaperone and buspirone and the serotonin uptake inhibitor chlomipramine. All of these groups displayed a significant dose dependent increase in spontaneous alternation and a decrease in vacillatory behavior in comparison to the SKF 38393 group [*$p < .001$]. Diazepam-treated animals showed no reversals.

In conclusion, we have reported what we believe to be the first finding of a serotonin-dopamine interaction in a cognitive behavior.

Supported by grants from NICHHD and NINDS.

5-HT_{1A}-RECEPTORS IN THE BRAIN OF THE MONGOLIAN GERBIL K.M. Bode-Greuel*, E. Horvàth*, M. de Jonge*, T. Glaser, J. Traber* (SPON: J. TAUTZ), Department of Neurobiology, Troponwerke GmbH & Co. KG, Berliner Strasse 156, D-5000 Köln 80, F.R.G.

The mongolian gerbil (meriones unguiculatus) is widely used as laboratory animal for a variety of experimental studies, especially for work on forebrain ischemia. In the course of our work on characterization of serotonin (5-HT)$_{1A}$-receptors it was of interest to look for the presence of 5-HT_{1A}-receptors into the gerbil brain by means of receptor binding and autoradiographic techniques. Furthermore, it was investigated, whether or not learning paradigms such as the 8-arm radial maze could be applied to gerbils to study cognitive processes in this species. The receptor binding assay revealed specific high affinity binding sites for ^{3}H-Ipsapirone on hippocampal and cortical membranes, the K_D- and B_{max}-values being 7.9 nM, 0.57 pmol/mg protein and 8.3 nM, 0.16 pmol/mg protein, respectively. Binding affinity and capacity were comparable to those detected in several other species. In addition, the autoradiographic distribution of ^{3}H-Ipsapirone binding site did not show any qualitative differences in comparison to rat brain. In the 8-arm radial maze gerbils acquired the learning task even faster than rats. The present study revealed the existence of 5-HT_{1A}-receptors in the gerbil brain and thus provides a basis for further functional studies.

93.19

INVOLVEMENT OF THE DORSAL RAPHE NUCLEUS IN THE DISCRIMINATIVE STIMULUS PROPERTIES OF THE 5-HT1A RECEPTOR AGONIST 8-OH-DPAT. R. Schreiber* and J. De Vry*. (SPON: D.G. Spencer), Department of Neurobiology, Troponwerke, Berliner Strasse 156, D-5000 Köln 80, F.R.G.

Male Wistar rats were trained to discriminate either 8-OH-DPAT [(8-hydroxy-2-(di-n-propylamino)tetralin), DPAT, 0.1 mg/kg], a selective 5-HT1A receptor agonist, or 5-OMe-DMT [(5-methoxy-N,N-dimetyltryptamine), DMT, 1.25 mg/kg], a mixed 5-HT1A/5-HT1B/5-HT2 receptor agonist, from saline (i.p., t-15 min) in a FR-10 food-reinforced two-lever operant procedure. The DPAT cue generalized to DPAT (ED50 in mg/kg: 0.04) and the selective 5-HT1A ligand ipsapirone (1.5), partially to DMT and the non-selective 5-HT ligand quipazine and not to the mixed 5-HT2/5-HT1C ligand DOI [1-(2.5-dimethoxy-4-iodophenyl)-2 aminopropane]. The DMT due generalized to DMT (0.35), DPAT (0.07) and ipsapirone (4.2), and partially to DOI and quipazine. These results suggest that both cues are 5-HT1A receptor mediated, although the latter one may involve additional 5-HT receptor subtypes. Local application of DPAT into the dorsal raphe nucleus (nRD) of DPAT and DMT trained rats resulted in dose-dependent and complete generalization (ED50's: 9.2 and 3.9 µg/kg, respectively, t-15 min); in similarly trained rats the ED50 obtained with DPAT after icv administration was 8.1 µg/kg (DMT cue) and after i.p. administration was 15.5 (DPAT cue) and 10 µg/kg (DMT cue). These results suggest that the nRD mediates at least partially the discriminative effects of DPAT.

93.20

DIFFERENTIAL EFFECT OF 5-HYDROXYTRYPTOPHAN (5-HTP) ON APPROACH AND AVOIDANCE RESPONDING IN THE SAME RAT. W.K. Park, J.N. Hingtgen and M.H. Aprison. Depts. of Psychiatry; Biochem.; Inst. Psychiat. Res.; Program in Medical Neurobiol.; Indiana U. Sch. Med.; Indianapolis, IN 46202.

The hypersensitive serotonin (5-HT) postsynaptic receptor theory of depression has been developed and expanded by Aprison and Hingtgen, based on an approach behavior model. We now wanted to compare the effect of both the L- and D,L-forms of the immediate precursor of 5-HT, 5-HTP (25-50mg/kg. I.P.), on Sidman avoidance (SS10;RS20) as well as on approach (VI 1) behavior in rats trained on both schedules in the same experimental chamber. From our earlier data only 5-HTP-induced suppression of approach behavior appeared to be mediated by 5-HT postsynaptic receptors. In the present study behavioral suppression was found with a food-reinforced approach schedule in a dose-dependent manner with either L- or D,L-5-HTP ($p < 0.001$), whereas no significant suppression was seen with avoidance behavior. We previously showed that 5-HTP increased the release of 5-HT and pretreatment with postsynaptic receptor antagonists blocked the behavioral suppression. Other laboratories have reported that decreases in catecholamine levels have been shown to suppress Sidman avoidance responding. Thus, the results of present study are consistent with our theory of 5-HT postsynaptic receptor involvement in depression. (Supported in part by Indiana Dept. of Mental Health).

93.21

ANTAGONISM OF THE DISCRIMINATIVE STIMULUS (S^D) EFFECTS OF 8-HYDROXY-2(DI-*N*-PROPYLAMINO)TETRALIN (8-OH DPAT) BY THE PUTATIVE SEROTONIN 1A ANTAGONIST 1-(2-METHOXYPHENYL)-4-[4-(2-PHTHALIMMIDO)BUTYL]PIPERAZINE HBR (NAN-190). J.L. Arbuckle*, C.M. Canan*, and J.E. Barrett (SPON: S.T. Ahlers). Uniformed Services Univ. of the Health Sciences, Bethesda, MD 20814-4799.

The serotonin ($5\text{-}HT_{1A}$) agonist 8-OH DPAT has been shown to function as an S^D. This S^D function of 8-OH DPAT has been antagonized by pindolol and alprenolol. Although these ß-antagonists have a high affinity for $5\text{-}HT_1$ rather than $5\text{-}HT_2$ receptors, their affinities for both $5\text{-}HT_{1A}$ and $5\text{-}HT_{1B}$ receptors are similar. Recently the putative $5\text{-}HT_{1A}$-selective ligand NAN-190 been shown to block the 8-OH DPAT stimulus in rats. The present experiment attempted to block the S^D functions of 8-OH DPAT with NAN-190 in pigeons, a species that serves as a good model for novel $5\text{-}HT_{1A}$ compounds. Pigeons were injected with either saline or 0.3 mg/kg 8-OH DPAT before daily experimental sessions. Key-peck responses were reinforced according to a fixed ratio schedule of food presentation for pecks to the right key during 8-OH DPAT sessions and for pecks to the left key during saline sessions. NAN-190 (0.3-5.6 mg/kg) produced a dose-dependent shift to the right of the 8-OH DPAT function. Alone, NAN-190 produced only saline-key responding. NAN-190 appears to be an effective antagonist of the S^D functions of 8-OH DPAT with little intrinsic activity under these conditions. Supported by DA-02873.

CHARACTERIZATION OF ALPHA-METHYLSEROTONIN IN SYNAPTOSOMES FROM RAT BRAIN. T.J. Montine* and T.L. Sourkes. Departments of Psychiatry and Biochemistry, McGill University, Montreal, Quebec, H3A 1A1.

Alpha-methylserotonin (AM5HT) accumulates in whole brain of rats administered alpha-methyl-DL-tryptophan (AMTP) (Roberge et al., Neuropharmacology 11:197, 1972). The objective of these experiments was to characterize the behavior of AM5HT in nerve terminals. Synaptosomes from rat brain were prepared and intrasynaptosomal concentrations were measured by fluorescence detection after separation of indoles by HPLC. Rats treated with 50 mg/kg AMTP 24 h prior to sacrifice yielded synaptosomes with 505±15 pmol AM5HT/mg protein and 11±2 pmol serotonin (5HT)/mg protein; control rats had 99±6 pmol 5HT/mg protein. K^+ concentrations ranging from 5 to 100 mM in the medium induced fractionally equivalent release of intrasynaptosomal AM5HT and 5HT. This was maximal (72% of the initial content) between 35 and 100 mM K^+. Reserpine or p-chloroamphetamine treatment of rats resulted in synaptosomes with reductions of 58% and 68% resp., in AM5HT. Synaptosomal accumulation of AM5HT from the medium was similar to 5HT and was inhibited by 5HT and fluoxetine. It is concluded that AM5HT is stored in brain nerve terminals and its uptake into and release from synaptosomes corresponds to 5HT. (Research supported by MRC and Merck Frosst, Canada)

EFFECTS OF TRYPTOPHAN ON NEUROCHEMICAL ESTIMATES OF THE ACTIVITY OF HYPOTHALAMIC 5HT NEURONS FOLLOWING STIMULATION OF THE DORSAL RAPHE NUCLEUS (DNR) OR ADMINISTRATION OF THE $5HT_{1A}$ RECEPTOR AGONIST 8-HYDROXY-2-(DI-n-PROPYLAMINO) TETRALIN (8-OH-DPAT). Y. Tian*, J.L. Goudreau*, K.J. Lookingland and K.E. Moore (SPON: J.E. Thornburg). Dept. of Pharm./Tox., Mich. State Univ., East Lansing, MI 48824.

Neurochemical estimates of the activity of 5HT neurons in the brain are based upon the coupling between neurotransmitter synthesis, release and metabolism. A potential problem with the use of neurochemical estimates of 5HT neuronal activity relates to the availability of substrate for the rate-limiting enzyme tryptophan hydroxylase. In the present study, the effects of tryptophan on the synthesis (5HTP accumulation following administration of a decarboxylase inhibitor) and metabolism (5HIAA concentrations) of 5HT were determined in discrete hypothalamic regions of the male rat following: 1) activation of 5HT neurons by electrical stimulation of the DRN, and 2) inhibition of 5HT neuronal activity by administration of 8-OH-DPAT. Tryptophan caused a two-fold increase in the rate of 5HTP accumulation and a concurrent increase in the concentrations of 5HIAA and 5HT in all hypothalamic regions. DRN stimulation produced similar increases and 8-OH-DPAT produced similar decreases in 5HTP and 5HIAA concentrations in vehicle- and tryptophan-treated rats. These results indicate that precursor administration has little effect on the coupling between the activity of hypothalamic 5HT neurons and the synthesis and metabolism of 5HT. (Supported by a MSU-BRSG grant.)

ANALYSIS OF TRYPTOPHAN HYDROXYLASE (TPH) mRNA FROM RAT PINEAL GLANDS, DORSAL RAPHE NUCLEI AND BRAINSTEMS BY NORTHERN BLOT AND IN SITU HYBRIDIZATION, USING TPH OLIGONUCLEOTIDE PROBES. D.H. Park, T. Wessel and T.H. Joh, Lab. of Mol. Neurobiol., Cornell Univ. Med. Coll., Burke Rehab. Ctr., White Plains, NY 10605.

In the present study we sought to analyze TPH mRNA from rat pineal glands (PG), dorsal raphe nuclei (DRN) and brainstems (BS) by northern blot and in situ hybridization techniques, using synthetic oligonucleotide probes, and to determine TPH specific activity from PG and DRN. Several TPH oligonucleotides based on published rat pineal TPH nucleotide sequence (Darmon, M. C. et al., J. Neurochem., 51:312,1988) were synthesized. These oligonucleotides were radiolabelled with either α-^{32}P- or ^{35}S-deoxy CTP. Poly A^+ RNAs were prepared from rat PG, DRN and BS. By northern blot all probes hybridized with two TPH mRNA species from PG but none hybridized with mRNA species from DRN and BS. By in situ hybridization ^{35}S - labelled TPH oligonucleotide probes exhibited strong hybridization with pineal TPH mRNA but did not hybridize with DRN and BS. However, TPH activity in DRN (11.3 nmol/5-hydroxytryptophan (5-HTP) formed/region/15 min,37°C; specific activity, 17.2 nmol 5-HTP/mg protein/15 min,37°C) is much higher than in PG (0.304 nmol 5-HTP formed/ PG/15 min,37°C; specific activity, 4.0 nmol 5-HTP formed/mg protein/15 min,37°C). The inability to demonstrate TPH mRNA in DRN using oligonucleotide probes based on pineal sequences, despite higher TPH activity in this brain region, may be attributed to low relative abundance of the mRNA in CNS. However, the present data could also be interpreted to suggest that TPH enzyme in pineal gland differs from that in CNS. Supported by grant # MH 44043.

MDL 27,777A: A SELECTIVE INHIBITOR OF SEROTONIN UPTAKE. J. Freedman*, M. Dudley, B. Baron, A. Ogden* and T. Holman* (SPON: M. Palfreyman). Merrell Dow Research Institute, Cincinnati, OH 45215.

MDL 27,777A (2,3-dihydro-N-methyl-1-[4-(trifluoromethyl) phenoxy]-1H-indene-2-methanamine·HCl) inhibited [3H]serotonin (5-HT) and [3H]norepinephrine (NE) uptake into rat cortical synaptosomes with IC50 values of 0.2 µM and 8.4 µM, respectively. In vivo, MDL 27,777A and fluoxetine were equipotent as inhibitors of p-chloroamphetamine-induced 5-HT depletion from rat cortex following either intraperitoneal (IC50 values were 1.9 and 2.5 mg/kg, respectively) or oral (IC50 value was 5.0 mg/kg for both) administration. MDL 27,777A at doses up to 40 mg/kg, ip did not inhibit the xylamine-induced depletion of NE from rat cortex or the MPTP-induced depletion of dopamine from mouse striatum. MDL 27,777A was inactive at adrenergic, serotinergic and cholinergic receptors as measured by radioligand binding assays. The combined treatment of desipramine (DMI) (5 mg/kg, ip) and MDL 27,777A (15 mg/kg bid, ip) for 4 days was able to significantly down-regulate rat cortical ß-adrenoceptor density and isoproterenol-stimulated cAMP accumulation in rat cortical slices to an extent similar to the previously reported effect of DMI plus fluoxetine (Baron et al., Eur. J. Pharm. 154:125, 1988). Therefore, MDL 27,777A is a selective inhibitor of 5-HT uptake and may prove effective in the monotherapy of depression; or in combination with a NE uptake inhibitor may provide a novel treatment of depression with a more rapid onset of action.

SUBCLASSES OF PLATELET ^{3}H-IMIPRAMINE BINDING RESPOND DIFFERENTLY TO CHRONIC IMIPRAMINE TREATMENT. E. M. DeMet, K. Bell, R. Gerner*, C. Reist*, and A. Chicz-DeMet. Dept. Psychiatry and Human Behavior, Univ. of California, Irvine, Irvine, CA 92717.

A number of studies suggest that platelet ^{3}H-imipramine (^{3}H-IMI) binding is decreased in depressed patients and is subsequently increased by chronic imipramine treatment. However, total ^{3}H-IMI binding is thought to consist of 2 separate subclasses of high affinity sites. Binding to one site is trypsin sensitive with properties similar to serotonin (5HT) uptake whereas binding to the other site is not. The present study measured platelet ^{3}H-IMI binding in the presence/absence of 0.25 nM cyanoimipramine (CNIMI), a potent 5HT uptake blocker, and irreversible inhibitor of ^{3}H-IMI binding. At this concentration CNIMI inhibited ca. 50% of total ^{3}H-IMI binding. Both CNIMI resistant and CNIMI sensitive binding sites were decreased in depressed patients although only the latter was significant. Chronic (6 wk) imipramine treatment increased total and CNIMI resistant binding but decreased CNIMI sensitive binding. Post-treatment Bmax values of CNIMI resistant sites were inversely correlated with plasma cortisol levels whereas the Bmax of CNIMI sensitive binding was not. The results suggest that treatment induced changes in the more specific CNIMI sensitive sites are not secondary to improvements in mood state whereas CNIMI resistant binding may fluctuate with plasma cortisol levels.

STIMULATION AND INHIBITION BY ETHANOL ON THE HIGH-AFFINITY UPTAKE OF [^{3}H]5-HT BY BRAIN SYNAPTOSOMES. T. Alexl, J. Poblete and E.C. Azmitia (SPON: J.A. McCaughran). Department of Biology, New York University, NY, NY 10003.

Ethanol has long been shown to be associated with the CNS serotonin system. Our investigation of the effects of ethanol on the uptake of [^{3}H]5-HT by rat brain synaptosomes shows that acute application of ethanol is stimulatory at 0.15-0.6% and is inhibitory at concentrations above 9.5%. With a 5 minute pre-incubation, stimulation of 5-HT uptake was no longer observed, and the inhibitory concentration 9.5%, which normally decreased uptake 44%, decreased uptake 65%. The serotonergic transporter is probably not involved, since ethanol was unable to alter control [^{3}H]paroxetine binding levels.

To examine whether ethanol altered calcium homeostasis, we tested a variety of drugs known to mobilize internal calcium or to affect calcium channels directly or through NMDA receptors. 0.5mM glutamate was able to protect by 37% the inhibition caused by 12% ethanol. Nimodipine, Bay K8644 and MK801 were without effect. With a 5 minute pre-incubation, 10^{-6} M fluoxetine in combination with 0.3% ethanol caused an inhibition of uptake. Nimodipine, potassium depolarization and MK801 had no effect. External 1mM calcium supplement had no effect on the inhibition by ethanol. Research supported by NIDA 271-87-8144.

INHIBITION OF 5HT UPTAKE BY THE 5HT1B AGONIST TFMPP. W.A. Wolf* and D.M. Kuhn. Lab. of Neurochemistry, Lafayette Clinic and Cellular and Clinical Neurobiology Program, Dept. Psychiatry, Wayne State Univ. Sch. of Med., Detroit, MI 48207.

1-(m-Trifluoromethylphenyl)piperazine (TFMPP) is an agonist at 5HT receptors of the 1B subtype and it is used frequently to study the pharmacological and physiological properties of 5HT receptors. The in vivo effects of TFMPP on 5HT neurochemistry are reminiscent of the effects of selective uptake inhibitors such as fluoxetine on 5HT and 5HIAA levels. Thus, we considered the possibility that TFMPP could also inhibit the neuronal uptake of 5HT. Synaptosomes from rat brain were incubated in modified Krebs Ringer phosphate buffer and the uptake of exogenous 5HT (50 nM) was determined at 37°C. The addition of TFMPP produced a concentration dependent inhibition of 5HT uptake into synaptosomes. The IC50 for uptake inhibition by TFMPP was estimated to be 350 nM. TFMPP did not cause the release of endogenous synaptosomal 5HT at any concentration which inhibited uptake. TFMPP could be differentiated from a "classical" 5HT uptake inhibitor such as fluoxetine, in that the in vitro 5HT releasing properties of p-chloroamphetamine could not be prevented by TFMPP. Other 5HT1B agonists of the aryl-piperazine class (e.g. quipazine and MK 212) also share 5HT uptake inhibiting properties with TFMPP. The results indicate that the pharmacological properties of TFMPP may reflect, in part, its 5HT uptake inhibiting effects. Furthermore, these results suggest that a relationship may exist between 5HT1B sites and the recognition site which is part of the presynaptic neuronal 5HT uptake complex.

MOLECULAR MODELING OF SEROTONIN UPTAKE INHIBITORS. L. A. McQuaid*, R. P. Pioch*, and J. A. Nixon* (SPON: M. J. Schmidt). Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, Indiana 46285.

A series of serotonin (5HT) uptake inhibitors were examined using MacroModel (C. Still) molecular modeling program in order to develop a three dimensional model for the recognition site of the uptake pump. Citalopram, Indalpine, Paroxetine, CGP-6085A and Fluoxetine were chosen based on their superior potency and selectivity. In addition, a new 5HT uptake inhibitor, LY233708, was evaluated in the resulting model. Using the MULTIC submode of MacroModel, multiple conformations of each compound were generated through the use of a dihedral angle driver and stored. Each conformation was subjected to energy minimization using the blocked diagonal Newton-Raphsson method with a MM2 force field. The lowest energy conformations were further refined using the full matrix Newton-Raphsson method. The distance between the aromatic ring(s) and the nitrogen atom was calculated for the low energy conformations of the 5HT uptake inhibitors. The distance between the aromatic ring(s) and the nitrogen atom was found to vary between 5.14 to 7.71 Å. However, the average distance between the two aromatic rings in Citalopram, Paroxetine and Fluoxetine was found to be very similar, 4.84-5.05Å. A model was developed describing the relative positions of the two aromatic binding sites (Ar and Ar') and a basic nitrogen binding site (N). LY233708 was found to have only one low energy conformation and a comparison of LY233708 with the above series of uptake inhibitors will be presented.

94.9

QUASI- AND TRUE OPIOID WITHDRAWAL IN 14 DAY-OLD CHICKEN EMBRYOS: ASSOCIATION WITH ALTERED BRAIN SEROTONIN METABOLISM. G.Seran,* M.E.Bronson* and S.B.Sparber (SPON: G.Livezey). Dept. of Pharmacology, Univ. of Minnesota, Minneapolis, MN 55455.

Previous attempts to induce and maintain opioid dependence in 14 day-old embryos, expressed as withdrawal-induced increased motility, were unsuccessful (PB&B,30:357,1988). We report here that isobutylmethylxanthine causes increased motility at this age, demonstrating the capacity of the embryo to express quasi-opioid withdrawal, confirming the maturity of the output component (i.e. expression). If appropriate receptors and/or adaptive capacity are sufficiently developed, true opioid dependence/withdrawal should be expressed. Injection of various doses of l-alpha-noracetylmethadol, methadone or morphine, as soon as 1 hr or up to 11 days before injection of various doses of naloxone enabled us to demonstrate that the 14 day-old embryo can be studied for effects of early opioid dependence/withdrawal. Changes in brain 5-HIAA, but not dopamine metabolites, at a time when acute dependence can be demonstrated (i.e. 1 hr) confirms the importance of 5-HT in the adaptive process or its expression (JPET 236:157,1986; Kleven & Sparber, Psychopharmacol., in press). Such studies will determine if sensitive periods exist for long-term consequences of exposure to opioids and/or withdrawal, and to understand the mechanism for such effects. Moreover, strategies for early treatment interventions (detoxification and/or pharmacologic, with non-opioids) might be derived from such studies. It is possible that opioid detoxification at early stages of development can prevent potential long-term neurobehavioral dysfunction, which may attend severe perinatal opioid withdrawal. Supported in part by USPHS grants DA01880 and T32DA07097.

SEROTONIN RELEASE AND MONOSYNAPTIC RESPONSE AMPLITUDE INCREASES FOLLOWING 5-HYDROXYTRYPTOPHAN INJECTION IN RATS. P. Duffy*, G. Samathanam*, P.W. Kalivas and S.R. White (SPON: D.Sarkar). Dept. of VCAPP, Washington State University, Pullman, WA 99164-6520.

Intravenous administration of the serotonin precursor, 5-hydroxytryptophan (5HTP), markedly increases the amplitude of the lumbar monosynaptic response (MSR) in cats (Anderson and Shibuya, JPET 153:352, 1966). However, a recent report suggests that 5HTP may decrease lumbar MSR amplitude in rats (Nagano et al., Eur. J. Pharmacol. 139:315, 1987). The present study used in vivo dialysis to measure 5HT release in the lumbar spinal cord of urethane-anesthetized rats in response to 5HTP injection. Small dialysis probes were placed in the lumbar enlargement and 5HT and 5HIAA in 15 min dialysate samples were measured using HPLC and electrochemical detection. Lumbar MSRs were measured in L5 dorsal roots in another set of rats. Intravenous injections of a 50 mg/kg dose of 5HTP significantly increased 5HT release and significantly increased the amplitude of the MSR whereas a 25 mg/kg dose had no effect on 5HT release or MSR amplitude. These results indicate that (1) 5HTP enhances the lumbar MSR amplitude in rats as well as cats and (2) the enhancement of MSR amplitude by 5HTP is correlated with increased 5HT release in the lumbar cord. (Supported by NS24388).

OPPOSITE EFFECTS OF INTRAVENOUS AND IONTOPHORETIC ADMINISTRATION OF THE $5HT_{1A}$ AGONIST, 8-OHDPAT, ON SPINAL MOTONEURON EXCITABILITY. D.A. Jackson and S.R. White. Dept. of VCAPP, Washington State University, Pullman, WA 99164-6520.

$5HT_{1A}$ receptor binding sites are relatively abundant in the rat spinal cord (Huang and Peroutka, Brain Res., 436:173, 1987) but the functional significance of these receptors is not known. The present study compared the effects of intravenous and iontophoretic administration of the $5HT_{1A}$ agonist, 8-hydroxy-2-di (propylamino) tetralin (DPAT), on spinal motoneuron excitability. Lumbar laminectomies were performed on urethane anesthetized rats and multibarrel micropipettes were used to record glutamate-evoked responses from identified spinal motoneurons and to apply serotonin (5HT), DPAT and control solutions. Serotonin ejection increased glutamate-evoked motoneuron firing and the increase was sometimes preceded by brief inhibition. The inhibition was more prominent with higher than with lower 5HT ejection currents and was mimicked by acid control ejections. Iontophoretic application of DPAT decreased glutamate-evoked firing of the motoneurons. However, intravenous injections of DPAT markedly enhanced glutamate-evoked firing of the motoneurons. These results suggest that (1) DPAT indirectly enhances spinal motoneuron firing by acting on as yet unidentified spinal cord or supraspinal neurons and (2) enhancement of spinal motoneuron excitability by microiontophoretically applied 5HT is not mediated by $5HT_{1A}$ receptors. (Supported by NS 24388).

SEROTONIN RELEASE IN THE MEDIAL AND LATERAL HYPOTHALAMUS DURING FEEDING AND ITS ANTICIPATION. D.H. Schwartz, L. Hernandez* and B.G. Hoebel, Department of Psychology, Princeton University, Princeton, NJ 08544-1010

We have previously used intracerebral microdialysis to show that a large meal increased lateral hypothalamic (LH) serotonin release in food deprived rats (Schwartz et al., 1989). The present experiment was carried out in order to confirm the effect and to test (1) anticipatory release of serotonin, (2) medial vs. lateral hypothalamic release, (3) verification that dialysate serotonin was neural in origin, (4) verification of serotonin chromatographic peaks using a dual potentiostat, (5) assessment of the distance monitored by the microdialysis probe. In this experiment, a serotonergic reuptake blocker (fluoxetine, 10 uM) was added to the Ringer's solution in order to enhance serotonin recovery by microdialysis probes. The sight and smell of food as well as eating food caused extracellular serotonin to increase in both the medial hypothalamus (MH) and the LH. This increase in extracellular serotonin before the meal began suggests that hypothalamic serotonin release was not alone sufficient to cause satiety. The experiment found no difference between LH and MH serotonin release and did not distinguish between serotonin released during feeding and feeding-related arousal. The chromatographic peaks had the same voltage characteristics as serotonin standards. Serotonin levels were reduced after systemic treatment with 8-OH-DPAT (250 ug/kg ip), a serotonin cell body autoreceptor ($5\text{-}HT_{1A}$) agonist suggesting that serotonin observed in this experiment was neurogenic in origin. Large elevations in LH serotonin by local fenfluramine infusion were not detected by MH probes about 1 mm away, suggesting that dialysis probes were in fact sampling from separate regions. This experiment confirms that hypothalamic serotonin is released during feeding behavior as reported earlier, and suggests that preingestive events also increase serotonin release.

THE EFFECT OF GEPIRONE ON SOUND STRESS (SS) INDUCED INCREASES IN TRYPTOPHAN HYDROXYLASE (TRPH) IN RAT. K.C. Corley, V. Singh*, T-H. Phan*, and M.C. Boadle-Biber. Physiol. Dept., Med. Col. of Va., Va Commonwealth University, Richmond, VA 23298

Short term electrical stimulation of the dorsal raphe nucleus and acute SS (1-2 h) produce a reversible increase in in vitro TrpH activity that is non-additive with the increase seen under phosphorylating conditions and is reversed by preincubation with alkaline phosphatase. Repeated SS (1 h/day for 3 days) induces a stable increase in enzyme activity that is insensitive to alkaline phosphatase. Since 5-HT neuronal firing is inhibited by activation of autoreceptors on the cell body, we examined the effect of gepirone, a novel anxiolytic and partial $5\text{-}HT_{1A}$ agonist, on the increase in TrpH of acute and repeated SS in Fischer 344 rats. In chronic experiments, gepirone infused s.c. (40 mg/kg per day over 28 days) by an Alzet Minipump (2ML4; Eison, A.S. and Yocca, F.D. Eur. J. Pharmacol. 111: 389, 1985) completely blocked the effects on TrpH to both repeated and acute SS (110 dB, 2.9 kHz, 100 ms, VI-1, 1 h/day over 3 days). In rats stressed once (acute SS) for 1 h 15 m after dosing (2, 5, or 10 mg/kg i.p.) the increase in TrpH activity was completely blocked by the highest dose tested. Supported by Bristol-Myers.

ANTIDEPRESSANT-LIKE EFFECTS OF $5\text{-}HT_{1A}$ AGONISTS. D. Z. Press*, S. Wieland and I. Lucki (SPON: O'Connell). Dept. of Psychiatry, University of Pennsylvania, Philadelphia, PA 19104

Recent studies have suggested that $5\text{-}HT_{1A}$ selective agonists may produce antidepressant-like effects in animal models of depression. The selective $5\text{-}HT_{1A}$ agonist 8-hydroxy-2-(di-n-propylamino)tetralin (8-OH-DPAT) has been shown to be effective in both the restraint-hypolocomotion and forced swim test models of depression. We utilized the forced swim test to evaluate a number of $5\text{-}HT_{1A}$ selective agonists for their antidepressant-like properties.

8-OH-DPAT (0.12-1.0 mg/kg) and SM-3997 (5-20 mg/kg) both produced dose-related decreases in immobility time following sub-chronic treatment of rats. These effects were similar to those of the tricyclic antidepressant desmethylimipramine (5-15 mg/kg). In addition, the $5\text{-}HT_{1A}$ agonists, buspirone (20 mg/kg), gepirone (20 mg/kg) and ipsapirone (10 mg/kg) demonstrated antidepressant-like effects by significantly reducing immobility time. Other groups of rats treated sub-chronically with each of the $5\text{-}HT_{1A}$ agonists showed no increase in locomotor activity so that general changes in activity could not account for the effects of $5\text{-}HT_{1A}$ agonists in the forced swim test.

5-HT agonists selective for other receptor subtypes, such as the $5\text{-}HT_{1B/1C}$ agonist m-CPP (5 mg/kg) and the $5\text{-}HT_2$ agonist DOB (1 mg/kg) were not effective in this animal model of depression. Moreover, the benzodiazepine diazepam (5 mg/kg) was also ineffective on this behavior. The stimulant d-amphetamine (2 mg/kg) did significantly reduce immobility time, but also significantly increased locomotor activity, and therefore was considered a false positive as an antidepressant drug in this test.

These results suggest that $5\text{-}HT_{1A}$ agonists may have antidepressant efficacy and act as a novel class of antidepressant drug. In addition, the forced swim test is an effective animal model of depression for studying drugs that are selective for the $5\text{-}HT_{1A}$ receptor.

94.15

PRESYNAPTIC SEROTONIN MECHANISMS IN LEARNED HELPLESSNESS. E. Edwards, W. Kornrich*, K. Harkins*, H. Willmott* and F.A. Henn. Dept. Psychiatry,SUNY, Stony Brook, NY 11794.

We report on changes of presynaptic serotonergic activity in the learned helplessness animal model of depression. The K^+-evoked release of ^{3}H-serotonin from hippocampal slices after shock testing was significantly higher in learned helpless rats (LH) when compared to naive controls (NC) and non-helpless rats (NLH): 17.5 ± .67% vs 11.94 ± .82% and 12.3 ± 1.7%. High affinity uptake of ^{3}H-serotonin was measured in hippocampus and hypothalamus of NC, NLH and LH rats. In the hippocampus, ^{3}H-5HT uptake was significantly increased in LH rats as compared to NC and NLH (+41%). In contrast, it was decreased in the hypothalamus of LH rats as compared to NC and NLH (-20%). Ligand binding studies of the 5-HT uptake site were carried out using ^{3}H-paroxetine in cortex, septum, hippocampus, hypothalamus and striatum of NC, NLH and LH rats. In the hippocampus, uptake binding sites increased significantly in LH rats as compared to NC and NLH rats (B_{max}, fmol/mg: +120% and +40% vs NC and NLH). In the hypothalamus these sites were decreased in LH rats (B_{max}, fmol/mg: -40% and -31% of NC and NLH. No changes in ^{3}H-paroxetine binding were seen in the other brain regions. These data support a major role for serotonin in the neurochemistry of the LH model with a limbic-hypothalamic pathway as a control center for behavioral response to stress. (Supported by BNS 8614098 to E.E.)

ELECTRICAL STIMULATION OF THE DORSAL RAPHE AS A DISCRIMINATIVE STIMULUS: GENERALIZATION TO (±)-DOI. L. Stambaugh* and D.J. Mokler, Dept. Pharmacol., Univ. New England, Biddeford ME 04005.

Electrical stimulation (ES) of the dorsal raphe nucleus increases the release of 5-hydroxytryptamine (5-HT) in forebrain areas and has been shown to act as a discriminative stimulus which generalizes to the hallucinogen LSD. The purpose of the present experiment was to examine this discrimination using a new discrimination paradigm, the discriminated taste aversion (Lucki, J. Pharmacol. Exp. Ther. 247: 1120, 1988); and to examine the effects of the $5\text{-}HT_2$ agonist DOI in this discrimination. Male rats were trained to discriminate ES of the dorsal raphe by pairing ES with LiCl injection following access to saccharin for half the animals. ES consisted of 100 uA biphasic square wave pulses delivered at 20 Hz. Over 6 sessions animals decreased saccharin drinking during electrical stimulation from 14 to .5 mls in sessions 1 and 6 respectively. In a parallel group of animals, non-stimulation was paired with LiCl injection. A similar decrease in saccharin consumption was seen in this group during non-stimulation sessions. Thus, ES of the dorsal raphe per se did not alter saccharin drinking. Administration of DOI (0.1, 0.5 and 1.0 mg/kg) substituted for ES of the dorsal raphe. Therefore, stimulation of $5\text{-}HT_2$ receptors with the agonist DOI has stimulus properties in common with the effects of ES of the dorsal raphe. (L.S. supported by a UNE Dean's Summer Research Fellowship.)

DIFFERENTIAL MODULATION OF THE STIMULUS PROPERTIES OF 5-HT AGONISTS BY 5-HT NEURONS. I. Lucki, S. Wieland and R. Andrews*. Departments of Psychiatry and Pharmacology, University of Pennsylvania, Philadelphia, PA 19104

Rats can be trained to discriminate the stimulus effects of 5-HT agonists that are selective for individual 5-HT receptor subtypes using the discriminated taste aversion procedure (Lucki, JPET, 1988, 247:1120-1127). This study examined whether presynaptic or postsynaptic components are involved in the stimulus effects of the 5-HT_{1A} agonist 8-OH-DPAT or the 5-$HT_{1B/1C}$ agonist TFMPP.

Separate groups of rats were trained to discriminate the stimulus effects of the 5-HT_{1A} agonist 8-OH-DPAT (0.4 mg/kg) from saline or the 5-$HT_{1B/1C}$ agonist TFMPP (0.8 mg/kg) from saline. Rats treated with the tryptophan hydroxylase inhibitor PCPA (300 mg/kg 72h prior to testing) and injected with saline demonstrated generalization to 8-OH-DPAT but not to TFMPP.

In other groups of rats, the 5-HT uptake inhibitor sertraline substituted completely for TFMPP but not for 8-OH-DPAT. The effect of sertraline was due to enhancing 5-HT neurotransmission because it failed to generalize in other rats treated with the toxin 5,7-DHT. These results suggest that the stimulus properties of the 5-HT_{1A} agonist 8-OH-DPAT ordinarily involve presynaptic actions on 5-HT neurons whereas those of the 5-$HT_{1B/1C}$ agonist TFMPP involve effects at postsynaptic 5-HT receptors. This research was supported by USPHS grant MH 36262.

GLYCINE (GLY) INDUCES RELEASE OF ACETYLCHOLINE (ACh) FROM NUCLEUS TRACTUS SOLITARIUS. W.T. Talman and L. Wellendorf*. Lab. of Neurobiol., VAMC and Univ. of Iowa, Iowa City, IA 52242.

GLY microinjected into the nucleus tractus solitarius (NTS) of rat decreases blood pressure and heart rate. The effect, which is like that produced by ACh, is blocked by atropine and prolonged by physostigmine. Thus, we sought to determine if GLY induces release of ACh from NTS. Adult male Sprague-Dawley rats were decapitated, the brain was removed, and a 1 mm transverse slice of the brain stem was taken through the "cardiovascular" NTS. [^{3}H]-ACh released from bilateral 1 mm punches of NTS was measured by the method of Arneric and Reis (Brain Res 374:153-161). Release during control studies was compared with that after exposure of tissues to 35 mM KCl or 100 uM or 1 mM GLY. [^{3}H]-ACh released was measured in DPM/mg tissue; data were expressed as mean $\pm$ SEM. Control measures of ACh release were -2.8 $\pm$ 1.2 DPM/mg in contrast to 41.7 $\pm$ 4.3 DPM/mg after KCl, 22.3 $\pm$ 8.0 DPM/mg after 100 uM GLY and 67.4 $\pm$ 9.0 DPM/mg after 1 mM GLY. These data support the hypothesis that GLY induced cardiovascular responses in NTS are mediated through release of ACh. (Support: VA Merit Review, HL32205, HL14388, and NS24621).

OCCLUSION OF SEROTONIN (5HT-2) EXCITATIONS BY SUBSTANCE P IN THE NUCLEUS TRACTUS SOLITARIUS. J.Champagnat, T.Jacquin and M.Denavit-Saubié (SPON: R.Naquet) Laboratoire de Physiologie Nerveuse, C.N.R.S., 91198 Gif-sur-Yvette, France.

Afferent fibers containing both serotonin and substance P immunoreactivity project to the nucleus tractus solitarius, a brainstem structure controlling respiratory and cardiovascular parameters. We thus have investigated modulation of serotonin actions by substance P in the rat nucleus tractus solitarius using coronal brain stem slices and intracellular recordings. Serotonin (4-100 µM) was excitatory causing depolarization and increasing input resistance. These effects involved postsynaptic receptors of the 5HT-2 type sensitive to methysergide and to the selective 5HT-2 antagonist ketanserin (0.05-0.2 µM).

5HT-induced excitations were reversed using a protocol of conditioning applications of substance P (0.1 µM, >5 min) and shorter (20-60 s) test applications of serotonin: serotonin, which was excitatory during controls, became inhibitory of the steady action potentials discharges induced by conditioning substance P. Prolonged conditioning applications were required since addition or potentiation of the effects, but no reversion, was found combining 20-60 s substance P and serotonin applications. Thus, functional effects of serotonin in the nucleus tractus solitarius can be reversed after occlusion of 5HT2-related excitations by substance P.

95.3

SEROTONIN ATTENUATES GLUTAMATE ELICITED EXCITATION OF CEREBELLAR PURKINJE CELLS AT SOMATIC AND DENDRITIC SITES IN VITRO. H.K. Strahlendorf and J.C. Strahlendorf. Depts. of Neurology and Physiology, Texas Tech University Health Sciences Center, Lubbock, TX 79430.

We previously reported that serotonin (5-HT) potently reduced glutamate (GLU)-induced excitation of cerebellar Purkinje cells (PCs) when both were applied iontophoretically in the in situ anesthetized rat (Lee, et al. Brain Res 361, 1986). To elucidate sites and mechanisms underlying this modulatory effect of 5-HT we have initiated extracellular and intracellular recordings of PCs in the in vitro cerebellar slice. Extracellular recordings of somatic PC action potentials and iontophoresis of GLU and 5-HT were accomplished with multibarrel micropipettes. A second multibarrel pipette was positioned in the molecular layer for dendritic ejection of GLU and 5-HT. 5-HT applied at somatic and dendritic sites caused a 75-100% reduction in GLU elicited excitation. Superfusion with 100-400µm 5-HT failed to affect GLU responses elicited from the soma or dendrites. Intracellular recordings revealed an 8-10 mV depolarization in response to dendritically applied GLU. 5-HT superfusion did not markedly affect the resting potential or input resistance and did not attenuate GLU elicited depolarizations and decreases in input resistance. These results demonstrate that 5-HT can potently modulate GLU actions when both agents are focally applied to either the dendrites or soma of PCs. Additional intracellular studies are aimed at resolving the membrane ionic mechanisms mediating this interaction. Supported by NS 19296.

ACh - NMDA SYNERGISM IN RAT OESOPHAGEAL MOTONEURONS **Y.T. Wang* and D. Bieger.** Faculty of Medicine, Memorial University of Newfoundland, St. John's, Nlfd. CANADA A1B 3V6

The interaction between acetylcholine (ACh) and glutamate (Glu) at the nucleus ambiguus was investigated in rats anaesthetized with urethane. 1) Micropneumophoretic ejection of either Glu (6-10 pmol) or ACh (20-50 pmol) at the tip of the ambiguus complex produced propulsive or synchronous oesophageal contractions. 2) The Glu-evoked response was dramatically enhanced in a dose-dependent manner by a prepulse of ACh (15-40 pmol) at the same site. This effect was reversibly inhibited by a prepulse of the NMDA receptor antagonist, AP-7 (DL-2-amino-7-phosphono-heptanoic acid, 8-10 pmol). ACh also facilitated NMDA-induced responses at Glu-responsive sites. 3) The excitatory and facilitatory effects of ACh were mimicked by the nicotinic agonist, DMPP (1,1-dimetyl-4-phenyl-piperazinium iodide, 5-8 pmol), but not by muscarine, and reversibly blocked by dihydro-β-erythroidine, 8-10 pmol. These results suggest that there is a synergistic interaction between the two excitatory transmitters, ACh and Glu, at the level of ambiguus oesophageal motoneurons. ACh facilitates the NMDA-mediated response via an action at a nicotinic cholinoceptor site.

IMMUNOCYTOCHEMICAL EVIDENCE FOR THE CO-LOCALIZATION OF GABA AND GLYCINE IN SYNAPTIC TERMINALS OF THE LOWER AUDITORY BRAINSTEM. R.A. Altschuler, José M. Juiz, R.H. Helfert, J.M Bonneau* and R.J. Wenthold+. Kresge Hearing Research Institute, Univ. of Michigan, Ann Arbor, MI, 48109; +LMO, NIDCD,NIH.

GABA and glycine are believed to be major inhibitory transmitters in the auditory brainstem. While these transmitters are generally in separate neural pathways, coexistence of GABA and glycine has been shown in cerebellar Golgi cell terminals, using immunocytochemical techniques (Ottersen et al. '88). In the cochlear nucleus light microscopic studies have shown GABA and glycine to be co-contained in small cells in the dorsal cochlear nucleus as well as in puncta in all cochlear nuclei (Wenthold et al.'87). Glycine receptor immunoreactivity has been shown to appose GABA and GAD immunoreactive terminals (Oberdorfer et al '88). In the present study we have used post-embedding immunoperoxidase and immunogold techniques on serial sections, at the LM and EM levels respectively, to identify and characterize terminals co-containing GABA and glycine immunoreactivities in the cochlear nuclear complex (CNC) and the superior olivary complex (SOC). These were compared to terminals immunolabeled for GABA only, glycine only or neither.

Terminals co-labeled with GABA **and** glycine were identified in all divisions of the CNC as well as in the SOC. These terminals contained oval/pleomorphic synaptic vesicles and made symmetric axo-somatic or axo-dendritic contacts. The size and shape of the co-labeled terminals appeared to be heterogeneous. They were particularly numerous in the anteroventral and dorsal divisions of the cochlear nucleus. Glycine immunoreactive terminals contained either flattened or oval/pleomorphic vesicles. Terminals labeled for GABA only contained oval/pleomorphic vesicles.

Interaction between a2 receptors with Noradrenaline, Serotonin, Dopamine, Glutamate and Aspartate. B. Delbarre, G. Delbarre, F. Calinon*, C. Loiret* and A. Ferger*. Faculté de Médecine,37032, Tours, FRANCE.

Interferences of a2 adrenoceptors with 5-HT and DA release had been demonstrated. Recently, J. Mitra (Mitra, J., Br. Res. Bulletin, 18 : 681,1987) found vasomotor effects of excitatory amino acid on ventral medullary surface.

In the brain stem of the young chicken, clonidine, a2 agonist(0.025-0.75 mg/kg) modified levels of NAD, DA, HVA, 5-HT and 5-HIAA (HPLC method). 5-HTP (50 mg/kg) significantly increased NAD, DA, HVA, 5-HT and 5-HIAA. In the anesthetized dogs, 90 min after treatment, clonidine (0,01mg/kg I.V.) decreased mean blood pressure (21%) and in the CSF (lateral ventricle) significantly decreased NAD (60%), HVA (86%), 5-HIAA (81%), glutamate (57%) and aspartate (45%) (HPLC method).

In the brain, small and high doses of clonidine had opposite effects on levels of catecholamines and indoleamines. Decrease of B.P. after clonidine implicated not only NAD but also 5-HT, DA and excitatory amino acids.

ENDOGENOUS OPIOID AND DOPAMINERGIC INTERACTIONS PRODUCE A HYPERSALIVATION RESPONSE FOLLOWING RADIATION EXPOSURE. D.E. Morse*, and G.A. Mickley, (SPON. J. Frascella), Dept. of Behavioral Sciences, AFRRI, Bethesda, MD 20814-5145

Endogenous opioids and dopamine modulate a wide variety of behaviors, including "appetitive behaviors". Radiation exposure alters release of the endogenous opioids and dopamine, and suppresses appetitive behavior. We observed that opiate receptor blockade (IP inj. of naloxone or naltrexone) in conjunction with radiation exposure resulted in hypersalivation in Sprague-Dawley rats. Saliva production was pronounced 15 minutes following radiation exposure and, was maintained for approximately 15 minutes. Postirradiation administration of an opiate antagonist resulted in hypersalivation among 75% of test animals. Shielding the torso or head from radiation exposure resulted in a reduction in the hypersalivation response. Administration of haloperidol or spiperone in combination with naltrexone, resulted in a reduction in postirradiation saliva production. Apomorphine administration in conjunction with opiate receptor blockade resulted in saliva production at lower doses of apomorphine than would induce salivation independently. The data suggest a role for opioid and dopamine involvement in the regulation of saliva production. Understanding radiation-induced changes in this regulatory system may be useful for biological radiation dosimetry and for design and testing of anti-emetic drugs.

EFFECTS OF 5HT ON GABA-INDUCED DEPOLARIZATIONS OF FROG AFFERENT FIBERS. A. Gharagozloo*, J.C. Hackman, A.M. Holohean and R.A. Davidoff. Neurophysiology Laboratory, VA Medical Center and Department of Neurology, University of Miami School of Medicine, Miami, FL 33101.

We examined the effects of serotonin (5-HT) and selective 5-HT receptor agonists on dorsal root (DR) depolarizations induced by gamma-aminobutyric acid (GABA). Sucrose gap recordings were made from the DR of the isolated, hemisected frog spinal cord superfused with HCO_3^--buffered Ringer's solution.

All concentrations of 5-HT (1-100 μM) reduced the depolarizations produced by 15-20 sec applications of GABA (0.1 mM). Low concentrations of 5-HT (1 μM) reduced the GABA responses by 12±7% (n=3), while the high doses of 5-HT (100 μM) decreased the GABA responses by 44±3% (n=5). The reductions resulted from a direct action on afferent terminals since comparable results occurred in the presence of TTX (0.625 μM). The 5-HT_{1A} receptor agonists, 8OH-DPAT (0.01 μM) and ipsapirone (1 μM) produced reductions of 22±5% (n=10) and 29±7% (n=6) in GABA-induced depolarizations respectively. These effects were reversed by the addition of 20 μM spiperone, suggesting the reductions are 5-HT_{1A} receptor related. 5-$HT_{1C/2}$ receptors also contributed to the reduction of the GABA depolarizations since α-methyl-5-HT (100 μM) reduced the GABA-induced depolarizations (54±8%, n=3). In addition, the 5-$HT_{1C/2}$ antagonists, methysergide (0.1 μM) and mianserin (10 μM) antagonized the reduction of the GABA responses. The site of interaction may be the $GABA_A$ receptor since 8OH-DPAT and α-methyl-5-HT reduced the depolarization of the DR produced by muscimol (3-10 μM). MDL 72222 (20 μM), a $5HT_3$ antagonist, had no effect on the 5-HT-induced decrease of GABA responses.

These results indicate that activation of both 5-HT_{1A} and 5-HT_{1C}/5-HT_2 act to reduce the depolarization produced by GABA on primary afferent terminals. (Supported by VAMC funds MRIS #1769 and #3369 and USPHS grant #17577).

SP AND CGRP MODULATE RELEASE OF GLUTAMATE AND ASPARTATE FROM THE RAT SPINAL DORSAL HORN. I. Kangrga, J. S. A. Larew & M. Randic, Depts. of Vet. Physiol. Pharmacol. and Biochem., Iowa State University, Ames, IA 50011, U.S.A.

Glutamate (Glu), aspartate (Asp), substance P (SP) and calcitonin gene-related peptide (CGRP) have been proposed as neuromediators or neuromodulators of primary afferent transmission. Coexistence of SP and CGRP and SP and glutamate in the small rat dorsal root ganglion neurons was shown. The potential interactions between SP or CGRP with endogenous Glu and Asp were investigated by measuring their basal and electrically-evoked efflux using rat spinal slice. A slice was incubated in Krebs solution at 32°C and a lumbar dorsal root stimulated (25V, 0.02-0.2s, 3-5Hz for 5 min) in the absence or the presence of SP or CGRP. Samples were analyzed for amino acids using HPLC with OPA derivatization. Bath-applied SP ($2\text{-}5x10^{-7}$M) produced a 3-fold increase of the basal efflux of Glu and at a higher dose (10^{-6}M) a 2-fold increase in Asp. The effects were present in a zero-Ca^{2+} solution. SP produced also an increase in electrically-evoked efflux of Glu. CGRP (10^{-7}M) increased the basal efflux of Glu and Asp and electrically-evoked efflux of Asp and GABA. Neonatally-applied capsaicine reduced the evoked efflux of Glu and Asp, and modified the basal efflux. The effects of CGRP and SP were reduced in the capsaicine-treated rats. It is suggested that SP and CGRP may be physiologically involved in modulation of Glu and Asp release during primary afferent neuro-transmission. Supported by NIH, NSF and USDA.

NEUROPEPTIDE Y IS REGULATED DIFFERENTLY THAN SOMATOSTATIN AND SUBSTANCE P IN CULTURED SYMPATHETIC NEURONS. M. Freidin* and J.A. Kessler, Departments of Neurology and Neuroscience, Albert Einstein College of Medicine, Bronx, New York 10461.

The regulation of Neuropeptide Y (NPY) was examined in sympathetic neurons cultured from the neonatal rat superior cervical ganglion. Particular emphasis was placed on defining the effects of environmental factors which are known to regulate other neurotransmitter systems in the same neurons. Levels of NPY increased with time in culture. Co-culture of these neurons with ganglion nonneuronal cells, a condition which stimulates cholinergic and substance P (SP) expression while decreasing noradrenergic development, had no effect on levels of NPY. Similarly, treatment with media conditioned by nonneuronal cells, which has striking effects on cholinergic, somatostatin (SS), and SP expression, had no effect on neuronal content of NPY. Potassium or veratridine induced membrane depolarization which decreased levels of SS, SP, and cholinergic traits and increased noradrenergic traits, but did not alter levels of NPY. Finally, dexamethasone and long term forskolin treatment were similarly without effect on neuronal NPY content. These observations indicate that the mechanisms regulating other neuropeptides and neurotransmitters are not the same as those regulating NPY.

INTERACTIONS OF ALPHA$_2$ ADRENOCEPTOR ANTAGONISTS WITH THE HYPOTHERMIC AND HYPERGLYCEMIC EFFECTS OF 8-OH-DPAT.

M.J. Durcan, K.M. Wozniak* and M. Linnoila. Laboratory of Clinical Studies, Blg10 3C218, NIAAA, Bethesda, MD 20892.

8-hydroxy-dipropylaminotetralin (8-OH-DPAT), which has a high affinity for 5HT$_{1A}$ sites, produces both hypothermia and hyperglycemia in mice. In this study pretreatment with novel alpha$_2$-adrenoceptor antagonists on 8-OH-DPAT-induced responses was investigated. The antagonists used were: atipamezole (ATZ), which occupies both central and peripheral receptors, and L659,066, which poorly penetrates the blood/brain barrier. NIH Swiss mice were pretreated with either 0, 1 or 3mg/kg i.p. ATZ immediately after body temperatures and blood glucose levels had been recorded. 20min later each treatment group (N = 10-14) received either 0 or 0.25 mg/kg s.c. 8-OH-DPAT and temperature and blood glucose measured every 20 min thereafter for 1hr. ATZ alone had no effect on temperature whereas 8-OH-DPAT induced hypothermia was significantly ($p<.01$) attenuated by both doses of ATZ. The 8-OH-DPAT hyperglycemia was also attenuated ($p<.01$) by ATZ pretreatment. L659,066 (3, 10 or 30mg/kg i.p.) failed to alter 8-OH-DPAT-induced hypothermia but did attenuate 8-OH-DPAT-induced hyperglycemia. The results suggest that the attenuation of 8-OH-DPAT hypothermia caused by alpha$_2$-adrenoceptor antagonists may be centrally mediated whereas the hyperglycemia blockade may involve peripheral mechanisms.

95.12

IMIPRAMINE ANTAGONIZES TRH-INDUCED GASTRIC ULCERS IN RATS.

B.G. Xue , M.E. Arredondo and D.E. Hernandez. Depts. of Medicine and Neurology, University of Southern California School of Medicine, Los Angeles, CA 90033.

Brain thyrotropin-releasing hormone (TRH) may play a role in experimental ulceration. Intracisternally (IC) -administered TRH aggravates stress- and indomethacin -induced gastric lesions and produces gastric ulcers in naive rats [Life Sci 39(4):279-296, 1986]. Other studies have shown that TRH potentiates the antidepressant effect of imipramine in the forced-swimming test (Br J Pharmacol 85:463-470, 1985). However, potential interactions between TRH and imipramine on the development of gastric ulcers have not been investigated. Adult male SD rats (200-250g) were food- but not water deprived for 24h prior to IC injections of vehicle (10µl of 0.9% NaCl) or TRH (1ug) concomitantly with imipramine (0-5mg/Kg, IP). Rats were sacrificed 4h after IC and IP treatments and the stomachs examined for evidence of gastric lesions. In another experiment, the effect of imipramine (5mg/Kg,IP) on TRH-induced acid secretion was examined in rats with pylori ligation. Rats were killed by decapitation after 2h and gastric acid quantitated. IC TRH induced a high (100%) incidence of gastric lesions. Imipramine dose-dependently inhibited TRH-induced gastric glandular lesions and blocked TRH-induced acid secretion. These findings provide evidence for a functional dicotomy between TRH and imipramine in regards to ulcer formation.

DOPAMINERGIC AND ADRENERGIC REGULATION OF HYPOTHALAMIC PROOPIOMELANOCORTIN RNA.

D.L. Allen, M. Blum AND J.L. Roberts. Fishberg Research Center for Neurobiology, Mt. Sinai School of Medicine, New York, NY 10029.

Monoaminergic neurotransmitters regulate levels of beta-endorphin in the hypothalamus. In order to better understand monoaminergic regulation of beta-endorphin synthesis, levels of proopiomelanocortin (POMC) RNA were measured with a solution hybridization/nuclease assay using a cRNA probe containing 100 bp of exon 1 and 60 bp of intron A.

After treatment with haloperidol (dopaminergic antagonist, 2 mg/kg s.c.) for six days, levels of POMC hnRNA were decreased by 55% ($p < 0.05$) in both intact and ovariectomized female rats. Levels of cytoplasmic mRNA were decreased by 24%, but this was not significant. In two separate experiments, levels of POMC hnRNA were decreased by 23% and 21% ($p = 0.05$ for each experiment) one hour after a single injection of haloperidol.

Treatment with clonidine (alpha-adrenergic agonist, 500 ug/day for 6 days) decreased POMC mRNA levels by 42% ($p < 0.01$). One hour after clonidine, levels of POMC hnRNA were decreased by 60%. These results suggest that POMC-containing neurons in the hypothalamus are regulated by dopaminergic and adrenergic inputs. (Supported by NIH-NICHHD Post-doctoral fellowship HD-07186).

α_1-RECEPTOR MEDIATED NORADRENERGIC TRANSMISSION IS INVOLVED IN THE INDUCTION OF HYPOTHALAMIC OXYTOCIN RECEPTOR BINDING BY ESTRADIOL.

C.R.Harbaugh* and A.E.Johnson (SPON: C. Flicker). Section on Comparative Studies of Brain and Behavior, Laboratory of Clinical Sciences, NIMH, Poolesville, MD 20837.

Several studies have shown that some of the effects of ovarian steroids on reproduction are mediated by noradrenergic transmission (NAT). For example in rats, α-receptor antagonists attenuate the steroid-dependent display of sexual receptivity and reduce the concentration of cytosolic estrogen receptors in hypothalamus. In guinea pigs, α_1-receptor blockade with prazosin (PRZ) reduces the concentration of estradiol (E_2)-dependent cytosolic progestin (P) receptors in the ventromedial hypothalamic nucleus (VMN), a brain region involved in reproduction. Another neurotransmitter system involved in steroid-dependent reproductive processes is the oxytocin (OT) system. Similar to hypothalamic P receptors, E_2 increases OT receptor binding in regions of the VMN that contain a high density of E_2 concentrating cells. The purpose of this study was to determine if α_1-receptor mediated NAT is involved in the regulation of E_2-dependent OT receptors.

Adult female rats (4/group) were ovariectomized and treated 7 days later with 10µg E_2 and PRZ, E_2 and Veh or Oil and Veh. Animals given PRZ were injected at the time of E_2 treatment and 40 h later (10mg/inj). Animals were killed by decapitation 48h after E_2 treatment, brains were removed and frozen on dry ice. Brain slices (20µm) through the hypothalamus were cut on a cryostat and stored at -60°C. OT receptors were labeled with 70pM ^{125}I-d(CH$_2$)$_5$[Tyr(Me)^2,Thr^4,Tyr-NH$_2^9$]OVT (^{125}I-OVTA) according to published methods (Elands et al., 1987) with unlabeled OT (5µM) used to define nonspecific binding. Receptor binding was measured using standard receptor autoradiographic methods (Kuhar, 1986).

Results of this study showed that PRZ treatment reduced OT receptor binding in caudal regions of the vlVMN compared to animals treated with E_2 alone. These data suggest that NAT is involved in the modulation of OT receptor binding by E_2. Whether the inhibitory effects of PRZ on E_2-dependent OT receptors are the result of a decrease in E_2 sensitivity (due to a decrease in estrogen receptors) or to an inhibition of E_2-stimulated protein synthesis remains to be determined.

95.15

FMRF-NH$_2$-LIKE PEPTIDE IN PITUITARY OF BRATTLEBORO RAT AND SALT TREATMENT.

E.A. Majane and H.-Y.T. Yang. Lab. Biochem. Gen., NIMH Neuroscience Center at St. Elizabeths, Washington, D.C. 20032.

FLFQPQRF-NH$_2$ (F-8-F-NH$_2$), a mammmalian FMRF-NH$_2$-like neuropeptide, was isolated from bovine brain. F-8-F-NH$_2$ can decrease rat tail flick latencies and attenuate morphine induced analgesia suggesting a role in opiate mediated antinociception. F-8-F-NH$_2$ immunoreactivity (IR) is most highly concentrated in the rat neurohypophysis, an area rich in vasopressin (VP), oxytocin and dynorphin. In order to explore the role of F-8-F-NH$_2$ in this area, we have studied F-8-F-NH$_2$-IR in the CNS and pituitary of the Brattleboro (DI) and the control Long Evans (LE) rat. In the DI animal, which lacks Arg^8-VP, there is no detectable F-8-F-NH$_2$-IR in pituitary gland while there are normal levels in hypothalamus and spinal cord as compared to the LE. We have also subjected normal rats to both chronic and acute NaCl treatment. Acute IP injection of 2M NaCl failed to change F-8-F-NH$_2$-IR in either pituitary, hypothalamus or spinal cord when compared to controls. Animals who drank water containing 1% NaCl for 13 days also showed no differences in F-8-F-NH$_2$-IR in CNS or pituitary when compared to controls. The mechanism underlying the deficiency of F-8-F-NH$_2$-IR in the DI rat still remains unclear.

95.16

TYROSINE HYDROXYLASE (TH)-IMMUNOREACTIVE NERVE FIBERS IN THE RAT NEUROINTERMEDIATE LOBE: ENHANCED STAINING AFTER PARACHLOROPHENYLALANINE (PCPA) TREATMENT.

L.C. Saland, A. Samora*, S. Desai* and E. Vigil-Palmer*. Dept. of Anatomy, Univ. New Mexico Sch. Med., Albuquerque, NM 87131.

The pituitary neurointermediate lobe (NIL) of adult rats receives both TH and serotonin (5-HT)-immunoreactive nerve fibers from hypothalamic and brainstem cell bodies, respectively. Some fibers in the NIL co-localize both TH and 5-HT (Saland et al.,'88, Neurosci. Lett. 94: 39). PCPA, an inhibitor of tryptophan hydroxylase, has been shown to increase TH synthesis in mammalian brain, and to enhance visualization of TH-positive perikarya in the cat brain (Kitahama et al, '87, Neurosci. Lett. 77:155). Here, adult male Sprague-Dawley rats received three successive daily intraperitoneal (i.p.) doses of PCPA (300, 100, 100 mg/kg). Controls received i.p. saline injections. One week after the first dose, rats were ether-anesthetized, and perfused with saline followed by buffered paraformaldehyde. Paraffin sections incubated with anti-TH (Eugene Tech, 1:300) were treated with avidin-biotin-peroxidase or IgG-5nM gold, and coded slides were examined by two observers. After PCPA treatment, TH fiber staining was enhanced in both neural and intermediate lobes, particularly along the border between the two areas. PCPA, by reducing 5-HT, may increase TH synthesis in hypothalamic neurons, and may enhance catecholamine input to the NIL. Supported by NIH NS-21256 and RR-08139.

96.1

TOPOGRAPHICAL ORGANIZATION OF THE CHOLINERGIC CELLS PROJECTING FROM THE LATERODORSAL TEGMENTAL (LDTg) AND PEDUNCULOPONTINE TEGMENTAL (PPTg) NUCLEI TO THE THALAMUS IN RAT BRAIN.

S. Saxena* and B.K. Hartman. Dept. Psychiatry, Division of Neuroscience, Univ. of Minn. Medical School, Mpls. MN 55455

The LDTg and the PPTg provide the major cholinergic input to the thalamus. Previous studies have indicated that the LDTg projects only to those thalamic nuclei associated with the limbic system while the PPTg projects to all thalamic nuclei. This study provides a detailed analysis of the entire span of these two cholinergic nuclei and demonstrates that they are better understood as a single nucleus which is topographically organized according to the function of the thalamic nuclei to which it projects.

Injections (30nl) of Fluoro-Gold were placed into anterior, ventrolateral, and posterior thalamic nuclei. Cholinergic projections to these nuclei were traced using simultaneous visualization of retrogradely transported Fluoro-Gold and choline acetyltransferase immunofluorescence. Anterior thalamus is supplied primarily by the LDTg and the caudal PPTg, which are continuous both anatomically and functionally and can be understood as the "limbic pole" of the entire cholinergic group. Ventrolateral and posterior nuclei, involved in sensory-motor processing, are supplied primarily by the rostral part of the cholinergic group, which can be understood as the "sensory-motor relay pole". In the middle portion of this group cells project to both limbic and relay nuclei, but the exact pattern of cells projecting to any nucleus can be predicted by the function of that nucleus. This functional organization is also reflected in the degree of crossover of the projections. Projections from the limbic pole cross more frequently than those from the sensory-motor relay pole.

96.2

SITE-DIRECTED ANTIBODIES DESIGNED FOR THE IMMUNOCYTOCHEMICAL LOCALIZATION OF NICOTINIC ACETYLCHOLINE RECEPTORS IN RAT BRAIN

P. Séguéla, P. Gaudreau, M. Dennis, P. Brazeau* and L. Descarries. Centre de recherche en sciences neurologiques (Département de physiologie), Université de Montréal, Montréal H3C 3J7, Laboratoire de neuroendocrinologie, Hôpital Notre-Dame, Montréal H2L 4M1 and Receptor Group, Biotechnology Research Institute, Montréal H4P 2R2, Québec, Canada.

Polyclonal antibodies were raised in rabbits against a non-conserved intracellular domain of the predicted sequence of the α4 agonist-binding subunit of rat central nicotinic acetylcholine receptor (Goldman, D. et al., *Cell*, 48:965, 1987). A dodecapeptide corresponding to the segment 535-546 was synthesized and conjugated with glutaraldehyde to BSA and poly-D-Lys for immunization. Several antisera showed high titers in RIA with the iodinated peptide analog. One of these, N-94, bound to a major band of Mr = 65-70 kdaltons in Western blots of rat brain membranes. This binding was insensitive to aldehyde fixation of blotted proteins. In sections from 4% paraformaldehyde-perfused brain, processed for PAP immunohistochemistry with 1/200-800 dilutions of N-94, strong and selective neuronal labeling was observed in anatomical regions where α4 transcripts have been detected by in situ hybridization (Wada, E. et al., *J. Comp. Neurol.*, 1989, in press). This immunostaining appeared confined to neuronal perikarya and dendrites, and spared the nucleus. In cerebral cortex, it was restricted to pyramidal neurons and conspicuously absent from the granular cells of layer IV. Such subtype-specific immunoprobes visualized at light and electron microscopic levels should allow the cellular and ultrastructural localization of nicotinic acetylcholine receptors in rat brain. (Supported by MRC, NRC and FRSQ).

96.3

REGIONAL DISTRIBUTION OF BINDING SITES FOR SELECTIVE MUSCARINIC ANTAGONISTS IN RAT BRAIN.

F.J. Ehlert and P. Tran*, Dept. Pharmacol., Univ. Calif. Irvine, Irvine, CA 92717.

The distribution of subtypes of the muscarinic receptor in homogenates of the rat brain was investigated by measuring the competitive inhibition of the binding of [^{3}H]N-methylscopolamine ([^{3}H]NMS) by pirenzepine and AF-DX 116 (11[[2-[(diethylamino)methyl]-1-piperidinyl]acetyl]-5,11-dihydro-6H-pyrido[2,3-b][1,4]benzodiazepine-6-one). Pirenzepine and AF-DX 116 have been shown to exhibit selectivity for M1 and M2 receptor subtypes, respectively. In most brain regions, the pirenzepine/[^{3}H]NMS and AF-DX 116/[^{3}H]NMS competition curves were consistent with a two-site model. The dissociation constant of pirenzepine for its high affinity site (M1 receptor) was approximately 10^{-8} M, whereas the dissociation constant of AF-DX 116 for its high affinity site (M2 receptor) was approximately 10^{-7} M. In many regions, particularly those in the forebrain, the sum of the densities of the M1 and M2 receptors was substantially less than 100% of the total sites, indicating the existence of a third population of sites lacking high affinity for either pirenzepine or AF-DX 116. We have designated these latter sites as non-M1, non-M2 muscarinic receptors. In general, the relative densities of the M1 and non-M1, non-M2 binding sites were highest in cerebral cortex, corpus striatum and hippocampus, intermediate in thalamus and hypothalamus, and lowest in midbrain, medulla-pons and cerebellum. In contrast, the relative density of the M2 binding site was exactly the converse. *Supported by NIH Grant NS26511.*

MUSCARINIC ACETLYCHOLINE RECEPTORS IN NEURAL AND NON-NEURAL HUMAN EYE STRUCTURES

N. Gupta* , C.Shaw, V.A.White*, J. Rootman*, M.S. Cynader, and S.M. Drance* (SPON: K. Dakshinamurti)
Dept. of Ophthalmology , University of British Columbia
2550 Willow Street, Vancouver, B.C., Canada V5Z 3N9

The neurotransmitter actions of acetylcholine play an important role in the function of the eye , most notably manifest in the muscarinic cholinergic actions of miotics. We studied the localization of muscarinic cholinergic binding sites in human donor eyes . Autoradiograms were generated after incubation with the tritiated ligands, Quinuclidinyl Benzylate (QNB) and N-Methylscopolamine (NMS). In addition, characterization studies of the iris-ciliary body were done. The results of these experiments demonstrate binding sites in the retina, and of particular interest, the non- neural uveal tract structures, within which marked density differences are present. Characterization studies show normal binding kinetics for the iris-ciliary body , with a Kd value of 0.51 nM. Preliminary studies of the iris-ciliary body point to a predominance of the muscarinic M2 subtype. The present results may be relevant to the future development of more specific ophthalmic drug therapy, and to a greater understanding of its effects on muscarinic cholinergic actions in the eye.

96.5

[^{11}C]-BENZTROPINE AS A POSSIBLE MUSCARINIC CHOLINERGIC RECEPTOR LIGAND IN HUMAN BRAIN FOR PET.

S.L.Dewey, R.MacGregor*, J.D.Brodie*, N.Volkow, J.S.Fowler, D.Schlyer*, A.P.Wolf*, and B.Bendriem*. Chemistry, Brookhaven Nat'l. Lab., Upton, NY 11973, Psychiatry, NYU Medical Center, NY 10016

Involvement of the cholinergic system has been implicated as one of the underlying causes of Alzheimer's disease. Benztropine is a widely prescribed anti-cholinergic agent used to relieve the extrapyramidal side effects of neuroleptics. Preliminary studies in baboons using [^{11}C]-benztropine demonstrated that the regional distribution of binding closely paralled the known distribution of muscarinic receptors in the primate brain (Dewey, et al. Brain 89). We investigated the regional distribution and temporal profile of [^{11}C]-benztropine in human brain with high resolution PET. More than 50% of the brain uptake occurred within the first 5 min. Accumulation continued throughout the 80 min of scanning for all brain regions except for cerebellum. Regional concentration of [^{11}C]-benztropine was striatum > cortex > thalamus > cerebellum. Analysis of [^{11}C]-labelled metabolites revealed no significant metabolism of [^{11}C]-benztropine. Sequential injections of [^{11}C]-benztropine done 2 hrs apart in the same subject revealed a test/retest variability of < 10%. The regional uptake of [^{11}C]-benztropine corresponded to the known distribution of muscarinic receptors in the human brain as measured with postmortem autoradiographic techniques (J. Neurochem. 43, 1984). USDOE, OHER, NIH NS-15638.

96.6

IDENTIFICATION OF B-2 BRADYKININ RECEPTORS IN SHEEP NASAL TURBINATE MEMBRANES.

R.A. Lyon, P.S. Weisshaar* and R.J. Phipps*+. The Procter & Gamble Co., Miami Valley Laboratories, Cincinnati, OH. +Norwich Eaton Pharmaceutical Co., Norwich, NY.

Bradykinin (BK) has been implicated as a potential mediator of the nasal symptoms associated with colds and allergy and may exert its effects by interacting with at least two receptor subtypes named B-1 and B-2. B-2 receptors have been studied in a variety of tissues using radioligand binding methods. In order to determine the subtypes of BK receptors present in nasal tissues, we performed in-vitro binding assays using ^{3}H-BK in membranes prepared from middle and inferior nasal turbinates from sheep. Binding was saturable and specific (K_D of 0.02nM) and revealed a low density of sites (Bmax of 0.6 pMoles/g tissue) with a pharmacology characteristics of a B-2 receptor (shown below).

	K_D (nM) +/- SEM	N:
1) BK	.039 +/- .008	7
2) Lys-BK	.09 +/- .03	4
3) des-Arg^9	952 +/- 143	3
4) Leu^8, des-Arg^9-BK	4735 +/- 1160	3

The B-2 receptor agonists BK and Lys-BK competed with high affinity for ^{3}H-BK-labelled sites while the B-1 agonist des-Arg^9-BK and B-1 antagonist Leu^8, des-Arg^9-BK competed in the micromolor range. These data identify the presence of B-2 receptors in sheep nasal turbinate membranes. Saturation, kinetic, displacement and guanine nucleotide analog studies will be presented.

DIFFERENCES IN HUMAN AND SALMON CALCITONIN BINDING ON RAT BRAIN SECTIONS SUGGEST RECEPTOR SUBTYPES. D.I.Lambie* J.M. Hill A. Harris* J. Barbour* L. Kwart* M.R. Ruff* and C.B. Pert.* (SPON: C. Sharp). NSB, NIMH Bethesda, Md. 20892 and Peptide Design 12321 Middlebrook Rd. Germantown, Md 20874.

Studies of the Scatchard analysis of salmon calcitonin (SCt) binding to brain tissue have reported either a single high affinity site or both high and low affinity.sites. SCt and human calcitonin (HCt) have only 50% of their amino acid composition in common, however, both are assumed to bind to the same brain receptors. In this study the autoradiographic binding patterns of ^{125}I-SCt and ^{125}I-HCt are compared on adjacent rat brain sections as are the patterns achieved with competition with cold SCt, HCt, or PD89.010, a calcitonin analog.

Both HCt and SCt bound in many brain regions, however, the HCt binding pattern was more restricted in its boundaries and encompassed fewer regions than that of SCt. Although HCt revealed dense binding in the hypothalamus and central grey as did SCt, in many areas in which SCt had dense or moderately dense binding HCt apparently did not bind at all. Although SCt at micromolar concentrations displaced both ^{125}I-SCt and ^{125}I-HCt completely, HCt at this concentration, displaced ^{125}I-HCt but reduced ^{125}I-SCt only slightly. At micromolar concentrations PD89.010 displaced ^{125}I-HCt and reduced ^{125}I-SCt binding.

These results are consistent with the hypothesis that SCt may bind to more than one receptor subtype in brain tissue.

96.8

RADIOLABELING OF THE RAT CNS BY BLOOD-BORNE ^{125}I-SAR^{1},ILE^{8} ANGIOTENSIN II (^{125}I-SIAII). B.P. Rowe* and R.C. Speth (SPON: E.A. Daigneault). Dept. Physiol., Coll. Medicine, E. Tenn. State Univ., Johnson City, TN 37614 and Dept. of VCAPP, Washington State Univ., Pullman, WA 99164-6520.

Blood-borne angiotensin II (AII) acts at circumventricular organs (CVO's) in the brain which lack a blood-brain-barrier (BBB). This study examined binding of ^{125}I-SIAII, in the rat CNS after administration into the bloodstream. 65-90 g rats were anesthetized and injected intracardially with 44 pmoles of ^{125}I-SIAII in 1 ml of 0.1 M sodium phosphate (n=3) or ^{125}I-SIAII plus 4 nmoles of AII (n=2). Two min later the rats were perfused with chilled phosphate buffered saline for 2 min and 50 ml of 3% paraformaldehyde. The brain, spinal cord (C-1) and pituitary were removed and frozen. Each entire brain was frozen sectioned at 20 micron thickness. The sections were placed in apposition to X-ray film for 2-3 days to localize ^{125}I-SIAII binding. The ^{125}I SIAII binding was present in the choroid plexus of the lateral, 3rd and 4th ventricles, and the pineal recess, the subfornical organ, area postrema, pineal, anterior and posterior pituitary, pia-arachnoid and organum vasculosum of the lamina terminalis. ^{125}I-SIAII binding was only partially reduced with 100-fold excess of AII. Therefore some of the ^{125}I-SIAII binding may be nonspecific. This study confirms prior studies indicating that AII does not cross the BBB, and suggests that AII acts in the choroid plexus as well as the CVO's in the brain.

QUANTITATIVE AUTORADIOGRAPHY OF HIGH AFFINITY SOMATOSTATIN BINDING SITES IN RAT BRAIN USING A NOVEL ANALOGUE [125I] L 363,586 AND RECEPTOR DESATURATION PROCEDURES. M. Dugich-Djordjevic, R. Vandlen*, and C.A. Altar, (SPON: B.S. Glaeser) Dept. of Pharmacological Sci. and *Dept. of Protein Chemistry, Genentech, Inc. South San Francisco, CA 94080

Evidence has suggested the existence of somatostatin receptor populations in the rat and human CNS with varying affinities for [125I]-somatostatin-28 (SST-28). [125I]-L 363,586, a potent cyclic hexapeptide somatostatin analogue, binds to rat brain homogenates with high affinity, but differs from SST-28 in its sensitivity to GTP (Vandlen et al., in press). We employed guanine nucleotides (Leroux et al., Neuroendocrinol., 47:533, 1988) or high NaCl to dissociate endogenous somatostatin from CNS binding sites and to characterize binding to unoccupied receptors using quantitative autoradiography. Adjacent sections of rat brain were prewashed in buffer (20 mM Hepes, pH 7.4, 5 mM $MgCl_2$, 0.1% BSA, 0.1% bacitracin) alone or in buffer containing GTP (10 µM) or 120 mM NaCl and then 90 min in buffer only. Sections were incubated 2 h in 5-600 pM [125I]-SST-28 or [125I] L 363,586 with or without 100 nM SST-14 or L 363,586. Either GTP or NaCl prewashes significantly ($p<.001$) increased 100 pM [125I]-SST-28 specific binding 3-5 fold. L 363,586 displaced all specific [125I]-SST-28 binding after GTP desaturation, but only 30-80% after the NaCl prewash. Scatchard analysis revealed saturable binding of comparable affinity for both ligands (Kd=30-150 pM) in the cingulate and entorhinal cortex, claustrum and septum, and lower affinity binding (Kd=350-430 pM) in the CA1 region of hippocampus for [125I] L 363,586. The area of highest binding for [125I]-SST-28 was in neocortical layers V and VI, the cingulate, claustrum, olfactory nuclei, dentate gyrus and CA1, with intermediate levels of binding in the septum and subiculum. The caudate-putamen, n. accumbens, hippocampal CA2 and CA3 regions, outer neocortical layers and cerebellum exhibited low levels of unsaturable binding. 85-90% of [125I] L 363,586 was specifically bound compared to 70% for [125I]-SST-28 binding. The binding of [125I]-SST-28 and [125I] L 363,586 in the rat CNS is differentially affected by NaCl and GTP. L 363,586 and the desaturation procedures described here should be useful in determining the distribution and specificity of decreases in somatostatin binding in Alzheimer's patients (Beal et al., Science, 229:289,1985).

MU OPIOID RECEPTOR AUTORADIOGRAPHY: RELATIONSHIP TO MIDBRAIN DOPAMINERGIC NEURONS. S.G. Speciale, M. Sadeq* and D.C. German. Dept. of Psychiat., Univ. of Texas Southwestern Med. Cntr., Dallas, TX 75235.

The present study sought to map the distribution of µ opioid receptors within the midbrain and relate the pattern of binding to the location of the midbrain dopaminergic (DA) neurons. Coronal sections were cut from the mammillary bodies to the level of the rostral pons in the rat. Sections were incubated at 4°C for 40 min. in 50 mM Tris HCl (pH 7.4) containing 3 nM [3H] D-Ala2MePhe4Glyol enkephalin (3H-DAGO) to assess total binding. Adjacent sections were incubated under the same conditions with the addition of the opioid agonist levorphanol (1 µM). Every 3rd section was processed for film autoradiography, along with Amersham 3H standards, using LKB Ultrofilm (exposure time = 30 days). Other sections were processed for tyrosine hydroxylase immunohistochemistry. Within 7 brains, 3H-DAGO labeling was ++++ within the rostral substantia nigra (SN) pars compacta, +++ within the SN from rostral to caudal, ++ within the ventral tegmental area and 0 within the retrorubral area. Research supported by DA-05314.

AUTORADIOGRAPHIC LOCALIZATION OF KAPPA OPIOID BINDING SITES WITH [^{3}H]NalBzoH. D. Paul,* E. Huang* and G.W. Pasternak. (SPON: R. Price). Cotzias Lab. for Neuro-Oncology, Memorial Sloan-Kettering Cancer Center and Depts. of Neurology and Pharmacology Cornell U. Medical College, New York, NY 10021

In brain homogenate binding studies, naloxone benzoylhydrazone, NalBzoH, labels a novel class of κ binding site (κ_3) as well as the classical κ_1 binding site. Using conditions to selectively label κ_3 sites, we directly examined the autoradiographic distribution of κ_3 binding sites labelled by [^{3}H]NalBzoH. Nonfixed thin rat brain sections (9µm) were incubated with 1 nM [^{3}H]NalBzoH (45.1 Ci/mmole) for 1 hr at 0°C in the presence of K_2EDTA (5mM). Nonspecific binding was defined as that remaining in the presence of 1µM unlabeled NalBzoH. The regional distribution of the κ_3 binding sites was quite distinct from previously reported κ distributions. In fact, the distribution of κ_3 binding sites labelled by [^{3}H]NalBzoH more closely resembled the distribution of µ sites, with high levels of binding in layers I and IV of the cerebral cortex, clusters of the striatum, superficial layer of the superior colliculus, the interpeduncular nucleus, and the presubiculum. Moderate levels of binding were also seen in the pyramidal cell layer of the hippocampus, the periaqueductal gray and the lateral thalamus.

VENTRAL STRIATOPALLIDAL COMPARTMENTS REVEALED BY COMBINING TRACER HISTOCHEMISTRY AND RECEPTOR AUTORADIOGRAPHY. L. Churchill, R.M. Bowker, H. Eberhardt*, R.P. Dilts, & P.W. Kalivas. Dept. of VCAPP, Washington State University, Pullman, WA 99164-6520.

GABA and met-enkephalin coexist in striatopallidal neurons. The receptors for these transmitters, $GABA_A$ and µ-opioid respectively, are localized on neurons in both the ventral striatum and ventral pallidum. Quinolinic acid lesions in the dorsomedial shell of the nucleus accumbens correlate with upregulation of $GABA_A$ receptors in the dorsal rim of the ventral pallidum, without a change in µ-opioid receptors; whereas quinolinic acid lesions that destroy neurons in the lateral nucleus accumbens do not change either the $GABA_A$ or µ-opioid receptors in the ventral pallidum. Since lesions in the ventrolateral caudate decrease $GABA_A$ receptors throughout the entire ventral pallidum, $GABA_A$ receptors may be localized on presynaptic terminals. Fluoro-Gold injections into the dorsal rim of the ventral pallidum retrogradely-labeled neurons from the dorsomedial core of the nucleus accumbens through the ventrolateral caudate; whereas injections in the ventromedial pallidum labeled neurons in the nucleus accumbens shell. Specific [125I]D-Ala-Tyr-Gly-mePhe-Gly(ol) binding to µ-opioid receptors occurred over Fluoro-Gold labeled neurons in the nucleus accumbens shell. The autoradiographic grain distribution suggested that the receptors were localized on the neuropil as well as the cell bodies.

This work was partially supported by NIH program project # NS 24388-03.

DIFFERENTIAL EXPRESSION OF CALBINDIN IMMUNOREACTIVITY IN THE THALAMOLIMBIC AND THALAMOSTRIATAL CELL POPULATIONS

M. BENTIVOGLIO, D. SCHIFF*, H.S.SU*
Institute of Anatomy, University of Verona, Italy

Calcium binding protein calbindin D28k (Cb) displays an inhomogeneous distribution, as evidenced by immunocytochemistry (ICC), in the rat thalamus. Cb-positive cell bodies are densely grouped in medial, midline and anterior intralaminar nuclei traditionally included in the 'nonspecific' thalamus whose efferents reach multiple cortical and subcortical targets. The occurrence of Cb-positive neurons was verified in some of these pathways by means of combined retrograde axonal tracing and ICC. The vast majority (75%-95%) of thalamic midline cells projecting to the hippocampus and only 20%-40% of those projecting to the amygdala were found to be Cb-positive. These findings indicate that the flow of information between thalamus, amygdala and hippocampus is characterized by a different neurochemical expression. In the study of midline and intralaminar cells projecting to dorsal striatum and nucleus accumbens a high proportion of neurons was found to be Cb-positive. However, topographic and quantitative differences in the Cb-positivity of thalamo-caudate and thalamo-accumbens cells point to a different neuroregulation of the two circuits.

PURIFICATION, IDENTIFICATION AND IMMUNOHISTOCHEMICAL LOCALIZATION OF A BRAIN-SPECIFIC CALCIUM BINDING PROTEIN (PROTEIN 10) .

L. Winsky, B. M. Martin*, H. Nakata, and D.M. Jacobowitz, Lab. of Clinical Science and Clinical Neuroscience Branch, NIMH, Bethesda, MD 20892.

We previously identified a protein (MW = 29 kD, pI = 5.3) which is particularly abundant in the cochlear nuclei of rabbits, rats and guinea pigs and recently reported the calcium binding property of this protein 10. We report here the complete purification of protein 10 from guinea pig brain, the partial amino acid sequence of proteolytic digests and an immunocytochemical mapping of protein 10.

Protein purification was monitored by two dimensional gel electrophoresis. Protein 10 was precipitated by 60-80% ammonium sulfate in homogenates of guinea pig brain. Complete purification steps included two DEAE cellulose columns followed by gel filtration (TSK 3000) column chromatography on FPLC. Partial amino acid sequence was obtained for fragments of protein 10 following partial digestion with Asp-N, trypsin and V8 proteases. Results indicate a sequence homology of 58% between protein 10 and rat brain calbindin and 82% between protein 10 and chick retinal calretinin. Immunohistochemical analysis of protein 10 revealed specific label in CNS sensory systems (visual, auditory/vestibular, olfactory, nociceptive) and other discrete circuits in brain.

IMMUNOHISTOCHEMICAL LOCALIZATION OF THE NEURON-SPECIFIC FORM OF THE c-src GENE PRODUCT, pp60$^{c\text{-}src(+)}$, IN RAT BRAIN.

M.M.Sugrue*, J.S.Brugge*, P.Greengard‡ and E.L.Gustafson+ (SPON:S.Gandy). Dept. of Microbiol., SUNY, Stony Brook, N.Y. 11794 and + Lab. of Mol. and Cell. Neurosci., The Rockefeller Univ., N.Y., N.Y. 10021.

Neurons express high levels of a variant form of the c-src gene product, denoted pp60$^{c\text{-}src(+)}$, which contains a six amino acid insert in the amino-terminal half of the c-src molecule. We have determined the localization of pp60$^{c\text{-}src(+)}$ in rat brain using a polyclonal antiserum raised against a synthetic peptide containing the six amino acid insert of pp60$^{c\text{-}src(+)}$. The antibodies which specifically recognized the neuron-specific form of the c-src gene product were purified using a pp60$^{c\text{-}src(+)}$-affinity column. pp60$^{c\text{-}src(+)}$ immunoreactivity was localized within the cell soma and processes of specific types of neurons throughout the brain. In the cerebellar cortex the dendritic arbor as well as the cell bodies of Purkinje cells were densely immunoreactive while granule cells exhibited lower levels of pp60$^{c\text{-}src(+)}$. In the pons and in the medulla motor neurons also displayed strong immunoreactivity. Pyramidal cells in layer V of cerebral cortex were densely labeled while some layer VI neurons were moderately immunoreactive. The caudate-putamen also contained a few densely immunoreactive neurons, which appear to be of the large aspiny type. These results indicate that pp60$^{c\text{-}src(+)}$ is differentially expressed in neurons in rat brain, suggesting a role for this variant form of the c-src gene product in specific classes of neurons in the adult central nervous system.

MAPPING OF ALPHA AND BETA THYROID HORMONE RECEPTOR GENE EXPRESSION IN RAT BRAIN AND PITUITARY BY IN SITU HYBRIDIZATION HISTOCHEMISTRY.

D.J. Bradley*, W.S. Young, III, C. Weinberger* (SPON: W.M. Cowan). Laboratory of Cell Biology, NIMH, Bethesda, MD.

Thyroid hormone (T3) is essential for normal brain development, and in adults abnormal thyroid hormone levels have been associated with neurologic and behavioral disturbances. Multiple thyroid hormone receptor cDNAs have previously been identified in rat and are classified into alpha and beta subtypes. Alternative splicing of the alpha gene gives rise to the functional receptor, rTRα1, and the non-T3-binding isotype, rTRα2. The beta gene encodes two functional receptors, rTRβ1 and rTRβ2. Using 35S-labelled synthetic DNA probes common to rTRβ transcripts and specific for rTRα1 and rTRα2 transcripts, we mapped the expression of these mRNAs in adult rat brain and pituitary by hybridization histochemistry. rTRα1 and rTRα2 transcripts were widely distributed in a similar, if not identical, pattern. rTRα1 and rTRα2 mRNAs were most abundant in the olfactory bulb, hippocampus, and granular layer of the cerebellar cortex. In contrast, rTRβ transcripts were found in a more restricted pattern with highest levels in the hippocampus, hypothalamic paraventricular nucleus, and anterior pituitary. High levels of rTRβ mRNAs in the parvocellular part of the paraventricular nucleus and the anterior pituitary suggest beta receptors may mediate thyroid hormone feedback regulation of thyrotropin-releasing hormone and thyroid-stimulating hormone. Neither alpha nor beta mRNAs were detected above background in Purkinje cells. Our results identify sites in the mammalian CNS in which regulation of gene expression by specific thyroid hormone receptor subtypes may occur.

96.17

ISOLATION OF A NEW G-PROTEIN COUPLED RECEPTOR FROM NG108 CELLS.

J.A. Salon, H.H.M. Van Tol*, J. Bunzow* and O. Civelli. Vollum Institute for Advanced Biomedical Research, Oregon Health Sciences University, Portland, OR 97201.

A variety of neurotransmitter receptors have been shown to exist in the hybrid cell line NG108, including opioid, adrenergic, serotonergic, kinin and prostaglandin receptors. Receptors coupled to the G-protein transduction apparatus display sequence similarity within their predicted membrane topology. This observation has led to a strategy for isolating new receptor cDNA clones. Based on best conserved regions of primary structure, nucleic acid probes can be selected and used to screen for other members of the G-protein receptor family.

Using a hamster β-adrenergic receptor probe we have isolated several clones from an NG108 cDNA library. One of these clones codes for a protein which shares a significant degree of sequence similarity with other G-protein coupled receptors but is sufficiently different to suggest that it is an entirely new receptor. We shall discuss the predicted structure, tissue distribution and ligand specificities of this new receptor.

96.18

REGIONAL DISTRIBUTION OF INSULIN-LIKE GROWTH FACTOR-2 (IGF-2) IN RAT BRAIN.

W. L. Russell*, J. M. Apathy*, R. R. Bowsher* and D. P. Henry*. (SPON: L. Lemberger). Lilly Lab.for Clin.Res., Eli Lilly & Co.,Indianapolis, IN 46202.

The measurement of IGF-2 in brain tissue has been problematic because of its low levels and the presence of binding proteins. We have developed a method for the extraction and quantification of IGF-2 in rat brain. Brains from 6 week old rats were dissected at 4°C and homogenized with 4 vol. of 3.3 M HCOOH/5% Tween-20. After centrifugation, the supernates were treated with acetone (70% final), vortexed and centrifuged. The extracts were diluted and analyzed by a nonequilibrium RIA at 4°C using rat IGF-2 as standard. Separation of bound and free IGF-2 was achieved by precipitation using 6.6% PEG/second Ab. Assay sensitivity was 1 pg/tube with an ED50 of 30 pg/tube.

Rat [IGF-2] (ng/g tissue; mean ± SEM; n=6)

Olfactory Bulb	25.9 ± 2.0	Striatum	13.7 ± 0.8
Pituitary	354.7 ± 29.3	Thalamus	19.6 ± 1.5
Brain Stem	17.5 ± 1.4	Hippocampus	26.5 ± 0.9
Cerebellum	21.8 ± 2.3	Cortex	24.4 ± 1.2
Hypothalamus	21.9 ± 1.5	Serum	13.6 ± 0.6

IGF-2 is heterogeneously distributed in rat brain with the highest concentration in the pituitary. The concentrations of IGF-2 are higher in brain than in the serum, suggesting that it is synthesized there. In summary, we have developed a new method for extracting and quantifying IGF-2 in rat brain tissue, which should facilitate further investigation of its functional role in the CNS.

96.19

IMMUNOHISTOCHEMICAL IDENTIFICATION OF A NOVEL CORTICAL CELL POPULATION. M.N. Gordon, S. Scully*, W.A. Schreier*, S. Kumar*, A. Espinosa de los Monteros* and J. de Vellis. Dept. of Anatomy and MRRC, UCLA Medical School, Los Angeles, CA 90024-1759.

The cytoplasmic enzyme glycerol phosphate dehydrogenase (GPDH) is believed to represent a specific oligodendrocyte marker. During experiments to examine the postnatal appearance of GPDH-like immunoreactivity relative to other specific markers in oligodendrocytes, a novel population of cells was identified in the rat cerebral cortex. Coronal vibratome sections of paraformaldehyde perfused rat brain (aged 1 d to 17 mo) were stained using a rabbit polyclonal antiserum against GPDH and appropriate fluorescent or peroxidase-conjugated secondary antibodies. A population of large cells was observed in the cerebral cortex, with morphology and time course of appearance during ontogeny which was strikingly different from that observed for perineuronal oligodendrocytes. These large cells were bipolar, with a major axis of 15-20 um, and were oriented perpendicular to the pial surface. Long, immunoreactive processes extended across several cortical laminae, and appeared beaded. Bipolar cell soma area was twice that of perineuronal oligodendrocytes. Bipolar cells were present in small numbers on the day of birth (P1), then increased in density to peak at P11-15, before decreasing to adult cell density. Bipolar cells are not astrocytes, radial glia or myelinating oligodendrocytes; sequential immunohistochemistry and in situ hybridization for combinations of cell-type specific markers revealed that GPDH+ cells do not contain protein or RNA encoding glial fibrillary acidic protein, vimentin or myelin basic protein. In addition, the myelin deficient mutant rat brain displayed a 50% reduction in the number of GPDH+ perineuronal oligodendrocytes, but no reduction in bipolar cell density. The morphology, cortical localization and ontogenic appearance of these bipolar cells most resembles that of peptidergic interneurons. Supported by HD06576.

AROMATASE NEURONS IN THE MONKEY FOREBRAIN DEMONSTRATED BY ANTIBODY AGAINST HUMAN PLACENTAL ANTIGEN X-P_2(hPAX-P_2). K.Shinoda[1], N.Sakamoto*[2], Y.Osawa*[3], J.Pearson[2]. [1]Dpt. Neuroanat. Osaka Univ, Japan; [2]Dpt. Path. NYUMC NY; [3]Dpt. Endo. Biochem., Med. Fdn., Buffalo, NY

Aromatase, which converts androgen into estrogen, appears to be involved in brain sexual differentiion, control of gonadotropin secretion and triggering of puberty. Immunohistochemical study was made of Japanese monkeys with hPAX-P_2 antibody to an antigen associated with aromatase activity. Most hPAX-P_2 immunoreactive cells are in the ventral pallidum extending from the area surrounding the islands of Calleja to the sublenticular substantia innominata (not in the preoptic area as previously reported). Others are in the second layer of the cerebral cortex, in a cluster in the mediocortical zone of the amygdala anteriorally, and in the nucleus of the diagonal band. Structures resembling axons are seen in the medial preoptic area, the hypothalamic periventricular zone, the supraoptic nucleus, the hypothalamic paraventricular nucleus and the median eminence including the arcuate nucleus. These may represent ventral pallidal projections to preoptico-hypothalamic regions involved in sexual differentiation or in the neuroendocrinergic system including the hypothalamo-hypophyseal tract.

96.21

ADENOSINE A_1 RECEPTORS ARE LOCATED ON THE INTRINSIC NEURONS OF THE VENTROBASAL COMPLEX OF THE THALAMUS. J. I. CHOCA, R. D. GREEN*, AND H.K. PROUDFIT. DEPARTMENT OF PHARMACOLOGY, UNIVERSITY OF ILLINOIS AT CHICAGO COLLEGE OF MEDICINE, CHICAGO, IL 60612.

Adenosine agonists modulate nociception when administered intrathecally or centrally. We have previously shown that some spinal cord adenosine A_1 receptors are located on the cell bodies or dendritic branches of the spinothalamic tract (STT) neurons. The following studies were performed to determine if adenosine A_1 receptors of the ventrobasal complex (VBC) of the thalamus are located on the terminals of the STT neurons. In autoradiography studies, unilateral microinjections of kainic acid into the dorsal horn or hemitransections of the thoracic spinal cord failed to alter the A_1 receptor density in the VBC of the thalamus. In contrast, the microinjection of kainic acid into the VBC eliminated greater than 90% of these binding sites. In conclusion, the STT neurons express adenosine A_1 receptors on their cell bodies or dendritic branches in the spinal cord, but not on their terminals in the thalamus. Rather these thalamic adenosine receptors are located on intrinsic neurons. Whether these receptors mediate part of the central antinociceptive action of adenosine analogs remains to be explored. (Supported by PHS Grant 03980).

96.22

IDENTIFICATION OF A SPECIFIC, HIGH AFFINITY PGE BINDING SITE IN GUINEA PIG CEREBELLUM. M. Savage* and M. Reichman* (SPON: D.L. Hammond) CNS Diseases Research, G.D. Searle & Co., Skokie, IL 60077

Prostaglandin E_2 has numerous central effects; however, its exact role in neural communication remains unclear. Progress in this area is hindered in part by the lack of information regarding PGE_2 receptors in the CNS. We report here the identification and characterization of a specific, high affinity, saturable binding site for [^{3}H]PGE_2 in neural membrane suspensions prepared from guinea pig cerebellum. The K_d of the site is 1.28 ± 0.08 nM with a B_{max} of 29.4 ± 0.4 fmole/mg protein. Specific binding represents up to 90% of total binding, exhibits a distinct regional distribution, and is sensitive to heat denaturation at 50°C and to trypsin exposure, as well as to the composition and pH of the incubation buffer. Eicosanoids at low nM concentrations compete effectively with [^{3}H]PGE_2 with differing relative potencies whereas numerous non-eicosanoids are ineffective at concentrations as high as 10 μM. Taken together, the results indicate that the specific binding site has many of the features expected of a pharmacological receptor for PGE in the CNS.

OTHER BIOGENIC AMINES AND PURINES: ADENOSINE AND HISTAMINE

97.1

MECHANISMS UNDERLYING SYNAPTIC MODULATION BY ADENOSINE IN RAT HIPPOCAMPUS: EFFECTS OF K^+ CHANNEL BLOCKERS AND THE ROLE OF ARACHIDONIC ACID METABOLITES. T. V. Dunwiddie, T. S. Worth, C. Lupica and M. Taylor. Dept. of Pharmacology, Univ. of Colo. Health Sciences Center and Veterans Administration Medical Center, Denver, CO 80262

Adenosine modulates the efficacy of synaptic transmission in the CA1 subregion of the hippocampal formation via a presynaptic A1 receptor. This response is elicited by selective A1 receptor agonists such as cyclohexyladenosine, is potently antagonized by A1 antagonists, and the selective A2 receptor agonist CGS 21680 is only weakly active. Arachidonic acid metabolites formed by a lipoxygenase pathway have been proposed as mediators of similar modulatory effects in other systems. To determine whether adenosine acts via this mechanism, we characterized the actions of cyclooxygenase and lipoxygenase inhibitors, and inhibitors of phospholipase A_2; none of these agents had significant effects upon responses to adenosine at appropriate concentrations. A potassium channel blocker (4-aminopyridine; 4AP) also had no significant effect on adenosine responses. We conclude that unlike the adenosine A1 inhibition of DA release in striatum (W.A. Cass et al, this meeting), modulation of hippocampal neurotransmission by adenosine is unlikely to be mediated by arachidonic acid metabolites. Unlike adenosine modulation of excitatory transmission in the olfactory cortex, hippocampal responses to adenosine are not blocked by 4AP. These data suggest that adenosine may act through similar receptors but with a variety of mechanisms in different brain regions to inhibit neurotransmission.
Supported by the Veterans Administration and DA02702.

LOCAL CEREBRAL BLOOD FLOW RESPONSES TO 2-CHLOROADENOSINE AND CO_2 IN THE PIGLET.
T. S. Park and J.M. Gidday. Dept. of Neurosurgery Univ. of Virginia, Charlottesville, VA 22908.

2-chloroadenosine (2CADO) is a nonmetabolizable adenosine analogue. Topical application of 2CADO was shown to dilate pial arterioles and increase cerebral blood flow (CBF) in adults. This study examined the effect of 2CADO on resting CBF and CO_2 reactivity of CBF in neonatal piglets. Isoflurane-anesthetized piglets (<5 d, n=7) had brain dialysis probes placed in the bilateral frontal cortex. The probe contained a platinum wire for measurement of local CBF by H_2 clearance. One probe was infused with artificial CSF, while the contralateral probe was infused with 10^{-5} M 2CADO in CSF to deliver the substance to tissue. Local CBF was measured under conditions of varied $PaCO_2$.

Results:

MABP (mmHg)	$PaCO_2$ (Torr)	CBF (ml/100 gm/min) control	CBF (ml/100 gm/min) 2CADO
64±4	37±1	28±4	72±10^
63±3	77±4	55±10*	99±13^
62±4	110±5	72±11**	122±16**^
42±2	23±2	20±3*	43± 4*^

*=<0.05,**=<0.01; vs normocapnia in the same group ^=<0.01;control vs 2CADO

This study of neontal piglets indicates that 2CADO is a potent cerebral vasodilator but has little effect on CO_2 reactivity of CBF. Supported by NS00924 & 21045; American Heart Association (Virginia Affiliate).

97.3

BINDING OF BIS(N^6-ADENOSYL)ALKANES TO THE ADENOSINE A_2 RECEPTOR DEPENDS ON THE LENGTH OF THE ALKANE SPACER.
J. B. Wollack. Dept. of Neurology, Div. of Pediatric Neurology, Columbia University, New York, NY 10032.

Bivalent analogs of adenosine (Ado) represent a novel class of ligands for the adenosine receptor which may be useful in elucidating inter-receptor spacing. A series of bis(N^6-adenosyl)alkanes (Ado-$(CH_2)_n$-Ado) was synthesized by reaction of the appropriate alkane diamines with 6 chloropurine riboside. Compounds were thus obtained with spacing groups of 2 to 10 carbons between the adenosyl groups. Binding to A_2 receptors was investigated in rat striatal tissue using ^{3}H-NECA (N-ethyl-carboxamidoadenosine) as a radioligand and 50nM cyclopentyl-adenosine to block the A_1 component of binding. The order of binding affinities was found to be NECA>Ado-$(CH_2)_{10}$-Ado≈ Ado-$(CH_2)_8$-Ado>Ado-$(CH_2)_6$-Ado>Ado-$(CH_2)_2$-Ado. Full evaluation of Ado-$(CH_2)_3$-Ado, was limited by its low solubility, however, it appeared to bind less well than Ado-$(CH_2)_2$-Ado.

Ado-$(CH_2)_2$-Ado and Ado-$(CH_2)_6$-Ado, the compounds with the highest solubilities, were also tested for their ability to inhibit platelet aggregation, a physiologic effect which may depend on the A_2 receptor. At a concentration of 100uM, Ado-$(CH_2)_6$-Ado significantly inhibited platelet aggregation, whereas Ado-$(CH_2)_2$-Ado had only minimal effects. These results suggest that separation of adenosyl moieties by a six or more carbon distance appears to be optimal for A_2 receptor activation.

SPECIFIC AUTORADIOGRAPHIC LOCALIZATION OF ADENOSINE A_2 RECEPTORS IN RAT BRAIN USING THE A_2-SELECTIVE AGONIST, [^{3}H]CGS 21680.
M.F. Jarvis and M. Williams, Research Depart. CIBA-GEIGY Corp. Summit, NJ 07901

A specific neuromodulatory role for adenosine is supported by the identification of discrete distributions of adenosine A_1 and A_2 receptor subtypes in the mammalian brain. Characterization of of the biochemical and functional properties of the A_2 receptor has been limited due to the lack of available ligands which have high affinity and selectivity for this receptor subtype. Recently, a highly selective A_2 agonist radioligand, [^{3}H](2-[p-(2-carboxyethyl)phenethylamino)-5'-N-carboxamidoadenosine ([^{3}H]CGS 21680) has been shown to directly label the A_2 receptor (Kd = 16 nM) without the need to block binding to the A_1 receptor (Williams et al., 1989, FASEB J 3: A1047). In the present study, 5 nM [^{3}H]CGS 21680 was used to localize A_2 receptors in the rat brain. Specific [^{3}H]CGS 21680 binding to 20 μm thick sagittal rat brain sections represented approximately 95% of total binding and was highly localized in the striatal region. The highest density of binding was found in the caudate nucleus (80 ± 4 fmol/mg tissue). Specific [^{3}H]CGS 21680 binding was also observed in the nucleus accumbens and olfactory tubercle and represented approximately 80% of the binding found in the caudate nucleus. No significant amounts of specific [^{3}H]CGS 21680 binding were observed in any other brain region. These results are consistent with and extend the localization of brain high affinity A_2 receptors (A_{2a}) obtained with the nonselective agonist, [^{3}H]NECA, in the presence of 50 nM CPA to block binding to the A_1 receptor. The highly selective localization of A_2 receptors in the striatal region provides further support for a specific neuromodulatory role of adenosine in basal ganglia function.

PURIFICATION OF ADENOSINE A_1 RECEPTOR OF RAT BRAIN MEMBRANES.
H. Nakata. Lab. of Clinical Science, NIMH, Bethesda, MD 20892.

Adenosine receptors have been classified into two subtypes, A_1 and A_2. The A_1 receptor (A_1R) is linked to inhibition and the A_2 receptor is linked to activation of adenylate cyclase. In order to obtain more knowledge of the molecular properties of these receptors, purification of the A_1R has been performed using a newly developed affinity chromatography system (Nakata, H. Mol. Pharmacol. in press). The A_1R was solubilized with digitonin/cholate from rat brain membranes and then purified by sequential use of affinity chromatography on XAC immobilized-agarose, hydroxylapatite chromatography and re-affinity chromatography on XAC-agarose. SDS-PAGE of the final preparation showed a single broad band with silver stain, migrating with a M_r about 34,000. This M_r 34,000 peptide was covalently labeled by affinity labeling reagent, [^{3}H]p-DITC-XAC (Stiles, G. et al., Mol. Pharmacol. 34:724,1988). The A_1R preparation gave a specific binding activity of about 30 nmol[^{3}H]DPCPX/mg of protein (60,000-fold purification) and a K_d of 1.4 nM which is similar to that found for the receptor in crude membrane preparations. The purified receptor also showed essentially the same specificity for adenosine agonists and antagonists as unpurified receptors. The ability to purify the A_1R should facilitate the molecular characterization of this receptor and the production of specific antibodies.

HETEROGENEITY OF ADENOSINE A_1 RECEPTOR SYSTEMS BUT NOT 5-HT_{1A} RECEPTOR SYSTEMS IN HIPPOCAMPUS ACROSS MAMMALIAN SPECIES,
J. Zgombick, C.D. Mahle, and S. Maayani, Depts. of Pharmacology and Anesthesiology, Mt. Sinai Sch. Med., CUNY, N.Y., N.Y., 10029

Functional and binding assays were conducted in hippocampal membranes of 3 species using the selective adenosine (AD) A_1 agonist, R-phenylisopropyladenosine (R-PIA). R-PIA inhibited forskolin-stimulated adenylyl cyclase (FSAC) activity in these preparations. Cyclopentyltheophylline (CPT) was a potent, competitive antagonist of R-PIA-mediated responses. [^{3}H]-R-PIA labeled an apparent homogeneous population of CPT-sensitive AD A_1 binding sites which were sensitive to 5'-guanylylimidodiphosphate (Gpp(NH)p) and NaCl. In contrast, no species differences were observed in 5-HT_{1A} receptors and related binding sites in mammalian hippocampal membranes. The ensemble of data indicate heterogeneity across species of AD A_1 receptor systems in mammalian hippocampus. [Supported by USPH GM34852 and DA07135]

A_1 ADENOSINE RECEPTOR REGULATION OF ADENYLYL CYCLASE ACTIVITY IN BRAIN MEMBRANES OF A DEEP-LIVING TELEOST FISH.
M. Leid[1], T.F. Murray[1], P.H. Franklin[1] and J.F. Siebenaller[2]. Oregon State Univ., College of Pharmacy[1], Corvallis, OR, and Louisiana State Univ. Dept. of Zoology and Physiol.[2], Baton Rouge, LA. 70803.

A_1 adenosine receptors in central nervous tissue have a wide phylogenetic distribution among vertebrates (Siebenaller and Murray, *Biochem. Biophys. Res. Commun.* **137**: 182, 1986). We have undertaken a characterization of the A_1 adenosine receptor, G_i protein, adenylyl cyclase system in a deep-living, cold-adapted teleost fish, Antimora rostrata, to determine whether the A_1 receptor of this species is functionally coupled to adenylyl cyclase under the deep-sea conditions of low temperature (0-6°) and high hydrostatic pressures (85-250 atm.) which this species experiences. Adenylyl cyclase activity was assayed using [α-^{32}P]ATP as a substrate. At an incubation temperature of 5°C both the basal and forskolin-stimulated rates of adenylyl cyclase activity were linear for at least 120 min. Cyclopentyladenosine (CPA) had no effect on adenylyl cyclase in the absence of GTP; however, at GTP concentrations of 1-100 μM, the A_1 selective agonist inhibited activity. The maximal percentage of inhibition of basal activity by CPA ranged from 7 to 17%. The basal adenylyl cyclase activity of A. Rostrata brain membranes was unaffected by 272 atm. of pressure which is comparable to the pressures experienced by this species at the lower end of its depth range. The efficacy of CPA as an inhibitor of adenylyl cyclase was not affected by this increased pressure. In contrast, investigation of CPA inhibition of adenylyl cyclase activity in brain membranes of shallow-living marine teleosts has shown that elevated pressure reverses CPA-induced inhibition. (Supported by ONR Contracts N00014-88-K-0426 and N00014-88-K-0432).

ROLE OF CYCLIC AMP IN RELEASE OF ADENOSINE BY MORPHINE FROM THE SPINAL CORD.
D. Nicholson*, T.D. White, and J. Sawynok (SPON: J. Rutherford).Dept. Pharmacology, Dalhousie University, Halifax, Canada.

Spinal antinociception produced by morphine may involve release of adenosine (JPET 243:657,1987). Recent studies suggest that spinal opioid effects are mediated via inhibition of adenyl cyclase (Brain Res. 370:61, 1986). Pertussis toxin reduces spinal antinociception produced by morphine (EJP 146:65,1988) and morphine-evoked release of adenosine (submitted). This study examined the role of cyclic AMP in release of adenosine induced by morphine. The phosphodiesterase inhibitors, Ro 20-1724 1-100μM and Rolipram 1-100μM, and Forskolin 10uM, a direct activator of adenylate cyclase, increased basal release of adenosine from whole spinal cord synaptosomes by 15-40 pmoles/mg protein/15 min as detected by HPLC. This adenosine may originate from released nucleotide, as it is reduced 40-77% by 5'-nucleotidase inhibitors. Forskolin 10μM and Ro 20-1724 10μM inhibited adenosine release induced by 50μM morphine (30 pmoles/mg protein/15 min) by >90%. Rolipram 1μM and Ro 20 1724 1μM reduced evoked-release from dorsal spinal cord synaptosomes by >90%. Subsequently, isobutylmethylxanthine 500μM was shown to increase basal adenosine release by 50 pmoles/mg protein/15 min and inhibit morphine-induced release by 68%. These data support the involvement of cyclic AMP in spinal actions of morphine. (Supported by MRC).

2'-DEOXYCOFORMYCIN INHIBITION OF ADENOSINE DEAMINASE IN RAT BRAIN: SPECIFICITY, DOSE DEPENDENCY AND ENZYME RECOVERY. R. Padua*, J.D. Geiger, S. Dambock* and J.I. Nagy. Depts. of Pharmacol. and Physiol., Univ. of Manitoba, Winnipeg, MB., R3E 0W3, CANADA.

2'-Deoxycoformycin (DCF) is a potent inhibitor of adenosine deaminase (ADA) and a clinically effective drug. DCF may prove useful for investigations of adenosine neuromodulation. We determined its inhibitory potency against ADA and adenylate deaminase (AMPDA), the rate of ADA recovery in 10 brain regions after single and double i.p. injections, and the effects of DCF on several neurotransmitter synthetic enzymes. Ki values for inhibition of ADA and AMPDA were 23 pM and 233 μM, respectively. In Vivo, DCF inhibited ADA with ED_{50} values of 155 to 280 μg/kg. AMPDA was not inhibited by doses up to 5 mg/kg. A second dose of DCF was not as effective as a single dose at inhibiting ADA. 40 days after a single dose of 5 mg/kg, ADA activity (% of control) recovered by 68 to 78 in regions with normally high levels of activity and from 44 to 59 in other regions. The activities of CAT, GAD and HDC-an enzyme colocalized with ADA in hypothalamic neurons- were unaffected by DCF treatment. The low doses of DCF required for ADA inhibition in vivo is consistent with its high potency against ADA in vitro and any physiological effects observed at low doses might therefore be ascribed to inhibition of ADA.

97.10

ADENOSINE DEAMINASE FACILITATES GLUTAMATERGIC TRANSMISSION IN CULTURED CEREBELLAR NEURONS. P.L. Canonico, M.V. Catania*, M.A. Sortino and F. Nicoletti*. Department of Pharmacology, University of Catania, Italy.

Addition of adenosine deaminase (ADA, 0.05-2 U/ml) to cultured cerebellar neurons induces large increases in $^{45}Ca^{2+}$ influx and [^{3}H]inositol-monophosphate formation. Both effects appear to be secondary to an enhanced release of endogenous glutamate acting at specific receptors coupled to either ion channels or inositol phospholipid hydrolysis. Stimulation of excitatory amino acid release by ADA requires the presence of extracellular Na^+ and is still present after 7 hours of dialysis to remove any possible ionic contaminant of the enzyme preparation. The effects of ADA are not reversed by a number of adenosine receptor agonists (L-PIA, NECA or 2-CADO) and are not mimicked by isobutylmethylxanthine or theophylline. In addition, the action of ADA is enhanced by exogenously applied adenosine, although the products of adenosine deamination (inosine and ammonia) are inactive. We suggest that, besides removing a tonic inhibition by the endogenous adenosine, ADA interacts with the plasma membrane stimulating excitatory amino acid release from cultured cerebellar neurons.

97.11

PROCONVULSANT ACTIONS OF BOTH CENTRALLY AND PERIPHERALLY ADMINISTERED ADENOSINE AGONISTS ON CAFFEINE-INDUCED SEIZURES. P.F. Morgan and M.J. Durcan. Laboratory of Clinical Studies, Bldg10 3C218, NIAAA, Bethesda, MD20892.

The effect of the adenosine agonists N-ethyl carboxamido-adenosine (NECA), cyclohexyladenosine (CHA) or 2-chloroadenosine (2-CL-ADO) on the seizure activity of the adenosine antagonist caffeine was investigated in NIH Swiss mice. Pretreatment with adenosine agonists (1 mg/kg, i.p., 20 min prior to caffeine infusion into a lateral tail vein) significantly ($p's < 0.05$) decreased the seizure threshold to caffeine whereas a similar pretreatment with the nucleoside transport inhibitors dipyridamole or nitrobenzyladenosine (both 0.25 mg/kg) were without effect. Intracerebroventricular administration, through an indwelling cannula, of 2.5 ug of adenosine agonists in 5ul artificial CSF, 20 min prior to i.p. administration of caffeine, significantly lowered the seizure ED_{50} of caffeine, whereas the same volume of artificial CSF alone was without effect. These results suggest that effects of adenosine agonists and antagonists on seizure activity may not be explained entirely by competitive interactions at adenosine receptors.

97.12

CENTRALLY MEDIATED ANTICONVULSIVE ACTIVITY OF ADENOSINE AGONISTS. J.B. Wiesner, R.M Krieger*, E.P. Rossi*. Gensia Pharmaceuticals, Inc., San Diego, CA 92121

Adenosine agonists have been shown to inhibit pentylenetetrazol (PTZ) induced seizures after systemic injection. In light of a recent suggestion (Brodie et al., 1987) that the behavioral effects of systemically administered agonists may be mediated by a non-CNS action, we wished to determine (1) whether the agonists exert their anticonvulsant activity within the CNS, and (2) whether intraventricularly (ICV)-injected agonists can reach the central site(s) of action required to inhibit convulsions induced by a systemically-administered convulsant.

Male CFW mice were administered either CHA (A_1 agonist) or NECA (mixed A_1/A_2 agonist) via either intraperitoneal (IP) or ICV route of administration at 20 (ICV) to 30 (IP) minutes prior to s.c. injection of PTZ (75 mg/kg). Both CHA and NECA exerted potent anticonvulsive activity following ICV administration. CHA exerted this activity with an approximate ED_{50} of 40 μg (2 mg/kg) for IP administration and 0.07 μg for ICV administration. NECA exerted anticonvulsive activity with an approximate ED_{50} of 2 μg (0.1 mg/kg) for IP administration and 0.04 μg for ICV administration. For both agonists, ICV administration achieved 100% protection at doses which were below threshold for protection with IP administration, indicating that leakage into the periphery cannot account for the efficacy of ICV administered agonists.

Central injections of adenosine agonists have been shown to mitigate seizures induced from localized foci of the rat limbic system that have been kindled (Barraco et al., 1984; Rosen & Burman, 1987) or locally injected with bicuculline (Franklin et al., 1988). The present results demonstrate that adenosine agonists exert anticonvulsant activity in mice, as in rats, via central mechanisms. Furthermore, these results also show that ICV administration of adenosine agonists provides access to all sites necessary to reverse the global, perhaps diffusely triggered seizures induced by systemic PTZ.

EXTRACELLULAR ATP INDUCES A RISE OF CYTOSOLIC CALCIUM ION IN PHEOCHROMOCYTOMA PC12h CELLS. N.Nakanishi, K.Akoba-Aono*¶, H.Suzuki*¶, and S.Yamada*. Depts of Biochemistry and Pedodontics, Meikai Univ. Sch. Dentistry, Sakado, Saitama 350-02, Japan.

Extracellular ATP has been reported to induce fluxes of ions such as Ca^{2+}, K^+ and Na^+, and to stimulate inositol phospholipid metabolism. This suggests the possibility that some actions of growth factors such as NGF can be affected by extracellular ATP, since the changes in cytosolic Ca^{2+} and the phospholipid metabolism are thought to play an important role in signal transduction system. We have examined by using fluorescent Ca^{2+} indicator, Indo-1, the effect of ATP on the cytosolic Ca^{2+} level of PC12h cells, a subclone of PC12. ATP induced a rise of the cytosolic Ca^{2+} (EC_{50}=1 uM). This rise was predominantly due to an increased influx rather than to intracellular mobilization of the ion, because EGTA inhibited this Ca^{2+} rise by more than 90%. ADP also induced the Ca^{2+} rise but to a lesser extent than ATP, whereas neither AMP nor adenosine showed such effect. Quinidine inhibited the ATP-induced rise of cytosolic Ca^{2+}. These results indicate the presence of P_2-type purinergic receptors whereby ATP could influence the physiology of the cells. In fact, NGF-induced neurite outgrowth from the cells was stimulated by the addition of ATP into the culture medium. Supported by a Grant from the Ministry of Education, Science and Culture of Japan (No.62570841).

[^{3}H](R)α-METHYLHISTAMINE BINDING TO RAT BRAIN MEMBRANES. R.E. West, Jr.*, A. Zweig*, C. Magatti*, M.I. Siegel*, R.W. Egan* (SPON: D.C. Bolser) Depts. of Allergy and Chemical Research, Schering-Plough Research, 60 Orange St., Bloomfield, NJ 07003.

A novel, high-affinity, histamine receptor, designated H_3, has been described recently as inhibiting depolarization-induced, rat brain histamine synthesis and release. To characterize the receptor we have synthesized the specific agonist [^{3}H](R)α-methylhistamine ([^{3}H]RAMHA). Saturation binding to rat brain membranes was characteristic of a single [^{3}H]RAMHA binding site with K_D=2.0 nM and B_{max} = 186 fmol/mg protein. Kinetic studies yielded k_1 = 0.025 $nM^{-1} \cdot min^{-1}$ and k_{-1}=0.057 min^{-1} for a K_D = 2.3 nM. The rank order of potency among a number of compounds tested in competition binding assays was N^{α}-methylhistamine, RAMHA > histamine, thioperamide > impromidine > burimamide > dimaprit. The k_i value of other H_1 and H_2 compounds was greater than 1 μM. [^{3}H]RAMHA binding was greatest in caudate, midbrain (thalamus and hippocampus), cortex and hypothalamus, less in brainstem, and least in cerebellum. While these data are generally consistent with the current understanding of the histamine H_3 receptor, they differ in that the site density is six times what has been reported and the affinity of the specific antagonist, thioperamide, is ten-fold lower than reported.

IN VIVO AND IN VITRO RELEASE OF ENDOGENOUS HISTAMINE FROM RAT HYPOTHALAMUS. A.Yamatodani*, T.Mochizuki*, J.Kishino*, J.Ono*#, M.Takemura*, N.Inagaki*, and H.Wada.* (Spon: Y.Fukuda) Dept. Pharmacology & #Dept. Pediatrics, Faculty of Med., Osaka Univ., Osaka 530, Japan.

In rats, histaminergic neurons are confined to the tuberomammillary nucleus, and the highest concentration of the fibers is found in the hypothalamic nuclei (J.Comp.Neurol., 273: 283, 1988). In this study, the effects of various neuroactive substances on the basal release and high K^+-evoked or electrically stimulated release of endogenous histamine from rat hypothalamus were examined using a brain microdialysis method in vivo and a continuous superfusion method in vitro. Released histamine was determined by a highly sensitive HPLC-fluorometric method (J.Chromatogr., 344: 115, 1985). In the in vivo experiments, the basal release of histamine from the anterior hypothalamic area was 80-100 fmol/20min, and about 1.5- to 2-fold increase in release was observed by dialyzing with high K^+ solution or on electric stimulation of the tuberomammillary nucleus. These evoked releases were Ca^{2+}-dependent. In in vitro superfusion experiments, high K^+-evoked release of endogenous histamine from hypothalamic slices was significantly enhanced by superfusion with glutamate, aspartate, Met-enkephalin, acetylcholine and neuropeptide Y, and suppressed by superfusion with substance P, GABA and adenosine. With these methods, it is possible to investigate the dynamics of histaminergic neurocircuits.

97.17

CHARACTERIZATION OF HISTAMINE H_1-RECEPTORS IN PRIMARY CULTURES OF RAT ASTROCYTES. N.Inagaki*, H.Fukui*, Y.Taguchi*, S.Ito*#, R.Yoshida*#, A.Yamatodani* and H.Wada* (Spon: S.Inagaki) Dept. Pharmacology II, Faculty of Medicine, Osaka University, Osaka 530, and #Osaka Bioscience Institute, Suita 565, Japan.

The characteristics of histamine H_1-receptors in primary cultures of astrocytes were analyzed by [^{3}H]mepyramine binding assay, and compared with those in brain tissue. Astrocytes were prepared from the cerebral cortex of newborn rats and maintained for three weeks in culture. Similar values for the dissociation constant (Kd value) of [^{3}H]mepyramine binding and the inhibition constants (Ki values) of mepyramine, triprolidine, d-chlorpheniramine, diphenhydramine and histamine for [^{3}H]mepyramine binding were obtained from the receptors in cultured astrocytes ($Kd=10.4\times10^{-9}M$) and in brain tissue ($Kd=9.4\times10^{-9}M$). The density of H_1-receptors in cultured astrocytes increased during culture for three weeks and reached a plateau. The pattern of increase in receptor density resembled that in the brain during postnatal development, and the Bmax value (262±60 fmol/mg protein) was comparable to that of 3-week-old rat brain tissue (194±24 fmol/mg protein). Furthermore, histamine elevated the intracellular Ca^{2+} concentration of the cultured astrocytes. These results suggest that the receptors in cultured astrocytes and in brain tissue are identical and that astrocytes are a major target of the central histaminergic system.

97.18

CHANGES IN OCULAR HISTAMINE IN RATS WITH EAU C. H. Lee[1]*, M. Kunkle[2]*, L. A. Smith[2]*, K. R. Aoki[2]*, and E. L. Orr[1], [1]Dept. of Anatomy, Texas College of Osteopathic Medicine and [2]Alcon Laboratories, Inc., Ft. Worth, TX 76107.

Degranulation of choroidal mast cells (MC) is an early event in experimental autoimmune uveoretinitis (EAU), suggesting that MC may participate in this disease. Since histamine (HA) is released from degranulating MC, we monitored the temporal changes of HA levels in various regions of the eye as a measure of MC activation in EAU. Lewis rats were immunized with purified S-antigen emulsified in complete Freund's adjuvant (CFA) or with CFA alone (control). Clinical signs of EAU were detected by direct ophthalmoscopic examination. Rats were killed on days 5, 7, 9, 11, and 13 postinjection (pi), and the retina, choroid, sclera and "rest" of each eye was dissected, weighed, and later assayed for HA. Clinical disease was present from day 10-13 pi. Retinal edema (i.e., increased wet weights) was present on days 9, 11 and 13 pi. Histologically, eyes taken on days 11 and 13 pi exhibited edema in both the outer nuclear layer and at the neural retina-choroid junction. Compared to control rats, EAU rats showed higher choroidal HA on days 9 (27%), 11 (79%) and 13 (84%) pi and higher retinal HA on day 11 (150%) pi; scleral HA was unaltered, but HA was decreased by as much as 57% (on day 13 pi) in the rest of the eye. The timing of these regionally-specific changes in ocular HA are consistent with a role for ocular MC in EAU.

97.19

HISTAMINE-STIMULATED LOW-K_M GTPASE ACTIVITY IN THE RAT BRAIN. S. Ghodsi-Hovsepian, G.J. Durant* and W. Hoss Department of Medicinal and Biological Chemistry, College of Pharmacy, University of Toledo, Toledo OH 43606.

Histamine H_2 receptors stimulate the activity of adenylate cyclase in the brain. This effect is amplified in the presence of H_1 receptor agonists, which stimulate phosphoinositide turnover in the brain. On the other hand, histamine H_3 receptors regulate the release of histamine presynaptically. In order to assess the role of G-proteins in the coupling of histamine receptors to their effectors, the ability of histamine agonists and antagonists to stimulate or inhibit low-K_m GTPase was measured in the rat brain membranes. Histamine produced a dose-dependent stimulation of low-K_m GTPase in rat cortical membranes, reaching a value of 40 percent above control, with an EC_{50} value of 1.5 mM. Cimetidine and diphenylhydramine inhibited histamine-stimulated low-K_m GTPase with IC_{50} values of approximately 1 μM with 1 mM histamine. The muscarinic antagonist atropine was ineffective as an inhibitor of histamine-stimulated low-K_m GTPase. Comparing different regions of the brain, the maximum value of histamine-stimulated GTPase activity displayed the following rank order: cortex > striatum > hippocampus > midbrain. Neither cerebellum nor pons-medulla displayed histamine-stimulated low-K_m GTPase. The distribution of histamine-stimulated low-K_m GTPase is correlated with the distribution of histamine receptors in the brain. The data suggest that at least some histamine receptors are coupled to their effectors through G-proteins in the brain.

97.20

IMMUNOHISTOCHEMICAL AND BEHAVIORAL EVIDENCE FOR SENSORY FUNCTION OF HISTAMINE IN MOLLUSCAN NERVOUS SYSTEM. S. Soinila, G. J. Mpitsos and P. Panula. Hatfield Marine Science Center, Oregon State Univ. Newport, OR 97365, and Deptment of Anatomy, University of Helsinki, Finland.

We conducted correlated immunohistochemical and behavioral studies to make a comparative analysis of histaminergic nervous systems in *Pleurobranchaea californica* and *Aplysia californica*. The distribution of histamine was obtained using an antiserum to histamine-protein conjugate. Histamine-immunoreactive neurons and nerve fibers were present in all major ganglia. Histamine fibers were also found in nerve roots innervating the tentacles, the major chemosensory organs, as well as in the neuropil of the peripheral tentacular ganglion, and in the tentacular subepithelial connective tissue. A behavioral measure of histaminergic function was obtained by injecting into the animals seawater (control), pyrilamine (H_1-receptor blocker) or cimetidine (H_2-receptor blocker) and determining threshold values for L-glutamate or beer solutions that provoke orientation and biting responses. Each blocker produced characteristic postural changes. In both species, pyrilamine increased the threshold values. In *Pleurobranchaea*, cimetidine had no effect on the thresholds, while in *Aplysia* it increased thresholds. These results suggest that histaminergic neurons modulate chemosensory input and that two different histamine receptor sites are involved in this function. The statocyst, the organ of spatial orientation, contained large ciliated histamine-immunoreactive neurons which projected into the statocyst nerve. Pyrilamine, but not cimetidine, inhibited the animals from righting when turned upside down. These results suggest that histamine is the primary sensory transmitter in the molluscan statocyst. In preliminary studies, the behavioral measures that have been ported from *Pleurobranchaea* to *Aplysia* indicate that they may be usefully applied to show rapid associative food-aversion learning in this animal also. Supported by AFOSR 89-0262.

SEIZURE-LIKE NEURONAL DISCHARGES IN BRAIN SLICES OF THE DENTATE GYRUS FROM EPILEPTIC PATIENTS DURING 1 HZ STIMULATION. L. M. Masukawa and M. O'Connor. Graduate Hospital Research Center, Depts. of Neurology and Surgery, Graduate Hospital, Philadelphia, PA 19146.

Brain slices from human hippocampi removed during surgical treatment of intractable epilepsy were studied at the Graduate Hospital to determine the neuronal activity of tissue obtained under different surgical conditions than used in the previous Yale study. In summary, two types of responses produced in the dentate gyrus by single stimuli presented to the perforant path were observed in the present study as well as the Yale study. That is, the field response was made-up of either 1-2 population spikes (Type I) or was composed of 3 or more population spikes (Type II) at a maximal stimulation intensity. In the present study, we observed a new response to individual stimuli during a short train of 1 Hz that was characteristically more explosive than what we observed routinely in tissue from the Yale study. This response was of long duration, from 200 msec to 1-2 sec, and therefore represented a prolonged afterdischarge. In some slices a refractory period occurred that lasted 1-3 hours during which only mild potentiation could be generated. The refractory period was greatest immediately following the maximal afterdischarge (about 5-10 sec) during which no field responses could be evoked. This new response was observed in both anterior and posterior biopsies of the dentate gyrus. Thus far, this response comes closest to resembling a seizure-like electrical response in its highly potentiated and prolonged afterdischarge, and the persistent refractory period. Supported by NIH grant NS 23077 to LMM.

AN NMDA-MEDIATED COMPONENT OF EXCITATORY SYNAPTIC INPUT TO DENTATE GRANULE CELLS IN "EPILEPTIC" HUMAN HIPPOCAMPUS STUDIED *IN VITRO*. P.G. Aitken[1,2], L. Urban[1]*, A. Friedman[3]*, G.G. Somjen[1,2]. Departments of Cell Biology[1], Neurobiology[2], and Division of Neurosurgery[3], Duke Medical Center, Durham, NC 27710 USA.

Hippocampi were obtained from patients undergoing temporal lobe resection for treatment of intractable seizures. Transverse 400μM slices were cut by vibratome and kept at 34.4-35.5°C in an interface chamber. Extracellular field potentials in stratum granulosum of gyrus dentatus (GD) were recorded in response to afferent fiber stimulation. The early part of the extracellular response was similar to that seen in rodent hippocampal slices: a positive field EPSP with, at higher stimulation intensities, a superimposed population spike. In some experiments, higher stimulus intensities (100-1200μA) also evoked a late component (LC) that followed the "normal" field EPSP. This LC was negative in 5 slices (30-50msec, 0.6-4.2mV) and positive in 2 slices (30-120msec, 2.0-8.5mV). Both positive and negative LC's were enhanced by lowering extracellular Mg^{2+} from 1.2 to 0.6mM, and were reversibly depressed 50-100% by application of the NMDA receptor antagonists CPP (4-10μM) or d-APV (20μM). The NMDA antagonists had no effect on the early portion of the evoked potentials. These results invite comparison with the NMDA component of synaptic input to GD that appears in kindled rats. Lacking proper controls, however, firm conclusions cannot be drawn. [Supported by NIH grant 17771]

CORRELATION OF UNIT RECORDINGS WITH REGIONAL CELL LOSS IN EPILEPTOGENIC HUMAN TEMPORAL LOBE. R.C. Frysinger, M.F. Levesque, and R.M. Harper. Dept. of Anatomy and Cell Biology, Division of Neurological Surgery, and the Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

More single cell activity can be recorded contralateral to a seizure focus than ipsilateral in humans undergoing long-term depth electrode recordings as part of their evaluation for surgical treatment of medically intractable epilepsy. This may result from cell loss in hippocampus and related structures. We examined records of single cell recordings and electrode localization in 28 patients who later received anterior temporal lobectomy and had cell count data from hippocampus. We determined the number of microwires showing activity greater than 25 μV in each of the 239 electrode bundles in these patients. Analysis of variance was used to test whether activity varied as a function of site (amygdala; anterior, mid, and posterior hippocampal gyrus; anterior and mid pes hippocampi) and side (ipsilateral or contralateral to the resected lobe). The number of active wires per bundle in resected areas was correlated with the percent cell loss in anterior pes, posterior pes, transitional cortex, or neocortex of the resected lobes. Resected regions had fewer active wires ($p=.045$), and some brain areas had more than others ($p=.004$), with amygdala and hippocampal gyrus having more activity than hippocampus and presubiculum. The ipsilateral mid pes showed 4 times the activity of contralateral mid pes, while contralateral anterior pes had 4 times the activity of the ipsilateral side. The A-P by Side interaction was significant ($p=.012$) for this region. Cell loss correlated with activity for both amygdala and hippocampal gyrus, but not hippocampus. These results suggest that cell loss is only one of several factors determining cell activity recorded from mesial temporal structures.

INCREASED PAIRED-PULSE INHIBITION IN THE EPILEPTOGENIC HUMAN TEMPORAL LOBE. S.U. KHAN*, C.L. WILSON, M. ISOKAWA-AKESSON, T.L. BABB, AND M.F. LEVESQUE. Dept. of Anatomy and Cell Biology, Dept. of Neurology, Div. of Neurological Surgery, and Brain Res. Inst. UCLA School of Medicine, Los Angeles, CA 90024.

Paired-pulse tests of perforant path excitability show increased inhibition of the dentate population spike during kindling in the rat (Tuff et al, Brain Res, 1983, 79-90). In order to examine excitability of the human epileptic hippocampal formation (HF) we employed paired stimuli in a study of 21 complex-partial epilepsy patients who were candidates for surgical seizure therapy, with depth electrodes implanted in the HF for diagnostic monitoring. Conditioning and test stimuli were delivered to HF sites individually while recording evoked field potentials from adjacent HF sites. Paired-pulses were delivered at interstimulus intervals (ISI) of 20 to 1600 msec, and response depression or facilitation measured by dividing test by conditioning response amplitude. Interictal recordings were made in epileptogenic HF (side of all recorded seizure onsets) vs. non-epileptogenic HF (no seizure onsets). The amplitude of evoked field potentials in response to the test pulse was significantly suppressed on the epileptogenic side at ISI's of 20 to 100 msec ($p< 0.01$). These results indicate interictal inhibition is significantly stronger in the epileptogenic HF, a functional difference consistent with the anatomical findings of Babb et al (J. Neurosci., in press) showing a major loss of principal neurons in human epileptic HF with no significant loss of GAD+ inhibitory interneurons. Supported by NS02808.

98.5

EXCITABILITY OF SPECIFIC HIPPOCAMPAL FORMATION PATHWAYS IN EPILEPTOGENIC HUMAN TEMPORAL LOBE. C.L. Wilson, S.U. Khan, M. Isokawa-Akesson, T.L. Babb and M.F. Levesque. Dept. of Neurology, Dept. of Anatomy, Div. of Neurological Surgery, and Brain Res. Inst. UCLA School of Medicine, Los Angeles, CA 90024.

Paired pulse stimulation in the human hippocampal formation in complex partial epilepsy patients shows reduced excitability in areas of seizure genesis (Khan et al, Neurosci. Abst., in press), which may be attributed to the synaptic reorganization associated with hippocampal sclerosis (Babb et al, J. Neurosci., in press). We employed paired pulse stimulation of the epileptogenic (EPG) and non-epileptogenic (NEG) hippocampal formation to determine relative excitability in each of three prominent hippocampal pathways: 1) perforant path, 2) retrohippocampal path, and 3) associational path. The results showed significant reductions in excitability in the EPG perforant path with interstimulus intervals (ISI) of 20 to 100 msec and in retrohippocampal pathway at ISIs of 50 msec. On the other hand, stimulation of associational pathways showed no significant differences between EPG and NEG hippocampus. Finally, recordings were made in the anterior hippocampus in an area in which epileptic neuronal loss is documented as greatest (Babb et al., Epilepsia, 1984, 721-740). Stimulation in entorhinal cortex, presubiculum and parahippocampal gyrus showed significantly decreased excitability between 20 and 100 msec in EPG hippocampus. These results indicate no decreases in excitability *within* epileptogenic regions prone to neuronal loss, but significantly increased inhibitory suppression of afferent pathways projecting *into* epileptogenic hippocampus. Supported by NS 02808.

LIGHT AND ELECTRON MICROSCOPY OF MOSSY FIBER TERMINALS IN HUMAN "EPILEPTIC" FASCIA DENTATA. T.L. Babb, W.R. Kupfer*, J.K. Pretorius* and M.F. Levesque. Department of Neurology, Division of Neurological Surgery and the Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

Reactive synaptogenesis by mossy fiber recurrent innervation of the inner molecular layer (IML) of the fascia dentata (FD) is positively correlated with the extent of hilar cell loss, (9 epileptics, 4 normals, $R = 0.61$, $p < .05$). The present studies have demonstrated mossy fiber recurrent zinc-labelled puncta and axon terminals in the IML. The terminals were typical of mossy fiber terminals because of their large size, large ovoid vesicles, zinc located in vesicles and apparent excitatory-type asymmetric synaptic profiles. These findings suggest that mossy fibers sprout and innervate synaptic zones denervated by mossy cells of the hilus, which are the major neurons projecting to the inner molecular layer (IML). Golgi studies of the hilus in two epileptics and two non-epileptics revealed a 77% loss of mossy cells in epileptics ($2.7/mm^2$ vs. $11.5/mm^2$) which would result in denervation of the IML.

Timm's-positive, zinc-labelled puncta located in the granule cell layer indicated that mossy fibers innervated sites denervated by loss of hilar GABA neurons whose fibers normally synapse on granule cell bodies. In the hilus of seven epileptics, there was a 33% loss of GABA neurons compared to GABA neuron density in normal monkeys. However, to date we have not yet found a typical zinc-labelled mossy fiber terminal synapsing on a granule cell. These results indicate that in the hilus of human hippocampal epilepsy, there is greater damage to mossy cells than GABA neurons, which leads to greater reactive synaptogenesis and recurrent excitation of the IML than on granule cell bodies. These electron microscopic studies also suggest that most of the MF terminals in stratum granulosum (SG) innervate dendrites passing through SG.

MORPHOMETRIC ANALYSIS OF HIPPOCAMPAL SYNAPTIC PROFILES IN TEMPORAL LOBE EPILEPSY. J. H. Kim, M. Y. Shen*, P. O. Guimaraes*, N. C. de Lanerolle and D. D. Spencer. Sections of Neuropathology and Neurosurgery, Yale Univ. School of Medicine, New Haven, CT 06510

Our previous quantitative analysis revealed no proportional differences in the number of hippocampal symmetric (putatively inhibitory) and asymmetric (putatively excitatory) synapses between tumor-associated epilepsy (TAE) and non-tumor epilepsy (NTE) (Epilepsia 29:684, 1988). TAE cases served as the control, as they revealed no statistically significant differences in neuronal density from the normal control. A morphometric study of the synaptic structures was conducted on the pyramidal layer of the hippocampal CA1 in 5 TAE and 7 NTE cases with intractable temporal lobe epilepsy. With a computer assisted scanning device the following parameters of symmetric and asymmetric synaptic structures were measured on electron micrographs: length of the postsynaptic density, length of the synaptic membrane, size of presynaptic terminals and postsynaptic profiles. Compared with TAE cases, NTE cases revealed a statistically significant enlargement of postsynaptic profiles associated with both symmetric (261%, $p < 0.02$) and asymmetric (246.5%, $p < 0.005$) synapses, but no significant differences were found in the length of synaptic membranes and postsynaptic densities, length of the postsynaptic density/length of the synaptic membrane, and size of presynaptic terminals. The enlargement of postsynaptic profiles in NTE may represent changes secondary to excessive neuronal stimulation.

MU AND DELTA OPIOID RECEPTORS AND TCP BINDING SITES ARE UNCHANGED IN THE EPILEPTIC TEMPORAL CORTEX. H.S. Pan, E.E. Weirich*, C. Kufta, and N.S. Nadi. NIH, Bethesda, MD and Bryn Mawr.

Many transmitter systems and their receptors are implicated in epilepsy. We used receptor autoradiography to study mu and delta opioid receptors and TCP binding sites in surgically removed spiking (S) and less spiking (LS) temporal cortices of patients with intractable seizures. Mu and delta opioid receptors were respectively labelled with [^{3}H]DAGO and [^{3}H]DADLE in the presence of morphiceptin. TCP binding sites were labelled with [^{3}H]TCP. The ligands bound with different laminar patterns. In LS, delta and TCP binding sites showed a gradient with layer I most heavily labelled; mu receptors were least numerous in layers I and VI. The binding patterns were not changed in S. Bmax's (fmol/mg tissue) were not different in LS vs S (38.1 ± 1.9, n=13, vs 38.0 ± 1.7, n=6 for mu receptors and 65.5 ± 4.8, n=9, vs 58.0 ± 3.5, n=6 for delta receptors). There were no K_d changes for the two ligands. The amount of [^{3}H]TCP bound (fmol/mg tissue) was not different between LS (39.6 ± 4.1, n=6) and S (32.4 ± 4.0,n=5). The lack of receptor changes along with previously shown changes in transmitter levels suggest the existence of complex changes in epilepsy.

PEPTIDE IMMUNOREACTIVITY AND mRNA ARE ALTERED IN HUMAN EPILEPTIC HIPPOCAMPAL FORMATION. J.F. McGinty, J.N. Simpson*, D. A. Hosford[1] and B.J. Crain[2]. Dept. of Anatomy & Cell Biol. E. Carolina U. Sch. Med. Greenville, NC 27858 and Depts. of [1]Neurology and [2]Pathology, Duke U. Med. Ctr. Durham, NC 27710.

An increase in dynorphin immunoreactivity (DYN IR) in the supragranular zone of the fascia dentata of temporal lobe epileptics (Houser and Miyashiro, Soc. NS 14:1033, 1988) and loss of somatostatin (SS) hilar neurons in rats after seizures (Sloviter. Science 235:73, 1987) have been reported. We report here immunostaining for DYN, enkephalin (ENK) and somatostatin (SS) in surgically resected human hippocampi with mesial temporal sclerosis. Also, the proDYN and proENK mRNA content of dentate granule and CA4 cells was investigated with in situ hybridization histochemistry (ISHH). Nine of 12 hippocampi immediately frozen after surgical removal for intractable epilepsy exhibited mesial temporal sclerosis. Four normal hippocampi were frozen 3-14 h. after non-neurological deaths. Adjacent frozen sections were cut for Nissl, immunohistochemistry (IHC) and ISHH. Nissl and IHC sections were collected directly into a cold buffered 4% paraformaldehyde solution for 1.5 hr. After rinsing and incubation in primary antisera, the sections were reacted with avidin-biotin Vectastain reagents. Nissl staining revealed a typical gradient of CA3-4 and CA1 neuronal loss and gliosis in sclerotic tissue; the most severely affected had a patchy loss of dentate granule cells. DYN and ENK IR was observed in CA4,CA2-3, and, in epileptic tissue, in the supragranular zone over remaining dentate granule cells. ENK-IR and SS-IR neurons were present in CA4; in epileptic tissue, fewer total cells but more large, pyknotic neurons were seen than in normal tissue. ISHH sections on slides were postfixed and incubated with S^{35}-labeled oligonucleotides followed by stringent washes. A strong DYN mRNA signal in the granule cell layer was present on film autoradiographs. Differences in opioid mRNA among epileptic and normal tissues will be determined by analysis of emulsion coated sections. Supported in part by DA 03982 (JFM).

SPECTRAL ANALYSIS OF EEG DURING STATUS EPILEPTICUS. N.Y. WALTON and D.M. Treiman. Neurology and Research Services, Wadsworth VAMC, and Department of Neurology, UCLA Sch. of Med., Los Angeles, CA 90024.

EEG changes which occur during the course of status epilepticus, previously described by us (Treiman et al, Epilepsy Res, in press), were studied using computer-generated frequency spectra. Status was induced in rats by injection of lithium chloride followed 20-24 hours later by injection of pilocarpine. EEG recorded from chronic epidural electrodes was digitized and frequency spectra were computed from EEG samples recorded periodically from the end of the last discrete seizure until periodic epileptiform discharges were the principal pattern.

Distribution of EEG power shifted from 2-6 Hz when the EEG pattern was waxing and waning epileptiform discharges to frequencies faster than 14 Hz during the first 30 minutes of continuous spiking. Power then gradually shifted back to 2-14 Hz over the next 90 minutes, as the EEG pattern evolved into periodic epileptiform discharges. Analysis of variance revealed these changes to be statistically significant, $p<.0001$.

The shift in power to frequencies greater than 14 Hz which takes place during the first 30 minutes of continuous spiking occurs at the time status becomes intractable to treatment. This is also the time when brain concentrations of aspartate and glutamate are significantly depressed. Successful treatment of status epilepticus at this time may require blockade of release of these amino acids.

COLPOCEPHALY: MAGNETIC RESONANCE IMAGING FINDINGS, NEUROPSYCHOLOGIC DATA AND ELECTROENCEPHALOGRAPHIC ABNORMALITIES. I.S.Brown, Ph.D., A.R.Riela, M.D.*, and A.D.Elster, M.D.*, Bowman Gray School of Medicine of Wake Forest University, Winston-Salem, NC.

Colpocephaly is a condition defined as a disproportionate enlargement of the occipital horns of the lateral ventricles. This condition is associated with abnormal motor and mental development, visual abnormalities and seizures. Pathogenetic causes are varied. We report 2 patients with this condition radiographically and clinically. Magnetic Resonance Imaging findings not only demonstrate enlargement of the occipital horns but also demonstrate abnormal signal in the occipital white matter and surprisingly, from the frontal periventricular white matter. Neuropsychological data in these two patients demonstrate diffuse mental retardation that cannot be explained solely on the visual abnormalities found in both patients. Both patients had partial seizures. Electroencephalographically, diffuse slowing and multi-focal epileptiform discharges were noted in both patients. These findings further suggest that colpocephaly is a generalized developmental abnormality most likely occurring in the first 8 weeks of gestation.

PURSUIT-RELATED, BEHAVIORALLY ENHANCED VISUAL RESPONSES IN MONKEY DORSOLATERAL PONTINE NUCLEUS (DLPN). D.A. Suzuki and R.D. Yee, Dept of Ophthalmology, Indiana Univ. Sch. of Medicine, Indianapolis, IN 46202.

The visual motion responses that have been observed in the DLPN have implicated a role in pursuit eye movement (PEM) control that was limited to PEM initiation. This limitation resulted from the use of visual stimuli moving at speeds that were higher than the retinal error speeds associated with the maintenance of PEMs. The present study compared the responsiveness of DLPN cells during visual motion stimulation with and without PEMs.

Extracellular activity was recorded in alert monkeys that were trained to fixate a 0.5 deg red spot that moved slowly on a tangent screen or was stationary during the presentation of moving visual stimuli.

The activity of DLPN units was studied during PEM when eye velocity lagged target velocity. Attention was focused on DLPN cells that exhibited a clear response to moving visual stimuli. The sensitivity to visual motion increased 50% or more when visual motion was behaviorally significant. The enhanced visual response was observed both at the initiation and during the maintenance of PEMs.

The results implicate a role for the DLPN in processing the visual motion information that is required in regulating both the initiation and the maintenance of PEMs.

Direction Selectivity of Pontine Burst Neurones L. Ling*, A.F. Fuchs, and C.R.S. Kaneko. Dept. Physiol.& Biophys. and Reg. Primate Research Center, Univ. Wash., Seattle, WA 98195

Amongst eye movement-related neurones in the pons are the short-lead burst neurones, which begin their discharge about 10 msec before the saccade. We have started to re-investigate the details of their response to determine whether their discharge reflects intermediate stages during the transformation from a spatial to a temporal coding of the saccade metrics. Alert Rhesus monkeys were trained to follow a specified pattern of target steps for food reward.

Many short-lead burst neurones exhibited the classical sinusoidal direction tuning curve in which the number of spikes encode linearly the magnitude of the **component** in an optimal direction, although the optimal direction was often oblique and not horizontal. In contrast, we found a class of units that displays no direction preference. Amongst these, one type discharges a few spikes irrespective of the direction and the size of the saccade. A second type increases its number of spikes with the amplitude of the movement regardless of direction. In addition, we encountered occasional previously undescribed short-lead burst neurones with distinct movement fields: the maximal number of spikes occurred for saccades of a specific size and direction, and declined for **both** smaller and larger movements. This rich variety of short-lead burst neurone types suggests that not all of them can act as immediately premotor elements.

ANATOMY AND PHYSIOLOGY OF LONG-LEAD BURST NEURONS (LLBNs) C.A.Scudder, S.Highstein, T.Karabelas, A.Moschovakis. Dept. Otol., Washington. Univ. Sch. Med. St. Louis, MO. 63110

In the pons of the alert squirrel monkey, neurons having "long-lead" presaccadic bursts were recorded and stained intraaxonally using HRP filled pipettes. Frequently encountered LLBNs fell in three classes. (1) Cells projecting to the cerebellum. Somata were in the NRTP and the rostral PPRF within and below the MLF. Axons coursed down the midline, laterally above the pontine nuclei, and dorsally in the brachium pontis where staining faded. Cells had ordinary vector and directional long-lead discharges. (2) Presumed efferents of the superior colliculus (SC), identified using electrical stimulation of the SC (somata were not recovered). Decending axons decusated in the predorsal bundle under N.III and branched sparsely until NRPo. Terminal arborizations were found throughout NRPo (esp. medially and dorsally), somewhat in NRPc (but sparse in the EBN area), densely in the raphe nuclei near the abducens (including the OPN area), and densely in the medullary RF (including IBN area). Axons faded near the obex while in the tectospinal tract. All were vector LLBNs, but often had non-saccadic discharges as well. (3) Reticulospinal neurons. Somata were at the level of rostral abducens nucleus. Axons decended in the reticulospinal tract, giving off many fine branches which arborized in the prepositus nucleus dorsally and in many parts of the medulary RF ventrally and laterally. Staining faded before C1. Presaccadic discharges were poorly related to saccade metrics and cells fired spontaneously in a way unrelated to eye movements.

99.4

DYNAMIC RESPONSES OF SACCADE RELATED BURST CELLS IN SUPERIOR COLLICULUS CONTRASTED DURING MEMORY AND DOUBLE JUMP PARADIGMS. D. M. Waitzman, T. P. Ma, L. M. Optican, and R. H. Wurtz. Lab. of Sensorimotor Research, National Eye Institute, Bethesda, MD 20892, USA.

The dynamic responses of superior colliculus neurons were recorded while monkeys (macaca mulatta) performed saccades of the same metrics under visually guided, memory contingent and double jump conditions. In the double jump condition the second saccade matched the preferred movement of the cell, but had no target in its visual receptive field.

Of the cells studied, all but one had visual receptive fields. About 23% of cells responded during the visually guided saccade, but did not fire under either memory or double jump conditions. Another 15% discharged under all three conditions. Interestingly, about twice this number of cells (32%) discharged during the double jump condition and not for memory contingent saccades. In each of these categories the dynamics of the discharge during the saccade were examined. There were at least two types of responses, either a burst that declined rapidly to end with the saccade (e_m), or a more gradual increase in activity which remained above background throughout the saccade and declined from 10 to 100 msec after the saccade(ΔE). In each of the behavioral categories listed, cells with both types of dynamics were identified.

These results show that there is a wide variety of cells in the superior colliculus that can be categorized by the behavioral paradigm and their dynamic characteristics. Different cells participate in identical movements under different behavioral conditions regardless of their dynamic properties (ΔE or e_m). This may indicate that the superior colliculus is a site of convergence for saccadic commands from different sources.

99.5

DIENCEPHALIC AND MESENCEPHALIC NEURONS PROJECTING TO THE ROSTRAL PONTINE NUCLEI IN THE RAT: FLUORESCENCE AND WGA-HRP METHODS. J. Yamada, H. Sato*, T. Kitamura* and K. Yamashita*, Dept. of Anatomy, Nippon Med. Sch., 1-1-5 Sendagi, Bunkyo-ku, Tokyo 113, Japan.

When WGA-HRP was injected into lobule VII of the cerebellum whose microstimulation evoked saccades, a large number of labeled neurons were seen in the medial (MPN) and the lateral (LPN) parts of the rostral pontine nuclei of the monkey. In the present study, first, WGA-HRP was injected into the MPN or the LPN of the rat to determine which neurons send their axons to the MPN and/or LPN in the diencephalon and midbrain. For the data analysis, we used cases in which anterogradely labeled terminals were seen in lobule VII of the vermis. In both injection cases, retrogradely labeled neurons were seen ipsilaterally in the same areas: lateral hypothalamic area, ventral nucleus of the lateral geniculate body, zona incerta, anterior and posterior pretectal areas, prerubral field, perirubral area, medial nucleus of the accessory optic tract and periaqueductal gray. Second, when fluorescent tracers (Diamidino Yellow and Fast Blue) were injected into the MPN and LPN to examine the collateralization of these projections, no double labeled neurons were seen in these areas. These results suggested that oculomotor function of lobule VII was affected by many areas in the diencephalon and midbrain via the LPN and MPN.

99.6

A SEARCH FOR THE NEUROANATOMICAL BASIS FOR UP- AND DOWN-GAZE PARALYSIS. A TRANSSYNAPTIC TRACING STUDY IN THE MONKEY. A.K.E. Horn* and J.A.Büttner-Ennever*, (SPON: U. Büttner). Inst. Neuropathology, LMU Munich, W.Germany

The rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF) contains premotor neurons important for the generation of vertical saccadic eye movements. Burst neurons in the riMLF are activated either during upward or downward saccades. (Büttner-Ennever et al., Brain 105:125, 1982). Although the premotor areas for vertical saccades are known, the anatomical basis for isolated up-, or down-, or combined up- and down-gaze paralysis in humans is not understood.

In this study we investigated, whether in riMLF there is a topographic organization of premotor neurons innervating upward (superior rectus, inferior oblique) or downward (inferior rectus, superior oblique) motoneurons. The injection of a retrograde transsynaptic tracer, non-toxic Tetanus Toxin - Fragment C, into individual vertical eye muscles enabled us to selectively label their premotor neurons in the riMLF of monkeys. We found no striking separation of "upward" and "downward" premotor neuron pools in the riMLF. This result suggests that isolated up- or down-gaze paralysis is not due to differential destruction of an "upward" or "downward" set of premotor neurons, but probably depends on selective damage to efferent pathways.

GAZE-RELATED ACTIVITY OF BRAINSTEM OMNIPAUSE NEURONS RECORDED IN THE ALERT HEAD-FREE CAT. M. Paré* and D. Guitton. Montréal Neurol. Inst. and McGill Univ., Montréal H3A 2B4, Canada.

The firing pattern of brainstem omnipause neurons (OPNs) is thought to act as a neural gate controlling the saccadic eye movement generator. In head-restrained animals, these inhibitory preoculomotor neurons fire tonically for stationary eye positions and cease firing just before and during all saccades. Munoz and Guitton (Soc Neurosci Abstr 1988) proposed that, when the head is unrestrained, the superior colliculus and some of its brainstem target elements control the displacement of gaze (= eye + head) rather than ocular motility alone; and that OPNs should be silent when dynamic gaze position error is not null. Here we report the discharge characteristics of OPNs during combined eye-head gaze shifts in the cat. OPNs ceased firing not for the duration of either the saccadic eye movement or head movement components but for the duration of gaze shifts. This relation was particularly evident in large (>50°) gaze shifts where the difference between ocular and gaze saccade durations is striking. The duration of the pause in activity of OPNs was strongly correlated with the duration of saccadic displacements of gaze, irrespective of whether these were accomplished by eye movements alone (head-fixed) or by combined eye-head movements (head-free). We propose that OPNs are part of a local gaze feedback loop that controls gaze shifts.

DISCHARGES OF FASTIGIAL NEURONS DURING SACCADIC EYE MOVEMENTS IN THE MONKEY. K. Ohtsuka and H. Noda. Sch of Optometry, Indiana Univ. Bloomington, IN 47405.

Discharges of fastigial neurons that receive Purkinje-cell projections from the oculomotor vermis (lobules VIc, VII) were recorded during spontaneous and targeting saccades, and during head rotation in trained monkeys. The units were identified by an inhibition of firing during repetitive microstimulation of vermal lobule VII.

All units were spontaneously active (10 - 110 imp/s) and in some units the tonic levels of firing were highly correlated with steady eye positions (r = 0.90 - 0.94). Preferred direction of eye-position was variable from contralateral horizontal to vertical, but none was ipsilateral. The majority of units also showed bursts during a saccade or a quick phase of nystagmus. Preferred direction for burst was also contralateral. Lead times of bursts during saccades in preferred directions ranged from 0 - 60 msec (group mean = 30 msec). Weak and late bursts or pauses were found during ipsilateral saccades in some units. Burst- and saccade-durations were highly correlated for saccades in the preferred direction (r = 0.91 - 0.97). Thus, a higher activity of neurons in the fastigial oculomotor region was associated with contralateral saccades and fixation. (Supported by NIH grant EY04063)

PATHWAYS OF AXONS OF OCULOMOTOR NEURONS IN THE FASTIGIAL NUCLEUS OF MACAQUE MONKEY. H. Noda and Y. Ikeda*. Sch of Optometry, Indiana Univ., Bloomington, IN 47405.

Anatomical studies show that cells of the fastigial nucleus (FN) give rise to two distinct efferent bundles: an uncrossed bundle that emerges from the cerebellum via the juxtarestiform body (JB); and a crossed bundle that forms the uncinate fasciculus (UF). A question is asked whether impulses for evoking saccades during microstimulation of the oculomotor vermis are conveyed via JB or UF, or both.

Stereotaxic locations of JB and UF in macaques were identified by anterograde transport of WGA/HRP following injections into the oculomotor region of FN. Mappings of thresholds and saccadic directions were conducted by stimulating an area rostral to FN. Low-threshold areas were correlated with the locations anatomically identified in other monkeys. Ipsilateral saccades were evoked consistently with currents less than 5 μA from the area corresponding to UF. Contralateral saccades were evoked only from FN and no saccade was evoked from the JB area even with currents more than 10 μA. We have already shown that stimulation of oculomotor fastigial neurons (receive Purkinje-cell axons from the oculomotor vermis) elicits saccades with a contralateral horizontal component. Since contralateral saccades were not evoked from the JB area, fastigial oculomotor neurons emerge from the cerebellum via UF. (Supported by NIH grant EY04063)

CONNECTIONS BETWEEN A VENTRAL, GABAERGIC SUBDIVISION OF ZONA INCERTA AND THE SUPERIOR COLLICULUS. U. Kim*, E. Gregory and W. C. Hall Department of Neurobiology, Duke University, Durham, North Carolina 27710

A ventral subdivision of zona incerta may contribute to gaze mechanisms by virtue of its connections with the intermediate grey layer of the superior colliculus. This ventral subdivision can be distinguished from the rest of zona incerta in both the cat and rat by its dense cytochrome oxidase staining, and by its dense population of medium-sized neurons that are immunoreactive to antibodies against glutamic acid decarboxylase (GAD) and γ-aminobutyric acid (GABA). The connections between this subdivision and the superior colliculus in the rat have been studied using anterograde and retrograde axonal transport techniques. Both horseradish peroxidase and *Phaseolus vulgaris* leucoagglutinin were used as tracers. The results indicate that this subdivision gives rise to a topographically organized projection to the superior colliculus which terminates in dense patches in the intermediate grey layer. Experiments in which the retrograde transport of horseradish peroxidase from the superior colliculus was combined with GAD immunocytochemistry in the same animal indicate that the majority of the zona incerta cells that give rise to this projection are GABAergic. The results also indicate that cells in the intermediate grey layer project to the same ventral subdivision of zona incerta. Thus, the ventral subdivision of zona incerta and the superior colliculus are reciprocally connected by a circuit that provides a major source of GABAergic input to the intermediate grey layer. LAMINAR ORIGINS OF THE DESCENDING TECTAL PATHWAYS IN MACAQUE MONKEY. Paul J. May and John D. Porter. Depts. of Anatomy and Ophthalmology, Univ. of Mississippi Med. Ctr., Jackson, MS 39216.

The superior colliculus is one of the major brainstem centers active in initiation of saccadic eye movements. It receives inputs from a wide variety of structures, but projects upon gaze-related regions in the midbrain, pons and medulla via only two descending output pathways, the crossed and uncrossed tectobulbar pathways. The distributions of the cells of origin for these two pathways have not been determined in the macaque monkey, despite the fact this is the most widely used species in studies of tectal eye-movement control. The present study retrogradely labelled the collicular cells of origin for these two descending pathways in 5 Macaca fascicularis. Following a large unilateral injection that included the entire pons and extended into the medulla and midbrain tegmentum, the approximately 3,500 contralateral labelled neurons were restricted to the intermediate gray layer. This represents less than 15% of the overall population in this layer, indicating that local circuit neurons may outnumber projection neurons. Only a small number of cells were observed ipsilaterally in the deep and intermediate layers, indicating that few ipsilateral tectobular axons descend caudal to the midbrain. Smaller brainstem injections distinguished the presence of subpopulations within the cells of origin for the predorsal bundle. Specifically, injections centered medially in the pontine reticular formation mainly labelled neurons in the superficial sublamina of the contralateral intermediate gray layer. In contrast, laterally placed injections mainly labelled neurons in the deeper sublamina of this layer. This pattern of lamination is significantly different from that of the cat, where predorsal bundle cells are found throughout the intermediate and deep gray layers, and of rodents, where they are restricted to the deeper sublamina of the intermediate gray. In light of the laminar arrangement of afferent terminations within the intermediate gray layer (e.g., cerebellotectal projections terminate in the deeper sublamina), these results indicate that the crossed tectobulbar pathway may contain at least two axonal populations with differing signals and targets. A CHOLINERGIC INPUT TO THE CAT ABDUCENS NUCLEUS. R.F. Spencer and R. Baker. Dept. Anat., Med. Coll. of Virginia 23298, and Dept. Physiol. & Biophys., New York Univ. Med. Ctr., New York, NY 10016.

A potential cholinergic input to the cat abducens nucleus previously was identified on the basis of the ultrastructural localization of acetylcholinesterase. In the present study, the light and electron microscopic immunohistochemical localization of choline acetyltransferase (ChAT) has revealed immunoreactive axons that establish *en passant* and terminal synaptic connections predominantly with the dendrites of ChAT-immunoreactive abducens motoneurones and non-immunoreactive abducens internuclear neurones. ChAT-immunoreactive synaptic endings contained spheroidal synaptic vesicles and synaptic contact zones were characterized by an asymmetrical pre-/postsynaptic membrane profile. Given the absence of axon collaterals of abducens motoneurones, a likely candidate for the source of these cholinergic synaptic endings is a population of ChAT-immunoreactive neurones in the caudal half of the nucleus prepositus hypoglossi. Injections of HRP into the abducens nucleus have retrogradely labelled both ChAT-immunoreactive neurones and non-immunoreactive neurones in the prepositus. The results suggest that the glycinergic inhibitory input to the abducens nucleus from the nucleus prepositus hypoglossi is balanced, at least in part, by a cholinergic excitatory input. Findings from other experiments in which the oculomotor nucleus was injected with HRP furthermore indicate a unique role of the cholinergic neurones in the nucleus prepositus hypoglossi in horizontal eye movement.

VESTIBULAR AND CEREBELLAR INPUTS TO ABDUCENS NEURONS IN THE RHESUS MONKEY. D. M. Broussard and S. G. Lisberger. Dept. of Physiology, UCSF, San Francisco, CA 94143.

We have investigated the brainstem circuitry underlying the vestibulo-ocular reflex (VOR) by recording the responses of abducens neurons (AbNs) to current pulses applied to the vestibular labyrinth and the cerebellar flocculus in alert, behaving monkeys. This method characterizes the strengths of synaptic inputs to neurons whose firing patterns can be studied during eye movements. Contralateral or ipsilateral AbNs responded to single shocks to the labyrinth with a transient increase or decrease in firing rate at a latency of 1.68 ± 0.27 or 1.68 ± 0.63 msec, respectively. These latencies are consistent with a disynaptic input. An index of the strength of the neuron's response was calculated by dividing the mean number of spikes in the response by the associated change in eye position. The mean response was 5.98 ± 3.4 spikes/deg for contralateral and -2.25 ± -1.07 spikes/deg for ipsilateral AbNs; the results were similar, with slightly smaller responses, in a second animal. This suggests that the excitatory disynaptic input to an abducens neuron from the contralateral labyrinth is 2 to 3 times as effective as the inhibitory input from the ipsilateral labyrinth. The response to contralateral stimulation had a shorter duration than the ipsilateral response, and often displayed a second, late component. The late component may represent input from multisynaptic VOR pathways. Stimulation of the flocculus caused a transient increase in firing in ipsilateral AbNs. Unexpectedly, a transient decrease in firing was observed in some contralateral AbNs, indicating that the flocculus exerts a modulatory influence on both crossed and uncrossed VOR pathways. (This investigation was supported by NIH grant EY03878.)

PROCESSING OCULOMOTOR INFORMATION WITHIN THE MONKEY CEREBELLAR FLOCCULUS. L. S. Stone †§ and S.G. Lisberger §, †Vision Group, NASA, Ames Research Center, MS 239-3, Moffett Field, CA 94035, and §Neuroscience Graduate Program, Department of Physiology, Box 0444, University of California, San Francisco, CA 94143.

The simple-spike firing rate of the majority of Purkinje cells (P-cells) in the monkey flocculus encodes gaze velocity (eye velocity in the world) and is only weakly sensitive to eye position in the orbit. However, the firing rate of the oculomotor mossy fiber afferents (OMFs) that are thought to drive these P-cells is very sensitive to eye position. The response of OMFs during the initiation of smooth pursuit eye movements sheds new light on how OMF inputs may be transformed into P-cell responses.

We recorded from 45 OMFs in the flocculi of two monkeys during pursuit of sinusoidal target motion and all 4 cardinal preferred directions were well represented (13 ipsi, 16 contra, 10 down, and 6 up). We examined the response of 26 of these during the initiation of pursuit to 30°/s motion of a small spot in the preferred direction. Ten (38%) had a brisk saturating response that was a near perfect analog of eye velocity. Sixteen (62%) had a sluggish non-saturating response that increased nearly linearly with eye position. In addition, the two groups differed in mean latency (4 ms after the onset on eye movement vs 29 ms), mean static eye-position sensitivity (2.21 vs 3.44 sp/s/°), mean eye-velocity sensitivity (2.28 vs 0.98 sp/s°/s), regularity of firing rate (mean coefficient of variation: 0.27 vs 0.11), and mean phase of the response during sinusoidal pursuit (16 vs 55° lag). A larger sample will be required to determine whether these two types represent two distinct populations or the extremes of a continuum. Nevertheless, within the cerebellar cortex, a weighted sum of inputs from two OMFs of opposite type and opposite directional preference, could produce a response during pursuit with a sensitivity to eye-velocity (~ 1 sp/s/°/s) and eye-position (~ 0.4 sp/s/°) that is appropriate for gaze-velocity P-cells.

SINGLE UNIT RECORDINGS FROM RAT CEREBELLUM DURING ADAPTIVE GAIN MODIFICATION OF THE BLINK REFLEX. **J. J. Pellegrini* and C. Evinger. (SPON: A.W. Seymour) Dept. Neurobiology & Behavior, SUNY, Stony Brook, NY 11794.**

Since cerebellar lesions prevent or severely impair motor learning, the cerebellum must be essential for some aspect of such learning. Understanding how the cerebellum can perform this function, however, requires an analysis of the activity of individual neurons during learning. We investigated the modification of cerebellar neuron response properties during adaptive gain changes of the blink reflex, a form of motor learning.

Airpuffs or electrical stimulation of the cornea of decerebrate or urethane anesthetized rats evoked a burst of orbicularis oculi activity (OOemg) and a concomitant blink. After upper eyelid restraint, these same stimuli elicited a larger burst of OOemg activity with time. Before restraint, blink stimulation elicited three patterns of responses from neurons found in Crus I & II of cerebellar cortex and the deep cerebellar nuclei (DCN): 1) a complex spike (latency 20-25 ms) followed by a transient increase in simple spike activity in Purkinje cells; 2) a long lasting (up to 1 s) suppression of tonic activity in cerebellar interneurons; and 3) a burst of spikes (latency 15-40 ms) followed by a brief pause in activity in DCN cells. Throughout adaptation and recovery, Purkinje cells' simple spike discharge correlated with the apparent motor error. The response of other cerebellar neurons, however, corresponded to the adapted blink magnitude. DCN units of this type also altered their discharge in a non-learning paradigm in which paired conditioning-test stimuli produced a reduction of long latency OOemg activity to the test pulse. These long latency components are the same ones that undergo modification during adaptation. These data suggest distinct functions for the different cell types of the cerebellum in modulating blink reflex gain. **Supported by grant EY07391.**

ON THE ROLE OF THE NUCLEUS OF THE OPTIC TRACT (NOT) DURING OPTOKINETIC NYSTAGMUS IN SQUIRREL MONKEYS (SAIMIRI SCIUREUS). J. Kröller*, F. Behrens*, O.-J. Grüsser and B. Schielke*. (SPON: ENA). Dept. of Physiol., Freie Universität Berlin, Arnimallee 22, 1000 Berlin 33, Germany

The aim of the present study was to elucidate the impact of directly activating retinal ganglion cells on neurons of the NOT compared to the situation with an additional loop through the visual cortex. Recordings from single NOT neurons were obtained in 3 awake monkeys. In order to evoke an optokinetic nystagmus (OKN) the animals were subjected to a vertical pattern of black and white stripes, moving horizontally at different velocities (1-400 deg·s^{-1}). Eye movements were monitored by means of search coils.

When the pattern movement was directed towards the recording side, all units but one were activated during the slow phase of the OKN, while the firing ceased abruptly during the backward saccades. Movements in the non-favoured direction maintained the discharge rate at the spontaneous level or, in most cases, lowered it. The receptive fields of NOT units always extended over more than 45x45 deg. and included the fovea. In darkness, the spontaneous activity was either between 50 and 70 or in the order of 20 imp·s^{-1}, and no eye-movement related modulation in discharging occurred during after-nystagmus or spontaneous eye movements. In order to determine the precise receptive field properties of NOT neurons, an open-loop OKN was evoked in one animal when one eye was temporarily immobilized by intraorbital injection of Botulinum toxin (BoTX). Supported by the Deutsche Forschungsgemeinschaft (Gr 161).

STIMULUS PATTERN DEPENDENCE OF HUMAN OPTOKINETIC AFTERNYSTAGMUS. S. H. Lafortune, D. Ireland*, G. Wei* and R.M. Jell. Depts of Physiol. and Otolaryngol., University of Manitoba, WINNIPEG, MB R3E0W3, CANADA.

Normal subjects were exposed to different optokinetic (OK) stimulus patterns in the following order: A) Vertical stripes, 2° black and 18° white using a cylindrical curtain 85cm diameter; B) Random dots on the inside of a white, plastic sphere, 85cm in diameter, which could be lowered over the subject's upper body; i) Large (1.9cm) and small (1.3cm) black dots (2:1 large/small), mean spacing 13.2° (±4°) ii) as in i) but small dots removed, mean spacing 15.5° (±4.6°); iii) as in i) but with small dots replaced by large dots; iv) as in iii) but with an irregular row of large yellow numbered dots placed at eye height, in which subjects were asked to call out the number on the dots they followed so as to increase mental alertness; C) During constant velocity (60°/s) rotation in a rotating chair, with a striped (2° black, 18° white) stationary surround 180cm diameter. In all conditions except C, stimulus velocity was 40 deg/sec. Subjects were asked to do mental arithmetic during OKAN. Statistical analysis of the results revealed that the parameters A, 1/B, C of the double exponential model (Jell *et al. Acta Otolaryngol* 1984,98:462-471) and the area under the decay curve were independent of stimulus conditions. Long time constant 1/D was found to be significantly higher ($p < 0.05$) in A) than in all other conditions. Whereas the first exposure consistently yielded a double exponential decay with normal parameter values in all subjects, subsequent stimulus conditions often yielded single exponential decays in which the long time constant component was absent [2 Ss in B(i) and 4 Ss in B(ii - iv)], or two-component decays with significantly lower long time constant (1/D) values. In two subjects, testing in C) with chair rotation brought back the long time constant component, but a control repeat of condition A did not. The full expression of OKAN decay is clearly pattern dependent, and most reliable after first exposure to the stimulus. (Supported by MRC and Winnipeg Health Sciences Centre Research Foundation.)

A UNIQUE SUBPOPULATION OF MEDIAL RECTUS MOTONEURONS AND ITS RELATIONSHIP WITH THE NUCLEUS OF EDINGER WESTPHAL. **J.T. Erichsen and C. Evinger. Dept. of Neurobiology & Behavior, SUNY, Stony Brook, NY 11794.**

A small subpopulation of medial rectus [MR] motoneurons in the pigeon (Columba livia) comprises an immunologically distinct and perhaps functionally unique class of motoneurons. Forming a dorsal crescent in the MR nucleus just medial to the nucleus of Edinger Westphal [nEW], these motoneurons [nMRd] share properties normally associated with neurons in nEW that innervate the ciliary ganglion.

Injections of HRP into the MR muscle label all ipsilateral MR motoneurons, including nMRd. The cells in nMRd, however, are generally smaller than the other MR motoneurons. Injections of a transneuronal tracer, fragment C of tetanus toxin [TTC], into the MR muscle result in direct retrograde labeling of the entire ipsilateral MR nucleus. In addition, the contralateral nMRd contains labeled terminals. This latter result suggests the possibility of an afferent shared by both nMRd's.

In common with cells in nEW, only developing nMRd neurons are transiently immunoreactive for enkephalin and substance P [SP] (Erichsen et al., 1982). In the adult, SP-positive neuropil is localized to nMRd as well as to nEW, but not to any of the other oculomotor nuclei. This result suggests that nMRd shares an input with the ipsilateral nEW. In addition, neuropil immunoreactive for vasoactive intestinal polypeptide [VIP] is found only in nMRd.

Our HRP and TTC results suggest that nMRd in the pigeon is similar to the C subdivision of the MR nucleus in the monkey, and thus may play a role in vergence. The pattern of immunoreactive staining for three peptides further indicates that nMRd, acting in concert with nEW neurons, might be involved in the near response. **Supported by grants EY04587 (JTE) and EY07391 (CE).**

BEHAVIOR OF IDENTIFIED EDINGER-WESTPHAL NEURONS DURING OCULAR ACCOMMODATION

P.D.R. Gamlin, Y. Zhang*, and L.E. Mays, Department of Physiological Optics, School of Optometry, and the Neurobiology Research Center, University of Alabama at Birmingham, Birmingham, AL. 35294.

The nucleus of Edinger-Westphal (EW) lies dorsal to the oculomotor nucleus and contains the parasympathetic preganglionic neurons that, by way of the oculomotor nerve and ciliary ganglion, innervate the ciliary muscle. Since sympathetic innervation has little influence on accommodation, EW neurons are responsible for controlling ocular accommodation. The goal of the present study was to investigate the behavior of identified EW neurons during accommodation in the primate.

Using a continuous recording infrared optometer, accommodation-related neurons were recorded in one trained rhesus monkey. Nine of these cells could be antidromically activated (current < 400 μA) by a stimulating electrode placed in the intracranial portion of the ipsilateral oculomotor nerve. In all cases antidromic activation was confirmed by collision. All EW neurons were located above the oculomotor nucleus within 1 mm of its dorsal extent. The activity of EW neurons is characterized by a low spontaneous activity (Mean = 11.7 spikes/sec; Range = 5-20 spikes/sec) and a mean relationship to accommodation of 9.4 spikes/sec per diopter (Range = 5-14 spikes/sec per diopter).

(Supported by NIH grants EY07558 to P.D.R.G., EY03463 to L.E.M., T32 EY07033 and CORE grant P30 EY03039).

CIRCADIAN ANALYSIS BY IMAGE PROCESSING: QUANTIFYING WHAT YOU SEE. W.N. Tapp and J. Heller*. Primate Neurobehav. Unit, VA Med. Ctr. and Dept. Neurosciences, New Jersey Med. Sch., East Orange, NJ 07018.

Circadian data is often presented in plots where the basic layout depicts one day's data as a single line with each successive day's data plotted on the line below. The level of the variable being studied has been encoded as pen strokes from chart recorders, darkness on gray scales and many other ingenious methods. While these plots can present circadian data in a format where the important details are easy to extract visually, it is often difficult to extract quantitative information that corresponds to the details seen in the plot. This is troublesome since the plots are the primary data in many cases and since it is often difficult to match the results of conventional time series analyses to the major landmarks on the plots. As an alternative, we have adapted image processing tools as a means of extracting quantitative information about visually important features, such as activity onsets and offsets. Further, we have developed error functions and their associated statistics to permit significance testing on data drawn from these analyses. After systematic and objective identification of image features (e.g. activity onset), period can be estimated by regression or other methods and phase can be determined directly. Supp by VA Res.

DIFFERENTIAL INVOLVEMENT OF SEROTONIN ACROSS THE SLEEP-WAKING CYCLE. RELATIONSHIP WITH HYPNOGENIC FACTORS. N.Chastrette@, R.Cespuglio@ and M.Jouvet@ (SPON:K.Jorgenson). Department of Experimental Medicine, INSERM U52, Cl.Bernard University, 8 Ave. Rockefeller, 69008 Lyon, FRANCE.

In order to clarify the involvement of serotonin (5-HT) in sleep, as well as its relationship to hypnogenic factors, we used differential pulse voltammetry to measure 5-hydroxyindoleacetic acid (5-HIAA) extracellular concentrations in rats chronically implanted for recording of sleep parameters. In the caudate nucleus, which contains 5-HT nerve endings, the voltammetric signal was maximum during waking state (W) and decreased during slow wave sleep (SWS) and paradoxical sleep (PS; -37%); in this nucleus, 5-HT release is thus diachronous to sleep. Conversely, in the cell bodies of raphe dorsalis nucleus, 5-HIAA concentrations were the lowest during W and markedly increased during SWS (+39%) and PS (+71%); this increase may reflect a dendritic release of 5-HT, synchronic to sleep; such a release could induce the auto-inhibition of the serotoninergic system, a necessary concomitant of sleep occurrence. Furthermore, corticotropin-like intermediate lobe peptide (CLIP, 10 ng/2 ul), a PS-inducing peptide, augmented this 5-HT release. Such an action could be one of the mechanisms through which hypnogenic factors exert their action.

REM SLEEP GENERATION BY CHOLINERGIC MICRO-STIMULATION AT DIFFERENT PONTINE TEGMENTUM SITES. M.L. Rodrigo-Angulo, I. de Andrés and F. Reinoso-Suárez. Depto. Morfología. F. Medicina. U.A.M. Madrid. Spain.

Injections of cholinomimetics in the brain stem have evidenciated that the effective sites for inducing REM sleep are situated in the pontine tegmentum (Badhoyan et al. 1984,87). However, there is a considerable controversy concerning the specific pontine structures mediating this effect. Given the diverse influence of pontine structures on sleep (De Andrés et al.1985) and the large volume of cholinomimetics injected in previous studies (200-500 nl), we have investigated the role of the locus of the injection by making carbachol microinjections (20-40 nl, 0.8-1.6 μg) in dorsal and ventral areas of oral pontine tegmentum (AP 0, -4) in adult cats. In order to label the stimulated area, HRP was injected together with carbachol.

Desynchronized EEG and atonia (median latency: 3 min.) occurred in all experiments. *Dorsal* injections produced wakefulness (open eyes, midriasis, increased respiration rate) during the initial period of atonia. Scarce or no PGO activity was observed and vertical eye movements were often present. After 10-20 min the cats started to move and active wakefulness prevailed during the next 4 hs.*Ventral* injections produced behavioral sleep simultaneously with atonia. PGO and REMs developed, although with some delay. Later, short periods of movements and arousal appeared and from the 2nd hour, some cats showed extended periods of quietness with the head up and still with PGOs.

The present results indicate that a contribution of dorsal pontine tegmentum to REM sleep atonia cannot be excluded but, the effective site to induce REM sleep by cholinomimetics is the pontine ventral tegmental area.

CORTISONE AND IMMUNIZATION ALTER THE SOMNOGENIC EFFECTS OF INFECTIOUS CHALLENGE IN RABBITS. L. A. Toth and J.M. Krueger. Depts. of Comparative Medicine and Physiology and Biophysics, Univ. Tennessee, Memphis, TN 38163.

Infectious challenge of rabbits produces time-dependent changes in sleep. To extend those observations, we examined the influence of prior immunization with killed Candida albicans (CA) (8 weekly IV inoculations) or 24-hr pretreatment with cortisone (40 mg/kg, i.m.) on sleep after IV inoculation with viable CA. CA alone enhanced slow-wave sleep (SWS) and delta wave amplitude (DWA) from 4-16 h after challenge, and later reduced both SWS and DWA. Rapid-eye-movement sleep (REMS) was inhibited for 48 h after challenge. Cortisone alone decreased DWA within 12 h and blocked the enhanced SWS and DWA induced by CA challenge. Immunization attenuated the CA-induced SWS increase. CA-induced attenuation of REMS occurred in both cortisone-treated and immunized rabbits. We conclude that somnogenic effects of infectious challenge can be differentially altered by manipulation of the host's immune system. Supported by NIH-NS-25378 and NS 26429.

VIP INDUCED REM SLEEP IS BLOCKED BY CLONIDINE AND ENHANCED BY ATROPINE IN PCPA PRETREATED CATS. A. Jiménez-Anguiano*, O. Prospéro-García and R. Drucker-Colín. Depto. Neurociencias, Instituto de Fisiología Celular, Universidad Nacional Autónoma de México, Apdo. Postal 70-600, México 04510, D.F. México.

Vasoactive Intestinal Polypeptide (VIP) may be a REM sleep factor. The purpose of this work is to study the interaction of VIP with acetylcholine (Ach) and norepinephrine (NE) to induce REM sleep. Adult cats (2.5-3.5 kg) implanted for standard sleep-wake cycle recordings were used in this study. A stainless steel cannula (22 gauge) was additionally implanted into the 4th ventricle to administer VIP or saline. All cats were treated with 2 i.p. injections of parachlorophenylaline (PCPA) to induce insomnia, then were divided into 6 groups (n=6) and additionally each 2 groups were treated with either: atropine (0.5 mg/kg i.p.); clonidine (0.01 mg/kg p.o.) or maintained only under PCPA effect. One hour after, each group of one drug received 50 ul of saline or 200 ng of VIP into the 4th ventricle. Cats were recorded during 11 hrs. Results showed that VIP induces REM sleep, but such an effect was abolished by clonidine but enhanced by atropine. Interestingly, atropine by itself induces REM sleep. These results suggest that VIP is interacting with Ach and NE to induce REM sleep in the PCPA insomniac cats.

THE SLEEP/WAKE ACTIVITY OF THALAMIC RETICULAR NEURONS IN THE RAT. G.A. Marks and H.P. Roffwarg. UT - Southwestern, Dallas, TX 75235-9171.

As a prelude to a study of the synaptic interactions between the thalamic reticular nucleus (TRN) and principal cells of the thalamic relay nuclei, spontaneous activity across the sleep/wake cycle of TRN cells was studied in unanesthetized, freely moving rats and compared to the activity of relay cells expressed respectively during the different states of arousal. TRN cell discharge was extracellularly monitored by a remotely driven etched tungsten electrode mounted to the animal's skull. Somatosensory responsive cells were identified by shocks to the medial lemniscus. The EEG, EMG and gross hippocampal activity served to identify state. Over 31 cells were examined and all were found to exhibit similar and pronounced changes in discharge pattern across states. Most of SW sleep is characterized by rhythmic trains of high rate bursting followed by pauses. At the transition from SW sleep to all REM sleep periods and many spontaneous arousals, activity assumes a tonic pattern with a higher mean discharge rate. Within the REM period pattern remains tonic, though more bursty, at a reduced mean rate. Upon arousal, there is either a low rate single spike pattern or complete cessation of firing. During waking, however, with specific somatosensory stimulation the cell can fire at its highest rate. In as much as the activity of TRN cells is not the reciprocal of that exhibited by thalamic relay cells across the sleep/wake cycle, these results do not support the concept of TRN mediation of sleep/wake activity in relay cells by inhibition and disinhibition. It does not, however, rule out partial control of this behavior. In the future it will be necessary to determine what factors modulate the action of TRN Gaba release as well as to determine the influence of other afferents to thalamic relay cells.

100.7

SLEEP AND RESPIRATORY PATTERNS IN LEAN AND OBESE ZUCKER RATS. K.A.Burgess* and S.DeMesquita (SPON:M.A Simmons). Dept. of Physiology Marshall Univ. School of Medicine, Huntington, WV 25755

Obese Zucker rats have been found to have altered levels of dopamine, serotonin and norepinephrine when compared to their lean litter mates (Orosco, M. et al. Physiol Behav 36:853, 1986). This study was undertaken to determine what effect the altered neuroendocrine levels would have on the Zucker sleep and respiration pattern. Nine lean (475±6g, mean±SEM) and six obese (743±20g) Zucker rats, instrumented with EEG and EMG electrodes; fitted with chest pneumographs were allowed to sleep for 4hr on five consecutive days

The obese rats had a significantly shorter latency to both Rapid Eye Movement (REM) and Non-REM sleep. Although there was no difference in total sleep time or REM sleep percent between the lean and obese rats, the latter had significantly ($p<0.05$) more frequent and shorter Wake and Non-REM periods. The obese rats had a significantly ($p<0.05$) faster breathing rate in Non-REM sleep preceeding REM sleep.

	obese	lean	signif.
Non-REM Latency(min)	13.9±1.9	50.9±5.2	p<0.05
REM Latency(min)	24.4±3.6	57.7±9.7	p<0.01

The obese Zucker rat had a more fragmented sleep pattern and an earlier sleep onset than the lean Zucker rat.

100.8

SEROTONINERGIC RECEPTORS BLOCKADE ENHANCES SLOW WAVE SLEEP IN PCPA PRE-TREATED CATS. O. Prospéro-García, and A. Jiménez-Anguiano*. Depto. de Neurociencias, Instituto de Fisiología Celular. Universidad Nacional Autónoma de México. Apdo. Postal 70-600, México, 04510, D.F. México.

The serotoninergic antagonists Ritanserin (5-HT_2 blocker) and Piremperone (5-HT unspecific blocker) induce slow wave sleep (SWS) in animals and humans. The purpose of this study is to test their effect on the sleep-wake cycle of cats with 5-HT depleted by parachlorophenylalanine (PCPA). Two groups A and B (n=15) of cats implanted for sleep-wake cycle recordings were used. Group B received a PCPA pre-treatment (2 i.p. injections of 400 mg/kg separated by 24 h.); whereas group A had no pre-treatment. Each group was subdivided (n=5) in 3 groups A1 and B1 that received piremperone (1 mg/kg p.o.); A2 and B2 that received ritanserin, (10 mg/kg p.o.), and A3 and B3 that received an empty capsule. Results showed that in group A, both drugs increase wakefulness and have a tendency to increase SWS II, whereas REM sleep is strongly reduced. In group B, both drugs reduced the wakefulness induced by PCPA enhancing SWS I and II. Piremperone preferentially increased SWS I whereas ritanserin SWS II. As for REM sleep, only piremperone enhanced it. These results suggest that serotoninergic receptors are differentially involved in the modulation of the different SWS phases.

100.9

EFFECTS ON SLEEP OF ADENOSINE, ADENOSINE ANALOGS, TRIAZOLAM, PENTOBARBITAL AND GABA MICROINJECTED INTO THE PREOPTIC AREA OF RATS. **S.R.Ticho and M. Radulovacki. Dept. of Pharmacology, University of Illinois Coll. of Medicine, Chicago, IL 60612.**

We have examined the effects on sleep of bilateral microinjections of adenosine (ADO), ADO analogs, and drugs effecting the GABA receptor complex in the preoptic area of the rat. The cannulae placements and the effects of the drugs on the sleep-wake cycle were analysed by a two-way ANOVA. EEG recordings were examined during a six hour period of the light cycle. Rats treated with a selective ADO A1 receptor agonist (CPA, 6.25 nmoles) had no changes in the sleep-wake cycle as compared to controls. However, microinjection of ADO (12.5 nmoles) and NECA, 0.5 nmoles, (an ADO A1/A2 receptor agonist) significantly increased deep slow wave sleep (SWS2) by 22% ($p<0.05$) and 28% ($p<0.05$) respectively. Furthermore, NECA caused a significant increase in total sleep (15%, $p<0.05$). In contrast, no changes in sleep parameters were observed with the drugs effecting the GABA receptor complex: Triazolam (0.125 ug), pentobarbital (3 nmoles), and GABA (250 nmoles). Although, we observed a 10%, 26%, and 13%, respectively, increase in light slow wave sleep (SWS1), this increase did not attain statistical significance.

EVOKED PONTO-GENICULO-OCCIPITAL (PGO) WAVES AND ORIENTING. W.A. Ball*, L.D. Sanford*, A.R. Morrison, R.J. Ross, W.H. Hunt*, G.L.Mann*. Lab. of Anatomy, Sch. of Vet. Med., U. of Pa., Phila., Pa. 19104.

PGO waves in cats' lateral geniculate bodies (LGB) occur spontaneously during paradoxical sleep (PS). In waking (W) tones produced head orienting and evoked PGO-like waves (PGO_E), perhaps modifying visual processing in the LGB. Orienting habituates readily and is inhibited during sleep; habituation of PGO_E is less well studied. We evaluated whether: 1) overt orienting and PGO_E covary; 2) a change of state to slow wave sleep (SWS) or PS inhibits behavior and PGO_E after exposure to tones in W. Nine blocks of 48 tones (90 ms, 90 dB, 1000 Hz, 2s ISI) were given to 6 cats in W on two days a week apart. Then, dishabituation tones were presented in SWS or PS on alternate weeks. PGO_E were recorded in the LGB on 45% of W trials, but overt behavior rapidly declined and occurred on fewer than 23% of trials. In PS PGO_E amplitude and probability increased despite 442 W trials; both declined significantly across the PS episode. SWS showed less recovery. Thus, behavior shows rapid habituation in W and inhibition in PS, while PGO_E are consistent in W and prominent in PS. The latter is consistent with the idea that PGO waves are indicators of the activation of alerting mechanisms. Supported by MH-42903, MH-09584, MH-14654.

TOWARD A PATHOPHYSIOLOGICAL MODEL OF NARCOLEPSY-CATAPLEXY. J. Quattrochi, J. Macklis, A. Mamelak*, J. Feldman*, and J.A. Hobson. Laboratory of Neurophysiology and Department of Neurology, Harvard Medical School, Boston, MA 02115.

To help understand the mechanism by which neuronal populations are organized so as to induce a cataplectic behavioral state, microinjections of carbachol-fluorescent microspheres (13μg/250nl) were performed at 4 sites in the anterodorsal pons in 2 unanesthetized adult male cats via cannulae inserted through stereotaxically implanted guide tubes. Polygraphic and behavioral data were collected using surgically implanted EMG, EOG, subcortical PGO, and EEG electrodes. Cataplectic behavior was assessed by monitoring the onset and time course of atonia in the EMG and desychronized patterns in the EEG. Results indicate a mean latency of 1.5±0.3 min. to onset of cataplexy with a mean duration of 55±2.7 min. Histological verification of cannula placement identified injection sites to be within the locus coeruleus α - a nuclear region associated with REM sleep atonia. It is now possible to map and define retrogradely fluorescent labeled neurons projecting to target sites, thereby ascertaining the neuronal network involved in the induction of this cataplectic behavioral state. These findings directly inform conceptualization of the human disease and may provide a model for understanding the pathogenesis of narcolepsy-cataplexy behavior.

THE DIMENSIONALITY OF EEG-RHYTHMS DURING SLEEP J. ROESCHKE*, H. SCHWARZE*, J.B. ALDENHOFF, Dept. of Psychiatry, University of Mainz, F.R.G.

According to Rechtschaffen and Kales five different states of EEG-activity can be defined. Conventional approaches of system theory have been useful for analyzing the brain waves. However, the highly nonlinear character of the brain's dynamic behaviour suggests to use phase space analysis: Every instantaneous functional state of the brain, such as represented by the EEG-signal, corresponds to one point in the phase space. The sequence of such states over the time scale defines a curve called a trajectory. As time increases the trajectory either penetrates the entire phase space or it converges to a lower dimensional subset called an attractor which can be identified in some cases with properties of deterministic chaos. Following a proposal of Grassberger and Procaccia (Physica D 9:183, 1983) we evaluated the (correlation-) dimension D_2 of the attractor. D_2 is a measure for the complexity and an estimation of the information content of the EEG. We investigated ten healthy male probands (20-25 years old) and find different values for D_2 between 4.50 (REM) and 7.10 (stage 1). This means, that the unpredictability of the brain waves might be caused by a finite dimensional dynamical system. The degrees of freedom during sleep vary within a wide range and are highly correlated to clinical observations and physiological approaches of information processing.

GENDER-DIFFERENCES IN CIRCADIAN TEMPERATURE RHYTHMS OF HEALTHY ELDERLY SUBJECTS. M.V. Vitiello*, P.N. Prinz, L.H. Larsen* and A.L. Marks* (SPON: A.C.N. Chen). Dept. of Psychiatry, Univ. of Washington and American Lake VAMC, Seattle, WA 98195.

Previously we and others have reported age-related diminished amplitudes in circadian core body temperature rhythms primarily as a result of elevated temperature nadir. These reports based on males only have not taken into account possible gender effects on temperature. 14 female (67.5±8.5 yrs, Mean±SD) and 12 male (65.0±5.3 yrs) healthy aged normal subjects were studied. Core body temperature of each subject was monitored continuously for ≈36 hours using a Vitalog/Yellowsprings system during a 72 hour Clinical Research Center stay. Data was edited to remove artifacts and entered into a cosinor analysis. Group analyses of cosinor-derived measures revealed significantly higher 24 hour mean temperature (36.9±.15 vs. 36.8±.08 °C; F=4.3, p<.05) and a non significant trend toward a higher amplitude (.9±.10 vs. .84±.09; F=3.7, p=.06) in females compared to males. No significant difference in group acrophases was observed. Analyses of raw (non-cosinor) temperature showed that females were warmer than males at mid-day but were similar at other times including nadir. We conclude that gender effects are not present near the circadian nadir. It is at the nadir when age effects on temperature are most notable, and are most likely to interact with sleep quality.

CIRCADIAN RHYTHMS IN CARDIOVASCULAR FUNCTION DURING TOTAL SLEEP DEPRIVATION J.B. Fertig, D.M. Penetar*, and P.A. Newhouse*. Walter Reed Army Institute of Research, Washington, D.C., 20307

In an effort to adequately characterize circadian changes in cardiovascular activity that occur during Total Sleep Deprivation (TSD) we studied 91 healthy males during 48 hours of TSD. Measurements of heart rate (HR), diastolic (DBP) and systolic (SBP) blood pressure were taken every two hours throughout the 48 hours of TSD. Time series data for each of these measures were subjected to linear regression analysis. Following extraction of linear trends, residuals were submitted to rhythmic analysis using a complex demodulation technique. Although significant linear trends were found for HR (increasing) and DBP (decreasing) the changes were of small magnitude and accounted for a relatively minor portion of the variance. Circadian rhythms, however, accounted for 39% of the variance in HR, 72% in DBP and 35% in SBP. Further complex demodulation of HR and SBP data also revealed higher frequency cycles accounting for significant portions of the variance in those measures. Circadian rhythms for HR and DBP were somewhat altered by 48 hours of TSD and showed increased peak amplitudes and moderately decreased periods during the second 24 hour cycle. These results suggest that sleep deprivation effects on cardiovascular functioning can best be described by rhythmic analysis and that the overall effect of TSD is in the direction of amplifying circadian rhythms and reducing circadian periods.

CIRCADIAN RHYTHM AND SLEEP DEPRIVATION EFFECTS ON COGNITIVE PERFORMANCE D.M. Penetar*, D.R. Thorne*, J.B. Fertig, and H.C. Sing* (SPON: Joyce C. Cochran). Walter Reed Army Institute of Research, Washington, D.C. 20307

Four cognitive tasks from a computerized performance battery were studied during 48 hours of Total Sleep Deprivation (TSD) and were analyzed for those changes due to TSD and those due to circadian rhythms. Normal male subjects (N=91) participated in studies where measurements of reaction time, sustained attention, and spatial and logical reasoning were made every 2 hours. Measurements of each task included accuracy of performance, speed (responses/time) and throughput (% correct/averaged reaction time). Time series data for each of these measures were subjected to linear regression analysis. Following extraction of linear trends, residuals were submitted to rhythmic analysis using a complex demodulation technique. Accuracy on the spatial and logical reasoning tasks was not affected by TSD. Accuracy on the sustained attention and reaction time tasks, however, was affected by TSD. Circadian rhythms accounted for a large portion of the variance in all tasks. The relative amplitude of the circadian component was smallest for the spatial rotation task with the other tasks having similar amplitudes. For all tasks, significant decreases in speed were found. Throughput measures largely reflected the changes in speed. Results indicate that accuracy is maintained at the expense of speed for complex cognitive tasks and that performance on the logical reasoning, sustained attention, and reaction time tasks are influenced strongly by circadian factors.

THE EFFECTS OF M1 AND M2 MUSCARINIC RECEPTOR AGONISTS AND ANTAGONISTS ON REM SLEEP GENERATION Javier Velazquez-Moctezuma, J. C. Gillin and P. Shiromani. Dept Psychiatry, San Diego VAMC and UCSD, La Jolla, CA 92161 and UAM-Iztapalapa, Mexico (JVM)

Specific agonists and antagonists for muscarinic receptor subtypes were infused into the medial pontine reticular formation of freely moving cats and sleep was recorded for five hours. M2 muscarinic receptor agonists, *oxotremorine-M* and *cis-methyl-dioxolane*, significantly increased REM sleep, decreased the percentage of slow wave sleep and did not affect wakefulness, when compared to Ringer's control. These effects were similar to that obtained with *carbachol*, a mixed M1 and M2 agonist. The M1 agonist *McN-A-343* did not show any effect on the sleep-wake percentage. The powerful effects of *cis-methyl-dioxolane* were blocked by *atropine*. The M1 antagonist *pirenzepine* did not block the effects of *cis-methyl-dioxolane*. Preliminary results using *gallamine*, a neuromuscular nicotine blocker which is also an M2 receptor antagonist, indicated that it blocked the effects of dioxolane in 3 of 7 trials.

These results strongly indicate that REM sleep generation by cholinergic stimulation in the medial pontine reticular formation is mediated by M2 muscarinic receptors. Now pharmacological treatments can be targeted at the M2 receptor to block the inadvertent intrusions of REM sleep in diseases such as narcolepsy.

EFFECTS OF THE NEW D-1 DOPAMINE RECEPTOR ANTAGONIST SCH 39166 ON THE SLEEP-WAKING CYCLE IN THE RAT. M. Trampus *, A. Monopoli * and E. Ongini. Research Labs, Essex Italia (Subsidiary of Schering-Plough), I-20060 Comazzo, Milan, Italy.

Sedation is an undesired effect of neuroleptic therapy. This action seems to depend upon concomitant blockade of both D-1 and D-2 receptor subtypes (Neuropharmacology, 27: 799, 1988). Sedation is best evaluated by measuring electroencephalographic (EEG) activity and drug effects on stages of the sleep-waking cycle. To investigate whether selective blockade of D-1 receptors induces similar effects, we studied the new selective D-1 antagonist, SCH 39166 (J. Pharmacol. exp. Ther., 247: 1093, 1988) in rats chronically implanted for the recording of the EEG. For comparison, SCH 23390 and haloperidol were used. Haloperidol (0.1-3 mg/kg po) typically induced a synchronization of the EEG, with a dose-dependent increase of slow-wave sleep. SCH 23390 (0.03-0.3 mg/kg sc) and SCH 39166 (3-30 mg/kg po) did not modify significantly the various features of the sleep-waking cycle. The data suggest that the new D-1 antagonist SCH 39166, which is active orally, may be devoid of sedation liability at clinically useful doses.

IS PERIODIC BREATHING "AROUSAL-STATE" DEPENDENT? W. Milsom, B. Krilowicz*, D. Grahn*, C. Radeke* and H. Heller*, Dept. of Zoology, Univ. of British Columbia, Vancouver, B.C. and Dept. of Biology, Stanford Univ., Stanford CA.

Recordings of the EEG, EMG, ECG, ventilation and the discharge from respiratory neurons in the ventral medullary respiratory center (nucleus retroambiguous, made from chronically implanted stainless steel microwire (25 micron) electrodes), were obtained from unanesthetized, unrestrained golden-mantled ground squirrels. Recordings were obtained from animals during wakefulness, slow-wave sleep, and rapid eye movement sleep as well as during entrance into, and arousal from hibernation. While many neurons with respiratory related discharge showed little state dependence, recruitment/derecruitment of other respiratory neurons was often seen during changes in arousal state and was commonly associated with changes in the repiratory pattern. These changes included waxing and waning of ventilation during sleep and entrance into and arousal from hibernation, and Cheyne-Stokes type breathing during deep hibernation (which is believed to be an extension of slow-wave sleep). Taken together, these data suggest that state dependent changes in the activity of the central respiratory neurons, rather than changes in peripheral inputs to the respiratory centers, underlie the genesis of periodic breathing during both sleep and hibernation. LATE MATURATIONAL DECLINE IN 0-3 HZ EEG AMPLITUDE DURING SLEEP: A REFLECTION OF SYNAPTIC ELIMINATION? I. Feinberg, MD, J. D. March*#, K. Flach*, T. Maloney*, W.-J. Chern*, MA and F. Travis*, PhD, VA Medical Center, Martinez, CA and University of California at Davis; #Delta Software, San Francisco, CA

We used period-amplitude analysis (1) to measure average sample amplitude (integrated amplitude/time in band) over the first 6 hours of sleep in 45 children (CH), 23 young adults (YA) and 36 normal elderly (NE) with mean ages 11.7, 23.6 and 71.9 yrs resp. ASA declined by 50% between CH and YA (38.3 vs 19.0, $p<.0001$) and by 26% between YA and NE (19.0 vs 14.0 $p<.0001$) (means are uV x 10^{-3}.) Thus, the absolute amplitude decline over twelve years of maturation was almost four times that produced by almost 50 yrs of aging. These maturational data confirm previous findings with hand measurement of EEG (see (2)). The 50% decline between CH and YA groups parallels the 50% reduction recently found for cortical metabolic rate over the same age range (3). Taken together, these new metabolic and EEG findings strongly support the hypothesis (2) that late, pervasive maturational changes take place in the human cortex as a result of the (?programmed) synaptic elimination discovered by Huttenlocher (4). A fault in these widespread regressive events may cause or permit the expression of the "functional" psychoses (notably schizophrenia); these subtle brain disorders rarely occur in typical form before puberty. Lastly, the sleep EEG may provide a non-invasive tool for tracking the maturational process longitudinally; deviations from the normal rate of decline may indicate vulnerability to mental disorder.(1) I Feinberg, et al. EEG Clin Neurophys, 1978:44,202. (2) I Feinberg, J Psy Res 1982/83:17,319. (3) HT Chugani, et al Ann Neurol 1987:22,487. (4) PR Huttenlocher, Br Res, 1979: 163, 195.

HUMAN BEHAVIORAL NEUROBIOLOGY: MEMORY AND LANGUAGE

101.1

COGNITVE SKILL LEARNING IN AMNESICS. E.A. Phelps*, W. Hirst*, M.K. Johnson*, B.T. Volpe and (Spon. F. McDowell). Dept.of Psych., Princeton Univ., Princeton, N.J. 08544, Dept. of Neurology, Cornell Univ. Medical School, The Burke Rehabilitation Ctr., White Plains, N.Y. 10605.

Evidence for skill learning in amnesics has been important for theories of amnesia (Schacter, 1988; Squire, 1987) as well useful for understanding normal skill learning (Anderson, 1983). However, there are very few instances of amnesics learning purely cognitive skills, that is, skills without a perceptual or motor component. The present work extends the domain of preserved functioning in amnesics to certain complex cognitive skills. Specifically, it demonstrates that amnesics can learn to use a rule system based on two linear equations. This is similar to the rule system Broadbent, Fitzgerald and Broadbent (1986) used to demonstrate that normals can learn rule systems in the absence of explicit knowledge of the rules. This finding is contrasted with findings of impaired cognitive skill learning in amnesics and an additional learning condition is added to demonstrate some specific components of cognitive skills that may impair performance. When amnesics are required to form relations between learning exemplars that are not simultaneously available they are no longer able to learn the cognitive skill. This method of examining the processes involved in different cognitive skills is a new approach common to both Johnson's Multiple Entry Modular Memory System (1983, 1988) and Hirst's Coherence Model of Amnesia (1988). The present work demonstrates that the use of this approach may help resolve some of the discrepancies in the skill learning literature.

101.2

FRONTAL LOBE AND VISUOSPATIAL MEMORY FUNCTION IN KORSAKOFF AND NON-KORSAKOFF ALCOHOLICS. E.M. Joyce* and T.W. Robbins.+(SPON: P.Dean). Institute of Psychiatry, London SE5 8AF, U.K and +Dept. of Expt. Psychology, Univ. of Cambridge, U.K.

Groups of subjects with the alcoholic Korsakoff syndrome (AKS), abstinent non-Korsakoff alcoholics (NKA) and age- and IQ-matched controls were compared on computerised tests of memory and frontal lobe function. Using a delayed matching-to-sample procedure (delays 0-16s) the NKA group showed a monotonic delay-dependent impairment in choice accuracy, with no deficit at 0s. By contrast, the AKS group was impaired at 0s and impaired to the same extent as the NKA group at 16s. In a test of spatial working memory the AKS group was significantly worse than the NKA group, which in turn was impaired relative to controls. Despite their mnemonic deficit, the NKA subjects were as accurate as controls on a test of planning (Tower of London), but were impaired at visual search and attentional set-shifting, to the same degree as the AKS group. The AKS group, however, showed some impairment in the test of planning, in terms of accuracy and thinking time. The results are considered in terms of differing degrees of diencephalic and frontal lobe pathology in the two test groups.

101.3

SPATIAL MEMORY PERFORMANCE IN TWO YEAR OLD HUMAN INFANTS. P. Mangan* and L. Nadel (SPON: A. W. Kaszniak). Dept. of Psychology, Univ. Arizona., Tucson, AZ 85721.

The maturation of the hippocampal formation has been implicated in the ontogeny of spatial learning in the rat. Prior to weaning rats perform in the water maze task at the level of adult rats with hippocampal lesions; several days after weaning they perform at the level of intact adult rats. Similar results should be obtained if human infants are tested on spatial tasks at comparable ages.

The hippocampal formation appears to mature between 18 and 24 months in humans. Thus, by 2 years of age the human infant should be able to perform tasks involving hippocampal-dependent spatial memory tasks. Recent work with infants performing 8-arm maze tasks and search tasks in the natural environment have not shown this; infants less than 26 months performed at or near chance levels on these tasks.

The present study further evaluated performance on spatial memory tasks of children aged 24 or 36 months. They were tested in a circular room and required to locate a toy hidden under one of eight evenly spaced identical covers. Subjects had to use cues located on the room walls, placed so as to not be contiguous with any of the eight possible targets. During the test trial subjects entered the room at a point 180° from that used during training. Both groups limited their search to the correct quadrant of the room, indicating that they recognized the location of the hidden toy.

We conclude that 24-month old infants can perform tasks requiring spatial memory skills when memory for only a single location is involved. Poor results obtained in the 8-arm maze could be due to the increased memory load of that task.

101.4

CORTICAL LESIONS DISSOCIATE SHORT AND LONG TERM COMPONENTS OF REPETITION PRIMING. Z.A.Kersteen-Tucker* & R.T. Knight (SPON: K. Sigvardt). Dept. of Neurology, Univ. of California, Davis, VAMC, Martinez, CA 94553.

Presentation of a word facilitates the subsequent identification of that word. This shortening of response latency has two components. A short term component is observed when two words are presented sequentially. The long term component is observed when different stimuli are interposed between the first and second presentation and results in a lesser but significant degree of response facilitation. We investigated the repetition effect in patients with unilateral lesions in dorsolateral prefrontal cortex (PFCx, N=7, Mean lesion volume=41 cc.), in temporal-parietal cortex (T-PCx, N=6, Mean lesion volume=50 cc.) and in age matched controls (N=7). In comparison to controls and T-PCx patients, PFCx patients showed a selective impairment in short term priming (Controls=102 ms, T-PCx=124 ms, PFCx=57 ms) In contrast to the short term priming effect, T-PCx patients exhibited a complete absence of long term facilitation in comparison to controls and PFCx patients (Controls=51 ms, PFCx= 45 ms, T-PCx=2 ms). The dissociation of short and long term priming by brain lesions supports the view that priming is not a unitary phenomena from either a behavioral or neuroanatomical perspective. (Supported by NIH grant NS21135).

101.5

EFFECTS OF SCOPOLAMINE ON THE MODULATION OF EVENT RELATED BRAIN POTENTIALS BY WORD REPETITION. M.D.Rugg*,D.D.Potter*,C.D.Pickles* & R.C.Roberts*. (SPON: Brain Research Association). Wellcome Brain Research Group, Dept Psychol, Univ St Andrews, and Dept Med, Univ Dundee, U.K.

The effects of scopolamine on event-related potentials (ERPs) were studied in three visual tasks. The incidental memory task required the detection of non-words interspersed in a series of words, some of which were repeats of previous items. The recognition task required subjects to discriminate words shown for the first or second time. The oddball task required a response to a low probability target letter occurring in a series of non-targets. 12 subjects received an IV injection of scopolamine (5.7 µg/Kg) before one session, and saline before another.

Scopolamine attenuated the positive-going ERP modulation evoked by repeated words in the incidental task. It had no effect on the size of either the positive shift evoked by repeated words in the recognition task, or the P300 component to targets in the oddball task.

The ERP word repetition effect in the incidental task may be more dependent upon cholinergic systems than either the apparently similar effect in the recognition task, or the 'oddball' P300.

101.6

COMPREHENSION AND RETENTION OF SCRAMBLED AND REGULAR TEXTS BY PATIENTS WITH UNILATERAL CORTICAL EXCISIONS. V. Frisk* (SPON: M. Moscovitch). Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada H3A 2B4.

Damage to the anterior temporal region in the dominant left hemisphere impairs the ability to remember stories (Milner, 1958, 1967). To investigate whether such an impairment results from difficulty in integrating information across sentences, patients with unilateral cortical excisions (28 left temporal [LT], 24 right temporal [RT], 6 left frontal [LF], 11 right frontal [RF]) and 13 normal control (NC) subjects listened to four stories, matched for difficulty. In two passages sentence order was scrambled so that textual continuity was disrupted. Immediately after presentation, subjects completed a free recall and answered questions. To rule out deficient comprehension as a reason for poor performance on the memory task, subjects later answered the same questions again, using the stories for reference. Retention of the stories by the LT group was expected to be impaired relative to that of other subject groups, but the disruption of textual continuity was anticipated to have a lesser effect on their recall. No group differences were expected in the ability to answer the questions when using the stories for reference. The LT group remembered substantially less of the stories than did the NC or RF groups, irrespective of the type of story. Only the LF group was impaired in locating the correct answers to the questions when using the stories for reference. These findings suggest that left temporal-lobe lesions do not affect the ability to integrate information across sentences, but do influence the amount of information retained. The impaired performance by the LF group is interpreted as another indication of difficulty in generating appropriate responses and in verifying the accuracy of these responses.

101.7

PLANNING AND SPATIAL WORKING MEMORY FOLLOWING FRONTAL LOBE LESIONS IN MAN. A.M.Owen,* J.J.Downes,* B.J.Sahakian,* C.E.Polkey,*† T.W.Robbins (SPON: B.J.Sahakian). Department of Experimental Psychology, University of Cambridge, Cambridge, CB2 3EB, U.K. †Institute of Psychiatry, University of London, London, SE5 8AF.

Thirty patients with unilateral or bilateral frontal lobe excisions primarily for epilepsy, were compared with age and IQ matched controls on a computerised battery of tests of spatial working memory and planning. A test of spatial short term memory capacity revealed no significant impairment in the patients' ability to execute a given sequence of visuo-spatial moves. In contrast, a computerised paradigm, designed to assess spatial working memory capacity, revealed significant impairments in the patient group in both possible types of search errors.

Higher level planning function was also investigated, using a test based on the 'Tower of London' problem. Frontal lobe cases required more moves to complete the problem and a yoked control condition revealed increased motor initiation times in these patients. Taking both of these factors into consideration, initial thinking (planning) time was unimpaired in the patient group although the subsequent thinking time, following the first move, was significantly prolonged. These data are compared to previous findings from patients with idiopathic Parkinson's Disease and will be discussed in terms of an impairment of higher cognitive functioning following frontal lobe damage.

101.8

THE PERFORMANCE OF AUTISTIC ADULTS ON TESTS SENSITIVE TO HIPPOCAMPAL AND PREFRONTAL (PF) DAMAGE. M. Rasmussen† E. Courchesne (SPON: R. Johnson). Neuropsychology Research Laboratory, Children's Hospital Research Center, 8001 Frost St., San Diego, CA 92123.

On the basis of behavioral findings, Boucher & Warrington (1976) and DeLong (1978) drew attention to a hippocampal theory of autism. However, evidence from anatomical studies has been mixed (Hauser, et al., 1975; Bauman & Kemper, 1985; 1988; Creasey, et al., (1986). Damasio & Mauer (1978) implicated the PF system in autism and Rumsey & Hamburger (1988) concluded that problem-solving deficits in autism are consistent with PF system dysfunction. There is neurophysiological evidence that the fronto-central P300 is reduced in amplitude in autistic persons (Courchesne, et al., 1984), yet no anatomical evidence of PF involvement has been found (Williams, et al., 1980; Bauman, et al., 1985; Coleman, et al., 1985).

As part of a neuropsychological/neurophysiological investigation of autism, a battery of behavioral tests found to be differentially sensitive to hippocampal and/or PF damage was used. We report here, the results from 4 high-functioning autistic adults matched to controls on the basis of age and Performance IQ.

The autistic group was most impaired on tests of spatial memory. They were less impaired on conditional associative learning and unimpaired on price estimation and recency discrimination. A similar pattern of impairment has been reported for people with hippocampal damage (Milner, 1985).

101.9

MAGNETIC FIELDS ASSOCIATED WITH SEMANTICALLY INCONGRUOUS SENTENCES. D. L. Arthur, A. Schmidt*[1], M. Kutas*[2] and E. Flynn, Biophysics Group, Los Alamos National Laboratory, Los Alamos, NM 87545; [1] Westinghouse, Pittsburgh, PA; [2] Dept. of Neurosciences, Univ. of Calif.-San Diego, La Jolla, CA.

Kutas and Hillyard (1980) reported a centro-parietal negative-going ERP component that occurred approximately 400 ms after subjects read sentences presented one word at a time which ended in a semantically anomalous fashion. Subsequent studies found that this "N4" component is slightly larger when recorded over the right compared to the left hemisphere. The present study is aimed at defining the magnetic field pattern which occurs over left and right hemispheres in a typical "N4" paradigm.

Subjects were right-handed adults with no left-handed relatives in their immediate families. Simultaneous magnetic and electrical data were recorded from various positions over left and right temporal and temporo-parietal areas; additional electrical data were also recorded from midline sites. Thirty congruent and thirty incongruent sentences were presented one word at a time at each neuromagnetic recording location. The subject's task was to read the sentences. To determine if a N4 was present, the responses to the last words of the congruent and incongruent words were compared. This difference was then compared to the electrical N4.

Preliminary recordings demonstrate a magnetic N4 response within the same latency range as the electrical N4. Complete field maps will be presented.

101.10

MAGNETOENCEPHALOGRAPHIC LOCALIZATION OF LANGUAGE CORTEX ADJACENT TO A CEREBRAL ARTERIOVENOUS MALFORMATION. R.A. Johnson[1], J. Beatty[1], N.A. Martin*[3], M.L. Collaer*[1], S. Jordan*[2], F. Vinuela*[4], J. Dion*[4], and D. Becker[3]. Departments of Psychology[1] and Neurology[2], Divisions of Neurosurgery[3] and Neuroradiology[4], UCLA, Los Angeles, CA 90024.

A case report is presented in which magnetoencephalography (MEG) was used to preoperatively and non-invasively map the intracortical source of speech-receptive cortex in RS, a 25 year old right handed male with a dominant left temporal lobe arteriovenous malformation (AVM). The speech-evoked magnetic field was analysed at 36 positions over the left hemisphere in response to presentations of the CV syllables /da/ and /ga/. The 250 msec duration syllables were generated by the DECtalk speech synthesizer and delivered binaurally with an interstimulus interval of 1.5 seconds.

A topographical map of the magnetic component 110 msec after stimulus onset, which was negative going at the vertex in concurrent electrical recordings, was congruent with a superficial cortical neuronal current source. This source was displaced from that usually observed in normals to tonal or click stimuli, being superior to the probable location of auditory cortex, and superior and anterior to the probable location of Wernicke's area as conventionally described.

The MEG results were in accord with the determination of position of language cortex as assessed by direct electrical stimulation of the cortex during surgery under local anesthesia. MEG and exposed brain stimulation sites were coordinated by cranial measurements and angiography. Investigations such as this, that compare MEG findings with those from established clinical procedures, are an essential step in determining the physiological and anatomical utility of magnetoencephalography. (Research supported by NIMH MH-37430-07 and NSF BBS-871057)

101.11

DISTINCT NEURAL SYSTEMS FOR LEXICAL AND EPISODIC REPRESENTATIONS OF WORDS. H.J. Neville, M.E. Pratarelli*, K.I. Forster*. The Salk Institute, La Jolla, CA 92037, The University of Arizona.

We investigated the hypothesis that specialized, linguistic or "lexical" representations of words exist and can be distinguished from general, non-linguistic or "episodic" representations of words. Adults rapidly decided whether a string of letters ("target") was or was not a word. On one half of the trials the targets were preceded by identity "primes" e.g. sun - SUN, gif - GIF, or by semantically related primes e.g. cat - DOG. Event-related brain potentials (ERPs) and behavior were examined for evidence that distinct patterns of priming occurred when episodic memory systems were normally present and subjects (N=10) were aware of the primes, as contrasted to when episodic traces were minimized by a masking procedure that rendered subjects (N=10) unaware of the primes. The results for the unmasked presentation displayed typical behavioral and ERP effects for semantic priming and for word and non-word identity priming. The ERP effect consisted of a negative peak maximal at 400 msec (N400) that onset at 300 msec, was 300 msec in duration and displayed a centro-posterior distribution. Remarkably, under masked conditions there was also a consistent ERP effect of semantic priming. However this onset at 200 msec, was 100 msec in duration and displayed a centro-anterior distribution. Moreover whereas both experiments provided evidence of identity priming for words, nonwords were primed only in the unmasked version. These data raise the hypotheses that the N400 indexes access to or decisions about general, episodic representations of words and nonwords. In contrast, we propose that the early negativity from 200-300 msec indexes access to a specialized representation of a word in a lexicon that does not include non-words. Most generally these data suggest that there exist separate lexical and episodic representation of words that are organized within non-identical brain systems.

COMPREHENSION OF COREFERENCE IN ALZHEIMER'S DISEASE. S.T. Smith, (SPON: C.R. Hamilton). Neurolinguistics Laboratory, Massachusetts General Hospital, Boston, MA 02114.

A two-choice picture verification test (PVT) was administered to Alzheimer's patients (AD) and age-matched controls to examine comprehension of sentences with forms of coreference. Correct interpretation of coreference between lexical items requires a complex system of grammatical rules, and thus provides a test for retention of complex aspects of syntactic ability. Subjects heard sentences that contained reflexive pronouns and reciprocals. Simple and complex sentences were tested to examine the effect of complexity. Good performance on simple sentences would suggest a processing limitation, not a syntactic deficit. The effect of task complexity was examined with a four-choice PVT in some subjects.

AD patients and controls performed nearly perfectly on simple sentences. On complex sentences, AD patients made more errors than controls. Their pattern of errors, however, was similar to that of controls. Task complexity affected both groups as indicated by increased errors and requests for repetitions with greater task difficulty. These findings are consistent with the interpretation that AD patients' performance reflects a limitation in processing, not a syntactic deficit. As processing demands increase, AD patients' ability to demonstrate retained syntactic ability is diminished.

101.13

DYSCALCULIA FOLLOWING IDIOPATHIC HYPOKALEMIA: A CASE STUDY. S.M. Sokol. Neurolinguistics Laboratory, Massachusetts General Hospital, Boston, MA 02114.

A case study is reported of a 55 year old female (B.B.) who complained of significant difficulty manipulating and remembering numbers. Twenty-three years prior to the present complaint, B.B. had been hospitalized for idiopathic hypokalemia and secondary hyperaldosteronism. At the time of original admission, she was quadriplegic; however, her condition soon improved, leaving her with a right hemiplegia which itself abated after two months. In addition to motor impairments, B.B. was severely dyslexic, dysgraphic and dyscalculic. Recovery of language processing skills occurred rapidly with minimal remediation. However, B.B. reports that her difficulties with numbers have persisted, despite excellent pre-morbid skill.

The present study examined the nature and extent of B.B.'s cognitive impairments. On standardized and experimental tests of language processing and general cognitive ability, she scored quite well. However, she demonstrated significant impairments in digit span, number processing and calculation, memory for biographical details involving numbers and general number knowledge. For example, she made a number of errors reading aloud Arabic digits and was severely impaired in the retrieval of basic multiplication facts (e.g., 7 x 6 = 42). She was unsure of her own age as well as those of her closest family members. Further, she could not recall a single digit of her brother's phone number, a number she calls at least once a week.

The relationship between potassium deficiency and cognitive impairment has received scant attention in the neurological and neuropsychological literatures. This report provides preliminary evidence that such impairments do occur; however, the precise mechanisms (either neural or cognitive) which could give rise to such circumscribed behavioral sequelae require further study.

101.14

ORGANIZATION OF HUMAN LANGUAGE CORTEX. G.A. Ojemann, Univ. of Washington Sch. of Medicine, Seattle, WA 98195.

Investigations of language during neurosurgical operations under local anesthesia include identification of essential areas, using electrical stimulation mapping, and of physiologic correlates in the electrocorticogram, and in subsequently resected areas, extracellularly recorded neuronal activity. Changes observed with these techniques during different language behaviors provide evidence on the organization of human dominant hemisphere lateral cortical language association cortex. That cortex includes separate systems for different language behaviors and languages. These systems are distributed widely across nonessential cortex, but separated at a neuronal level. Essential areas for different language functions and languages are in part grossly separated; usually two or more separate essential areas of 1-2 cm^2 extent with sharp boundaries function in parallel for each language behavior. Behaviorally specific selective attention characterizes activity in each system, of greater intensity at essential sites. Different subjects show substantial variability in the location of those sites, varying in part with sex and verbal ability. Essential areas are localized at age 4, but, in adults, may become more localized with increased languge skill.

NEURONAL ACTIVITY RELATED TO FACES AND MATCHING IN HUMAN RIGHT, NONDOMINANT TEMPORAL CORTEX. J.C.Ojemann*, G.A.Ojemann, O.D.Creutzfeldt*, Ettore Lettich*. (SPON: J. Loeser.) Univ. of Washington Sch. of Med.,Seattle, WA, 98195 and Max Planck Institute of Biophysical Chemistry, Göttingen, West Germany.

During craniotomy under local anesthesia, extracellular neuronal recordings were obtained from subsequently resected right, nondominant temporal cortex during measures of face matching (FM), labeling of facial emotional expression (FE), object naming (N) and complex figure matching (CM) using overt speech responses. Recordings from 21 neuronal populations in 12 patients showed statistically significant changes in activity during FM in 67% of populations, FE 48%, N 19%, CM 33%. The pattern of changes identified several roles for these neurons: 33% related to perception of faces, changed activity with both FM and FE, confirming in man the finding in animals of temporal lobe neurons related to face perception; 29% were related to the generic act of matching, changing activity with FM and CM; 14% located only in middle temporal gyrus were related only to FE, providing independent confirmation of the role for this gyrus in FE, previously identified by stimulation mapping (Brain 105:349, 1982). Two of 6 neuronal populations that increased activity during speech showed a greater increase when speech was part of a spatial task (FE in one, matching in the other), compared to N, indicating that nondominant hemisphere visuospatial neuronal systems include speech effector neurons.

BEHAVIORAL PHARMACOLOGY: ANALGESICS AND NMDA

102.1

Conditioned Stimulus Control of the Heart-rate Effects of Morphine. K.S. Schwarz and C.L. Cunningham, Dept. of Med. Psychology, Oregon Health Sci. Univ., Portland OR 97201.

The present experiment was designed to determine whether drug responses could be conditioned when intravenous morphine (5mg/kg) was paired with a 15-min light/noise conditioned stimulus (CS). Adult male rats were implanted with a jugular vein cannula and heart rate electrodes. Rats were housed 24 hrs/day in the experimental chambers. The Paired (P) group received morphine 30 sec after CS onset; therefore, the CS remained on for 14.5 min after morphine administration. The Unpaired (U) group received explicitly unpaired presentations of the CS and morphine, i.e., morphine was administered 75 min after CS offset.

Morphine produced a biphasic heart-rate response in both groups: bradycardia followed by tachycardia. After several CS-morphine exposures, the P group showed tolerance to the bradycardia, whereas the U group continued to show the biphasic response. When the P group received morphine without the CS, loss of tolerance was evident, in that it showed a biphasic response. Furthermore, presentation of the CS without morphine elicited a tachycardic response in the P group. No change in heart rate to the CS was observed in the U group. These data suggest that conditioned tachycardia contributes to tolerance of morphine bradycardia. In contrast to previous studies, conditioned bradycardia was elicited by a discrete CS in a situation where the response was not confounded by handling or the stress of injection.

BRAIN SITES INVOLVED IN KETOPROFEN-INDUCED ANALGESIA ON THE HOT PLATE TEST. R. de Beaurepaire, C. Suaudeau*, C. Cimetière* and A. Chait*. Laboratoire de Pharmacologie C.H.U. Côte de Nacre, 14032, Caen, France.

Ketoprofen is a non-steroidal anti-inflammatory drug (NSAID) used in the treatment of arthritis for its anti-inflammatory, analgesic and antipyretic properties. NSAID analgesic properties have a peripheral as well as a central origin since intracerebroventricular injections of NSAID in the rat produce analgesia. Male Sprague-Dawley rats were chronically implanted with fixed guide cannulae terminating 1.5mm over 20 different brain sites. Ketoprofen (10ug in 0.3ul) was injected into the 20 brain sites through an injection cannula descended 1.5mm below the guide cannula. Eight minutes after injection the pain thresholds were tested on a hot plate set to a constant temperature of 55±0.5°c. Latency to the first hindpaw lick were recorded in treated animals and controls injected with saline. An average of 8 treated and 8 control animals per site was used and each animal was only used for one measure. Student t-test for unmatched pairs was used for statistics. Significant analgesia was obtained in the 9 following sites: central gray, raphé magnus, centro-medial nucleus of the thalamus, nucleus reuniens, dorso-lateral geniculate nucleus, medial geniculate nucleus, dorso-medial/ventro-medial nuclei of the hypothalamus, posterior hypothalamic nucleus, lateral vestibular nucleus. A slight analgesia which did not reach significance ($p<0.2$) was observed in two structures: dorsal raphé and ventral postero-medial thalamic nucleus. In the following 7 sites, which included several thalamic structures, no analgesia was observed: centro-lateral nucleus of the thalamus, posterior thalamus nuclear group, parafascicular nucleus, bed nucleus of the stria terminalis, central tegmental tract, gigantocellular reticular nucleus, parvocellular reticular nucleus, nucleus of the tractus solitarius, spinal trigeminal nucleus oralis. Therefore the central analgesic action of ketoprofen is mediated by several different brain structures.

102.3

MU- AND DELTA-OPIOID RECEPTOR MODULATION OF AFFECTIVE DEFENSE BEHAVIOR ELICITED FROM MIDBRAIN PERIAQUEDUCTAL GRAY IN THE CAT. **C.L. Lu*, M.B. Shaikh and A. Siegel. Dept. of Neurosciences, UMDNJ, Newark, N.J. 07103.**

Recently, we have demonstrated that opioid peptides can regulate affective defense behavior (AD) elicited from the midbrain periaqueductal gray (PAG) in the cat. The present study sought to identify specific opioid receptor subtypes at the level of the PAG involved in the modulation of AD.

Cannula-electrodes were utilized for eliciting AD from the PAG as well as for microinjecting mu and delta agonists (morphiceptin and D-Pen^2,D-Pen^5 enkephalin [DPDPE]) and naloxone. Prior to drug infusion, stable baseline threshold values were determined over 3-4 days. Following microinjections of DPDPE (0.2- 1.5nmol/0.25ul) or morphiceptin (0.2-0.4nmol/0.25ul) into the sites from which AD was elicited, threshold values were determined.

The results indicated that DPDPE and morphiceptin suppressed AD in a dose and time-dependent manner. However, the magnitude and duration of suppression of AD was far greater following morphiceptin administration (i.e., morphiceptin [0.2nmol] suppressed AD for 180 min, while DPDPE [0.8nmol] suppressed AD for 60 min), indicating a preferential role of mu receptors in modulating AD. Pretreatment with naloxone blocked the suppressive effects of DPDPE. Administration of vehicle alone (saline/0.25ul) did not alter the threshold of AD. [Supported by NIH (NS07941) and the Fogarty Internat. Center (FO5TWO4110)].

102.4

INVOLVEMENT OF DEEP PREPIRIFORM CORTEX (AREA TEMPESTAS) IN MORPHINE-INDUCED ANALGESIA IN RATS. A. D'Amore*, P.Lorenzini* and M.Massotti.(SPON:R.Del Carmine). Lab. Farmacologia, Istituto Superiore di Sanità, 00161 - Roma, Italy.

Microinfusion of morphine into Area Tempestas (AT) delays the responses in tail-flick and hot-plate tests in rats (D'Amore and Massotti,17th Ann.Meet.Neurosci.,New Orleans,LA, 1987,Abst.n.-64.3). In this study we present evidences that AT can contribute to the antinociceptive effect of systemic administration of morphine.

In rats, injection of morphine-HCl (5 mg/kg sc) delays the responses in tail-flick (from 1 to 10 sec) and hot-plate (from 6 to 45 sec) tests. This effect initiates 10-20 min after injection and lasted about 2 hours.

These effects are antagonized by microinfusion into AT of the μ antagonist naltrexone (10-30 ng) and of δ antagonist ICI 154,129 (15-120 ng). In contrast, no significant changes can be observed after microinfusion of WIN 44,441-3 (120 ng) or saline.

These findings confirm that AT participates of the endogenous pain suppression system.

102.5

CHRONIC NEUROLEPTIC TREATMENT INDUCES A SUPERSENSITIVE FEEDING RESPONSE TO MORPHINE. J.S. Mogil[1], F.J. Vaccarino[1] and L. Stinus[2]. [1]Department of Psychology, University of Toronto, Toronto, Ontario, M5S 1A1. [2] INSERM Unite 259, Bordeaux, France.

The locomotor and feeding-stimulatory effects of systemically-administered opiates have been extensively studied. Current evidence indicates that dopaminergic (DAergic) influences modulate the behavioural effectiveness of opiates. It has been found that chronic DAergic blockade enhances the effects of opiates with regard to locomotor activation. The present study was aimed at examining the extent to which this "supersensitive" opiate response is also associated with feeding behaviour. To this end, the effects of chronic neuroleptic treatment on morphine-induced feeding were investigated.

Male Wistar rats were administered the long-acting neuroleptic, flupenthixol decanoate (12 mg/kg, s.c.), approximately every 10 days for 40 days. Rats were tested for their 2 hour feeding response to morphine (0.5 mg/kg, s.c.; a threshold dose) or saline on days 8, 16, 24 and 32.

The results indicated that chronic DAergic blockade enhanced the effectiveness of morphine. Rats receiving flupenthixol showed a progressive increase in the feeding response to morphine over time. This increase in feeding was statistically significant after the third week of neuroleptic treatment as evidenced by a 65% increase in food intake over controls. The similar time course of this effect and the therapeutic efficacy of neuroleptics supports a possible opiate involvement in the antipsychotic actions of neuroleptics.

This research was supported by a NSERC grant to FJV.

102.6

EVIDENCE THAT SIGMA RECEPTORS DO NOT MEDIATE FEEDING BEHAVIOR IN NONHUMAN PRIMATES. **N. L. Katz, R. F. Schlemmer, Jr., D. McGinness* and J. M. Davis. Univ. of Illinois at Chicago & Illinois State Psychiatric Institute, Chicago, IL 60612.**

Antipsychotic drugs frequently induce movement disorders in treated patients. Efforts to discover drugs devoid of this distressing adverse reaction have led to speculations about new mechanisms of psychotic behavior and to new 'atypical' antipsychotic drugs. A less recognized disturbing effect of most typical and atypical antipsychotic drugs is weight gain. In an animal model of psychosis developed in this laboratory using Stumptail macaque (Macaca artoides) monkeys housed in social colonies, we are able to observe many solitary, social, and drug-induced behaviors among which are several food-related behaviors. In the present study in which the effect of the selective sigma antagonist (±)-BMY14802, an antipsychotic candidate, was being studied in the model, several observations were made which suggested that the drug may have little or no effect on appetite and weight gain. Given acutely or chronically in oral doses up to 5 mg/kg, (±)-BMY14802 did not affect the frequency or time that the animals handled, chewed, or foraged food. The amount of time spent drinking was not affected. All of these behaviors were significantly decreased by chronically administered amphetamine and could not be reversed by (±)-BMY14802. Subsequently, we observed the effect of the prototype sigma agonist N-allylnormetazocine (NANM) on these same food-related behaviors and found them to be decreased in a dose-related fashion by racemic NANM. However, the decrease could be accounted for mainly by the (-)-NANM isomer, a ligand primarily for mu and kappa opiate receptors, and not by the (+)-isomer, a ligand for sigma receptors. These data support our previous studies in rats and do not suggest a role for sigma receptors in feeding. (Supported in part by Bristol Myers Company).

102.7

ISOMERIC SEPARATION OF THE MU, KAPPA AND SIGMA-MEDIATED STIMULUS EFFECTS OF METAZOCINE IN THE PIGEON; S. S. Negus, M. J. Picker* and L. A. Dykstra*; Department of Psychology; University of North Carolina; Chapel Hill, NC 27599

Metazocine is a benzomorphan related in structure to the prototype kappa agonist ketocyclazocine and the prototype sigma agonist N-allylnormetazocine (NANM). Like these other benzomorphans, metazocine exists as a racemic mixture of (-) and (+) isomers. Previous studies have demonstrated that (-)metazocine acts as an agonist at mu opioid receptors, whereas (+)metazocine appears to have sigma agonist activity. The present study aimed to extend this characterization of metazocine by evaluating both the agonist and antagonist properties of the (-) and (+) isomers of metazocine (0.3-10.0 mg/kg for both isomers) in pigeons trained to discriminate the kappa agonist bremazocine (0.01 mg/kg; N=3), the mu agonist fentanyl (0.05 mg/kg; N=4) or the sigma agonist (+)NANM from water in a two-lever, food-reinforced, drug-discrimination procedure. As expected, (-)metazocine generalized completely to the fentanyl (mu) stimulus, whereas (+)metazocine generalized to the (+)NANM (sigma) stimulus. Neither isomer generalized to the bremazocine (kappa) stimulus. In the antagonism studies, (-)metazocine was found to antagonize the bremazocine stimulus. In conclusion, these results suggest that (-)metazocine acts as both a mu agonist and as a kappa antagonist in the pigeon drug discrimination procedure, while producing neither agonist nor antagonist effects via the sigma receptor. (+)Metazocine, in contrast, acts as a sigma agonist with neither agonist nor antagonist activity at either the mu or kappa opioid receptors. (Supported by U.S. Public Service Grants DA05355 and DA02749)

102.8

NALOXONE DRUG DISCRIMINATION SUBSTITUTION BY NALTREXONE, DIPRENORPHINE AND NALORPHINE.
B. Geter, S. Smurthwaite*, M. Kautz and A. Riley. Psychopharmacology Laboratory, The American University, Washington, D.C. 20016.

Recently, Kautz and her colleagues reported rapid drug discrimination with low doses of naloxone (1 and 3 mg/kg) in non opiate-dependent animals, suggesting an opiate receptor mediation of the stimulus (Kautz et al., Drug Dev. Res., 16: 317, 1989). To further examine naloxone drug discrimination and its receptor mediation, in the present experiment a range of opiate antagonists were substituted for naloxone (1 mg/kg) in a test of their generalization. Specifically, rats were given naloxone 15 min prior to a saccharin - LiCl pairing. On intervening days, they were injected with distilled water prior to a nonpoisoned exposure to saccharin. This cycle was repeated until subjects were avoiding saccharin following naloxone and consuming saccharin following distilled water. Subjects were then given one of a range of doses of naltrexone (0.018 - 5.6 mg/kg), diprenorphine (0.1 - 18.0 mg/kg) and nalorphine (0.56 - 32.0 mg/kg) prior to saccharin. All drugs substituted for naloxone, producing dose-related decreases in saccharin consumption. That a range of opiate antagonists substitute for naloxone provides further evidence that the naloxone stimulus is mediated by the opiate receptor.

102.9

NONCONTINGENT TOLERANCE TO MORPHINE-INDUCED ANOREXIA IN RATS. D.L. Wolgin and H. Benscn*. Dept. of Psychology, Florida Atlantic Univ., Boca Raton, FL 33431.

In order to determine whether tolerance to morphine-induced anorexia is contingent on access to food during drug intoxication, rats were given one of two doses of morphine sulfate (10 or 20 mg/kg) either before (Before Groups) or after (After Groups) access to sweetened milk for 30 min. on alternative days. Control groups were given injections of saline. Dose-response curves were determined before and after the period of chronic treatment.

On the initial doses-response determination, morphine produced similar dose-dependent decreases in milk intake in all groups. Following chronic administration of the drug, there was a rightward shift in the dose-response curves of rats given chronic morphine, but not for rats given chronic saline. The extent of the shift was slightly higher in the Before Groups (2.5- and 1.8-fold) than in the After Groups (1.9- and 1.5-fold). We conclude that tolerance to morphine-induced anorexia is only minimally affected by access to milk in the drugged state.

102.10

SHORT- AND LONG-TERM FACTORS IN MORPHINE TOLERANCE: SINGLE OR MULTIPLE MECHANISMS? C. R. McLaughlin & M. S. Fanselow*. Depts. of Psychol., Dartmouth Col., Hanover, NH 03755 and University of California-Los Angeles, Los Angeles, CA 90024

Data from several laboratories indicate that Pavlovian conditioning plays an important role in the formation of tolerance to the analgesic effect of morphine. One account of these data, provided by Baker & Tiffany (1985), suggests that there are two forms of tolerance, long-term and short-term, which are a result of associative and nonassociative mechanisms, respectively. According to their model, the short-term and long-term processes should develop at the expense of one another, and only the long-term tolerance should be long-lasting. We tested these predictions.

Following the procedure described by Tiffany and Maude-Griffin (1988), adult male rats were administered either morphine sulphate (30 mg/kg, ip) or isotonic saline at intervals of either 24 hr (short-term acquisition) or 96 hr (long-term acquisition) for a total of 7 exposures. The animals were then reassigned to either short-term (24 hr after final acquisition exposure) or long-term test (96 hr after final acquisition exposure). The animals were tested with morphine (10 mg/kg, ip) in the hotplate (51.5 ± 0.5 °C) test of nociception.

All animals pre-exposed to morphine displayed shorter pawlick latencies than the saline controls, indicating tolerance, regardless of acquisition or test IDI. Contrary to the prediction of the Baker and Tiffany model, these results indicate that tolerance resulting from both short- and long-term acquisition parameters is long-lasting.

102.11

DEXTROMETHORPHAN, A NONCOMPETITIVE NMDA ANTAGONIST, IS RELATIVELY INEFFECTIVE AS A NEUROPROTECTANT IN A GERBIL ISCHEMIA MODEL. C.A. Boast, R.R. Notvest, C.A. Hoffman*, T.E. Emrey*, K. McMonagle-Strucko*, and T.G. Demetriou*, Wyeth-Ayerst Research, Princeton, NJ 08543-8000

Dextromethorphan (DM), like MK-801, is an NMDA antagonist. DM and MK-801 (ip) were compared in several *in vivo* tests related to NMDA modulation and neuroprotection. In mice, DM was less potent than MK-801 in blocking NMDA-induced lethality (ED50-mg/kg = 21 vs 0.2) and did not as readily disrupt traction reflex (ED50 = 45 vs 0.2). In gerbils, distinct changes in spontaneous locomotor activity were produced by both drugs, however, DM was weaker (MED = 30 vs 0.3). In gerbil ischemia studies MK-801 was active at 3 mg/kg (15 x ED50 for NMDA lethality). In normal gerbils DM was 100% lethal at 54 mg/kg (2.5x ED50 for NMDA lethality). DM (30 mg/kg) prevented ischemia-induced hyperactivity but not hippocampal brain damage. Relative to the NMDA lethality ED50, high doses of MK-801 are needed for neuroprotection. Even at proportionally lower doses, DM is lethal in gerbils and at still lower doses, is ineffective against ischemia. Thus, DM has a narrow therapeutic window.

102.12

THE EFFECTS OF GLYCINE AGONISTS AND ANTAGONISTS ON PHENCYCLIDINE-INDUCED STEREOTYPY AND ATAXIA. P. C. Contreras and I. Daly*. CNSDR, G.D. Searle & Co., St. Louis, MO 63198.

Glycine agonists of the strychnine-insensitive site associated with the NMDA complex potentiate the actions of NMDA. In contrast, agonists of the PCP receptor associated with the NMDA complex are noncompetitive antagonists of NMDA. The purpose of this study was to assess whether glycine ligands at the glycine-NMDA receptor modify the actions of PCP. Glycinamide (2 umol/rat, icv) and glycine (1 and 2 umol/rat, icv) antagonized PCP-induction of stereotypy and ataxia. Unlike glycine, d-serine (1.0 and 0.5 umol/rat) is a selective agonist at the strychnine-insensitive glycine site and was a more potent antagonist of PCP than glycine. D-Serine also antagonized MK-801-induced stereotypy and ataxia. Two glycine antagonists, HA-966 and ACBC (1-aminocyclobutane-1-carboxylate), at doses that did not produce ataxia did not significantly affect the behavioral actions of PCP. It is clear that glycine agonists at the strychnine-insensitive site antagonized the behavioral effects of PCP, but a more selective and potent glycine antagonist may be needed to demonstrate any effect on PCP behaviors.

102.13

BLOCKADE OF NMDA-INDUCED CONVULSIONS AND TASTE AVERSION BY ANTAGONISTS OF NMDA AND GLYCINE: RELATIONSHIP TO BEHAVIORAL EFFECTS INDUCED BY THE PUTATIVE ANTAGONISTS. A. Jackson* W. Koek* and F.C. Colpaert* (Spon: M. Marien). FONDAX-Groupe de Recherche SERVIER, 7, rue Ampère, 92800 Puteaux, France.

Antagonism of N-methyl-D-aspartate (NMDA)-induced convulsions by a variety of drugs was compared with their ability to produce phencyclidine (PCP)-like behavioral activity (locomotor stimulation and falling) in mice. Convulsions produced by i.c.v. administration of NMDA were antagonized, at doses that did not block kainate- and quisqualate-induced convulsions, by competitive NMDA-antagonists (e.g., AP5, CGS 19755), non-competitive antagonists (e.g., PCP, MK-801) and also by some putative glycine antagonists (e.g., 7-chloro-kynurenic acid,, HA-966). Only the competitive and the non-competitive NMDA antagonists produced locomotor stimulation and falling, and their potencies to do so were highly correlated with their relative potencies to antagonize NMDA-induced convulsions (r = 0.92). However, with the competitive antagonists, PCP-like behavioral effects were of a lesser magnitude than those seen with non-competitive antagonists and were only seen at doses higher than those required to block NMDA-induced convulsions. In a different series of experiments, the ability of some of these compounds to block taste aversion induced by i.p. administration of NMDA was studied in rats. Effects of these drugs as antagonists of NMDA-induced taste aversion were investigated as well as their ability to produce taste aversion when given alone.

102.14

STUDIES OF THE DISCRIMINATIVE CUE OF (+)-MBDB, THE ALPHA-ETHYL HOMOLOGUE OF MDMA. R. Oberlender* and D.E.Nichols (SPON. R. P. Maickel) Dept. of Medicinal Chemistry and Pharmacognosy, School of Pharmacy and Pharmacal Sciences, Purdue University, West Lafayette, IN 47907.

In 1988, we reported that rats trained to discriminate (+)-MBDB from saline responded on the drug lever when tested with the entactogens MDMA or MDA, but not the hallucinogens LSD, DOM, or mescaline, or the stimulants amphetamine, methamphetamine, or cocaine. We now report the results of further studies directed toward the analysis of the (+)-MBDB cue.

Complete substitution for the training stimulus was observed with drugs which are known to induce the release of serotonin (PCA, (±)-fenfluramine, (+)-fenfluramine) and drugs with 5-HT_{1B} agonist activity (TFMPP, RU-24969). The latter drugs also produced significant numbers of disruptions. No substitution was observed for compounds with selective 5-HT_{1A} agonist activity (8-OH-DPAT, buspirone).

The (+)-MBDB cue was effectively antagonized by the nonselective serotonin antagonist metergoline (0.5 mg/kg, 90 min prior to testing). No significant effect on the perception of the training stimulus resulted from pretreatment with the 5-HT_2 antagonist ketanserin, or the dopamine antagonist, haloperidol.

These results suggest that the cue produced by entactogens (MBDB, MDMA) may be primarily mediated by 5-HT_{1B} agonist effects of released serotonin.

EFFECTS OF CHRONIC COCAINE TREATMENT ON THE STRIATAL DOPAMINE AND ACETYLCHOLINE RELEASE. S.-J. Yi and K.M. Johnson (SPON: G. Greeley). Dept. of Pharmacol. & Toxicol., Univ. of Texas Medical Branch, Galveston, TX 77550.

Repetitive administration of cocaine is associated with both an enhanced behavioral effect upon acute challenge (behavioral sensitization) and an enhanced effect of amphetamine (Amph) on DA release in vitro. We tested the effects of chronically administered cocaine on Amph-induced potentiation of basal and K^+-stimulated ^{3}H-DA release and Amph inhibition of K^+-stimulated ^{14}C-ACh release from striatal slices in order to determine the relationship between dopaminergic transmission and the behavioral augmentation produced by chronic cocaine. Female Sprague-Dawley rats were injected with either saline or 15 mg/kg cocaine (i.p.) twice a day for 7 days. After 7 days of withdrawal, rats were injected with saline or cocaine and were sacrificed 30 min later. Brains were removed and striata were dissected to assay ^{3}H-DA and ^{14}C-ACh release in a dual K^+ stimulus paradigm. K^+-stimulated ^{3}H-DA release from striatal slices was not affected by acute or chronic cocaine; however, acute cocaine challenge after chronic cocaine injection potentiated Amph's effect on K^+-induced ^{3}H-DA release. This effect was mirrored by an increase in K^+-stimulated ^{14}C-ACh release in the absence of Amph. This may be due to a decreased dopaminergic inhibitory tone caused by an increase in DA uptake (Yi and Johnson, Soc. Neurosci. Abst. 14: 392, 1988). This increased capacity of the DA carrier could also account for the enhanced ability of Amph to potentiate K^+-stimulated ^{3}H-DA release. However, the latter effect is difficult to reconcile with the observation that chronic cocaine administration (with or without a cocaine challenge) resulted in a diminished effect of Amph on spontaneous ^{3}H-DA release. This may be the result of the paradigm used, in which Amph was added after a depolarizing stimulus, or may be associated with similar effects of Amph observed previously on the compartmentalization of ^{3}H-DA in striatal synaptosomes (ibid). These data suggest that repetitive administration of cocaine in a regimen that elicits behavioral sensitization alters the substrates through which Amph exerts its effects on release of ^{3}H-DA.

PERSISTENT COCAINE-INDUCED CHANGES IN ELECTRICALLY-STIMULATED DOPAMINE RELEASE FROM RAT STRIATAL SLICES. N.R. Zahniser, P. Curella and G. Larson. Dept. Pharmacology, Univ. Colorado Hlth. Sci. Ctr., Denver, CO 80262.

Previously we found that a single injection of cocaine (C) results in a persistent 30-50% increase in amphetamine-stimulated release of [^{3}H]dopamine ([^{3}H]DA) from rat striatal slices (Peris and Zahniser, Pharmacol. Biochem. Behav. 27:533-535, 1987). To test whether endogenous DA release is similarly changed, rats were pretreated with either saline (S) or C (10 mg/kg, i.p.) 1 day before release was measured. In contrast with [^{3}H]DA release, amphetamine-stimulated release (6 or 20 uM for 2.5 min) of endogenous DA or dihydroxyphenylacetic acid (DOPAC) did not differ between the two pretreatment groups. These results, together with the augmented amphetamine-stimulated [^{3}H]DA release, suggest that the specific activity of the pool of DA released by amphetamine, rather than release per se, may be increased by C pretreatment. Next, release evoked by 60 electrical pulses (1Hz) was measured in the presence of two uptake blockers. When 10 uM C was used to inhibit uptake, C pretreatment significantly decreased stimulated release of DOPAC by 30% from 150 ± 22 pmol/mg but not of DA [S: 27 ± 8.0, C: 22 ± 6.5]. In the presence 10 uM nomifensine, a more potent uptake blocker, evoked release of DA was higher (S: 86 ± 5.4 pmol/mg); and both DA and DOPAC release were diminished by 30-40% in response to C pretreatment. Regardless of the uptake blocker, evoked tritium release was also reduced by 35-40% following C pretreatment. Taken together, the results suggest that C can induce persistent alterations in both nonvesicular and vesicular release of DA in striatum and are more consistent with the development of dopaminergic tolerance than sensitization. 103.3

THE STIMULUS EFFECTS OF COCAINE: ROLE OF MONOAMINE REUPTAKE INHIBITION. P.M. Callahan, S.O. Idemudia*, J.M. Lakoski and K.A. Cunningham. Dept Pharmacology/Toxicology, Univ Texas Medical Branch, Galveston, Texas 77550.

Cocaine inhibits the reuptake of dopamine (DA), norepinephrine (NE) and serotonin (5-HT). To investigate the relative role of such processes in the stimulus properties of cocaine, male rats (N=16) were trained to discriminate cocaine (10 mg/kg, ip) from saline in a two-lever, water-reinforced task and were given various neuroactive compounds during substitution (generalization) tests. The DA reuptake inhibitor GBR 12909 (4-16 mg/kg) completely mimicked cocaine. The reuptake inhibitors for NE (desipramine, 2-8 mg/kg) and 5-HT (fluoxetine, 0.625-5 mg/kg) did not substitute for the training drug. In contrast to the lack of substitution engendered by these agents, a low dose of desipramine (3.0 mg/kg) or fluoxetine (1.25 mg/kg) significantly potentiated the stimulus effects of low doses of cocaine (0.313-2.5 mg/kg). The hypothesis that the stimulus properties of cocaine are mediated predominantly by DA systems is corroborated by the finding that GBR 12909 mimics cocaine. Reuptake inhibitors for NE and 5-HT systems may enhance the subjective (euphoric?) effects of cocaine possibly through increasing brain cocaine concentrations (Misra et al, Res Comm Subs Abuse 7: 85, 1986).

103.4

POTENTIATION OF THE COCAINE-LIKE EFFECTS OF DOPAMINE RECEPTOR AGONISTS. R.L. Barrett* and J.B. Appel. *Behavioral Pharmacology Laboratory, Department of Psychology, University of South Carolina, Columbia, SC 29208.*

The effects of several centrally acting dopamine (DA) agonists were studied in rats trained to discriminate cocaine (10 mg/kg, *i.p.*) from saline. When given alone over a wide range of doses, neither bromocriptine nor SKF 38393 substituted for the training drug; pergolide substituted only partially. However, combinations of a non-discriminable dose of cocaine (2.5 mg/kg) with each of these DA agonists resulted in significant amounts of cocaine-appropriate responding. These data suggest that central DA systems are involved in the behaviorally relevant actions of cocaine and that at least some inhibition of DA reuptake (e.g., by the 2.5 mg/kg dose of cocaine) may be essential to the induction of cocaine-like discriminable (subjective) effects. This hypothesis is being investigated further with several directly (LY-171555, apomorphine) and indirectly acting (L-DOPA) DA agonists.

REPEATED COCAINE ADMINISTRATION POTENTIATES THE HYPOMOTILITY EFFECTS OF APOMORPHINE. F. Weiss, Y.L. Hurd,* U. Ungerstedt*, and G.F. Koob. Research Institute of Scripps Clinic. La Jolla, CA 92037. Dept. of Pharmacology, Karolinska Institute, Stockholm, Sweden.

Several lines of evidence indicate that repeated cocaine (COC) administration may produce functional changes in dopamine (DA) neurotransmission including alterations in receptor sensitivity, DA synthesis and metabolism. Using apomorphine (APO)-induced changes in motility as a behavioral assay, we have further explored the nature and direction of changes in DA receptor function associated with repeated COC exposure in COC self-administering rats. Locomotor activity in response to APO (0.1 mg/kg) was assessed 24 h prior to (PRETEST), and 24h after POSTTEST) 10 daily 3h COC SA sessions. To determine the persistence of the observed changes, a second POSTTEST was given 7 days after the first. APO produced only slight reductions in motility during the PRETEST. In contrast, locomotor activity was strongly reduced in the POSTTEST (30-40% of PRETEST levels). This hypomotility was no longer observed after one week (POSTTEST 2). Identical results were obtained in a replication of the experiment after 10 daily IP injections of COC (30 mg/kg). Consistent with the behavioral results, preliminary in vivo microdialysis data from animals tested under the same experimental protocol suggest the APO-induced inhibition of DA release in the nucleus accumbens is enhanced by repeated COC pretreatment. Together, these results suggest that presynaptic DA receptor sensitization may be associated with repeated cocaine use.

103.6

SELECTIVE D1 AND D2 RECEPTOR ANTAGONISTS BLOCK THE REINFORCING EFFECTS OF COCAINE IN THE RAT. C.B. Hubner and J.E. Moreton. University of Maryland School of Pharmacy, Baltimore, MD 21201.

A role for dopamine in mediating the reinforcing effects of cocaine has been suggested from studies in which dopamine antagonists increase rates of responding maintained by cocaine under fixed-ratio (FR) schedules. Since rate of responding maintained by drug can be influenced by factors other than its reinforcing efficacy, progressive-ratio (PR) schedules have been used to compare the reinforcing efficacy of different drugs. The purpose of the present study was to investigate the effect of the D1 antagonist, SCH 23390, and the D2 antagonist, spiperone, in rats self-administering cocaine on a FR and PR schedule. Sprague-Dawley rats, trained to self-administer intravenous cocaine (0.75 mg/kg/inj) on a FR 5 or PR schedule, were pretreated 30 minutes prior to the session with s.c. 2.0 - 20.0 ug/kg SCH 23390 (n=12) or 2.0 - 40.0 ug/kg spiperone (n=13). Under the FR 5 schedule, the dose-effect curves for SCH 23390 and spiperone each had an inverted-U shape, with maximal increases in responding at 10 ug/kg. Under the PR schedule, both SCH 23390 and spiperone produced dose-dependent decreases in the highest ratio completed, with SCH 23390 having a greater potency. These results suggest that both D1 and D2 receptors are involved in mediating the reinforcing effects of cocaine. [Supported in part by DA05292 (CBH) and BRS grant 2S07RR05770-10 (CBH & JEM)].

103.7

PERSISTENCE AND DOPAMINE IN MORPHINE-INDUCED STEREOTYPY. J. Pollock and C. Kornetsky. Boston University School of Medicine, Boston, MA 02118.

Administration of morphine (MS) induces an oral stereotypy in rats characterized by compulsive gnawing behavior, a behavior believed to be mediated by the activation of the mesostriatal dopamine system. This study was designed to determine the persistence of this stereotypy. Male F-344 rats (N=5) received three injections of MS (10, 20, 20 mg/kg, sc), 12 hours apart. By the third MS dose all rats showed the oral stereotypy, lasting 2-3 hours. After the last high dose of MS, animals were challenged with 4 mg/kg (sc) of MS, a dose that does not induce the oral stereotypy in drug naive animals, at 30, 90, 180, 270, and 360 days. After each challenge dose all animals exhibited the stereotypy. Since the acute stereotypy can be blocked by naloxone (NX) (1 mg/kg, ip) or the D1 antagonist SCH 23390 (0.08 mg/kg, ip), but not by the D2 antagonist raclopride (0.25 mg/kg, ip) (Pollock and Kornetsky, 1989), we challenged the persistent stereotypy at approximately 30 and 270 days following the last high dose of MS. Raclopride antagonized the stereotypy at 270 days, while NX and SCH 23390 were effective antagonists at both test days. The results indicate that the stereotypy caused by brief high dose MS persists for at least 12 months, and after what appears to be a prolonged "kindling" period, the D2 as well as the D1 receptor system appears to be involved in the behavior. (Supported in part by NIDA grant DA02326 and Research Scientist Award DA00099 to CK).

103.8

DIFFERENTIAL DOPAMINE RECEPTORS AND PHENCYCLIDINE-INDUCED BEHAVIORS IN RATS. P.A. Beers* and A.P. Leccese. Psychology Department, Kenyon College, Gambier, OH 43022.

The roles of D_1 and D_2 dopamine receptors in phencyclidine (PCP)-induced hyperlocomotion and stereotypy were investigated. Rats were injected with the D_1 antagonists SCH 23390 (0.05 or 0.25 mg/kg ip) or the D_2 antagonist, metoclopromide (1.0 or 5.0 mg/kg ip). These injections were immediately followed by 0.0, 4.0, or 16.0 mg/kg ip PCP. PCP-induced hyperlocomotion and stereotypy were measured by an automated activity apparatus. The D_1 antagonist, SCH23390, potentiated the depressant effects associated with the larger doses of PCP. Conversely, the D_2 antagonist, metoclopromide, blocked the behavioral effects of PCP. These findings demonstrate the importance of D_2 receptors in PCP-induced hyperlocomotion and stereotypy, and have implications for the pharmacotherapy of PCP-induced psychosis.

103.9

REASSESSMENT OF THE INVOLVEMENT OF CATECHOLAMINERGIC MECHANISMS IN THE STIMULUS EFFECTS OF COCAINE. J. Broadbent, E.K. Michael,* E. Riddle* and J.B. Appel. *Behavioral Pharmacology Laboratory, Department of Psychology, University of South Carolina, Columbia, SC 29208.*

Recent reports that several antidepressants, which are known to inhibit the reuptake of norepinephrine (NE), are clinically effective in the treatment of cocaine "craving," accentuate the possibility that adrenergic as well as dopaminergic (DA) neuronal systems play a role in the subjective effects of cocaine. Thus, the present study was concerned with the extent to which the discriminative stimulus properties of this substance (in rats) resemble (generalize to) those of several compounds that act directly or indirectly as NE or DA agonists. Neither the relatively selective NE reuptake inhibitor nisoxetine nor the less selective uptake inhibitors desipramine and imipramine substituted for cocaine (10 mg/kg, *i.p.*) in a two-lever, water-reinforced (FR 20), drug discrimination procedure. However, the cocaine cue generalized to buproprion and nomifensine, both of which selectively inhibit DA reuptake. These data suggest that DA is involved in the subjective effects of cocaine; additional tests, which indicate that neither the direct D_2 agonist bromocriptine nor the indirect DA agonist amantadine substitute for cocaine, suggest that these mechanisms are more likely to concern DA reuptake than direct receptor activation.

103.10

THE EFFECTS OF AMPHETAMINE AND CATHINONE ON IN VIVO DOPAMINE RELEASE AND METABOLISM. E.A. Pehek, B.K. Yamamoto and M.D. Schechter. Department of Pharmacology, Northeastern Ohio Universities College of Medicine, Rootstown, OH 44272.

The major psychoactive alkaloid of the Khat plant is (-)cathinone (CATH). This plant grows in Africa and Asia where the leaves are chewed by some residents, producing an amphetamine (AMPH)-like euphoric state. Previous studies have shown that CATH's mechanism of action is similar to that of AMPH, but findings regarding the potency of CATH relative to AMPH are equivocal.

The present study employed *in vivo* microdialysis to compare the actions of equimolar doses of CATH and AMPH on extracellular DA, DOPAC, HVA, and 5-HIAA levels in the urethane-anesthetized rat. Both drugs increased DA and decreased DOPAC and HVA levels. However, CATH had a longer lasting effect on these amines in the caudate nucleus whereas AMPH had a greater effect in the nucleus accumbens. These findings demonstrate the importance of examining different brain areas when comparing psychostimulant drug effects.

CHARACTERIZATION OF COCAINE WITHDRAWAL: Dopamine function. Authors: Palumbo JM, Price LH, Woods SW, Kosten T, Krystal JH, Charney DS, Klebèr H (Sponsor: Sewitch,DE) Dept. of Psychiatry, Yale Univ. Sch. of Med., 34 Park St., New Haven, CT 06508

Between 15 and 22 million Americans have used cocaine at least once . 17% of all college students are said to use cocaine. To our knowledge, this study represents the first systematic description of dopamine metabolism following discontinuation of cocaine in hospitalized adult human chronic cocaine users.**Methods:** Men and women, ages 18 to 45, with a history of continuous cocaine abuse for a period of at least the 12 months immediately preceding entrance into the study, and a minimum consumption of at least 5 grams of cocaine per week were entered into the study provided that they demonstrated no significant medical or psychiatric disorders. Also excluded were patients with intercurrent use of other substances. 12 patients were entered into the study. All tested positive for cocaine, and negative for other substances, at the time of admission. All patients had used cocaine during the 24-36 hrs immediately prior to admission. Neurochemical studies: On admission, and at 8 AM Monday, Wednesday, and Friday, blood was drawn for assays of prolactin (PRL), growth hormone (GH), and homovanillic acid (HVA). **RESULTS:** Data were analyzed using Wilcoxon signed ranks tests with measurements made with respect to admission values for PRL, GH, and HVA. Significant increases from admission values were noted for the meaned interval day 10-12, and the meaned interval day 13-15 for HVA. Similar statistically significantly increases in PRL were noted during each of the three day intervals from day 13 through 21.**CONCLUSION:** Changes in dopamine function occur during cocaine discontinuation. Significant increases in HVA and PRL are both noted after day 12 of admission. These data do not support the conclusions of Mendelson, et al, who demonstrated persistent hyperprolactinemia during cocaine abstinence (1). Continued data analysis is ongoing in our facility. It is likely that additional patients will need to be studies to further understand the findings of the current study.

DOPAMINERGIC TREATMENTS IN COCAINE WITHDRAWAL. J.A. Cocores,* M.S. Gold, A.L.C. Pottash. Fair Oaks Hospital, Summit, NJ 07901 & Delray Beach, FL 33484.

Cocaine smoking is the most difficult to treat and addictive form of cocaine abuse (Verebey K & Gold MS, Psych Annals 18(9):513-520, 1988). After cocaine smoking very high brain concentrations are reached faster, resulting in greater behavioral effects than those experienced after cocaine snorting. Rapid mood alternation between positive and negative effects makes continued use or relapse likely. Forty consecutive crack cocaine addicts were assigned in groups to structured, outpatient treatment (S.O.T.) alone, S.O.T. with bromocriptine (1.25 mg bid x 21 days) and S.O.T. with levodopa (0.1gm tid x 21 days) to determine whether the high dropout rates for cocaine smokers could be reduced. We have previously reported S.O.T. dropout rates of 200% greater for cocaine smokers when compared to a sociodemographic matched group of snorters (Cocores JA & Gold MS, AMSAODD, 1989). Treatment with bromo or l-dopa during the earliest phases of cocaine rehabilitation may decrease relapse and improve treatment success rates. Further studies are necessary.

Treatment	Drug free at 28 days	Drug free at 120 days
S.O.T./Bromocriptine	8/10 = 80%	6/10 = 60%
S.O.T./Levodopa	8/10 = 80%	7/10 = 70%
S.O.T. alone	11/20 = 55%	6/20 - 30%

103.13

EFFECTS OF A NOVEL DOPAMINE AGONIST, SANDOZ 205-152, ON ETHANOL SELF-ADMINISTRATION. S. Rassnick*, L. Pulvirenti, and G.F. Koob (SPON, K. T. Britton). Research Institute of Scripps Clinic, La Jolla, CA 92037.

Previous evidence suggests an important role for the brain dopamine system in drug reinforcement. To examine whether pharmacological manipulation of the dopamine system would affect ethanol (EtOH) reinforcement in rats, we studied the effect of SDZ 205-152, a novel dopamine receptor agonist on oral EtOH self-administration in rats. A two-lever free choice task was used: responses at one lever delivered EtOH (10% w/v), while responses at the other lever delivered water during a 30 min. daily session. This model of oral self-adminstration of EtOH with limited access in non dependent animals represents a behavioral analogue of EtOH drinking in humans and is a valuable tool to examine CNS pharmacological actions without caloric value, taste or smell as confounds. SDZ 205-152 was administered at doses of 0.5, 1.0, 2.0 and 5.0 mg/kg sc 30 minutes prior to testing. The drug produced differential effects on responding for EtOH and water. Responding for EtOH was reduced by the treatment [$F(1,54) = 63.84$, $p<.001$], and there was a significant treatment vs dose interaction [$F(4,54)=4.498$, $p<0.01$]. Post hoc Newman-Keuls tests revealed that SDZ 205-152 at all doses tested significantly decreased EtOH drinking compared to baseline ($p<0.001$ in all cases). The lack of significance of SDZ 205-152 on responses for water suggests that nonspecific effects of this drug on motor performance cannot account for the reduction of responses for EtOH. These results contribute further support for the role of dopamine as a possible neurochemical substrate mediating EtOH reinforcement (This research was supported in part by NIDA 06420 and Sandoz Pharmaceuticals Corporation).

d-AMPHETAMINE AND MORPHINE WITHDRAWAL AGGRESSION: ROLE OF DOPAMINE RECEPTORS. J. W. Tidey* and K. A. Miczek (SPON: L. Erinoff). Dept. of Psych., Tufts University, Medford MA 02155.

Opiate withdrawal causes profound physiological and behavioral effects, including disruptions of motor activity and heightened aggressivity. Each of these effects is most sensitive to *d*-amphetamine at different times of opiate withdrawal. Male mice which had been pair-housed with females for 3 weeks were implanted s.c. with 75 mg morphine or placebo pellets for 3 days. Mice were challenged 5, 48 or 96 hours after pellet removal with *d*-amphetamine (0.3-3.0 mg/kg), SKF38393 (3.0-100 mg/kg) or quinpirole (0.1-1.0 mg/kg). The mice were videotaped alone in their home cages for five minutes, followed by a five minute period of interaction with a group-housed male "intruder". Rearing and walking were decreased at 5 hours but restored to control levels by 48 hours after pellet removal. Increases in threat and attack behaviors, however, were most enhanced at 48 hours and were still higher than control levels 96 hours after pellet removal. In placebo-implanted mice, *d*-amphetamine dose-dependently decreased grooming, increased walking and decreased or did not affect threats and attacks. In mice undergoing morphine withdrawal, *d*-amphetamine restored the suppressed rearing and walking seen at 5 hours of withdrawal to control levels and dose-dependently decreased grooming. Heightened aggressivity during morphine withdrawal was increased by 0.3 and 1.0 mg/kg and decreased by 3.0 mg/kg *d*-amphetamine at 5 and 48 hours after pellet removal. These effects are qualitatively similar to results with quinpirole at 5 hours after pellet removal, implicating D2 dopamine receptor mediation.

ENDOGENOUS CRF: ROLE IN STRESS- AND AMPHETAMINE- INDUCED SENSITIZATION OF FOREBRAIN DOPAMINE SYSTEMS. B J Cole[1]*M Cador[2]*L Stinus[2] G F Koob[1]M LeMoal[2]. (SPON: D A MacNiel). [1]Scripps Clinic and Research Foundation La Jolla, CA 92037. [2]INSERM U259 Bordeaux France.

Some aspects of affective disorders show a pattern of increasing pathology over time, and the animal model of behavioral sensitization has been suggested to provide a useful analogy to this longitudinal aspect of affective disorders. Behavioral sensitization refers to the observation that repeated administration of certain drugs produces a progressive increase in their effects on behavior. As CRF has been implicated in behavioral responses to stress, and stress shows cross sensitization with amphetamine (AMPH), we investigated the role of endogenous CRF in behavioral sensitization, using the CRF antagonist, alpha-helical CRF. In Experiment 1, rats were injected ICV with either 25µg alpha-helical CRF or vehicle, and then either restrained or returned to their home cage, once per day for 5 consecutive days. Starting 7 days later, they were tested for their locomotor response to systemic administration of saline and 0.75 mg/kg AMPH, and their stereotyped response to 3.0 mg/kg AMPH. The vehicle treated restrained rats showed a significantly greater locomotor response to saline, and a significantly greater stereotyped response to 3.0 mg/kg AMPH. These effects were reversed by the CRF antagonist. However, there was no effect of prior restraint on AMPH (0.75 mg/kg) induced locomotor activity. In Experiment 2, rats were initially injected ICV with either 25 µg alpha-helical CRF or vehicle, and systemically with 3.0 mg/kg AMPH or saline. They were then tested as in Experiment 1. The CRF antagonist was found to severely attenuate the AMPH-induced sensitization of both locomotor activity and stereotypy. These results suggest that although there are some behavioral differences between the nature of restraint stress- and AMPH-induced sensitization, central administration of the CRF antagonist significantly attenuates the development of both forms of sensitization.

103.16

CENTRAL ADMINISTRATION OF CRF PRODUCES SENSITIZATION OF AMPHETAMINE-INDUCED BEHAVIOR. M Cador[1]*B J Cole[2]*G F Koob[2] L Stinus[1]M LeMoal[1]. (SPON: M A Geyer). [1]INSERM U259 Bordeaux France. [2]Scripps Clinic and Research Foundation La Jolla, CA 92037.

The polypeptide corticotropin releasing factor (CRF) is the primary hypothalamic releasing factor involved in mobilizing the pituitary-adrenal axis response to stress. CRF has also been localized in extrahypothalamic regions of the CNS, where it is throught to play a crucial role in initiating behavioral responses to stress. The purpose of the present experiments was to examine whether central administration of CRF, like stress, would produce sensitization of the forebrain dopamine systems. Rats were initially given 5 ICV injections of CRF (0, 0.5 or 2.5µg). The injections were given on consecutive days and the rats locomotor activity was measured in photocell cages for 120 min after each injection. Seven days after the last CRF infusion, the rats locomotor response to systemically administered saline was measured. Two days later, half the rats were tested for their locomotor response to 0.75 mg/kg amphetamine (AMPH), and the other half were tested for their stereotyped response to 3 mg/kg AMPH. The rats treated with 2.5µg CRF showed a progressive increase in their locomotor activity over the 5 days of testing, while rapid tolerance developed to the hyperactivity induced by 0.5µg CRF. Furthermore, in comparison to rats pretreated with 0 and 0.5µg CRF, the rats pretreated with 2.5µg CRF showed a greater locomotor response to saline and 0.75 mg/kg AMPH, and a more intense stereotyped response to 3 mg/kg AMPH. The implications of the results for individual differences in the propensity to show stress-induced sensitization will be discussed.

DRUGS OF ABUSE: COCAINE I

104.1

COCAINE TOXICITY AFTER PRE- AND POST-NATAL VALPROIC ACID (VPA) EXPOSURE. S.K. Sobrian, N.K. Robinson*, L.E. Burton*, H. James* and A.K.N. Nandedkar*. Dept. of Pharm. Howard Univ. Coll. of Med., Washington, D.C. 20059.

We have reported that VPA pretreatment (VPA-P) prevents cocaine-induced convulsions (CICs) but increases cocaine fatalities two-fold. Prenatal VPA protects offspring against VPA/cocaine fatalities but reduces the anticonvulsant's postnatal efficacy. Offspring of rats exposed to VPA (PV) or water (control:PC) on gestation days 15-21 were treated at 60 or 180 days of age with 200 mg/kg of VPA, or vehicle, 30 min prior to a 60mg/kg i.p. dose of cocaine. Fatalities and convulsions were scored and compared with EKG and enzyme activity from serum taken immediately after behavioral testing. Total lactate dehydrogenase (LD) was elevated in animals that died without CICs. Liver enzymes (alanine aminotransferase: ALT) were increased in animals that convulsed but decreased in animals that died (gamma glutamyl transpeptidase: GGT). Neither total creatinine kinase (CK), CK-MM, (muscle), CK-MB (cardiac) nor EKG parameters correlated with cocaine toxicity. However, CK-MB was increased in all cocaine rats and CK-BB (brain) was increased by CICs. Results suggest that cardiac involvement in cocaine fatalities may be secondary to derangement in liver function. The increase in CK-BB following CICs implicates the CNS as a major mediator of cocaine toxicity, and introduces this isoenzyme as a serum marker for abnormal brain activity.

104.2

REGIONAL BINDING OF THE HIGH AFFINITY COCAINE ANALOG, [^{3}H]CFT, IN MONKEY BRAIN. D.R. Canfield*, R.D. Spealman*, B.K. Madras. (SPON: J.L. Neumeyer) Harvard Medical School, New England Regional Primate Research Center, Southborough, MA 01772.

[^{3}H]CFT (also designated WIN 35,428) binds with high affinity to cocaine receptors in monkey caudate-putamen. Regional distribution of [^{3}H]CFT binding was assessed on slide-mounted brain tissue (6 µm sections) of an adult monkey (Saguinus oedipus). Sections were selected from three areas: most anteriorly from the level of the nucleus accumbens, 2) just posterior to the optic chiasm at the level of the amygdala, 3) most posteriorly just caudal to the globus pallidus. Alternate sections from each area were incubated for 2 h at 4°C in the presence of [^{3}H]CFT (6 nM) alone or with unlabeled (-)-cocaine (50 µM). After washing, the slides were dipped in emulsion, stored in the dark for 4 weeks, developed, and examined for regional distribution of cocaine-specific binding. Binding of [^{3}H]CFT, which was specifically inhibited by (-)-cocaine, was most convincingly demonstrated in caudate nucleus, putamen, and nucleus accumbens septi. Binding was considerably lower in cortex, thalamic nuclei and white matter tracts. These findings indicate that [^{3}H]CFT binding is prominent in brain areas implicated in the stimulant effects and abuse liability of cocaine. 104.3

LONG-SLEEP AND SHORT-SLEEP MICE DIFFER IN RESPONSE TO HIGH DOSE EFFECTS OF COCAINE. C.M. de Fiebre, J.A. Ruth, and A.C. Collins. Inst. for Behavioral Genetics and Sch. of Pharmacy, Univ. of Colorado, Boulder, CO 80309.

Cocaine is often used simultaneously with ethanol. In an attempt to test whether common genes regulate sensitivity to both these drugs, we have measured the cocaine sensitivity of the long-sleep (LS) and short-sleep (SS) mouse lines which were selectively bred for differential ethanol-induced "sleep-time". In a battery of behavioral and physiological tests, differences between these mouse lines were subtle except at high doses where SS mice displayed greater sensitivity. Consistent with this finding, SS mice were found to be more sensitive to the seizure-producing effects of cocaine (ED_{50}'s: SS: 43 ± 3; LS: 65 ± 9 mg/kg). While the LS and SS mouse lines did not differ in sensitivity to the inhibition by cocaine of uptake of the monoamine neurotransmitters [^{3}H]dopamine, [^{3}H]norepinephrine and [^{3}H]5-hydroxytryptamine, SS mice were found to be more sensitive to the seizure-producing effects of lidocaine, a local anesthetic (ED_{50}'s: SS: 51 ± 4; LS: 76 ± 11 mg/kg). Therefore, it is concluded that the differential sensitivity of these mice to cocaine is due to differential sensitivity to cocaine's local anesthetic effects.

MODULATION OF THE LETHAL EFFECTS OF COCAINE BY CHOLINOMIMETICS. S. R. Goldberg*, M. J. Kuhar, J. L. Katz*, J. M. Witkin* (SPON: S. Bird). NIDA Addiction Research Center, Baltimore, MD 21224.

The finding that (-)-cocaine has antimuscarinic effects at high doses led to the suggestion that these actions may contribute to cocaine toxicity (Sharkey et al., J. Pharmacol. Exp. Ther. 246: 1048, 1988). This study was designed to elaborate on the possible involvement of muscarinic receptors in the lethal effects of cocaine. Cocaine HCl had an LD 50 of 81.7 mg/kg (95% CL: 77.3 - 86.4), ip, in male F344 rats. Atropine (1 - 30 mg/kg) did not alter the lethal effects of cocaine at doses that were effective in preventing oxotremorine-induced death. Physostigmine and oxotremorine markedly potentiated lethality of cocaine at doses devoid of convulsive or lethal effects of their own (1 and 0.3 mg/kg, respectively). At lower doses, pretreatment with physostigmine (0.3 mg/kg) but not oxotremorine increased the LD 50 of cocaine to 99.8 mg/kg (95% CL: 87.9 - 113.3). This prophylactic effect of physostigmine was not prevented by atropine. Protection against lethality was also conferred by 0.1 mg/kg neostigmine. These results suggest that whereas cocaine lethality may be related to muscarinic receptors, protection against death appears to involve nonmuscarinic receptors in the periphery.

104.5

DISCRIMINATIVE STIMULUS EFFECTS OF INHALED COCAINE IN SQUIRREL MONKEYS. J.L. Katz*, L. Sharpe, J.H. Jaffe*, and J.M. Witkin*. (SPON: J.E. Moreton). NIDA Addiction Research Center, POB 5180, Baltimore, MD 21224.

Squirrel monkeys (N=4) were trained with food reinforcement to press one of two levers after administration of i.v. cocaine (0.3 or 1.0 mg/kg) or the other lever after saline. After training, i.v. cocaine (0.03 - 3.0 mg/kg) produced dose-related increases in the percentage of responses on the cocaine lever (ED 50=0.15 mg/kg). Cocaine, delivered i.m. also produced dose-related increases in cocaine-appropriate responding (ED 50=0.32 mg/kg), but was less than half as potent (RP=0.42) as i.v. cocaine. Similar relative potency relations were obtained for decreases in response rates produced by cocaine. Prior to some sessions subjects were placed in a Plexiglas chamber and exposed for 60 sec to cocaine vapor created with an ultrasonic nebulizer. Exposure to vapor from cocaine solutions produced concentration-dependent increases in cocaine-appropriate responding and decreases in response rates. Exposure to vapor from a 30 mg/ml concentration produced virtually exclusive cocaine-appropriate responding. Concentration-effect curves for inhaled cocaine were not appreciably different from dose-effect curves obtained when cocaine was administered by the other routes. The minimally effective concentration of inhaled cocaine was examined at different times after exposure in one subject. In this subject, inhaled cocaine had a duration of action longer than i.v. cocaine. The results indicate that inhaled cocaine vapor has effects qualitatively similar to those of i.v. cocaine, and may have a duration of action longer than that of a functionally equivalent i.v. dose of cocaine.

104.6

DOPAMINE-1 RECEPTOR SPECIFIC INVOLVEMENT IN THE LETHAL EFFECTS OF COCAINE. J. M. Witkin,* S. R. Goldberg,* J. H. Jaffe,* and J. L. Katz* (SPON: C. W. Schindler). NIDA Addiction Research Center, POB 5180, Baltimore, MD 21224.

The D1 antagonist, SCH 23390, protects against the lethal effects of cocaine in rats; the LD 50 of cocaine HCl is increased by 20 mg/kg. In contrast, the D2 antagonist, haloperidol, is inactive against cocaine at doses which protect against amphetamine-induced lethality (Witkin et al., Life Sci. 44: 1285, 1989). The present experiments were designed to evaluate further the role of dopaminergic neurotransmission in cocaine-induced lethality. In male Swiss Webster mice, cocaine i.p. produced convulsions (ED 50 = 53 mg/kg) and lethality (LD 50 = 73 mg/kg). The dopamine uptake inhibitor, mazindol, shifted the dose-effect functions for both convulsions and lethality to the left and produced a dose-dependent potentiation of the toxic effects of cocaine. In male F344 rats, SCH 23388 which binds to D1 receptors with a 600-fold lower affinity than SCH 23390, did not alter the lethality of cocaine when given in doses 30 times higher than required for effective protection by the active enantiomer. The related D1-selective antagonist, SKF 83566, was also effective in increasing the LD 50 of cocaine. Lidocaine, a local anesthetic devoid of dopaminergic activity, also produced dose-dependent lethality. However, death induced by lidocaine was not altered by pretreatment with SCH 23390. The results of these experiments provide further support for a selective role of D1 receptors in the lethal effects of cocaine.

AN INVESTIGATION OF SENSITIZATION AS A PROCESS UNDERLYING ACQUISITION OF COCAINE SELF-ADMINISTRATION B. Horger, K. Shelton*, H. Bonavera*, and S. Schenk, Texas A&M University, Dept. of Psychology, College Station, TX 77843.

This experiment examined the role of sensitization in the acquisition of cocaine self-administration. Rats were injected daily with either cocaine HCl (10 mg/kg. i.p.) or the saline vehicle. Some were tested for the motor activating effects of cocaine during a 15 day treatment regimen. Others were tested for acquisition of intravenous cocaine self-administration following 9 days of chronic pre-treatment. Sensitization to the activating effects of cocaine in the locomotor tests was apparent after 3 days and became more pronounced with repeated exposure. In the self-administration tests, a higher percentage of cocaine pre-treated rats acquired the operant when compared to the saline pre-treated rats. Several of the cocaine pre-treated animals did not acquire until the original dose of 1.0 mg/kg/infusion was decreased. However, it is not clear as to whether this effect was do to a shift to the left in the dose response curve or simply a delay in latency to acquisition. Experiments are now being conducted to investigate these possibilities. HPLC analysis of the prefrontal cortex, nucleus accumbens and striatum failed to reveal differences in turnover or levels of dopamine between cocaine and saline treated rats. Thus, the sensitization effect may be due to postsynaptic rather than presynaptic alterations in dopamine functioning.

PRENATAL COCAINE EXPOSURE IN RATS: SENSORINEURAL HEARING LOSS AS EVIDENCED BY THE BRAINSTEM AUDITORY EVOKED POTENTIAL. M. W. Church and G. W. Overbeck.* Fetal Alcohol Research Center, Wayne State Univ. Sch. Med., Detroit, MI 48201.

Pregnant Long-Evans rats were injected daily with 60, 80 or 100 mg/kg cocaine HCl (s.c., 2% solution) from gestational days 7-20 (sperm positive = day 0). Daily doses were split evenly with half given between 9-10 a.m. and half between 3-4 p.m. An Ad Lib-fed group as well as nutritional control groups that were Pair-Fed to the 80 and 100 mg/kg Cocaine dams were also evaluated. One male and one female offspring from each litter were evaluated by brainstem auditory evoked potentials (BAEPs). Stimuli were clicks (0.1 msec) and tone pips (2000, 4000, 8000 Hz).

None of the animals in the Ad Lib, Pair-Fed, or the 60 mg/kg/day Cocaine groups had hearing loss (N = 12-15/group). So far, 4 of 20 offspring (20%) in the 80 mg/kg/day Cocaine group have tested positive for sensorineural hearing loss as evidenced by significant elevations in BAEP thresholds (ranging from 12-23 dB) and recruitment-type latency-intensity profiles. BAEPs in response to tone pips revealed a mixed picture of hearing loss in regards to pitch. One animal had the greatest hearing loss at 8000 Hz; another had the greatest hearing loss at 2000 Hz; the remaining two animals had roughly equal hearing losses at 2000, 4000 and 8000 Hz. Elevated BAEP thresholds are also being observed in the 100 mg/kg/day Cocaine group. (Supported by DA05536).

PRENATAL COCAINE EXPOSURE IN RATS: NEUROBEHAVIORAL EFFECTS. G. W. Overbeck,* M. W. Church, and A. L. Andrzejczak.* (SPON: C. S. Zajac), Fetal Alcohol Research Center, Wayne State Univ. Sch. Med., Detroit, MI 48201.

Pregnant Long-Evans rats were injected daily with 40, 60, 80 or 100 mg/kg cocaine HCl (s.c., 2% solution) from gestational days 7-20 (sperm positive = Day 0). Daily doses were split evenly with half given between 9-10 a.m. and half between 3-4 p.m. An Ad Lib-fed group as well as nutritional control groups that were Pair-Fed to the 80 and 100 mg/kg Cocaine dams were also evaluated (N=11-18 litters/group).

The **negative geotaxic reaction** of the offspring, evaluated from Day 2-14 (birth = Day 0), showed no group differences. **Spontaneous alternation** behavior showed no evidence of perseveration in any group on either Day 21 or Day 80. The Cocaine-Treated offspring generally showed shorter starting latencies on Day 21. **Activity monitor** behavior showed that the Cocaine-Treated and Pair-Fed offspring were hypoactive on Day 20. Some degree of hypoactivity was still evident on Day 49, but absent on Day 80. The **passive avoidance** behavior of Day 19 offspring showed no group differences in acquisition of task learning. The 100 mg/kg Cocaine offspring did show significantly poorer retention of task learning 48 hrs later. On Day 80, no group differences were seen in passive avoidance behavior. Acquisition of an **active avoidance** behavior on Day 80 was significantly poorer in the 100 mg/kg Cocaine group. (Supported by DA05536).

TIME COURSE OF COCAINE-INDUCED CHANGES IN BRAIN STIMULATION REWARD. R.A. Frank, P. Manderscheid & H.P. Williams*. Dept. of Psychology & Psychiatry, Univ. of Cincinnati, Cincinnati, OH 45221.

The time course of cocaine's mood altering effects was evaluated by assessing changes in self-stimulation thresholds over a period of chronic cocaine administration. Self-stimulation train-duration thresholds were determined for rats implanted with ventral tegmental area electrodes following injection of saline or 15-30 mg/kg cocaine HCl (IP). Testing times ranged from 15-435 min post-injection, and the animals were tested with cocaine for 18 consecutive days. Cocaine lowered thresholds during the initial post-injection tests across the entire 18 days of drug administration, a finding that supports the view that cocaine-induced euphoria does not exhibit tolerance with repeated drug use. In addition, cocaine treatment increased thresholds 6 to 7 hr post-injection, but only after 9 days of drug administration. This finding suggest that cocaine use can lead to rebound dysphoria, but only after an extended period of drug use.

This research was supported by NIDA grant # DA 04483 to R.A. Frank.

DIAZEPAM PRETREATMENT REDUCES THE CONFLICT BEHAVIOR OBSERVED IN RATS TRAVERSING A STRAIGHT-ALLEY FOR INTRAVENOUS COCAINE REWARD. T.Geist* and A.Ettenberg (SPON:G.Austin). Dept. Psychology, Univ. California, Santa Barbara, CA 93106.

Male rats implanted with jugular cannulae were trained to traverse a 5 ft runway for intravenous cocaine reward. Each animal was tested on a single trial per day during which the following dependent measures were recorded: the latency to initiate responding (i.e. to leave the start box), the latency to enter the goal box (once response initiation had occurred), the number of "retreats" (i.e. reversals in course back toward the start box), and the location within the alley where such retreats occurred. Once in the goal box, the passage back into the alley was blocked and a reward of five IV injections (5 s duration) of 0.75 mg/kg cocaine were administered at 30 s intervals. The reinforcing value of this treatment was determined by reductions in start latencies over trials and confirmed by conditioned place preference upon completion of the experiment. Although animals continued to run for cocaine reward, "retreat" behavior increased over trials with the probability of a "retreat" rising dramatically as a positive function of an animal's proximity to the goal box. This behavior was dose-dependently attenuated by pretreatments with IP diazepam (0.5, 1.0, 2.0 mg/kg). Our results suggest that animals experience a state of "conflict" when placed into the runway prior to reward presentation -- an effect presumably resulting from concurrent positive and negative consequences of cocaine administration.

104.12

ATYPICAL FETAL BREATHING PATTERNS ASSOCIATED WITH IN UTERO COCAINE EXPOSURE. J Gingras, R Hume*, K O'Donnell*, C Stanger* Dept of Peds, OB/GYN, Psychiatry, Duke U Med Ctr, Durham, NC 27710.

Fetal breathing demonstrates a specific ontogenetic pattern, is episodic, and is characterized by irregular rate with periods of apnea. In utero cocaine exposure is associated with poor obstetrical and neonatal outcome; increased incidence of SIDS has been suggested by some. We have observed a high incidence of abnormal breathing patterns in cocaine exposed fetuses, supporting the hypothesis that cocaine affects respiratory control. 30 cocaine using women were identified prenatally; serial ultrasound evaluations of fetal growth and behavior were recorded, analyzed with attention to patterns of breathing, and compared to controls. In 7/30 fetuses, fetal breathing was abnormal, characterized by persistent, rhythmic, hyperpneic respirations or by repetitive yawning that crossed behavioral states. The abnormal patterns were seen as early as 26 weeks of gestation and as late as 38 weeks in the exposed group, were not observed in controls, and were not associated with poor growth. All infants demonstrating abnormal breathing patterns were scored as abnormal in neurobehavioral exams in the neonatal period. These observations suggest that in utero cocaine exposure disrupts central neural mechanisms important in respiratory regulation.

VIOLENT BEHAVIORS AND COCAINE. N.S. Miller,* M.S. Gold, P. Herridge.* Cornell University Medical School, White Plains, NY 10605; Fair Oaks Hospital, Summit, NJ 07901.

Violent behaviors have been associated with cocaine use. The violent behaviors ranged from psychological aggressions to physical acts including murder of current cocaine users. A study examined by structured telephone interview 452 consecutive male cocaine users' reports of violent behaviors associated with cocaine. The mean age was 28.3 years. The route of administration for cocaine was intranasal=159, intravenous=32, freebase=136, crack=66, combination=66. As a group without regard to route of administration, the following effects induced by cocaine were confirmed. Cocaine made them: angry (42%), violent (32%), suspicious/paranoid (84%), stronger (32%), commit violent crimes (46%) (types of violent crimes; physical fights=23%, attempted murder=1%, armed robbery=22%, violent arguments=25%, verbal arguments=33%, child abuse=1%, wife abuse=7%, murder= less than 1%, rape=1%, robbery=14%); time of last use in relation to committing crime; during or immediately after use (30%), during withdrawal (19%); cocaine causes- to carry a weapon (17%), to see an ER or MD (22%), to commit violence (83%), violence to get money to pay for cocaine (82%). Crack users report more violent acts than intranasal users. Other characteristics of violence by route of administration are presented (Verebey K, Gold MS, Psych Annals 18(9):513-520, 1988).

ENVIRONMENTAL CUES INFLUENCE COCAINE- AND PROCAINE-MEDIATED CONDITIONED PLACE PREFERENCE. M. Coxen*, J.M. Carney and T.W. Seale (Spon: M.E. O'Connor). Univ. of Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK 73190.

The conditioned place preference (CPP) paradigm is a behavioral assay for drug-seeking behavior in animals. Specific context variables - i.e. environmental manipulations used to provide visual, olfactory and tactile cues - were characterized in 8 week-old male BALB/cByJ inbred mice. Mice were conditioned in 3 compartment chambers in which the compartment cues were hue (black, white, or gray) floor texture (wire mesh, smooth floor or wood chips), and scent (pine, cedar or none). Animals were conditioned for three daily trials with vehicle in one compartment and an optimal dose of cocaine (32 mg/kg ip) or procaine (100 mg/kg ip) in the other compartment. In one cue configuration, positive CPP of large magnitude (84% of total time spent in the drug-paired compartment; 1517 $\pm$ 94 seconds in cocaine treated animals versus 441 $\pm$ 70 seconds in vehicle treated animals) was appropriately paired with either compartment associated with drug administration. In another cue configuration, positive CPP of comparable magnitude occurred in one compartment but no CPP was observed when cocaine dosing was paired with cues in a second compartment. Tactile cues appeared to have the most salience. Cocaine and procaine induced identical CPP behavior across the various cue configurations. These data establish that environmental stimuli can markedly alter drug-induced CPP.

ELECTROPHYSIOLOGICAL ACTIONS OF COCAINE ON RAT DENTATE GRANULE NEURONS MEASURED INTRACELLULARLY IN VITRO. S.S. Jahromi,* and P.L. Carlen. Playfair Neuroscience Unit, Addiction Research Foundation, Departments of Physiology and Medicine (Neurology), The Toronto Western Hospital, University of Toronto, Toronto, Ontario, M5T 2S8.

Cocaine, a widely abused drug, has local anesthetic actions at high doses, and at low doses, it acts as a central nervous system stimulant. Having already studied the excitatory actions on dentate granule (DG) neurons of amphetamine (Jahromi et al, Soc. Neurosci. 14, 809) which is supposed to act similarly to cocaine, we have now studied the actions of cocaine on these neurons.

Cocaine (10 or 20 µM) was perfused onto DG neurons at 36°C. In the majority of cells, a few mV hyperpolarization occurred within about 20 min. The amplitudes of EPSPs and IPSPs elicited from perforant path stimulation were both decreased from 10% up to 40%. All effects were reversible upon drug washout. There was no significant reduction of the post-spike train afterhyperpolarization or spike frequency adaptation by cocaine perfusion. Contrary to what was expected, the above measured inhibitory actions of cocaine were essentially opposite from the excitatory actions of amphetamine on these neurons.

ALTERATIONS IN RAT BRAIN METABOLIC ACTIVITY FOLLOWING ACUTE AND CHRONIC COCAINE. A. Pert, S. Weiss, and R. Post. Biological Psychiatry Branch, NIMH, Bethesda MD 20892

The purpose of this study was to compare the effects of acute and chronic cocaine injections on the regional metabolic activity of rat brain. Different groups of rats were injected with either saline (i.p.), a single dose of cocaine (40 mg/kg), this dose for 15 days, or this dose of cocaine until the development of motor seizures. Standard 2-DG autoradiographic procedures were used to visualize ^{14}C-2DG uptake. Acute injections of cocaine increased metabolic activity in the anterior olfactory nuclei, frontoparietal motor cortex, striatum, lateral septum, globus pallidus, dorsolateral and ventrolateral thalamic nuclei, ZR and ZC of the substantia nigra, red n. and various pontine reticular nuclei. Activity decreased, on the other hand, in the dorsomedial thalamic n., lateral habenula and VTA. Chronic injections of cocaine produced a relatively similar profile. In addition, increases in activity were also seen in the ventral pallidum, subthalamic nucleus, PAG, superior colliculus and cerebellum. Alterations in behavior following chronic cocaine injections are likely related to these alterations in regional metabolic activity. The most striking changes noted during cocaine seizures were increases in metabolic activity of the n. accumbens, olfactory nuclei, and ventral hippocampus in some rats.

FACILITATORY EFFECT OF POSTTRAINING COCAINE ON MEMORY
I.B.Introini-Collison and J.L.McGaugh, Center for the Neurobiology of Learning and Memory and Department of Psychobiology, University of California, Irvine, CA 92717.

In previous studies we have found that retention is influenced by treatments affecting monoaminergic systems. The present experiments examined the effect of cocaine on retention. Mice were trained in a one-trial step-through inhibitory avoidance task and given immediate posttraining injections of cocaine (0.03-1.0 mg/kg). On a retention test 24 hr later, the retention latencies of mice given the 0.10 mg/kg dose were significantly higher than those of the controls. The effect of cocaine on retention was time-dependent: retention latencies were not altered in animals given cocaine 60 minutes after training, ruling out a proactive effect of cocaine on retention. Administration of cocaine (0.1 mg/kg) prior to the retention test did not modify the retention performance of mice that received either saline or cocaine (0.1 mg/kg) immediately posttraining. The findings suggest that cocaine affects retention by influencing posttraining processes involved in memory storage.

EFFECTS OF PRENATAL EXPOSURE TO COCAINE OR RELATED DRUGS ON RAT DEVELOPMENTAL AND NEUROLOGICAL INDICES. M. G. Henderson* and B. A. McMillen. (Spon. by J. P. DaVanzo), Dept. of Pharmacol., School of Medicine, East Carolina Univ., Greenville, NC 27858.

Gravid rats were injected s.c. with either cocaine (15 mg/kg b.i.d.), amitryptiline (10 mg/kg), amfonelic acid (1.5 mg/kg) or saline from gestational day 2 until parturition. Upon birth, 20 male pups from 3 mothers were cross-fostered to 2 surrogates. The pups were tested at birth and at 30, 60 and 180 days postnatal. Prenatal cocaine resulted in 4 of the 6 stillbirths. The AFA groups had a significantly smaller litter size while the other groups showed no differences. There were no differences in the ratio of male to female pups as compared to controls. Righting reflex was attenuated in the cocaine exposed pups as a group, but there was no difference in the median score, which suggests that the delay was due to outliers. The activity data showed that the cocaine pups had significantly increased spontaneous locomotor activity at 30 days: both during lights on and off. Beta 1 and 2 binding in the cortex revealed no changes at 30 days in any groups as compared to control. Preliminary results on cortex membrane Na/K ATPase activity show a trend towards increased activity in the cocaine exposed pups at 30 days. These data indicate that prenatal cocaine may cause some subtle abnormalities in rat development. (Supported by DA-04895)

EFFECT OF COCAINE ON ACETYLCHOLINE AND CHOLINE LEVELS FOLLOWING CHOLINESTERASE BLOCKADE. R.B. MILLER*, S.G. HOWARD AND C.L. BLANK, Dept. of Chemistry and Biochemistry, U. of Oklahoma, Norman, OK 73019, and Dept. of Pharmacology, UCLA, Los Angeles, CA 95432.

The normal human metabolism of cocaine involves ester cleavage by serum and other cholinesterases. Individuals at risk in the commonly encountered multiple dosage utilization found in the abuse of cocaine, thus, would be expected to include those which are homozygous for the so-called 'silent' gene as well as those which are exposed to pesticides such as diisopropylfluoryl phosphate, DFP. In one set of experiments, mice were pretreated with either isotonic saline or DFP (6.3 mg/kg, i.p.) 24 hours prior to a series of multiple cocaine injections (15 mg/kg, i.p., every 5 min). The mean number of cocaine injections required to cause expiration was: controls, 8.5±1.8, and DFP-pretreated experimentals, 3.9±1.1 ($P<0.001$). The decrease in serum cholinesterase activity resulting from DFP was also determined employing the same DFP or saline pretreatment alone. Using acetylcholine as substrate and liquid chromatography with electrochemical detection, the mean serum cholinesterase activities for controls and DFP-pretreated experimentals was determined to be, respectively, 76.6±4.6 and 23.3±2.0 μmol/mL/hr ($P<0.001$). These results clearly demonstrate the enhanced toxicity of cocaine following blockade of cholinesterase activity. The involvement of cholinesterase in the metabolism of cocaine as well as the similarity in chemical structure between this drug and many established cholinergic agents further suggests a possible direct or indirect effect of cocaine upon the cholinergic system. This possibility was examined by determining the choline and acetylcholine levels in seven mouse brain regions following treatment with 50 mg/kg cocaine, i.p., followed by sacrifice with microwave irradiation 5 min thereafter. The cocaine treatment was preceded by treatment with isotonic saline or DFP, as above, to determine the effect of cholinesterase blockade upon the levels.

CALCIUM CHANNEL ANTAGONIST ALTER SELF-ADMINISTRATION OF COCAINE IN RATS. L.G. Sharpe, N.L. Goodman* and J.H. Jaffe*. NIDA Addiction Research Center, Baltimore, MD. 21224

Two general classes of calcium channels have been identified (type I and type II) based on several years of research. One factor that distinguishes the two classes is that the dihydropyridines (nifedipine, nimodipine) interact with the type II calcium channels whereas other calcium channel antagonist (verapamil and diltiazem) interact with the type I calcium channel. Results from animal studies indicate that the dihydropyridine antagonist reduce dopaminergic transmission, a brain mechanism intimately involved in the reinforcing properties of cocaine and other psychoactive drugs. Our purpose was to assess the effects of both types of calcium channel antagonists in rats self-administering cocaine (0.5 and 1 mg/kg/inf, IV) on an FR 10 schedule of reinforcement. On day 1 and 2, the animals were treated with the antagonist vehicle before each 2-hr session to establish baseline responding. On days 3 and 4, the calcium antagonist were administered followed on day 5 with another vehicle pretreatment. The number of cocaine self-injections increased significantly after 0.5 and 1 mg/kg (IP) of nifedipine or nimodipine. Verapamil depressed responding at 20 mg/kg dose, whereas diltiazem (20 to 60 mg/kg, IP) was without effect. We conclude that the two types of calcium channel antagonist influence cocaine self-administration by separate mechanisms.

COCAINE BINDING SITES IN FETAL RAT BRAIN. J.S. Meyer and L. Collins*. Dept. of Psychology, Neuroscience and Behavior Program, Univ. of Massachusetts, Amherst, MA 01003

Although both human and animal studies have shown that cocaine exposure in utero can influence subsequent behavior in offspring, the mechanism of action of the drug prenatally is still unknown. As cocaine binding sites have been identified in the striatum, cortex, and other brain regions of adult animals, an important first step in elucidating prenatal cocaine effects is to determine whether similar sites are present during this stage of development. Fetuses were obtained from timed pregnant albino rats on gestational day (GD) 20, followed by preparation of standard P2 (synaptosomal) membrane fractions from whole brains. Saturation analyses were performed using a low-sodium medium (10 mM sodium phosphate buffer) and a range of ^{3}H-cocaine concentrations from 0.3 to 300 nM. EDBA/LIGAND analysis with a 2-site model yielded a high-affinity cocaine binding site with a K_D of 20-30 nM and a low-affinity site in the uM range. These affinities are commensurate with those reported for adult striatum under similar tissue preparation and incubation conditions (e.g., Calligaro and Eldefrawi, Membrane Biochem. 7: 87, 1988), although the B_{Max} values we obtained are understandably lower. The high-affinity binding site, which is already present even before GD 20, is an excellent candidate for mediating the effects of cocaine on the developing brain. THREE DIMENSIONAL STRUCTURE OF INTRACELLULARLY STAINED NEURONS AND THEIR PROCESSES REVEALED BY HVEM AND AXIAL TOMOGRAPHY D. N. Mastronarde, C.J. Wilson and B. McEwen*, HVEM Laboratory, Boulder, Colorado, Department of Anatomy and Neurobiology, Univ. of Tennessee, Memphis TN, and Wadsworth Ctr. for Labs and Res., NY State Dept. of Health, Albany NY.

The high voltage electron microscope can be used with very thick sections (i.e. 1-5 μm), and so can provide the images required for tomographic reconstruction of large pieces of dendrites, axons, or cell bodies of neurons injected with of electron dense markers. We have tested this approach with a portion of the dendritic tree of a spiny neostriatal projection neuron stained by intracellular HRP injection, postfixed with OsO_4, embedded in plastic, and cut into 3 μm thick sections. The sections were examined at 1000 kV with no further processing. Series of electron micrographs of a single section were taken at specimen tilts varying from -60 to +60° in 2° steps. These images were then digitized, converted to optical density, adjusted to remove differences in negative density, and aligned. A three dimensional reconstruction of the original dendrite was generated using the r-weighted back projection method. The accuracy of the reconstruction was evaluated by direct comparison with the original data set. Degradation of the reconstruction due to missing information was not severe, due to the unambiguous nature of the boundaries of intracellularly stained cell processes.

Tomographic reconstructions offer advantages for quantitative studies. Interactive computer programs can provide rapid and accurate linear measurements, such as dendritic or axonal diameter, spine lengths, etc., and can also extract measurements of membrane surface area or cytoplasmic volume. The resolution of the reconstruction is much higher than that available using any light microscopic methods, and is nearly as great as the resolution of conventional TEM.

105.2

SERIAL ELECTRON MICROSCOPY OF CA3 DENDRITIC SPINES SYNAPSING WITH MOSSY FIBERS OF RAT HIPPOCAMPUS. M.E. Chicurel and K.M. Harris (SPON: R. Tuttle). Dept. Neur. Children's Hosp. & Harvard Med. Sch. Boston, MA 02115

In their classic study, Blackstad and Kjaerheim (1961, JCN 11:133-146) obtained partial reconstructions of these CA3 dendritic spines from 10-12 serial thin sections and began to illustrate their complexity. We are obtaining more complete reconstructions of these spines so that modeling of their biophysical properties can be achieved. Preliminary results from a reconstruction through 42 serial sections revealed 2 spines synapsing with a single varicosity of the mossy fiber. One of these spines had 11 separate necks and heads (branches) emerging from a single primary neck at the dendrite. Seven branches were complete within the series, and 10 had synapses; the 11th was complete, contained 2 mitochondria, but had no synapse. The second spine had 4 branches; 2 were complete, and all had synapses. Of the 14 branches total, 6 had spinules, 5 had spine apparatuses, 10 had ribosomes, 10 had multivesicular bodies, and 8 had smooth endoplasmic reticulum. These results indicate: 1) that a single mossy fiber bouton can form synapses with more than 1 spine, and 2) that the complexity of the spine with multiple constrictions will require separate biophysical analysis for each branch. Supported by #NS21184, #P30-HD18655.

DETAILED COMPARTMENTAL MODEL OF AN EM RECONSTRUCTED SPINY STELLATE CELL IN THE MOUSE NEOCORTEX. I. Segev*, E.L. White and M.J. Gutnick, Dept of Neurobiology, Hebrew University, Jerusalem, and Depts of Morphology & Physiology, Faculty of Health Sciences, Ben Gurion University, Beersheva, Israel.

Integrative capabilities of neurons are determined by their morphology, synaptic architecture and electrical properties. At present there is only one neocortical neuron, a spiny stellate cell, that has be thoroughly reconstructed from serial thin sections (White,E.L and Rock,M.P.,*J. Neurocytol.*9:615,1980). We have used SPICE to construct a detailed compartmental model of this cell, based on the dimensions of its 5 dendrites and 310 spines, precise information on the sites and morphological types of all its synapses, and identification of each of its 48 thalamocortical synapses. Initial exploration revealed that a small R_m of 2000 ohmxcm^2 (R_i=70 ohmxcm) produced a large input resistance (R_N) of 140 Mohm; the presence of spines served to reduce R_N by about 20%. If, as physiological experiments indicate, GABAa-type IPSPs generated locally in a dendrite are depolarizing, they may serve to veto all excitation coming from that dendrite, while at the same time facilitating excitatory influences on other dendrites. Our observations demonstrate that neocortical neurons can have much greater computational power than the simple "integrate-and-fire" units that are often used in "neural network" models.

VESTIBULAR SYNAPTIC TRANSMISSION AT DEVELOPING CHICK TANGENTIAL NEURONS. K.D. Peusner and E. F. Stanley. LB, NINDS, NIH, Bethesda, MD 20892

The two main neuron classes in the tangential vestibular nucleus (TN) differ in membrane properties and synaptic properties following vestibular nerve stimulation. Elongate cells are activated by chemical transmission, whereas there is morphological evidence for mixed chemical and electrical transmission at the principal cells. In this study we have tested the mode of transmission by using low Ca solutions.

Field potentials were recorded from the TN in chick embryo (15-16 days) brain slices while stimulating the vestibular ganglion. An afferent volley and a biphasic response were recorded which were not abolished in low calcium solution or after addition of cobalt. The Ca-insensitive biphasic response cannot be accounted for by the elongate cells since intracellular recording confirmed that synaptic transmission to these cells was Ca sensitive. Supported in part by NIH grant R01 NS 18108.

MEMBRANE DENSITY HYPERTROPHY IN THE END BULB OF HELD IN CONGENITALLY DEAF CATS. S.A. Larsen and T.M. Kirchhoff*. Dept. of Anat. Sci. & Neurobiol., Univ. of Louisville Med. Sch., Louisville, Ky 40292.

Impulses conveyed from hair cells of the cochlea are received by neurons in the cochlear nucleus (CN). Bock et al (Brain Res, 239:608, 1982) concluded that synapses can be functional in the auditory pathway in the absence of peripheral stimulation and function may be restored by direct nerve stimulation contrary to Gulley's theory that stimulation is necessary to maintain synapses (Brain Res, 158:279, 1978). We studied synaptic terminations of the end bulb of Held (EB) on large spherical cells (LSC) of normal-hearing (NH) and white-deaf cats (WD). WD cats are prenatally deaf because of genetically determined cochlear degeneration.

We observed degeneration of cochlear hair cells, atrophy of the LSC and degeneration of the EB terminal in WD cats. Most of the remaining EB terminals in WD cats have few membrane densities, few synaptic vesicles and prominent presynaptic densities while in NH cats synaptic zones are asymmetrical and presynaptic densities are rarely observed. Cells were also observed in WD cats which exhibited hypertrophy of membrane densities by as much as 50%. While there is an increase of membrane densities in these cells, there is not an increase in the number of synaptic vesicles. Some of the membrane densities are synaptic zones as it is known that some neurons do respond to electrical stimulation.

Supported by Deafness Res. Found. & Univ. of Louisville Graduate Research Grant.

Pertussis toxin prevents long term potentiation (LTP) of intracellularly recorded hippocampal excitatory postsynaptic potentials (EPSP's). J.W. GOH AND P.S. PENNEFATHER. Faculty of Pharmacy, University of Toronto, Toronto, Ontario, CANADA M5S 2S2.

A brief, high frequency (400 Hz, 0.5s) stimulation of fiber tracts in brain slices from the rat hippocampus results in a long lasting potentiation of synaptic events mediated by those axons. Last year we reported that inactivation of hippocampal G-proteins with pertussis toxin (PT) prevented the induction of LTP measured in terms of the synaptically evoked population spike (see SFN Abst. 14, 12.8). It was of interest to confirm that LTP of EPSP's was also blocked by PT. We have recorded intracellularly from CA_1 pyramidal cells of transversely sectioned rat hippocampal slices and evoked EPSP's by stimulating the stratum radiatum. PT (2-5 μg total) was injected stereotaxically above the right hippocampus and slices were obtained 3-4 days post-injection. The effectiveness of PT pretreatment was assessed by monitoring the ability of adenosine (100 μM) to cause a membrane potential hyperpolarization of the CA_1 neuron. That action is mediated by a PT sensitive G-protein. In 6 out of 6 cells PT abolished the adenosine induced hyperpolarization and prevented the induction of LTP of the EPSP's. The presynaptic action of adenosine to reduce the EPSP amplitude was not significantly affected by PT pretreatment.

SYNAPTIC TRANSMISSION BETWEEN INDIVIDUAL NEURONS IN RAT VISUAL CORTEX. A.J.R. Mason*, A. Nicoll*, K.J. Stratford* & C. Blakemore. Univ.Lab. of Physiol., Oxford OX1 3PT, UK.

Using simultaneous intracellular recordings, we have investigated the properties of synaptic connections between pairs of neurons in slices of rat visual cortex. Impalements were made less than 250 μm apart in layer 2/3. Depolarizing current pulses, adjusted in strength and duration to evoke single spikes, were injected into one cell of each pair at 2 Hz. Spike-triggered averaging revealed synaptic connections between 8 of the 70 cell pairs tested. In 2 of these pairs, action potentials evoked in either cell elicited synaptic potentials in the other cell. All post-synaptic potentials (PSPs) were depolarizing at resting potential (67-83 mV). Their mean peak amplitudes ranged from 0.14 to 1.54 mV. Latencies were less than 2 msec, 10-90% rise-times were between 1.0 and 2.6 msec, and widths at half-amplitude ranged from 9.0 to 19.1 msec. All cells had electrophysiological characteristics typical of pyramidal neurons. The pyramidal nature of one cell of a synaptically coupled pair was confirmed by intracellular staining using biocytin. Amplitude fluctuation analysis was applied to 3 connections for which we had recorded at least 3000 sweeps. Under the assumption that the noise and PSP amplitude distributions could each be modelled by a single Gaussian distribution, the synaptic potentials fluctuated more than could be accounted for by the noise. Thus, for local synaptic connections between pyramidal cells in rat visual cortex, it appears that single pre-synaptic action potentials do not generate PSPs of constant amplitude.

105.8

COMPARISON OF FLUCTUATIONS IN ELECTRICAL AND CHEMICAL TRANSMISSION EVOKED BY STIMULI IN THE SAME SYNAPSE. Ch. Stricker*, H.-R. Lüscher and H.P. Clamann.. Dept. of Physiol., Univ. of Bern, Switzerland.

Synaptic transmission from spindle afferents to motoneurons in the frog is both electrical and chemical. By comparing fluctuations of the electrically and chemically evoked components, it may be possible to determine whether fluctuations are a result of uncertainty of potential propagation in afferent branches or of failure of transmitter release. The components of the EPSP can be identified by shape and latency. After isolation from anesthetized frogs, whole spinal cords were placed into a lucite chamber maintained at 10±1°C and superfused with oxygenated frog Ringer's solution. Motoneurons of the 9th or 10th spinal segment were impaled with electrodes filled with 3 M KCl and having 15-30 MΩ resistance. Cell input impedance was measured. 1024 composite EPSP's evoked by stimulating the corresponding dorsal root at ≥ 5 X threshold at 1/sec were recorded. The mean time course of the EPSP, of its variance and of a 10 msec segment of the baseline variance preceding the stimulus artifact were computed. The variance time course of the EPSP was corrected for baseline variance. In 7 of 14 cells, the variance of the monosynaptic chemical component did not differ significantly from that of the electrical component. Both corrected variances were nearly zero. In 3 cells, a slight monotone variance increase from the onset of the EPSP through the monosynaptic chemical component was seen. In 4 cells, the variance of the monosynaptic chemical component of the EPSP was less than the baseline variance. We conclude that in the isolated frog spinal cord at 10°C, neither electrical nor chemical transmission show much fluctuation. Thus electrical invasion of boutons and transmitter release are both reliable in this system. A decrease in the variance, and hence in the noise during an EPSP below baseline values suggests that noise signals may not always add linearly.

105.9

A POSSIBLE SOURCE OF ATTENUATION OF QUANTAL CURRENTS AT THE CRAYFISH NEUROMUSCULAR SYNAPSE.
J.M. Wojtowicz, K. Miller*, J. Winslow*, H.L. Atwood, Dept. of Physiology, University of Toronto, Toronto, Ontario. M5S 1A8.

Experiments were performed on the opener muscle of the crayfish in vitro. In each experiment the excitatory axon was stimulated at the frequencies of 1-5 Hz, and quantal release of transmitter was followed simultaneously with both intracellular and macropatch electrodes. The intracellular electrode, impaling a muscle fiber can detect individual quantal EPSPs; however, their site of release on the fiber is not known. The macropatch pipette (typically 20 microns diameter) detects quantal currents generated by transmitter released from a circumscribed area of the axonal terminal. Combined recordings showed that certain quanta are strongly attenuated or eliminated during transmission between the release site and the core of the postsynaptic muscle fiber. We propose that the attenuation of these quanta is caused by decremental conduction along the subsynaptic cytoplasmic folds. These filamentous projections appear to be analogous to dendrites or dentritic spines of neurones. Their structure has been investigated using serial sectioning and reconstruction from electron micrographs. Subsynaptic structures may regulate the transfer of quantal information. KINETICS AT THE NEUROMUSCULAR JUNCTION: A MONTE-CARLO SIMULATION. T.M. Bartol Jr.*, B.R. Land[1]*, E.E. Salpeter[2]*, M.M. Salpeter (SPON: A. Cohen). Section of Neurobiology and Behavior, [1]Cornell Theory Center/Cornell National Supercomputer Facility, and [2]Laboratory of Nuclear Studies Cornell University, Ithaca, NY 14853.

This study models events produced by the release of an acetylcholine (ACh) quantal packet at the vertebrate neuromuscular junction. Such modeling must include the chemical kinetics for two ACh binding and unbinding steps, an isomerization step for the acetylcholine receptor (AChR) as well as for ACh diffusion along a primary and secondary cleft. In the past we have done this using numerical methods for solving differential equations, but only for simplified versions of the cleft geometry (e.g. Land et al PNAS 1984 Vol. 81, pp.1594-1598). We have now implemented an alternative modeling method using a three dimensional Monte-Carlo computer simulation which follows individual released ACh molecules in space and time. The Monte-Carlo model presented here has considerable advantages over previous methods by allowing the inclusion of more realistic conditions. In particular we can 1) specify arbitrary three dimensional synaptic cleft geometry and 2) study more complex assumptions on the chemical kinetics, such as two non-equivalent binding sites on the AChR complex.

This simulation has been used to explore the effect of different initial geometric conditions on the spacial distribution of bound and unbound ACh and AChR, and on the shapes of the resultant miniature endplate currents (MEPC's). We report 1) that the presence of a secondary synaptic cleft can affect the MEPC shape, depending on the distance between the presynaptic ACh release site and the secondary fold and 2) that the extent of potentiation of MEPC amplitude and decay time depends on the distance between two ACh release sites. Comparisons with experimentally obtained MEPC shapes as a result of varying AChR and acetylcholine esterase (AChE) concentrations now permits the determination of rate constants for ACh diffusion and binding and for AChR gating which apply to the complex geometry of the vertebrate neuromuscular junction. This research was conducted using the Cornell National Supercomputer Facility, a resource of the Center for Theory and Simulation in Science and Engineering.

AN EVALUATION OF MEDIA FOR MAINTENANCE OF MOUSE DIAPHRAGM MUSCLE IN LONG TERM ORGAN CULTURE.
D. M. Wetzel & M. M. Salpeter. Section of Neurobiology, Cornell University, Mudd Hall, Ithaca, NY. 14853.

Denervation of vertebrate skeletal muscle results in many physiological changes such as the development of spontaneous fibrillations, increased levels of extrajunctional acetylcholine receptors (AChR), and accelerated turnover rates of junctional AChR. Studies of the molecular mechanisms by which the nerve might control these muscle properties would be greatly aided by the availability of a good *in vitro* system which would allow long term investigation and manipulation of denervated adult muscle. Yet to date no organ culture system has been able to maintain these denervation induced muscle responses for prolonged periods, especially if muscles have not been pre-denervated several days prior to being placed in organ culture. In this study we describe organ culture conditions and media which allow us to maintain both pre-denervated and non-predenervated muscle (i.e. muscles denervated at time of transfer to organ culture) for prolonged periods (up to 20 days) comparable in response and fine structure to that of denervated muscle *in vivo*.

A variety of culture media formulations were examined for their ability to support mouse diaphragm muscle in long-term organ culture. These included Trowell's 8, DMEM/F12, DMEM/F10, and M199. Medium 199 (with 5% fetal bovine serum, 1.17 iu/ml insulin, 1.6 mM L-glutamine, 2 mM β-hydroxybutryic acid, 10 μM ascorbate, 1nM dihydrotestosterone, and other supplements) was identified as best for maintaining diaphragm muscle for > 2 weeks as judged by the development of the above listed denervation induced changes as well as the maintenance of high quality muscle fine structure. Although muscles denervated *in vivo* and transferred to organ culture 6-8 days later (pre-denervated) are easier to maintain *in vitro* than muscles denervated at time of transfer to the organ culture (non-pre-denervated), this medium maintained even non-pre-denervated muscle for up to 16-20 days in culture.

105.12

NERVE TERMINALS AT SNAKE TWITCH AND SLOW ENDPLATES RESPOND DIFFERENTLY TO ISOTONIC POTASSIUM PROPIONATE. L.M. Coniglio*, G.M. Hendricks* and R.L. Parsons. Dept. of Anat. & Neurobiol., Univ. of Vt, Burlington, VT 05405.

We observed that during exposure to isotonic potassium propionate (KP) solution, MEPC frequency at twitch fiber endplates was maintained at high levels for up to 3 hrs., whereas at slow fiber endplates, examined after 10 min. to 3 hrs. in KP, the MEPC frequency was not elevated. Ultrastructural studies were undertaken to test whether morphological differences were correlated with the different MEPC responses to isotonic KP. Control preparations and preparations maintained in isotonic KP for 15-90 min. were examined by electron microscopy. We found that nerve terminals at slow fiber endplates were depleted of synaptic vesicles within 15 min., whereas even after 90 min., the nerve terminals at twitch fiber endplates contained numerous vesicles. These results indicate that the difference seen in MEPC frequency between fast and slow twitch fibers in isotonic KP is correlated with a morphological difference at the nerve terminals of fast and slow twitch fibers. Also, our results show that nerve terminals at snake twitch fiber endplates respond differently to isotonic K than nerve terminals at frog twitch fiber endplates, which are depleted of synaptic vesicles after a few minutes in isotonic K (Gennaro et al., J. Physiol. 280:237, 1978). Supported in part by a Grant from the MDA.

PRESYNAPTIC ACTIVE ZONE INTEGRITY AND ACH RELEASE FROM FROG MOTOR NERVE TERMINALS. S.D. Meriney, P.A. Pawson and A.D. Grinnell. JLNRC, UCLA Sch. of Med., Los Angeles, CA 90024.

At the frog motor nerve terminal, the active zone (AZ) is oriented linearly in regularly spaced double row segments directly opposite ACh receptor-dense postsynaptic folds. Patients with Lambert-Eaton myasthenic syndrome exhibit neuromuscular weakness, and make IgG that disrupts this tight organizational alignment (Fukunaga et al., 1982). Recently, Nystrom and Ko (1988) have shown that proteolytic enzymes also disrupt AZ structure. We have examined AZ structure and nerve terminal function following a 2 hour incubation in purified collagenase, and show that AZ segments average only about 50% of control length, frequently lose their orientation, and often break up into single rows or dispersed particles. Despite this change in structure, ACh release is not grossly affected. Subtle changes, such as a decrease in the average MEPP amplitude, probably due to a misalignment of pre- and postsynaptic elements, do occur and may decrease neuromuscular efficacy. However, disrupted AZ pieces appear to maintain function as they "float" in the presynaptic membrane. Supported by grants from the MDA and NIH.

AN INCREASE IN OSMOTIC PRESSURE INCREASES THE PERCENTAGE OF GIANT AND SKEW-MEPPs WHICH ARE COMPOSED OF SUB-UNITS. M.E. Kriebel, J. Vautrin and F. Llados. Dept. Physiol., SUNY Health Sci. Ctr., Syracuse, NY 13210.

Bell- and skew-MEPPs are composed of similarly sized sub-units (Erxleben and Kriebel, J. Physiol. 400:659, 1988) and the number is readily changed (Kriebel et al., J. Physiol. 262:553, 1982). Van der Kloot and Van der Kloot (Expt. 41:47, 1985) report an increase in MEPP size after hypertonic saline treatment whereas Kriebel and Pappas (Neurosci. 23:745, 1987) found more skew-MEPPs. BWSV, Ca^{++}, La^{+++}, ionophore, heat, K^{+} (Kriebel, Handbook Exp. Pharm. 86:537, 1988) reduce the size of the bell-MEPP and increase the percentage of skew-MEPPs with no change in sub-MEPP size. We have measured MEPC amplitudes and fiber input impedance during and after soaking frog and mouse muscle in up to 1M NaCl saline (gradual and step changes). Input resistance increased up to 50 times and stayed higher (20%) than normal after returning to normal saline. These results explain the increased bell-MEPP size. There was also an increase in skew-MEPPs, giant and atypically shaped MEPPs which had the same initial rising phase, and rising phases deviated at similar times. Thus it is meaningless to refer to the "average MEPP size." Skew-, giant and atypical MEPPs are explained with a sub-unit composition and with synchronizing and timing mechanisms that can be altered in number and time. NIH - NS 25683.

MORPHOMETRIC AND ACH ANALYSIS OF ISOLATED SYNAPTIC VESICLES AFTER LONG TERM, LOW FREQUENCY STIMULATION. G.Q.Fox,G.H.C.Dowe*and D.Kötting*. AbG.161, Max-Planck-Institut für biophysikalische Chemie, 3400 Göttingen, FRG.

Cholinergic(ACh) containing synaptic vesicles from Torpedo electric organ were isolated by sucrose density centrifugation and analysed morphometrically and biochemically after 1800 pulses of 0.1 Hz stimulation. Two subclasses of vesicles were identified based on previously established ACh criteria. Stimulation produced a 99% loss of estimated terminal vesicle numbers. These values did not recover after 2 h of rest indicating an absence of local recycling. Only a single 68 nm diameter size class of ACh vesicle was found. ACh levels were depleted by 66% and similarly failed to recover following rest. Gradient location of (^{3}H)choline uptake was influenced by stimulation but uptake efficiency amounted to only 1 label per 10^{7} vesicles or 10^{4} terminals. ACh content/vesicle covered a range of $1\text{-}3\times10^{5}$ molecules for both subclasses exceeding estimated quantal content by a factor of 15.

These findings contradict numerous claims pertaining to stimulation-induced heterogeneity of this vesicle population.

105.16

ULTRASTRUCTURE OF MUSCLES AND NEUROMUSCULAR JUNCTIONS IN THE LARYNX OF MALE AND FEMALE *XENOPUS LAEVIS*. Darcy Kelley, Martha Tobias and Mark Ellisman, Dept. Biol. Sci., Columbia Univ., New York, NY 10027 and Dept. of Neurosci., UCSD, La Jolla, CA 92093

Sex differences in the electrophysiological properties of the larynx contribute to the distinctive male and female vocalizations of *Xenopus laevis* (Tobias and Kelley, J. Neurosci.,1987, 1988). In response to repetitive nerve stimulation, female muscle fibers immediately produce action potentials while male fibers first produce sub-threshold potentials. Muscle fibers of adult females but not males are dye-coupled. Freeze fracture replicas as well as thick and thin sections were examined for ultrastructural clues into sex differences in synaptic efficacy and dye-coupling.

Male laryngeal muscles contain unusual multilamellar structures that surround lipidic inclusions,"whorls" not seen in females. In both male and female freeze fracture material, square arrays of intramembranous particles were apparent. No gap junctions have yet been observed between muscle fibers in either females or males. Areas of close membrane apposition that include apparent cytoplasmic continuity were seen in freeze fractured and sectioned muscles. To date, these specializations have been observed only in females and could account for female-specific dye-coupling of muscle fibers. In many female specimens, multiple small axon terminals occupy the primary synaptic cleft. Most male neuromuscular junctions appear to contain a single axon terminal. The number of synaptic vesicles and the dimensions of active zones appear similar in the sexes. These results suggest that differences in synaptic efficacy in males and females are not due to vesicle availability. Supported by NS 23684; NS 14718; NSF and RR00592.

FOCAL ADHESIONS OF NERVE TERMINAL TO SYNAPTIC MATRIX AND SCHWANN CELL AT MOUSE NEUROMUSCULAR JUNCTIONS. N. Robbins and J. Polak. Center for Neurosciences, Case Western Res. Schl. of Medicine, Cleveland, Ohio 44106.

The neuromuscular synaptic matrix contains information for localizing and aligning presynaptic and postsynaptic specializations, but it is not clear whether the matrix is uniformly adhesive or if there are unique and specific sites of nerve terminal adhesion. To address this question we utilized hypertonic fixatives to induce shrinkage at the mouse soleus NMJ.

In electron micrographs of such preparations, the synaptic matrix adhered to postsynaptic components, while the presynaptic terminal frequently retracted from the matrix except for discrete adhesive regions invariably overlying secondary folds. Some but not all of these adhesive sites were active zones. The adhesion of nerve terminal membrane was so strong that extended tabs of the nerve terminal membrane remained attached to the apices of junctional folds while the rest of the terminal retracted. Similar tabs were occasionally found at the apices of junctional folds in normally-fixed NMJ's. Also, phosphotungstic acid-stained material showed fibrillar elements running from active zones to the synaptic matrix. Hypertonic-fixed preparations also revealed adhesive focal attachments of the nerve terminal to the lateral borders of the Schwann cell cap. Finally, in tissue processed for immunoelectron microscopy, nerve terminal-matrix and nerve terminal-Schwann loci were sites of sub-membranous actin accumulation.

The density and strength of focal adhesive sites to matrix or Schwann cell may be critical in determining the stability or retraction of mature motor nerve terminals. (Work supported by NIH AG00795)

106.1

TIMING OF PREHENSILE COMPONENTS IN THE ELDERLY. V. Diggles and T. Iberall, Andrus Gerontology Center and Department of Computer Science, University of Southern California, Los Angeles, Calif 90089.

The disruption of movement automaticity into less fluid, modular motion in the elderly may be due to age-related changes in the CNS that affect the constraints that simplify motor control by reducing controllable degrees of freedom. The purpose of this study was to assess the integrity of these constraints in the elderly by examining the timing and kinematics of prehensile movement components. The transport and grasping components are believed to have independent control, but their timing appears synchronized such that the occurrence of specific kinematic landmarks are highly correlated (r=.76 to .89) in young adults (Jeannerod, 1984).

In this study, a WATSMART system was used to analyze the kinematics of female subjects, aged from 57-67, while reaching and grasping a cylinder. Movement amplitude, cylinder size and speed instructions were varied. There is a main effect of movement amplitude on movement time, as predicted by Fitts' law. Results indicate that the onset of the slow velocity phase of transport and the time of peak finger separation were not highly correlated (r=.10 to .47). While it is likely that a temporal correlation between the transport and grasping components reduces the control burden by constraining degrees of freedom temporally, the disruption of movement in the elderly may be due to the disintegration of this constraint.

106.2

DIFFERENTIAL EFFECTS OF AGING ON FORELIMB AND HINDLIMB MOTONEURONS IN THE RAT. K. Kanda and K. Hashizume*. Dept. of Physiol. Tokyo Metropol. Inst. of Gerontol., Itabashi-ku Tokyo 173, Japan.

We studied the number and the sizes of forelimb, ulnar motoneurons (Ul-MNs), which send their axons into the Ul nerve, of young (9 months of age) and old (27 months) rats. The data were compared with the data on hindlimb, MG-MNs. The MNs were labeled by retrograde transport of horseradish peroxidase (40% solution) injected bilaterally into both the Ul and MG nerves. Individual labeled cells were identified and counted. The cross-sectional area (CSA) of their somata was also measured with an image analysis system. The mean number of MG-MNs was significantly less in the old rats compared with that in the young rats, confirming our previous findings (Hashizume et al., J. Comp. Neurol., 269: 425, 1988). In constrast, no significant difference was found in Ul-MNs between young and old rats (mean $\pm$ SD: 285 $\pm$ 17 for the young and 290 $\pm$ 11 for the old rats). The mean cross-sectional area of Ul-MNs, however, was a little (7%) smaller in the old rats as was found in MG-MNs. The mean wet weight of the flexor carpi ulnaris muscle, which were innervated by the Ul nerve, was not significantly different for the two age groups, whereas that of the MG muscle in old rats was about 25% lighter than that in young rats. The results suggest that the effects of aging are weaker for forelimb MNs than for hindlimb MNs.

106.3

NEURONAL CHANGES IN AREA 4 DURING THE LIFE SPAN OF THE RHESUS MONKEY. J. Tigges, J. Herndon and A. Peters. Yerkes Reg. Primate Res. Ctr., Emory University, Atlanta, GA 30322, and Dept. of Anatomy, Boston Univ. Sch. Med., Boston, MA 02118.

One right or left area 4 of each of 19 rhesus monkeys, ranging in age from 1 day to 35 years, was processed (frozen sectioned at 30 or 40 μm) for light microscopic analysis in order to assess age-related changes. All neurons were considered regardless of their size. In addition, Betz cells were analyzed separately; to be regarded as Betz cells, pyramidal somata had to display a minimum height of 38 μm. — No age-related change in thickness of area 4 was found. A significant decrease of approximately one third was observed in the number of neurons in maturing monkeys (< 5.5 years). In contrast, in maturing rhesus monkeys significant increases with age were observed in the mean number of Betz cells, and in the means of Betz cell area, height, width, perimeter, and estimated volume. In adult monkeys (> 4.5 years), no age-associated loss of neurons was observed. Also, no loss of Betz cells occurred, although the perimeter, area, and estimated volume of Betz cells decreased slightly, but significantly, with increasing age in adult monkeys. Lipofuscin granules were discernable in Betz cells beginning at the age of 5 years and grew in number with increasing age. In the older rhesus monkeys, the granules were so large and numerous that in some Betz cell somata they displaced the nucleus from its usual location in the center of the cell. (NIH grants RR-00165 and 2PO1-AG00001).

GLIAL FIBRILLARY ACIDIC PROTEIN mRNA INCREASES WITH AGE IN THE MOUSE HIPPOCAMPUS AND CEREBELLUM. J.R.Goss, Kay-Min Chan*, and D.G.Morgan. Andrus Gerontology Center & Dept. of Biological Sciences, University of Southern California, Los Angeles, CA 90089-0191.

Previously, we reported an 80% increase in GFAP RNA in mouse cortex using a solution hybridization (RNase protection) analysis. The same study demonstrated no change in three other message levels: Thy-1 antigen, glutamine synthetase, and beta-tubulin. We report here that GFAP RNA increases 50% in mouse cerebellum and 70% in mouse hippocampus with aging.

Total RNA was prepared from cerebellum and hippocampus of female C57BL/6J mice of four different age groups: 4 months, 9-10 months, 17 months, and 26 months. Four samples for each age group were analyzed by solution hybridization for GFAP and Thy-1 antigen message levels. Solution hybridization was performed in triplicate using six concentrations of total RNA per sample. The mass of each specific message per mass of total RNA was calculated (pg/ug).

A 50% increase in GFAP RNA (4.2 ± 0.74 to 5.95 ± 1.1) in the cerebellum and the 70% increase in GFAP RNA (1.68 ± 0.17 to 3.0 ± 0.6) in the hippocampus were the only significant changes. We feel that this increase in GFAP RNA represents a change in the fibrous character of the astrocytes in these regions, perhaps similar to reactive gliosis. Supported by NIA Training Grant AG00093 (JRG), The Anna Greenwall Award and The American Federation for Aging Research (DGM).

106.5

TEMPORAL RELATED CHANGES IN THE AGING RAT LATERAL ENTORHINAL CORTEX (LEC): A GOLGI-EM STUDY. A.A. Carboni and W.G. Lavelle. Dept of Surgery, Div. of Otolaryngology/Head and Neck Surgery, UMASS. Med. Center, Worcester, MA. 01655.

Focal neuropil lesions and neuronal changes in olfactory cortical structure (Hooper and Vogel, '76; Bondareff et al, '82) and function (Hyman et al, '86; Doty et al, '87) have been implicated in the earliest changes of Alzheimer's disease. Similar changes in the rat (Vaughan and Peters, '81), however, may be found as a result of normal aging.

Correlated light and electron microscopic observations were made of tissue impregnated by the Golgi-Colonnier-Gold method (Braitenberg, '85). Layers III and V of the LEC, in a series of 22 day and 22 mo. old rats, were analyzed and a significant thickening of the layers and basal laminae of the blood vessels was found with an increase in the primary dendritic lengths of the pyramidal neurons. There appeared to be no change in the terminal dendritic segment lengths, branching or synaptic density of these pyramidal neurons. There was, however, a significant decrease in the synaptic sizes of these neurons determined by ultrastructural serial sections. Supported by BRSG #6-32724.

106.6

CHRONIC EXPOSURE TO ELEVATED CORTICOSTERONE ALTERS SPATIAL MEMORY AND HIPPOCAMPAL MORPHOLOGY IN YOUNG, ADULT RATS. S.R. Bodnoff, M. M. Miller, R.M. Sapolsky, & M.J. Meaney. Douglas Hospital Research Ctr., Depts. of Psychiatry and Obstetrics & Gynecology, McGill Univ., Montreal H4H 1R3, Canada and Dept. Biological Sci., Stanford Univ., Stanford, CA 94305.

Chronic exposure to elevated, stress-like levels of corticosterone results in the loss of neurons in the hippocampus (Sapolsky et. al, J. Neursci., 1985), a brain region of considerable importance for learning and memory. We have implanted 4 month-old, Long Evans rats with fused pellets of corticosterone that produce plasma corticosterone levels in the upper physiological range (20-25 µg/dl), comparable to peak basal levels produced by aged animals. Spatial memory was assessed using the Morris water maze, a test that is extremely sensitive to hippocampal dysfunction. Following 3 months of treatment, the corticosterone-treated animals showed significant spatial memory impairments compared with cholesterol-treated controls. The impairments were robust and highly significant for the first 6 trials, but eventually the corticosterone-treated animals reached the same level of performance as controls. Treatment for 1-month has no effect whatsoever on spatial memory.

Corticosterone treatment resulted in the loss of hippocampal neurons in selected regions. These data will be discussed in the context of the corticosterone-induced morphological changes and their relevance for the study of aging.

106.7

AGING, BLOOD VESSELS AND NEUROVASCULAR APPOSITIONS IN THE RAT DENTATE FASCIA. A. Topple, E. Fifkova and K. Cullen-Dockstader*. Dept. of Psychology, Univ. of Colorado, Boulder, Co 80309.

Aspects of mural ultrastructure of capillaries and larger vessels as well as frequency of different types of appositions made by neuronal processes onto the vessel wall were studied. A report on the preliminary findings of this study has appeared (Topple, et al., Soc. Neurosci. Abstr., 1987). Tissue was taken from the left dentate gyrus of 3-, 9-, 24- and 30-month old male Fischer 344 rats (n=18). 719 vessels were analyzed for 15 variables. We report that with increasing age there is thickening of the basal lamina and an increase in mitochondrial presence in capillaries but not in large vessel populations. These age-related changes may be considered as possible vascular markers for the aging brain. A comparison of capillaries and large vessels irrespective of age shows differences in wall size, mitochondrial area and the fraction of vessel wall occupied by mitochondria. In addition, there are more axon terminals, axons and dendrites on capillaries than on large vessels. If these appositions are functional, this suggests a more significant role for them in capillary function than for the larger vessels. Since age did not alter this arrangement, it also suggests that age-related compromises in vessel function may not be related to neuronal regulation. The unchanged frequency of appositions with age is in contrast to the finding in the preliminary study (355 vessels).

DENDRITIC EXTENT OF GRANULE CELLS IN AGING F344 RAT DENTATE GYRUS. D. G. Flood and R. Moromisato*. Depts. of Neurology and Neurobiology and Anatomy, Univ. of Rochester Sch. of Med. & Dent., Rochester, NY 14642.

Aging human dentate gyrus granule cells have shown dendritic growth between middle age and old age, followed by regression between old age and very old age. The growth is thought to be compensatory for age-related loss of neighbor neurons. Because rat granule cells also die in aging (Curcio and Hinds, Neurobiol. Aging, 4, 77, 1983) and because rat dentate gyrus displays a remarkable degree of lesion-induced plasticity in both adult and aged subjects, we suspected that rat dentate gyrus granule cell dendrites might also be plastic in normal aging. We measured dendritic extent in 9 male rats aged 12, 20, or 30 months (3 per group). Rats aged 3, 27, and 37 months are currently being analyzed. Twelve neurons per rat were randomly selected from the lateral blade, point, or medial blade of the dentate gyrus in coded 240 µm thick, Golgi-Cox stained, horizontal sections. Camera lucida drawings were made at 1000X and digitized using a graphics tablet linked to an Apple II Plus microcomputer. Dendritic measures were made as a function of the entire dendritic tree and of the segments ordered centrifugally or centripetally with respect to the cell body. Although there was a slight increase at 30 months in total dendritic length and average segment length for both the entire dendritic tree and the terminal segments, this increase was not statistically significant. The addition of new subjects may help to clarify whether rats do mimic humans in their ability to demonstrate dendritic plasticity in aging or whether dendritic extent of rat granule cells does not change in age. ADRENALECTOMY DECREASES CALCIUM SPIKE DURATION IN RAT HIPPOCAMPAL NEURONS. D.S. Kerr*, L.W. Campbell*, S-Y Hao*, and P.W. Landfield (SPON: Dr. J. Ryu). Dept's. Anatomy and Physiol. & Pharmacol., Bowman Gray Sch. Med., Wake Forest Univ., Winston-Salem, NC 27103.

Recently, we reported that adrenalectomy (ADX) reduces and corticosteroid (CORT) administration increases the duration of the Ca-dependent afterhypolarization in rat hippocampal neurons. Moreover, the effect of ADX was more pronounced in neurons from aged rats in which the AHP normally is prolonged (Kerr, Landfield, Soc. Neurosci. Abstr., 1988; Kerr et al, under review).

If this CORT effect is mediated by Ca conductance, it could link together the glucocorticoid hypothesis of brain aging (cf. Landfield et al, 1981, Science; Sapolsky et al, 1984, J. Neurosci.) with the altered Ca hypothesis of brain aging (cf. Khachaturian, 1984, Handbook of Studies on Psychiatry and Old Age, Elsevier; Landfield, Pitler, 1984, Science; Gibson, Peterson, Neurobiol. Aging, 1987). Moreover, it could have important implications for the normal functions of glucocorticoids in the hippocampus (cf. McEwen, 1982, Adrenal Actions on Brain, Springer-Verlag). However, the AHP provides only an indirect measure of Ca influx. In the present studies, therefore, we quantified the effects of ADX (31 cells, 24 intact and ADX rats) on relatively "pure" calcium spikes which are prominent in cesium-loaded hippocampal pyramidal cells treated with tetrodotoxin. In this preparation, the Ca spike elicited by an intracellular depolarizing current pulse is characterized by a fast, large spike, followed by a longer, lower amplitude plateau phase. (ADX rats were maintained on 1% NaCl drinking saline, and all were healthy at study).

Significant decreases (ANOVA) in Ca fast spike width, plateau amplitude and spike duration were found in cells from ADX animals, although no clear differences in fast spike amplitude or spike inactivation during a 2-Hz train were found. Although additional studies are needed, these data suggest that adrenal steroids modulate brain Ca conductance. This possible relationship may have implications for our understanding of both the normal and the aging-like effects of adrenal steroids in the hippocampus. (Supported by AG04542, NIH).

AGING-RELATED INCREASES IN L-LIKE CALCIUM CURRENTS IN RAT HIPPOCAMPAL SLICES. L.W. Campbell*, S-Y Hao*, and P.W. Landfield (SPON: C.E. Dunlap). Dept. Physiol. & Pharmacol., Bowman Gray Sch. Med., Wake Forest Univ., Winston-Salem, NC 27103

Recent studies have indicated that Ca-dependent afterhyperpolarizations and Ca spikes are prolonged in CA1 hippocampal slice neurons from aged rats (cf. Landfield, Pitler, Science, 1984; Soc. Neurosci. Abstr, 1987; Pitler, Landfield, under review), which could be a factor in the altered Ca homeostasis that occurs in nerve cells during aging (cf. Khachaturian, 1984, Handbook of Studies on Psychiatry and Old Age, Elsevier; Gibson, Peterson, Neurobiol. Aging, 1987).

However, it is not clear which components of voltage-sensitive Ca currents may be affected most by aging. In the present studies, therefore, we used single-electrode voltage-clamp methods to conduct quantitative analyses of Ca currents in cesium-loaded, tetrodotoxin- and TEA-treated CA1 neurons in slices from 15 young-adult (3-5 mo. old) and 10 aged (24-27 mo. old) specific-pathogen-free Fischer rats.

Studies triggering large spike currents from a holding potential of -70 mV did not show aging differences. However, at holding potentials of -40 mV, large regenerative currents were partially inactivated (possibly T- or N-like currents) and good voltage control could be achieved over remaining L-like currents. Under those conditions, significant aging-related increases in Ca current were found.

When nimodipine, a DHP-class of Ca channel antagonist that blocks L channels, was applied, Ca current was reduced. Moreover, this effect of nimodipine was stronger in cells from aged rats. The sensitivity to nimodipine and the prominence of the aging effect at a -40 mV holding potential, suggest that aging is associated with increases in L-like Ca currents in hippocampal neurons, which could have implications for our understanding of aging-related neuronal degeneration. However, these data do not exclude the possibility of aging changes in other Ca channels or Ca homeostatic mechanisms as well (supported in part by AG 04542 and Miles, Inc.)

CHANGES IN CHOLINERGIC AND ADRENERGIC RECEPTORS IN PREFRONTAL CORTEX OF AGED RHESUS MONKEY: CORRELATION WITH PERFORMANCE ON DELAYED-RESPONSE TASK. M.V. Wagster*, L.C. Cork*, L.C. Walker and D.L. Price. Neuropathology Lab., The Johns Hopkins Univ. Sch. Med., Baltimore, MD 21205.

Neurotransmitter markers for the cholinergic and adrenergic systems were examined in the prefrontal cortices of 13 rhesus monkeys (*Macaca mulatta*) ranging from 2-34 years of age. Three years prior to sacrifice, the four oldest animals were tested on a spatial delayed-response task (DRT). In all subjects, *in vitro* receptor autoradiography was used to measure the binding concentrations of: [^{3}H] pirenzepine (PZ) for M1 cholinergic sites; [^{125}I] iodocyanopindolol (ICYP) for β1 and β2 adrenergic sites; and β-([^{125}I]iodo-4-hydroxyphenyl)-ethyl-aminomethyl-tetralone (HEAT) for α1 sites. Total ICYP binding concentration correlated negatively with age and DRT performance. A trend for a decrease with age in ICYP binding for β1 sites was detected but did not correlate with DRT performance. ICYP binding to β2 sites did not change appreciably with age but correlated negatively with DRT performance. HEAT binding decreased with age but did not correlate with performance on DRT. No correlation between PZ binding and age was detected, but PZ binding correlated positively with DRT performance.

106.12

DISCRIMINATION AND REVERSAL LEARNING IN THE AGED MONKEY. P.R. Rapp. The Salk Institute, La Jolla, CA 92037

Previous studies have demonstrated that behavioral deficits in the aged nonhuman primate are task-dependent. Since different brain regions make relatively specific contributions to learning and memory, the pattern of deficits aged monkeys exhibit across a battery of memory tasks provides a basis for predicting which neural structures mediate age-dependent cognitive dysfunction. In an ongoing series of studies, 4 young adult and 5 aged rhesus monkeys were tested in a variety of discrimination and reversal tasks. These monkeys were previously trained in 3 memory tasks, and 2 tests of response preference. Testing was conducted in a WGTA. Subjects were trained to a 90% correct level of performance in a pattern discrimination task in which one of two concurrently presented stimuli was always associated with reward. During subsequent reversal training, subjects were rewarded only when they chose the previously nonreinforced pattern. Although the average performance of the groups did not differ during pattern discrimination acquisition, some aged subjects required 2.5 to 5 times more training than young animals to reach criterion levels of performance. Since this form of learning is not dependent on intact medial temporal lobe function, these findings point to the involvement of other neural structures in mediating age-related cognitive decline. Most aged monkeys, however, performed as well as younger subjects during pattern discrimination reversal training. The normal discrimination and reversal learning observed in many aged monkeys therefore suggests that the acquisition of simple stimulus/reward associations remains largely intact during normal aging.

106.13

REACTION TIME CHANGES WITH AGING IN THE MONKEY. J. Bice*, H. Edwards*, J.W. Ashford. Southern Illinois Univ. Sch. of Med., Springfield, IL 62794.

Reaction time (RT) slows with age and Alzheimer disease (AD), particularly choice RT. We assessed simple (alerting function) and choice RT in young and old rhesus monkeys. In 3 old monkeys (23 years old), simple and choice RT measures declined over a 2 year period (average 3 sessions per week, 240 trials per 1 hour session). Simple RT was measured following a white flash, a delay interval (0-3 sec) and a blue light (down response required). Choice RT was measured to red (down) vs. green (up) light. The simple RT improved over this time from an average of 970 ms (880,780,1250) to 630 ms (600,490,800). The choice RT-red improved from 790 ms (730,470,1170) to 487 ms (550,400,510). Younger monkeys (6 years old) showed little improvement of RT over 4 months of training, average simple RT=675 ms (623,717,685) and average choice RT-red=497 ms (524,448,517). These data confirm studies in the aged human showing that extensive practice can overcome the RT disadvantage associated with age. Further analysis of the alerting function showed similar peak performances between 400 and 600 ms for both groups, similar to humans. However, the choice RT-red remained faster than the minimum simple RT, suggesting a confounding design factor. Manipulation of these variables by drugs and comparing them to human data will assist in the development of a monkey model of AD.

106.14

EVALUATION OF L-ACETYL CARNITINE (LAC) TREATMENT ON BRAIN AND BEHAVIORAL MEASURES IN AGED RATS. R.L. Spencer, J. Ganem*, S. Chapman*, W.K. O'Steen[1], B.S. McEwen. Rockefeller Univ., New York, NY 10021, and [1]Bowman Gray Sch. Med., Winston-Salem, NC 27103.

LAC has been shown to attenuate some of the age-related decline in physiological and behavioral function of rats. We studied the effect of LAC treatment on some biochemical and anatomical measures of septal-hippocampal circuitry and on behavioral measures of spatial learning. Old male and female Sprague-Dawley rats (21 mos at onset of treatment) were given LAC in their drinking water (75mg/kg) for 4 months. Choline acetlytransferase (ChAT) was significantly lower in old rats at 21 and 25 mos of age compared to young rats (2-4 mos). Age differences in spatial learning as measured in the Morris water maze were, however, confounded by visual ability. Based on retinal morphometry, there was 50-100% retinal degeneration in old rats by 21 mos of age. Of 37 old rats with the least retinal degeneration, 36 were able to learn the location of the hidden platform. Thus, when factoring in visual ability, spatial ability was retained in rats as old as 25 mos, even though some decline in ChAT activity was evident. Further evaluation of the utility of LAC treatment of aged rats may require more sensitive measures of behavior and perhaps an earlier onset of treatment.

DIETARY NIMODIPINE IMPROVES ASSOCIATIVE LEARNING AND OPEN FIELD BEHAVIORS IN AGING RABBITS. K.T. Straube, R.A. Deyo*, J.R. Moyer, Jr. and J.F. Disterhoft. Dept. of Cell Biology and Anatomy, Northwestern Univ. Med. Sch., Chicago, IL 60611.

Recently, the Ca^{++} channel blocker nimodipine (NIM) administered intravenously was shown to facilitate learning in aging rabbits (Deyo, et al. *Science, 243:* 809-811, 1989). In the present experiment we evaluate the effects of NIM given orally on associative learning and open field behaviors.

Sixteen aging rabbits (32-50 mo) were assigned to 1 of 2 groups (n=8) and fed 860 ppm NIM or the same diet without NIM (aging-controls). An additional 8 (3 mo) rabbits were maintained on the control diet (young controls). Animals were fed these diets for 28 days prior to and during testing. Rabbits were trained a maximum of 25 days in a trace conditioning task in which the CS was a 100 ms, 85 db, 6 KHz tone followed by a 500 ms trace interval followed by a 150 ms 2.5 psi corneal airpuff (UCS). A conditioned response (CR) was any response occurring after the CS onset but prior to the UCS onset. Immediately after training, rabbits were tested on a 4' x 4' open-field. The number of crossings, rearing and grooming behaviors were recorded for 10 minutes each day for 5 consecutive days.

NIM accelerated acquisition (4 CRS in any block of 5 trials) in aging rabbits relative to aging controls ($p < .05$). The oral dose of 860 ppm NIM used here was not as effective as i.v. administration at 1.0 µg/kg/min as was previously reported (Deyo, et al., 1989). Aging rabbits showed significant learning impairments when compared to young animals ($p< .05$). In addition, the increased open field activity observed in aging rabbits was reduced by NIM ($p < .01$), while rearing behavior increased ($p < .05$). These behavioral rates in aging NIM rabbits were similar to the young controls. These data provide further evidence of NIM facilitation of learning and open field behavior in aging subjects.

EFFECTS OF NIMODIPINE AND OTHER CA^{++} CHANNEL AGENTS ON THE ACTIVITY OF SINGLE HIPPOCAMPAL PYRAMIDAL CELLS AND CLOSELY ASSOCIATED INTERNEURONS. L.T. Thompson, R.A. Deyo*, & J.F. Disterhoft. Dept. Cell Biology & Anatomy, Northwestern Univ. Med. Sch., Chicago, IL 60611.

Studies of eye-blink conditioning show that the calcium-dependent afterhyperpolarization following firing is reduced in hippocampal pyramidal cells in slices taken from conditioned rabbits (Disterhoft *et al., PNAS 83:* 2733,1986). The firing of these neurons is enhanced during conditioned eye-blink responses (Berger *et al., J. Neurophysiol. 50:* 1197, 1983). Nimodipine, a dihydropyridine calcium antagonist, facilitates learning of the eye-blink response in aging rabbits (Deyo *et al., Science 243*, 809, 1989). Since pyramidal cell activity is regulated by calcium -dependent currents, we examined the effects of nimodipine and other antagonists and agonists on hippocampal neurons to begin describing the neural mechanisms underlying nimodipine's behavioral facilitation in aging.

Anesthetized young or aging adult albino rabbits were chronically implanted with driveable bundles of ten 32 µm nichrome microwire electrodes over the dorsal hippocampus and with jugular catheters. After one week of recovery, extracellular unit activity was analyzed using a BrainWave™ workstation, allowing simultaneous discrimination of up to 32 single-units. The characteristic waveforms and firing frequencies of pyramidal cells and interneurons permitted separation of these neuronal populations for study. Unit activity was continuously recorded prior to, during, and following infusion of calcium channel agents. Nimodipine enhanced firing of pyramidal cells in aging animals and suppressed activity of interneurons at the same time. This effect on activity was reversed by removal of the drug. Other agents, including BAY-K-8644 and flunarizine, are also being tested.

Nimodipine enhanced pyramidal cell firing in the aging hippocampus. These cells were previously shown to have enhanced activity during associative responses in young animals. The simultaneous reduction in interneuron firing rates is also consistent with nimodipine facilitation of hippocampal function in aging.

NEUROCHEMICAL, ENDOCRINE AND IMMUNOLOGICAL RESPONSES TO STRESS IN YOUNG AND OLD F344 MALE RATS. S. Lorens, N. Hata*, R. J. Handa*, L. Van de Kar, M. Guschwan* and J. Clancy*. Dept. Pharmacology and Anatomy, Loyola University Medical Center, Maywood, IL 60153.

Forebrain dopamine (DA) but not norepinephrine (NE) or serotonin (5-HT) metabolism is significantly reduced in old non-stressed rats. Conditioned fear increased medial frontal cortex, nucleus accumbens and amygdaloid DA turnover in both young (7 mo) and old (22 mo) rats; decreased medial frontal NE content only in young rats; and, increased medial frontal cortical and hypothalamic 5-HT turnover only in old animals. These observations suggest age-related differences in the response of central NE and 5-HT systems to stress. No age-related differences were observed in the basal (morning) plasma corticosterone levels. However, the corticosterone response to ether stress and to conditioned fear was significantly higher in old rats. Hippocampal corticosterone type I but not type II receptors were decreased by 47% in 17.5 mo old rats. Thus, age-related changes in hippocampal corticosterone receptor types do not occur in unison, and the exacerbated corticosterone response to stress precedes the reported down-regulation of hippocampal type II receptors in aged rats. Immune function was impaired in the old non-stressed rats, and further compromised by exposure to conditioned fear. The old non-stressed rats showed an increased percentage of splenic large granular lymphocytes, reduced natural killer cytotoxicity, and impaired Con-A stimulated T lymphocyte proliferation. Compromised immune function also was observed in the young rats subjected to fear conditioning, but not to the same extent as in the old rats. Thus, aging male F344 rats evidence major alterations in central monoamine, endocrine and immune functions, and an increased sensitivity of these systems to stress.

106.18

STABILITY OF POSTSYNAPTIC DENSITY DIMENSIONS IN HIPPOCAMPAL SYNAPSES OF AGED RATS WITH POOR AND GOOD SPATIAL MEMORY. L. deToledo-Morrell, Y. Geinisman and F. Morrell. Depts. of Neurol. Sci. and Psychol., Rush Med. Coll. and Dept. of Cell Biol. & Anat., Northwestern Univ. Med. Sch., Chicago, IL 60612.

Spatial memory (SM), which crucially depends on the integrity of the hippocampal formation, is impaired in the majority, but not all, aged rats (deToledo-Morrell et al., Behav. Neurosci., 1984, *98:* 902). Structural substrates of this memory dysfunction may include decreases in the number and size of hippocampal synapses. We have reported earlier that the extent of loss of perforated axospinous synapses in the hippocampal dentate gyrus of aged rats correlates with the degree of SM deficit (Geinisman et al., Brain Res., 1986, *398:* 266). The present study was designed to verify whether the size of the postsynaptic density (PSD), the area of greatest concentration of postsynaptic neurotransmitter receptors and ion channels, is diminished in hippocampal synapses as a function of the age-related decline in SM. Young adult rats (5 mo. old) with good SM (as assessed in an 8-arm maze), aged rats (27 mo. old) with impaired SM and equally aged rats with intact SM were compared. Axodendritic, axospinous perforated (with discontinuous PSDs) and axospinous nonperforated (with continuous PSDs) synapses were differentially analyzed in the middle molecular layer of the dentate gyrus. Using serial sections, the maximal profile length was determined for each PSD sampled. Differences on this measure among the groups of rats under comparison were found to be small and statistically not significant. There was no significant correlation between the PSD maximal profile length and the extent of SM loss. Thus, PSD dimensions are unaffected by advancing chronological age and by the age-related memory dysfunction. It appears that a specific loss of certain hippocampal synapses, rather than a reduction in synaptic size, is a major morphological substrate of the age-related decline in SM. LONG-TERM BEHAVIORAL AND NEUROCHEMICAL EFFECTS OF INTRADENTATE ADMINISTRATION OF COLCHICINE IN RATS. H.A. Tilson, K. Nanry, M. Bonner, S. Barone Jr., E.G. Drust, and P. Tandon. LMIN, NIEHS/NIH, RTP, NC 27709.

Deficits in learning and memory and alterations in the signal transduction process for the cholinergic muscarinic receptor have been observed 12 wks after colchicine (COL) treatment. To study the long-term effects of COL administration on cognitive function and the cholinergic system, 6 mo-old male, Fischer-344 rats were injected with 2.5 ug of COL bilaterally in the dorsal and ventral hippocampus. A significant deficit in acquisition in the water maze was observed in animals 1 yr after COL administration. After [^{3}H]-inositol was incorporated into hippocampal slices, neurochemical studies showed an increase in the carbachol-induced PI metabolism in the rat hippocampus 1 yr post-lesion with COL. A significant hyperstimulation of ibotenic acid-induced PI turnover was also observed 1 yr after COL treatment. However, in contrast to results obtained 12 wks after lesioning, no significant changes were observed in norepinephrine or serotonin-induced PI metabolism 1 yr post-lesion. Pirenzepine, an M_1 receptor antagonist, produced a greater degree of inhibition (60%) in lesioned animals as compared to the age matched controls (20%). Increased staining for AChE was found in the hippocampus of treated rats, similar to that observed 12 wks post-lesion.

MONOAMINERGIC & CHOLINERGIC CORRELATES OF IMPAIRED SPATIAL MEMORY IN AGED RATS. V. Luine, D. Bowling*, M. Hearns* & C. Milio* Psychology Dept., Hunter College, N.Y., N.Y. 10021

Spatial memory performance in aged (25 months) and young (3 mo.) Fisher 344 rats was assessed on the 8-arm radial maze, and levels of NE, DA, 5HT and metabolites, and ChAT activity were measured in micropunched brain samples. Analyzed were cholinergic and monoaminergic cell body areas, frontal cortex (FCx), hippocampal regions, and other areas. Monoamines were measured by HPLC with EC, and ChAT by radiochemistry. Aged rats showed significant decrements in choice accuracy and trials to criterion. Numerous age related differences, some of which correlated with performance, were found. ChAT activity decreased by 17-25% in aged rats in the vertical diagonal bands (vDB), striatum and dentate gyrus; only vDB changes correlated with performance. Also correlated with performance were: 50% declines of NE in locus coeruleus and n. basalis (nBM) of aged rats and 30-66% declines of DA, DOPAC or HVA in entorhinal Cx, FCx, nBM and substantia nigra. DA and metabolites showed the greatest number and magnitude of age related changes and correlations with choice accuracy. The relatively few age related differences in the hippocampus were noteworthy. Results suggest that attenuated catecholaminergic activity, especially DA, makes a substantial contribution to the impaired performance of aged rats on a memory task. Cholinergic contributions, as indexed by ChAT activity, were less evident. (Supported by AG06384).

BIOGENIC AMINES IN THE AGED RAT BRAIN: RELATION TO BEHAVIOR. P.R. Miller*, M.H. Kodsi*, S. Southerland*, R.D. Burwell*, M. H. Lewis and M. Gallagher (SPON: R.J. Fanelli). Departments of Psychology and Psychiatry, University of North Carolina at Chapel Hill, Chapel Hill, NC 27599.

Young (5 mo, N=29) and aged (25 mo, N=31) male Long-Evans rats were tested on a number of behavioral tasks providing measures of learning, diurnal behavior and sensorimotor function. A subpopulation of the aged rats (N=17) had a spatial learning deficit that was of comparable severity at both the beginning and end of the 13 wk testing protocol. The spatial learning capacity of the remaining aged rats (N-14) was within the range of the young group's performance. The "impaired" aged subgroup was also distinctly impaired on some, but not all, other behavioral measures that declined with age. Markers for biogenic amines (NE, DA, DOPAC, HVA, 5HT, 5HIAA, AND ChAT) were measured using HPLC and radioenzymmatic assays. For the measures that showed a significant change with age, some were equally altered in both subgroups of aged animals, i.e. 5HIAA elevation in all forebrain regions and a decline in striatal DA, DOPAC and HVA. In contrast, other neurochemical parameters were significantly altered only in the "impaired" subgroup of aged rats, i.e. ChAT reduction in basal forebrain and frontal cortex, DA and DOPAC reduction in basal forebrain, and NE elevation in both frontal and parietal cortices. The relation between age-related neurochemical changes and other behavioral indices of aging in these animals will be discussed.Supported by a NSF Predoctoral Fellowship to RB, a NIMH Research Scientist Development Award to MG (K02-MH00406) and grants NIMH MH39180 and NSF BNS 87-19881.

106.22

CHRONIC DEPRENYL TREATMENT AND PSYCHOMOTOR FUNCTION IN AGED MICE. *M. E. Chachich[1,4], M. Gupta[2], H. L. Wiener[3]*, J.A. Joseph[4], and D.K. Ingram[4]*.* [1]Dept. Psychol., Towson St. U.; [2]Dept. Anat., U. Louisville Sch. Med., Louisville, KY 40292; [3]N.S. Kline Inst. for Psychiat. Res., Ward's Island, NY 10035; [4]Geront. Res. Ctr., NIA, NIH, Baltimore, MD 21224.

MPTP cytotoxicity can be blocked by inhibiting monoamine oxidase-B (MAO-B). This observation has suggested a hypothesis that aging of the nigrostriatal system might result from the generation of oxy-radicals through normal action of MAO-B metabolism of dopamine (Cohen, G., *Adv. Neurol.*, 45:119, 1986). To examine this hypothesis, 18-mo old male C57BL/6J mice were tested in a psychomotor battery that included locomotor activity in an open field (10-min), a runwheel cage (48-hr), and on an inclined screen (10-min) and for their ability to perform on a rotorod (3 rpm), an accelerated rotodrum (up to 48 cm/sec), and a tightrope (three 60-sec trials). Mice were then provided *l*-deprenyl (a MAO-B inhibitor) in distilled water (0, 0.5 or 1.0 mg/kg per day) for 6-9 mo. When mice were retested at 24 and 27 mo of age, longitudinal declines in control groups were observed in tests of open field, runwheel, inclined screen, and rotodrum performance. No deprenyl effects were observed in any parameter except the rotodrum test, *i.e.* mice treated with 1 mg/kg maintained their maximum running speed over 9 mo. Compared to values observed among controls, HPLC analysis of catecholamines and enzymatic analysis revealed significant reduction in striatal MAO-B activity induced by deprenyl as early as 3 weeks after treatment and sustained over 6 months. Analyses of age-related loss of striatal dopamine receptors as well as changes in dopaminergic neurons in substantia nigra using fluorescence histochemistry are being conducted. However, present results indicate that chronic MAO-B inhibition during normal aging does little to retard decline in psychomotor performance in mice as assessed in this battery.

AGING AND SERIAL LIST MEMORY. A.S. Gilinsky and M.Korsnes Department of Psychology, University of Bridgeport,Bridgeport, CT 06601.

The easiest item to remember in a series is either the first or the last depending on the length of the interval between exposure to the series and the recognition test. A short interval favors the recent item; a long interval shifts superiority from recency to primacy; both primacy and recency effects operate at intermediate intervals. Wright, Santiago, Sands et al, Science,229:287,1985, found the list memory of pigeons, monkeys, and humans for visual recognition items showed the same modification of the memory process in the the three species with increasing retention intervals but the time course of these changes was fastest for pigeons and slowest for humans. Our experiment investigated human age differences in the serial position modification effect using the Wright et al paradigm in young (25-35 year-old) and old (65-75 year-old) college graduates. Increasing delay intervals gave a consistent modification of the recency effect in both groups. Short intervals gave strong recency effects;long intervals reduced the recency effects to chance levels. Older subjects were significantly more accurate than the young at brief delays and crossed over to primacy effects earlier in the time course than younger persons, not unlike Wright et al's monkeys compared to humans.

107.1

CNS CELL GROUPS INNERVATING THE PARASYMPATHETIC PREGANGLIONIC NEURONS REGULATING THE PTERYGOPALATINE GANGLION AS REVEALED WITH THE RETROGRADE TRANSNEURONAL VIRAL LABELING METHOD

S.E. Spencer, W.B. Sawyer, K.B. Platt*, and A.D. Loewy, Dept. of Anatomy & Neurobiology, Washington Univ. School of Medicine, St. Louis, MO 63110, and *Dept. of Veterinary Microbiology, College of Veterinary Medicine, Iowa State Univ. Ames, IA.

The pterygopalatine ganglion, also called the sphenopalatine ganglion, provides parasympathetic innervation to the lacrimal gland, the nasal and palatal mucosa, and the cerebral vasculature. The central innervation of these preganglionic neurons is unknown. We have used the retrograde transneuronal viral technique to identify central nuclei that innervate the preganglionic neurons regulating the pterygopalatine ganglion.

Pseudorabies virus injections were made into the pterygopalatine ganglion of rats. Four days later, the rats were perfused with 4% paraformaldehyde. The brains were processed for immunohistochemical detection of viral infections. Labeling of the ipsilateral parasympathetic preganglionic neurons was seen in the ventrolateral medullary reticular formation. In addition, viral infections of second order neurons in the brain that project to the preganglionic neurons were identified at several CNS levels. These were labeled as a result of retrograde transneuronal viral transfer.

Bilateral labeling was seen in the ventrolateral medullary reticular formation, A5 cell group, parabrachial nuclei, raphe magnus and pallidus nuclei, central gray matter, lateral and paraventricular hypothalamic nuclei, zona incerta, and bed nucleus of the stria terminalis. Ipsilateral cell body labeling was seen in the nucleus tractus solitarius, parapyramidal nucleus, and amygdala. Contralateral labeling was seen in the tuberomammillary nucleus of the hypothalamus.

107.2

ALTERED BONE REMODELING IN SYMPATHECTOMIZED AND SENSORY DENERVATED RATS.

E.L. Hill, R.T. Turner*, and R. Elde, Dept. of Cell Biol. and Neuroanat., Univ. of MN, Mpls. MN 55455 and * Mayo Clinic and Mayo Graduate School, Rochester MN 55901

Bone metabolism may be influenced by the nerves in bone tissues. Neuropeptides such as vasoactive intestinal peptide (VIP, from sympathetic nerves) and calcitonin gene-related peptide (CGRP, from sensory nerves) have been implicated as local modulators of bone metabolism. The effect of guanethidine sympathectomy or capsaicin sensory denervation in rats on the following was studied : 1) the presence of VIP-, CGRP-, substance P (SP)-, and dopamine-ß-hydroxylase (DßH)-immunoreactive nerve fibers in periosteum; 2) the radial growth and apposition rate in tibiae (normal growth and modeling); 3) the percentage of periosteal surface of the mandible occupied by osteoclasts during induced remodeling. Neonatal rats were treated with guanethidine, capsaicin, or appropriate vehicle. At 7 weeks, maxillary molars were removed to induce remodeling on the buccal surface of the mandible. Animals were perfused 4 days after surgery. Whole mounts of periosteum were stained for immunofluorescence using antisera to VIP, CGRP, SP, and DßH. Tibial cross-sectional cortical area, medullary area, and periosteal apposition rate were measured by histomorphometry in ground sections. The percentage of periosteal surface at the remodeling site occupied by osteoclasts (stained for acid phosphatase) was measured in frozen, undecalcified sections. CGRP-and SP-immunoreactive nerves fibers were dramatically reduced in periosteum of capsaicin-treated animals as compared to controls; VIP- and DßH-immunoreactivity (IR) appeared unchanged. VIP- and DßH-IR were dramatically reduced in guanethidine-treated animals; CGRP- and SP-IR appeared unchanged. There was no significant difference in cortical or medullary area or periosteal apposition rate between each drug treatment and its control. Sympathectomy resulted in a 45.5% ($p \leq .005$) increase over controls in the mandibular bone surface occupied by osteoclasts. Sensory denervation resulted in a 21.2% ($p \leq .04$) decrease from controls. These data suggest that selective denervations did not affect normal bone growth and modeling. The alteration of at least one parameter (osteoclast surface) of bone remodeling by both treatments indicates that sensory and sympathetic nerves play a role in focal bone metabolism.

107.3

A GENERAL PATTERN OF CNS INNERVATION OF THE SYMPATHETIC OUTFLOW DEMONSTRATED BY TRANSNEURONAL PSEUDORABIES VIRAL INFECTIONS.

A.M. Strack, W.B. Sawyer, K.B. Platt*, and A.D. Loewy, Dept. of Anatomy & Neurobiology, Washington Univ. School of Medicine, St. Louis, MO 63110, and *Dept. of Veterinary Microbiology, College of Veterinary Medicine, Iowa State Univ. Ames, IA.

Pseudorabies virus (PRV) injections of various sympathetic ganglia (viz., superior cervical, stellate, celiac and lumbar paravertebral ganglia and the adrenal gland) were made in rats. Two days later, colchicine (100 µg/10 µl saline) was injected into the lateral ventricle. After two days, the rats were perfused with 4% paraformaldehyde. Immunohistochemically detectable retrograde viral infections of ipsilateral sympathetic preganglionic neurons (SPNs) and transneuronal infections of the specific sets of second order neurons in the spinal cord and brain that innervate the infected SPNs were seen.

Five cell groups in the brain appear to regulate the entire sympathetic outflow: the paraventricular hypothalamic nucleus (PVH), A5 noradrenergic cell group, caudal raphe region, rostral ventrolateral medulla, and ventromedial medulla. Other CNS areas also became transneuronally labeled after infections of certain sympathetic ganglia, most notably the superior cervical and stellate ganglia. These areas include the central gray matter and lateral hypothalamic area. The zona incerta was uniquely labeled after stellate ganglion infections. The cell body labeling was specific. This specificity was demonstrated in the PVH where the neurons of the parvocellular PVH that form the descending sympathetic pathway were labeled in a topographic fashion.

ULTRASTRUCTURAL ANALYSIS OF AUTONOMIC PREGANGLIONIC NEURONS IDENTIFIED WITH A MONOCLONAL ANTIBODY TO CHOLINE ACETYLTRANSFERASE.

J.A. Markham and J.E. Vaughn, Div. of Neurosciences, Beckman Res. Inst. of the City of Hope, Duarte, CA 91010

A monoclonal antibody to the acetylcholine synthesizing enzyme choline acetyltransferase (ChAT) was used to identify autonomic neurons in the intermediolateral nucleus (ILp) of the adult rat thoracic spinal cord. Labeled cells were identified in the electron microscope, and an ultrastructural analysis was made of their dendritic processes and afferent input. Synaptic terminals on identified ChAT(+) ILp neurons consisted of three types: (1) terminals containing round, clear vesicles with or without dense-cored vesicles (DCVs); (2) terminals containing clear pleomorphic or flattened vesicles; and (3) terminals containing a large proportion of DCVs. The first group was the predominant terminal type, and serial section analysis indicated that the third group may be a subset of the first, with the predominance of DCVs being a consequence of the section plane. Dendrites of labeled ILp cells formed extensive transverse bundles. Longitudinal bundles of labeled dendrites were also found between ILp cell clusters located rostrocaudally along the spinal cord. Such dendritic bundles were closely associated with fascicles of thin, unmyelinated axons. Both dendritic and axonal groups were surrounded by astroglial sheaths. Axons contained within fascicles occasionally formed varicosities that synapsed upon labeled ILp dendrites. The results suggest that dendritic bundling may maximize the convergence of afferent systems upon groups of autonomic neurons, and that astroglial processes may isolate these units from the surrounding neuropil. *Supported by NIH grant NS25784.*

107.5

DIFFERENTIAL COEXISTENCE OF SUBSTANCE P (SP)-IMMUNOREACTIVITY (IR) WITH OTHER NEUROCHEMICALS IN INTERMEDIOLATERAL CELL COLUMN (IML)-PROJECTING NEURONS IN THE VENTRAL MEDULLA OBLONGATA (VM)

C. Sasek & C. Helke Dept. of Pharmacol. Uniformed Services Univ. Bethesda MD 20814.

SP-IR coexists with serotonin (5HT)- and thyrotropin releasing hormone (TRH)-IR in VM neurons that project to the IML. Enkephalin (ENK)-IR neurons are similarly distributed and also project to the IML. Neuropeptide Y (NPY)-IR neurons in the VM have a small overlap in distribution with SP-IR neurons. The overlapping distribution of ENK- and NPY- with SP-IR suggests that these neurochemicals may coexist with SP-IR in IML-projecting neurons. The present study investigated the possible coexistence of SP- with NPY- or ENK-IR in IML-projecting neurons.

Rats received 40nl injections of rhodamine beads into the T3 IML. Colchicine was given ICV 4d later, and 24h later animals were perfusion fixed. Tissue was sectioned at 4µm and stained using dual color immunofluorescence.

Despite their similar distributions ENK- and SP-IR coexisted only rarely in IML-projecting neurons. NPY-IR was identified in IML-projecting neurons but coexistence of NPY- and SP-IR was also rare, although it was somewhat greater than that of ENK- and SP-IR. The results of these studies indicate that there are several neurochemically coded subsets of IML-projecting neurons in the VM. (NS24876-CH; HL07565-CS)

107.6

SPATIAL RELATIONSHIP OF NERVE TERMINALS CONTAINING OPIOID PEPTIDES TO THE DENDRITIC TREE AND CELL BODY OF SACRAL PREGANGLIONIC PARASYMPATHETIC NEURONS.

J. Wang, W. Wu and R. Elde (SPON: V. Seybold). Dept. Cell Biology and Neuroanatomy, Univ. Minnesota, Minneapolis MN 55455.

Although much is known about the regional distribution of opioid peptides in the CNS, less is known concerning the cellular arrangements which enable opioids to be delivered to receptors on target neurons.

In order to address this, preganglionic parasympathetic neurons were retrogradely labeled by exposing the proximal end of the severed pelvic nerve to 1% FluoroGold. After perfusion fixation, one or two such labeled neurons in 200µm vibratome sections were intracellularlly filled by iontophoresis with 3% Lucifer Yellow. Sections were immunostained for enkephalin and dynorphin using rhodamine-labeled second antibodies. Sections were examined using laser scanning confocal microscopy.

Neurons filled with Lucifer Yellow were often found to have two aspiny, primary dendrites, one of which extended laterally into the white matter. The other dendrite often extended medially toward the central canal. Branching of dendrites was sparse. Nerve terminals containing enkephalin and dynorphin immunoreactivity were not restricted to the vicinity of the cell body, but were found to appose even the most distal portions of the dendrite. SACRAL SPINAL REFLEX PATHWAYS IN THE CLAWED FROG, **XENOPUS LAEVIS**. J.C. Bresnahan, H.L. Campbell, and M.S. Beattie. Depts. of Anat., Surg., and Neurosci. Prog., Ohio State U., Cols., OH 43210.

HRP was applied to pelvic visceral structures, or to the 10th spinal nerves, in juvenile **Xenopus laevis** frogs in order to determine the location and morphology of neurons involved in sacral spinal reflexes.

Labelling of the 10th nerve showed, in addition to lateral motor column (LMC) neurons, a group of small neurons located in the medial and lateral intermediate zones. These cells were similar in location and morphology to mammalian sacral parasympathetic nucleus (SPN) preganglionic neurons (PGNs). Labelled dorsal root afferents made apparent direct contacts with their somata and proximal dendrites. HRP applied to peripheral nerves innervating the cloaca, cloacal sphincter, and bladder labelled this same population of cells, and also revealed a group of lamina IX neurons located in a medial column extending from the caudal cord through the 10th spinal segment. These putative motoneurons were smaller than LMC motoneurons, and their location and morphology was reminiscent of neurons in Onuf's nucleus in mammals. The organization of sacral reflex systems in **Xenopus** is thus similar to that in mammals. (NS-10165)

107.8

DISTRIBUTION, CONNECTIVITY, AND ORIGIN OF TRH-IMMUNOREACTIVE (TRH-I) FIBERS IN THE DORSAL MOTOR NUCLEUS OF THE VAGUS AND NUCLEUS OF THE SOLITARY TRACT (DMV/NST) IN RAT. R.B. Lynn*, L. Rinaman, and R.R. Miselis (SPON: G.R. Christoph). Animal Biology & Institute of Neurological Sciences, University of Pennsylvania, Philadelphia, Pennsylvania 19104-6045.

Central TRH stimulates gastric activity, perhaps by direct effects on gastric neurons in the DMV/NST. This anatomical study examined that possibility in rats. The stomach wall was injected with 25 µl of the β-subunit of unconjugated cholera toxin (CTB; Sigma; 0.25%) to label gastric vagal motoneurons and dendrites. Rats were perfused 72 h later, and brain sections processed for localization of transported CTB and/or TRH-I using goat anti-CTB (Calbiochem) and rabbit anti-TRH (gift of M.S. Kreider, Univ. Penn.). A two-color peroxidase reaction showed TRH-I fibers associated with CTB-labeled dendrites in the DMV/NST. Ultrastructural analysis showed TRH-I terminals forming asymmetric synaptic contacts with CTB-labeled gastric vagal motoneuronal dendrites. In addition, TRH-I terminals formed asymmetric and symmetric synapses with unlabeled dendrites, and non-synaptic TRH-I varicosities were present throughout these nuclei. In a second group of rats, the DMV/NST was injected with 50 nl of Fluorogold to retrogradely label the source of these afferents. After 3-8 days, rats received colchicine ICV, and were perfused 48 h later. Brain sections containing retrogradely-labeled neurons were processed for TRH-I using FITC immunofluorescence. Double-labeled neurons were found only in the nuclei raphe obscurus and pallidus. This work demonstrates that 1) TRH-I terminals in the DMV/NST synapse on the dendrites of gastric vagal motoneurons and non-motoneurons; 2) TRH may also be released non-synaptically in the DMV/NST; and 3) the raphe nuclei provide at least part of this TRH-I innervation. This work was supported by GM27739 and E.I. duPont de Nemours & Co.

107.9

REPRESENTATION OF CECUM IN LATERAL DORSAL MOTOR NUCLEUS AND COMMISSURAL SUBNUCLEUS OF THE NUCLEUS TRACTUS SOLITARIUS IN RAT. D. A. Ferenci*, S. M. Altschuler*, R. R. Miselis (SPON: J. Metzler). Depts Pedia., An. Biol., and Inst. Neurol. Sci., Univ. of Penn., Phila., PA 19104.

This study demonstrates vagal innervation of the cecum using a sensitive retrograde neural tracer, cholera toxin-horseradish peroxidase(CT-HRP). CT-HRP was injected into exteriorized cecum(n=22). In separate rats stomach, ileum, or ascending colon were injected. After 72-120 hour survival periods brainstems were processed. With all cecal injections, strong labeling of the lateral 1/3 of the dorsal motor nucleus(DMN) occurred bilaterally above, at and below the level of the area postrema. Dendrites of laterally positioned neurons projected medially and rostrocaudally within the DMN and dorsally into the medial and commissural subnuclei(sn) of the nucleus tractus solitarius(NTS). Afferent labeling occurred in the anterolateral and medial area of the commissural sn of the NTS. Stomach injections labeled the medial column of the entire rostrocaudal extent of the DMN and the gelatinosus sn of the NTS. Ileal and ascending colonic injections labeled neurons very sparsely in the lateral columns. The vagal complex has a prominent viscerotopography: DMN has a mediolateral organization corresponding to end organ innervation; NTS has a rostrocaudal axis of visceral representation corresponding to rostrocaudal positioning along the alimentary canal. Supported by NIH grants GM27739, DK01747, and DK07066.

107.10

VISCEROTOPIC ORGANIZATION OF ABDOMINAL VAGAL BRANCHES AS DETERMINED BY INDUCED MOTILITY RESPONSES. N. Carlson*, H.-R. Berthoud, and T.L. Powley (SPON: F.R. Brush). Lab. of Regulatory Psychobiology, Purdue Univ., W. Lafayette, IN 47907.

In order to examine the functional implications of the longitudinal columnar organization of the dorsal motor nucleus of the vagus (dmnX), the innervation field for each column and associated branch needs to be identified. Cervical vagal stimulation-induced motility responses were monitored all along the GI tract, using miniature strain gauges, before and after selective abdominal vagal branch cuts in anesthetized rats. Because motility fronts can propagate "enterically" along the gut without vagal input, only short latency (<30sec), stimulus-locked responses were considered. The branches were found to mediate such responses at the following sites:

	STOMACH	DUODENUM prox.	DUODENUM mid.	DUODENUM dist.	JEJUNUM & ILEUM	CECUM & COLON
gastrics	X	X				
hepatic		X	X			
celiacs		X	X	X	X	X

Therefore, because the gastric columns are medial in the dmnX and the celiac columns are lateral, there is a viscerotopic organization of vagal control over gastrointestinal motility. The oral-aboral axis of the gut is represented on a medial-lateral axis within the dmnX. Furthermore the duodenum is a major site of overlapping innervation of all vagal branches/columns. Finally, this is the first functional demonstration of vagal innervation of the cecum and supports the results of anatomical studies (Berthoud, H.-R., et al., this meeting; and Miselis, R.R., personal communication). (DK27627 and NS26632)

107.11

SIMULTANEOUS IDENTIFICATION OF AFFERENT INPUTS AND EFFERENT PROJECTIONS OF THE DORSAL MOTOR NUCLEUS OF THE VAGUS WITH DiI. H.-R. Berthoud, A. Jedrzejewska* T.L. Powley. Lab. of Regulatory Psychobiology, Purdue U., W. Lafayette, IN 47907.

To develop a protocol that would concurrently label CNS inputs to vagal preganglionics as well as the terminals of these motor neurons in the periphery, we made bilateral DiI injections into the dmnX (0.2-5%, in EtOH, 2-4 per side, 50nL per injection) in SD rats. At sacrifice (15-30days), animals were perfused with, and the tissue samples stored in, 10% formalin at 4°C. Brains were cut with a cryostat; gut tissues were prepared as peels of particular wall layers. Both were processed in PBS, counterstained with Bisbenzimide, cleared and mounted in Glycerol, and viewed with epifluorescence.

The extensive injections labelled most, if not all, dmnX cells and typically encroached on neighboring structures. Afferent projections to the dmnX, including those from the parabrachial n., the PVN, and the central n. of the amygdala, were brightly and selectively labeled. Corroborating and extending previous anterograde tracer demonstrations of vagal preganglionics (e.g Kirchgessner & Gershon, Neurosci. Abs., 14(1988) 1317), labelled vagal profiles (single and multiple axons, fine and large varicose endings) were found exclusively in the myenteric plexus throughout the GI tract, including the most distal small bowel as well as the cecum and proximal colon. The stomach (all parts) showed by far the densest innervation, with labelled vagal profiles present in virtually every myenteric ganglion and connective. The cecum evidenced extensive vagal innervation as well. In the intestine, single fibers could be observed coursing through a number of ganglia, giving off collaterals and fine endings in each of them. (DK27627 and NS26632)

107.12

3-D DIGITAL ATLAS OF THE DORSAL MOTOR NUCLEUS OF THE VAGUS. T.L. Powley, F.B.Wang and E. Baronowsky.* Lab. of Regulatory Psychobiology, Purdue Univ., W. Lafayette, IN 47907.

To facilitate high resolution analyses of vagal motor function (e.g. electrophysiology, picospritzing, microsurgery, dendroarchitectonic reconstruction, etc.) and to make it feasible to map these functions onto the defined columns or subnuclei of the dorsal motor nucleus (dmnX), we have developed a 3-D database and atlas of the different subpopulations of dmnX preganglionics.

In separate groups of rats (10 or more/group), each of the primary branches of the abdominal vagus was independently soaked with HRP to retrogradely label the corresponding dmnX cell column. Serial coronal sections (56µm) of the medulla oblongata were saved and processed with TMB. Additional groups representing the full ventral and dorsal trunks as well as secondary gastric branches were similarly prepared. Using standard medullary surface landmarks, the x-, y-, and z-coordinates of all labeled cells were then digitized (Bioquant System IV). For each defined pool of preganglionics as well as for the entire dmnX, exact dimensions (confidence limits) in all three planes were then calculated and expressed in stereotaxic coordinates. The results confirm our earlier descriptions (e.g. Fox & Powley, Br.Res., 1985; Powley et al., AJP, 1987) and graphically illustrate the fine-grained pattern of the columnar organization of the dmnX. For each identified pool of motorneurons, numbers of cells, packing densities, and relative concentrations in different regions of the dmnX were determined. These results provide a 3-dimensional database for experimental manipulations of the vagal preganglionic neurons controlling the different viscera. (DK27627 & NS26632)

107.13

DIFFERENTIAL PROJECTIONS TO THE NUCLEUS OF THE SOLITARY TRACT FROM UTERUS. R. Guevara-Aguilar, M. García-Bazán and M. Ortega-Villalobos. Depto. de Fisiol. UNAM. México, D.F.

Previously, we reported labelled cells in the nucleus of the solitary tract (N.T.S.), after the application of HRP in the body of the uterus of the rat. The aim of this paper was to learn more about the distribution of the afferent fibers from the different parts of the uterus to the different nuclei which compound the NTS complex. WGA-HRP 40% solution was injected at different levels of the uterus body. The first group was injected in the anterior third; the second group was administered in the half third, including both ductus; in the third group the HRP was injected in the cervix and the fourth one, was injected in all parts mentioned above. The percentage of labelled cell bodies in the medial, lateral and commissural nucleus of the NTS complex was different for each group. The first group has the highest percentage of labelled cell bodies localized in the lateral nucleus; the medial nucleus was weak labelled and no labelled cells were found in the commissural nucleus. The second group had similar label cells in the lateral as well as in the medial nucleus. The commissural nucleus presented more label cells. In the third group, the highest percentage of label cell bodies was observed in the commissural and in the lateral with the lowest percentage of labelled cells in the medial nucleus. The fourth one has similar percentage of cell bodies label in the three nucleus.

107.14

EFFERENT PROJECTIONS FROM THE BED NUCLEUS OF THE STRIA TERMINALIS TO THE NUCLEUS OF THE SOLITARY TRACT AND VENTROLATERAL MEDULLA IN THE RAT. A.M. Zardetto-Smith, D.J. Magnuson and T.S. Gray. Dept. of Anatomy, Loyola University Stritch School of Med., Maywood, IL 60153.

The lateral portion of the bed nucleus of the stria terminalis (BST) is closely related to the central nucleus of the amygdala (CeA) in terms of connectivity to central autonomic nuclei, such as the nucleus of the solitary tract (NTS) and ventrolateral medulla (VLM). The CeA has previously been shown to selectively innervate subpopulations of catecholaminergic cells within the NTS and VLM (Neurosci. Lett. 97:252, 1989). To examine in detail the pattern of termination of BST efferents within the NTS and VLM, small unilateral deposits of the anterograde tracer Phaseolus vulgaris leucoagglutinin (PHA-L) were iontophoretically placed within lateral and ventral subnuclei of the BST of male Long-Evans rats. PHA-L fibers and terminals were visualized using the avidin-biotin immunoperoxidase technique. Catecholaminergic cell bodies were visualized via glucose-oxidase immunocytochemistry to catecholamine markers (TH, PNMT, DBH). The densest projection to the NTS and VLM arose from posterior and lateral parts of the BST. PHA-L fibers and terminals were found in close proximity to both the A2 noradrenergic and C2 adrenergic catecholaminergic groups. In the VLM, PHA-L fibers terminated in and around both the A1 and C1 catecholaminergic groups. Amygdaloid axon contacts on PNMT-immunoreactive dendrites within the ventrolateral reticular formation were frequently observed. The results demonstrate that the lateral BST, like the CeA, may directly influence both subpopulations of catecholaminergic neurons within the NTS and VLM. (Supported by NS 20041)

107.15

NEUROPEPTIDE IMMUNOREACTIVITY OF LATERAL PARABRACHIAL NEURONS THAT PROJECT TO THE MEDIAN PREOPTIC NUCLEUS IN THE RAT. N.L. Chamberlin and C.B. Saper. Depts. of Pharm. & Physiol. Sci. and Neurology, University of Chicago, Chicago, IL 60637.

The median preoptic nucleus (MnPO), in the center of the anteroventral third ventricular region, receives a major projection from the parabrachial nucleus (PB), mainly originating in the dorsal, central and external lateral subnuclei. A small percentage of these neurons are immunoreactive for corticotropin releasing factor (CRF) or enkephalin (ENK) (Lind and Swanson, Brain Res. 321:217, 1984). However, the neuropeptide content of most of the PB neurons that project to the MnPO is unknown. In a further attempt to identify the neurotransmitters in this pathway, we injected the MnPO in a series of rats with 5-20 nl of 3% Fluorogold. After 12 to 15 days, the animals were treated with intraventricular colchicine, perfused and the brains were cut at 30-50 μm. Sections through the parabrachial nucleus were immunohistochemically stained with antisera raised against galanin (GAL), somatostatin (SOM) or porcine brain natriuretic peptide (BNP). Small numbers of retrogradely-labeled neurons, mainly in the dorsal lateral subnucleus but occasionally in the central lateral nucleus as well, were immunoreactive with ezch of the antisera. Our data indicate that GAL, SOM and BNP, in addition to CRF and ENK, contribute to the projection from the PB to the MnPO. However, a predominant neurotransmitter for this pathway has yet to be identified.

107.16

A POTENTIAL ROLE FOR RECEPTOR CELLS IN A BRAINSTEM MIDDLE EAR AERATION REFLEX. P.J. Gannon, J.T. Laitman*, K.J. Chandross* and A.R. Eden. Departments of Otolaryngology and Anatomy, Mount Sinai Medical Center, New York, NY 10029.

The dynamics of air pressure maintenance in the mammalian middle ear (ME) are poorly understood. Whether physiologic levels of ME gas partial pressures (critical for efficient audition) are passively or neurally maintained remains controversial. Our previous anatomic and physiologic studies have demonstrated a polysynaptic brainstem reflex which may subserve control of ME aeration. The means by which this reflex may monitor ME pressure is currently unknown. This study advances our understanding of the hypothesized reflex by examining potential chemo/baro-receptor cells located within the tympanic plexus (TP) of the ME. These cells are intimately associated both with autonomic (caroticotympanic and tympanic) and sensory (branches of CN VII, IX, & X) nerves.

The anatomy of the TP in an age graded (newborn, 3mo, 6mo, adult, n=10) series of Macaca fascicularis was studied. In 3 adults, the superior cervical ganglion (SSG) was removed unilaterally. After degeneration of postganglionic fibers, glomus/ganglion cell clusters (GGC) in the TP were processed for EM analysis. In normals, when present, the GGC were processed for EM. Results indicate a maturational sequence in which the GGC first appear at adult levels in 6mo animals. The 2 newborns did not have GGC. Axosomatic contacts with glomus/ganglion cells were numerous at all other ages. Similar, but degenerating, synapses, were seen bilaterally after gangliectomy. The bilateral distribution of sympathetic postganglionics identified here supports similar findings of physiological studies in the parotid gland. Our studies also demonstrate the delayed/later postnatal development of a system which may represent the receptor cell end of the hypothesized ME aeration mechanism. Such a maturational sequence, if also present in humans, could explain the prevalence of middle ear disease in human infants as being due to an immaturity of the neural substrate.

TRANSPLANTATION: CORTEX AND BRAINSTEM

108.1

FETAL RAT FRONTAL CORTICAL TISSUE TRANSPLANTATION INTO THE LESIONED CEREBRAL CORTEX OF ADULT RATS. B.W. Chopko, T.J. Voneida, and R.E. Stoll. Neurobiology Dept., NE Ohio Univs College of Medicine, Rootstown, OH 44272.

Blocks of presumptive frontal cortical tissue (initial total volume ranging from 10 to 100 microliters/host) obtained from fifteen day fetal rats were transplanted into adult rats immediately after the production of a transcortical lesion cavity. Two transplants were placed into cavities in the rostral sensorimotor cortex, and one was placed into a cavity which included the olfactory bulb, prefrontal cortex, and rostral frontal cortex. After a three to five month survival period, the rats were perfused, and the brains sectioned and stained for cells (cresyl violet) and myelin (Weil). Estimated total graft volumes ranged from 11 to 17 mm^3. All transplants contained a heterogeneous population of cells exhibiting morphologies consistent with both neuronal and glial elements. Although an obvious laminar pattern was not present, transplants contained foci demonstrating columnar packing, cell nests, and rosette formation. All transplants demonstrated widespread evidence of myelin production. The myelin was arranged in compact, whorled bands and was typically confined entirely to the transplant. In a few instances, wisps of myelinated fibers extended between the host and transplant.

We conclude that fetal frontal cortical transplants survive and proliferate after transplantation into cerebral cortical lesion cavities in adult rats. The transplants produce myelin and exhibit subregions suggestive of cellular organization.

108.2

THE LONG-TERM FUNCTIONAL AND MORPHOLOGICAL EFFECT OF THE CORTICAL TRANSPLANT DEPENDS ON THE DELAY BETWEEN BRAIN DAMAGE AND GRAFTING. V. Valousková*, R. Macías-Gonzales*(SPONS: K. Anderson), Institute of Physiology, Czechoslovak Academy of Sciences, 142 20 Prague 4-Krc.

The degree of functional integration of cortical grafts and their capability to substitute for the function of the sensory-motor cortex removed by suction was studied in adult Long Evans rats by correlating the behavioral effects with the character of the host-transplant integration.

Embryonic neocortex (ED 14) was transplanted into the cavity in the left hemisphere either 14 days (group TR_{14}, n=11) or immediately (group TR_0, n=12) after the lesion. Food deprived animals were trained 4 months later to reach into a horizontal tubular feeder for food pellets. This task, specifically subserved by the ablated cortex, was mastered to the level comparable with intact rats by 38% of transplanted rats with adequately connected graft (n=13), but none of the rats with lesions only (group C, n=9) or the rats with poorly connected graft (n=9). Seven months after the surgery rats were trained in the Morris navigation task, and found to be impaired by the lesions in a non-specific way. No statistically significant differences were found between TR_0 and intact rats. TR_{14} and C had longer escape latencies than the former groups. There was an inverse relationship between the area and type of the host-transplant contact and the size of the opposite hemicortex cavity.

The data indicate that cortical grafts are capable of substituting for the specific function of damaged sensory-motor host cortex and prevent long-term deterioration of non-specific function, probably by the reduction of secondary degenerative changes. These effects depend on the delay between brain damage and grafting and on the corresponding characteristics of the host-transplant integration.

108.3

FUNCTIONAL MOTOR CORTEX TRANSPLANTS. Rick Sandor*, Manuel F. Gonzalez, Frank R. Sharp (SPON: J. Mueller). Depts. of Neurology and Physiology, University of California and VA Med. Ctr., San Francisco, CA 94121.

Fetal frontal cortex was transplanted into cavities formed in the motor cortex of neonatal rats. When host subjects reached adulthood, they were trained to use one arm to press two levers in succession as rapidly as possible. Attempted removal of the transplant in adult rats significantly increased the time for three subjects to accomplish the task. This occurred in 2/4 attempted surgical removals and 1/6 attempted immunological removals. Since the motor deficits produced were similar to those produced by removal of normal motor cortex, it is proposed that these fetal motor cortex transplants were functional.

No histological evidence of host brain injury was present in any subject. Therefore, host brain damage is unlikely to explain the behavioral deterioration following transplant removals. The failure to produce behavioral deterioration in 2/4 attempted surgical removals and 5/6 attempted immunological removals may be due to significant residual transplant tissue present in the host brain of all of these subjects, or to the fact that some transplants are non-functional.

108.4

KAINIC ACID METABOLICALLY ACTIVATES TRANSPLANTS AND ACTIVATES FUNCTIONAL CONNECTIONS BETWEEN FETAL CORTICAL TRANSPLANTS AND HOST THALAMUS AND STRIATUM. S.F. Ciricillo*, M.F. Gonzalez, and F.R. Sharp (SPON: P. Weinstein). Depts. of Neurology, Neurosurgery, and Physiology, UCSF and VA Med Ctr, SF, CA 94121.

Since little is known concerning the epileptic potential of fetal cortical transplants, we have examined the effects of kainic acid injections in rats with surviving grafts. Fetal cortical transplants were transplanted into cavities formed in sensory or motor cortex of adult rats. Following 1-2 month survivals, kainic acid (10mg/kg) was injected subcutaneously into the host subjects. Following induction of limbic seizures, (14C) 2-deoxyglucose was injected. Local cerebral glucose utilization (LCGU) increased markedly in all fetal cortical transplants compared to adjacent host neocortex. Marked, symmetrical increases of host LCGU occurred in the cingulate cortex, hippocampus, subiculum, and other limbic structures. Moreover, focal increases of LCGU occurred in the host thalamus and host caudate-putamen of some subjects ipsilateral to the transplant. These data suggest (a) fetal cortical transplants are particularly susceptible to systemic kainate which induces seizures and increases LCGU in transplants and (b) kainic acid activated neurons in transplants which project to host brain and increased LCGU in host thalamus and striatum.

SPROUTING OF TRANSECTED RAT MEDIAN FOREBRAIN BUNDLE CATECHOLAMINE FIBERS INTO FETAL NEOCORTICAL GRAFTS. A.A. Dunn-Meynell and B.E. Levin, Neurology Service, VA Med. Cent., E. Orange, NJ 07019

Catecholamine (CA) fibers in the median forebrain bundle (mfb) fail to regenerate after 6-hydroxydopamine (6OHDA) lesions made at the level of the anterior commissure. To examine the effect on sprouting, E15-16 rat fetal neocortical grafts were placed into lesion sites 1 or 14d following mfb 6OHDA injections into adult SD rats. Animals were sacrificed at 12 weeks. Fluorescent histochemistry showed little or no sprouting from transected mfb fibers in control brains (without grafts) with a 79.3±1.9% depletion of frontal cortex norepinephrine (NE) content measured by HPLC. However, grafts became innervated by fluorescent sprouts from both the mfb and striatum, and frontal cortex NE depletion was less (69.3±4.8%; $P<0.05$) than controls. Both NE and dopamine fibers appeared to innervate the graft as shown by autoradiographic demonstration of high affinity uptake sites on graft CA terminals by binding of ^{3}H desmethylimipramine and mazindol. Thus neocortical grafts appear to stimulate collateral sprouting from intact CA fibers and regenerative sprouting from otherwise non-regenerative severed CA fibers. This work was supported by the VA Medical Research Svc.

IMMUNOHISTOCHEMICAL CHARACTERIZATION OF THE EARLY DEVELOPMENT OF AND DIVERSE NEUROTRANSMITTER PHENOTYPE DISPLAYED BY EMBRYONAL CARCINOMA-DERIVED NEURONS Wm.A.Staines, D.Morassutti and M. McBurney* Depts. of Anatomy and Medicine, University of Ottawa Medical School, Ottawa CANADA, K1H 1M5

Cultures of a mouse embryonal carcinoma cell line, P19, were induced with retinoic acid to form a mixed population of neurons, glial cells and fibroblasts. This cell population was subsequently characterized up to 32 days post-induction using a wide variety of immunohistochemical and histochemical techniques.

Subpopulations of neurons were found to display immunoreactivity for a large number of neuropeptides (most notably somatostatin and neuropeptide Y), glutamic acid decarboxylase and GABA, tyrosine hydroxylase and other catecholaminergic marker enzymes. Individual cultures displayed a great deal of mophological diversity within the neuronal population. The immunochemical characterization also indicated a marked heterogeniety within each culture but an equally marked consistency between cultures. In terms of morphological diversity, neurotransmitters expressed, patterns of coexistence, and relative representation of transmitter phenotypes, these cultures were very reminiscent of natural mammalian forebrain neurons. As such, embryonal carcinoma-derived neurons may prove a useful source of tissue for transplantation experiments.

TRANSPLANT SURVIVAL IN AN IN VIVO WINDOW CHAMBER. W.J. Levy, J. Mora, M.F. Humphrey, V. Holets. Dept. of Neurological Surgery, Univ. of Miami Sch. of Med., Miami, Florida 33136.

We have previously described an in vivo chamber which is implanted in the hindlimb of the rat and allows repeated observation of neural elements. The chamber consists of two cover slips, 150-200 microns apart, separated by a silicone elastomer spacer. The chamber is sealed circumferentially except for two ports at opposite sides. The chamber is implanted under surgical conditions and the sciatic nerve severed, and each end placed in one of the ports, then secured with a suture. The nerves will regrow through the chamber an innervate the distal stump. The contents can be reexamined by opening the chamber and visualizing the contents with an operating microscope or a video enhancing system. In six animal transplants were done of E 16 fetal motor cortex into the chamber, through a removable top. The transplants were placed at the tip of the growing fan of regenerating nerve when it was about one third of the way into the chamber. We observed that the transplants grew and attracted a blood supply. The transplant merged into the distal nerve stump, but the proximal nerve stump did not integrate into it. Sacrifice of the chamber and histological examination revealed neuron specific enolase positive cells, and GFAP positive cells, and neurofilaments supporting the survival of neural and astrocytic elements.

OLFACTORY BULB REPLACEMENT IN RODENTS. T. Zigova,* P. P. C. Graziadei and G. A. Monti Graziadei (SPON: P. F. Cancalon). Dept. of Biological Science, Florida State University, Tallahassee, FL 32306.

The results from a previous study in rats seem to suggest that new central connections may be established after transplantation of an embryonic olfactory bulb in place of a neonatal bulb. In order to explore this eventuality, before transplantation we autoradiographically labeled the embryos' (E13-E14) olfactory bulbs by injecting the mother with 3H-thymidine. The hosts were sacrificed at survival times from 1 to 3 months. Forty-eight hours before sacrifice, they received several WGA:HRP injections in the pyriform cortex. Sections from the pyriform cortex and the olfactory bulb were processed for HRP histochemistry. Furthermore, the sections from the olfactory bulb were processed for autoradiography. Several autoradiographically labeled neurons were also HRP-positive. This finding provides evidence that output neurons from the transplanted olfactory bulb can send their axons to the appropriate target location in the host brain. (NIH Grant NS 20699.)

TRANSPLANTATION OF FETAL NEURONS INTO THE THALAMUS INDUCES A TRANSITORY PERIOD OF ACTIVE SYNAPTOGENESIS IN ADULT SOMATOSENSORY FIBERS M. Peschanski and F. Nothias* INSERM U 161 rue d'Alésia 75014 Paris. France.

Interactions between adult axons of host origin and fetal neurons transplanted into an excitotoxically lesioned CNS area allow reconstruction of specific circuitry. In the somatosensory thalamus, synaptic contacts between host specific afferents and fetal neurons transplanted as a cell suspension permit somesthetic activation of these neurons. In the present study, time-course of establishment of these synaptic contacts was studied using anterograde axonal labeling with WGA-HRP from the dorsal column and trigeminal nuclei. Rats were perfused with aldehydes 7 to 30 days post-grafting (dpg).

Transplanted neurons first occupied only the mechanical lesion produced during implantation then progressively spread into the neuron-depleted area (between 10 and 20 dpg). There was no ingrowth of somatosensory fibers into the transplant, and therefore no synaptogenesis in the original transplantation site. In contrast, when fetal neurons were displaced into the lesioned host (10 to 20 dpg), intermingling with WGA-HRP labeled fibers, synaptic contacts were formed. Morphology of synaptic contacts progressively acquired mature characteristics of large terminals with round vesicles, asymmetric contacts and adhesion plaques.

This study demonstrates that adult sensory fibers previously deprived of their normal target-neurons are induced -by hitherto unknown mechanisms- to perform active synaptogenesis when, but only when, neurons enter their topographically determined terminal region.

SEROTONERGIC AND HISTAMINERGIC NEURONS IN DOUBLE GRAFTS IN OCULO: ELECTROPHYSIOLOGICAL AND STRUCTURAL CORRELATES. A.-C. Granholm and A. Blomqvist. Department of Cell Biology University of Linköping, S-58185 Linköping, Sweden.

The monoaminergic transmitter systems have long been postulated to play a role in diseases like Alzheimer, schizophrenia and affective disorders. With this focus of attention on transmitter-defined systems, the need for a simplified brain model has emerged. By grafting monoamine neurons with appropriate target areas each system may be studied separately during normal or pathologic conditions. This study was focussed on histamine neurons in tuberomamillary nucleus and serotonin neurons in raphe dorsalis. Brain stem and hypothalamic tissues were dissected from fetal rat(E17) and injected into the anterior eye chamber of adult hosts. Fetal hippocampal (E18) and cerebellar (E15) tissues were co-grafted 4 weeks after initial grafting. Double grafts were studied with electrophysiological and morphological techniques after cessation of growth of the second graft. Serotonin and histamine nerve cell bodies were identified in corresponding grafts by immunohistochemistry. Monoamine-containing neurites innervated cerebellar and hippocampal grafts with functionally appropriate connections. The receptor specificity of this innervation in double grafts was evaluated using extracellular recordings and local application of monoaminergic agents. In conclusion, the present study suggests that histamine and serotonin physiology and structure can be studied during isolated conditions in a controlled environment using intraocular double grafts.

HABENULA CELL TRANSPLANTS AMELIORATE SLEEP CYCLE DYSFUNCTION AND INCREASE LEVELS OF SUBSTANCE P IN THE INTERPEDUNCULAR NUCLEUS OF RATS WITH FASCICULUS RETROFLEXUS LESIONS. T. Eckenrode, F. Haun, P. Onda, and M. Murray, Dept. of Anatomy, Medical College of Pennsylvania, Phila., PA 19129.

Bilateral lesions of the fasciculus retroflexus (FR) result in diminished Substance P (SP) and Choline acetyltransferase (ChAT) staining in FR target areas in the interpeduncular nucleus (IPN). We tested whether these transmitter levels would be altered by transplants of SP- and ChAT-containing medial habenula cells into the FR lesion site, and whether these transplants also produced a functional effect. Medial habenula cells from E15 Sprague-Dawley rats were "pre-cultured" then transplanted into adult rats with bilateral FR lesions sustained at either postnatal day 3 (P3) or as adults. Three months later the transplant (TP) animals, lesion-only (LO) controls, and normals were tested for normalcy of their sleep cycles. Animals were placed on a small-base inverted flower pot in a tank of water during their sleep period; the normal decrease in muscle tone associated with stage IV (paradoxical) sleep results in the animal falling toward the water. Normals have 14.5 sleep periods/hr, contacting the water .81 times/period; both P3 and adult LO's have <1 sleep period/hr and rarely contact the water. TP animals are intermediate, with 7.9 sleep episodes/hr overall; those with P3 lesions contact the water 1.14 times/sleep period, those with adult lesions .76 times/period. Compared to LO animals, TP's have enhanced intrinsic SP staining in the IPN, plus the presence of SP staining in the denervated lateral subnuclei, normal target of the medial habenula SP projection. Supported by NIH Grant NS16556.

IS OUTGROWTH FROM THIRD VENTRICULAR PREOPTIC AREA (POA) GRAFTS OF THE HYPOGONADAL (HPG) MOUSE LIMITED TO GNRH FIBERS? R.C. Silverman, A.J. Silverman, and M.J. Gibson. Dept. Anat. and Cell Biology, Columbia Univ., N.Y., 10032 and Dept. Medicine, Mount Sinai School of Medicine, N.Y. 10029

Hpg mice are infertile as a consequence of a deletion in the gene which encodes gonadotropin hormone releasing hormone (GnRH). Some reproductive function is restored in hpg mutants when GnRH rich POA grafts from normal mice are placed into the third ventricle. GnRH neurons from the graft extend fiber projections to the median eminence (ME), one of the normal targets of these neurons.

Although the outgrowth of GnRH axons has been documented, it is unclear whether other neurons project out of the graft. In order to discover if there is non-ME outgrowth, we employed the carbocyanine dye, DiI. Five or 30 days after surgery, hpg mice were sacrificed by perfusion and brain tissue cut into 1mm slices. A DiI crystal was applied to the graft tissue with a micropipette. After storage in buffer at 37 degrees for two weeks, 40u sections were cut and examined with rhodamine optics. Fluorescent axons appeared along a trajectory similar to that of GnRH fibers. Axons generally exited at the level of the arcuate nucleus or directly into the ME. Fibers were rarely found exiting at other levels into the hypothalamus. A few axons left the ME into the hypothalamus. A few axons left the ME and coursed laterally along the ventral surface of the brain. In addition to anterogradely labeled axons, retrogradely filled neurons in the graft and host arcuate nucleus were identified. These observations suggest that the majority of graft outgrowth is to the ME. These studies also support the idea that host neurons can send axons into the graft tissue. Supported by NS 20335.

RECOVERY OF SEXUAL BEHAVIOR BY HYPOTHALAMIC FETAL BRAIN TRANSPLANTS IN MEDIAL PREOPTIC AREA LESIONED RATS. R. Paredes*, A.L. Piña*, J. Fernández* and F. Bermúdez-Rattoni. Instituto de Fisiología Celular, UNAM. Apdo. Postal 70-600, 04510. Escuela de Psicología, Universidad Anáhuac, 11000 México, D.F.

The medial preoptic area (MPOA), plays a crucial role in the expression of sexual behavior in different species. Bilateral lesions within this area completely abolish sexual behavior in male rats. In the present study, sexually experienced rats were lesioned in the MPOA. Those rats who did not show sexual behavior within 15 days after the lesion, received fetal hypothalamic grafts. After one week of recovery the animals were tested once a week with a receptive female, until they reached 15 weeks. From 18 animals that received bilateral grafts, the histological (Nissl) and immunocytochemical analysis showed that in 8 animals the grafts were healthy and well integrated. No signs of transplanted tissue was observed in 10 animals. All grafted animals recovered sexual behavior by the fifth week, while the lesioned subjects without graft did not show any parameter of sexual behavior even 15 weeks after the transplant. The grafts contained tyrosine hydroxylase but not methionine-enkephaline immunoreactive neurons. These results showed that fetal brain transplants can restore an innate complex behavior in MPOA lesioned rats.

EFFECT OF TARGET TISSUES ON THE EXPRESSION OF PNMT AND TH IN GRAFTS OF FETAL RAT MEDULLA OBLONGATA GROWN IN OCULO A. Seiger[1], V.R. Holets[2] and M.C. Bohn[3]. [1]Dept. of Geriatric Medicine, Karolinska Institute, Stockholm, Sweden; [2]Dept. of Neurological Surgery, Univ. Miami, Miami, FL 33136; [3]Dept. of Neurobiology & Anatomy, Univ. Rochester, Rochester, NY 14642.

The expression of PNMT and TH was studied in fetal rat medulla oblongata (MO) neurons grown in the anterior eye chamber of adult rats. The effect of age (E12.5 and E18.5), and the presence of a co-graft (thoracic or cervical spinal cord, hypothalamus) on neuron survival, PNMT and TH expression, and PNMT activity were analyzed.

Nearly twice the number of PNMT- and TH-immunoreactive neurons were observed in single MO grafts obtained from E12.5 rats compared to E18.5 grafts. In co-grafts of E18.5 MO with hypothalamus, thoracic or cervical spinal cord, a significant increase in the number of PNMT- and TH-immunoreactive cells was observed, as well as an increase in the PNMT activity. No effect of the co-grafts on the number of PNMT-immunoreactive cells was observed in the E18.5 group, although there was a four-fold increase in the number of TH-immunoreactive neurons in the MO-hypothalamus co-grafts. These data suggest that central targets promote the survival and differentiation of central catecholaminergic neurons. EFFECTS OF PIMOZIDE IN A REACQUISITION PARADIGM. J.L. Wiley, J.H. Porter, and D.I. Schiff*. Dept. of Psychology, Virginia Commonwealth Univ., Richmond, VA 23284.

Neuroleptic drugs have been shown to produce both motor and anhedonic effects in animals. Previous studies (Horvitz & Ettenberg, 1989; Wiley, Porter, & Faw, in press) have shown that haloperidol blocks the reacquisition of operant running during extinction following a single priming trial with food reward. This reacquisition paradigm, in which drug injection and behavioral testing occur on different days, allows the effects of neuroleptics on reward processes to be examined without the confound of motor effects. The present study tested pimozide (.25, .50, and 1 0 mg/kg) in this reacquisition paradigm. Fifty-one rats (80% BW) were run (single daily trials) in a straight-arm alleyway reacquisition procedure for four successive phases: acquisition, extinction, injection day, and test day. Vehicle control animals that received food reward on injection day ran significantly faster on test day than animals that did not receive food reward. The rats that received pimozide and food reward on injection day also ran faster on test day. Thus, pimozide at the doses tested did not produce the anhedonic effects in this reacquisition procedure that have previously been shown with haloperidol.

109.2

DIFFERENTIAL EFFECTS OF CLOZAPINE AND PIMOZIDE ON FIXED-RATIO RESPONDING DURING CHRONIC DOSING. J.H. Porter, J.L. Wiley, and A.D. Compton. Dept. of Psychology, Virginia Commonwealth Univ., Richmond, VA 23284.

With a chronic dosing regimen, tolerance to the rate suppressing effects of clozapine (CLZ) on fixed-interval responding develops within 6 to 10 days, whereas pimozide (PMZ) continues to suppress responding (Kaempf & Porter, JPET, 243: 437-445, 1987). Rats tested on a multiple fixed-interval (FI) fixed-ratio (FR) reinforcement schedule develop complete tolerance to CLZ's disruption of FI responding, but only partial tolerance to CLZ' disruption of FR responding (Villanueva et al, NEUROSCI. ABST., 1989). The partial tolerance to CLZ during the FR schedule was unexpected, and the present study was conducted to determine if an interaction between FI and FR responding on the multiple schedule was responsible for this effect.

Twelve rats were tested on a FR 30 food reinforcement schedule. Chronic dosing with 10 mg/kg CLZ produced an initial disruption of responding, and over 10 days responding recovered to 50% of baseline levels. Subsequent dosing with 1 mg/kg PMZ produced an initial disruption of responding that was maintained over 10 days of dosing. These results confirm that only partial tolerance to CLZ's disruption of operant behavior occurs for FR responding, and no tolerance occurs to PMZ's rate disrupting effects.

109.3

MECHANISMS OF TOLERANCE TO THE EFFECTS OF CLOZAPINE AND PIMOZIDE ON A MULTIPLE FI 60-SEC FR-30 OPERANT SCHEDULE IN RATS. H.F.Villanueva, J.H.Porter, N.Narasimhachari, J.K.Stewart, B.Landa* & J.L.Wiley. Depts. of Pharmacology Psychology & Biology, VCU/MCV, Richmond, VA 23298.

10 mg/kg clozapine (CLZ) and 1 mg/kg pimozide (PMZ) were administered to male Sprague-Dawley albino rats in order to assess the mechanisms of tolerance to these compounds. Behavioral effects were measured on a multiple FI 60-sec FR-30 food reinforcement schedule; the biochemical effects of CLZ and PMZ were measured in the plasma, frontal cortex and striatum via HPLC.

Presession administration of both drugs produced initial disruptions of response rate, response duration and reinforcement rate. Complete tolerance developed to CLZ's disruption of FI responding, but only partial tolerance developed for FR responding over the 10 day chronic dosing regimen. The disruption of FI and FR responding by PMZ increased over the 10 days. Post-session administration of CLZ and PMZ failed to disrupt operant responding and did not affect subsequent presession drug administration, suggesting that both the tolerance to CLZ and the sensitivity to PMZ are mediated by functional mechanisms (i.e. behavioral tolerance).

Biochemical assays revealed no significant differences between acute and chronic drug administration, suggesting that dispositional mechanisms (i.e., changes in metabolism) were not responsible for the behavioral changes.

109.4

DIFFERENCES IN REGULATION OF D1, D2, AND 5-HT2 RECEPTORS AFTER CHRONIC TREATMENT WITH CLOZAPINE OR HALOPERIDOL. S.J. O'Dell, G.J. LaHoste, C. Widmark*, R. Shapiro*, J.F. Marshall, and S.G. Potkin* Depts. of Psychobiology & Psychiatry; University of California, Irvine, CA. 92717

The atypical neuroleptic clozapine (CLZ) is often effective in diminishing psychosis in schizophrenics who respond poorly to typical antipsychotics such as haloperidol (HAL). In addition, CLZ is relatively free of the extrapyramidal side effects (EPS) associated with typical neuroleptics. To investigate the neural mechanism by which CLZ can attenuate psychosis without inducing EPS, we used quantitative autoradiography to measure changes in dopamine and serotonin receptors in rats after injection with CLZ or HAL for 28 days at clinically relevant doses. Levels of D1, D2, and 5-HT2 receptors were determined in frontal cortex, caudate-putamen, nucleus accumbens, and substantia nigra. Rats that received CLZ chronically showed CNS receptor changes markedly different from those in chronic HAL-treated animals. Rats treated chronically with HAL showed enhanced D2 binding, while those treated with CLZ did not. In contrast, chronic CLZ induced enhanced D1 binding, whereas these sites were unchanged in HAL-treated rats. Finally, CLZ treatment decreased 5-HT2 receptor binding while HAL had no significant effect. The differential effects of CLZ and HAL on D1, D2 and 5-HT2 receptors may be relevant to their antipsychotic potential and their propensity to induce EPS.

109.5

IN VIVO DIALYSIS STUDY OF THE CHRONIC ADMINISTRATION OF CLOZAPINE (CL) OR HALOPERIDOL (H) ON DOPAMINE RELEASE AND METABOLISM IN RAT STRIATUM (S) AND NUCLEUS ACCUMBENS (NA). J. Ichikawa* and H.Y. Meltzer. Department of Psychiatry, Case Western Reserve University, Cleveland, Ohio 44106.

CL has been suggested to produce less impairment of dopaminergic neurotransmission in the S than the NA compared to H. Male Sprague-Dawley rats were given CL (20 mg/kg/day) or H (2 mg/kg/day) in their drinking water. After 21 days, dialysis probes of differing sizes were implanted into the S and NA. After perfusion with Ringer's for 24 hours, (one day drug withdrawal), CL (40 mg/kg, S; 20, NA) or H (2 mg/day, S and NA) were administered after obtaining 3-5 basal samples. Chronic administration of H decreased but CL had no effect on basal DA efflux in the S and NA. In the 3 hr period after H administration, DA efflux in the S or NA in the rats receiving chronic H was less than that in vehicle-treated rats; DA efflux following CL was decreased only in the S. These results indicate that H produces a greater decrease in DA release in the S than CL which could account for the greater ability of H to produce EPS.

109.6

S-ADENOSYL-L-METHIONINE REVERSES TOLERANCE PRODUCED BY CHRONIC HALOPERIDOL TREATMENT IN RATS. A.M. KASK*, C. MARIN, T.N. CHASE, (Spon: R.-T. Wang) ETB,NINDS, Bethesda, MD 20892.

Haloperidol (HAL) induced catalepsy has been reported to be mediated by dopamine (DA) D2 receptors. Chronic treatment with HAL results in an increase in D2 receptor number and tolerance to its cataleptogenic action. Some neuroleptic drugs, including HAL, have been reported to decrease membrane fluidity after long term use. Such physical/chemical transformations in the cell membane may compromise receptor integrity and thus responsivity. S-adenosyl-L-methionine (SAMe) is a methyl donor to phosphotidylcholine, a major component of cell membranes, and has been shown to increase membrane fluidity. The present study was designed to determine whether SAMe's effect on membrane fluidity could affect DA receptor activity, and whether supersensitivity and tolerance induced by chronic HAL could be manipulated by changing the physical/chemical properties of the membrane. Catalepsy ratings were performed on individual animals; receptor content was measured in pooled groups. Chronic HAL treatment (5 weeks, 1mg/kg s.c.) increased D2 receptor content from 0.26 to 2.3 pmoles/mg protein and decreased catalepsy ratings from 2.7±0.15 (Scale 0-3.0) to 1.1±0.37. Adding SAMe (50 mg/kg i.p.) to the treatment schedule for the last two weeks reduced D2 content to 1.5 pmoles/mg protein and increased catalepsy ratings to 2.5±0.12. The data suggest that it may be possible to modify or prevent onset of tolerance to certain neuroleptic drugs by the addition of S-adenosyl-L-methionine to the treatment regimen.

109.7

THE ELECTROANALYTICAL DETERMINATION OF HALOPERIDOL IN VIVO WITH CARBON BASED ELECTRODES. M.T. Morocco*, T.A. Patterson, and J.O. Schenk. Department of Chemistry and Prgms. of Biochemistry and Pharmacology/Toxicology, Washington State University, Pullman, WA 99164-4630.

An electroanalytical probe for the determination of Haloperidol (HAL) in vitro and in vivo was developed. Adsorption of HAL to surfaces of these electrodes enables HAL to be detected electroanalytically. The sensitivity of the measurement is enhanced by the use of carbon paste electrodes, presumably by adsorption/extraction mechanism.

Experiments were conducted using conventional as well as 300 um diameter electrodes. Carbon paste electrodes were constructed by mixing ultra-carbon with nujol oil or silicon grease. Calibration curves were obtained by adding incremental amounts of HAL stock solution to 150 mM NaCl/20 mM $NaHCO_3$ buffer (pH=8.1). For the carbon paste electrodes, the linear range was 0.1-1 uM, while for the solid carbon electrodes, no signal was obtained below 3 uM. Therefore, the solid carbon electrodes were judged inadequate for in vivo measurements of HAL.

To illustrate the usefulness of this method for HAL detection, the determination of some in vivo parameters of the pharmacodynamics of HAL were investigated. The striatal extracellular diffusion coefficient was determined to be 0.36 ± 0.15 SEM x 10^{-6} cm^2/sec, N=4, and the uptake rate of HAL into striatal tissue was 200 um/g/sec. Supported by MH42759 (J.S.) and the State of Washington.

ACUTE HALOPERIDOL INHIBITS THE EFFLUX OF CALCIUM FOLLOWING DEPOLARIZATION IN THE STRIATUM IN VIVO. T.A. Patterson and J.O. Schenk. Dept. of Chemistry and Programs of Biochemistry and Pharmacology/Toxicology, Washington State University, Pullman, WA 99164-4630.

Recent studies of the ability of haloperidol (HAL) to act as a Ca^{++} channel blocker resulted in mixed results. Gould, et al. (PNAS 80:5122 (1983)) observed that HAL did not antagonize the voltage dependent Ca^{++} channel, while Flaim, et al (PNAS 82:1237 (1985)) found that HAL does inhibit the influx of Ca^{++} through the voltage sensitive Ca^{++} channel. We have studied the effect of acute HAL on Ca^{++} influx and efflux during depolarization in vivo and have found that HAL inhibits the efflux of Ca^{++}.

Experiments were conducted using small (< 10μm) Ca^{++} selective electrodes (Fluka) with a Ag/AgCl reference electrode < 5μm away. An injection syringe was placed 1 mm from the sensing electrode and the electrode assembly placed in the striatum of a chloral hydrate anaesthetized rat. At baseline, $[Ca^{++}]$ was measured, a control stimulation of 200 nl of 300 mM KCl given, and then either 1 mg/kg HAL or saline was injected ip and a second stimulation was performed 1 hr later. The results of these experiments showed a significant increase ($p < .10$) in the $t_{1/2}$ of the efflux of Ca^{++}. Studies on the effect of HAL on the influx of Ca^{++} as well as the effect of chronic administration of HAL on Ca^{++} influx and efflux are currently underway. Supported by MH42759 and the State of Washington.

109.9

METABOLITES OF HALOPERIDOL EXIBIT HIGH AFFINITY AND BIOLOGICAL ACTIVITY AT SIGMA RECEPTORS. E.L. Moses[1]*, P. Varghese[1]*, J.M. Walker[2], and W.D. Bowen[1] (SPON: J. Daniels). [1]Sect. Biochem., Div. Biol. & Med. and [2]Dept. Psychol., Brown University, Providence, RI 02912.

We examined the relative binding affinities of haloperidol and its metabolites for sigma and dopamine-D_2 receptors in rat brain homogenates. Haloperidol bound with K_i = 2.8 nM to both receptors. Compared to haloperidol, reduced haloperidol (RH) bound to sigma receptors with equal affinity, but to dopamine receptors with 85-fold lower affinity (K_i = 239 nM). The piperidine metabolite (PM) lacked affinity for dopamine receptors, but bound to sigma sites with K_i = 326 nM. Sigma-related biological activity of metabolites was determined in vitro by assessing ability to attenuate carbachol-stimulated phosphoinositide (PPI) turnover (Eur. J. Pharmacol. 149:399), and in vivo by assessing ability to produce postural changes upon microinjection into the rat red nucleus (Neurology 38:961). Preliminary results indicate that RH exibits potency in both assays comparable to that of haloperidol. PM was devoid of activity in the PPI assay, suggesting possible antagonist properties. These results suggest that haloperidol treatment may result in formation of sigma-active metabolites which can produce sigma receptor-mediated effects, long after dopaminergic activity is terminated.

109.10

EFFECTS OF CHRONIC ADMINISTRATION OF NEUROLEPTICS ON SYNAPSES OF LAYER VI MEDIAL PREFRONTAL CORTEX. S.L. Vincent, J. McSparren*, R.Y. Wang and F.M. Benes. Department of Psychiatry, Harvard Medical School and Mailman Research Center, McLean Hospital, Belmont, MA 02178, and SUNY, Stony Brook, NY 11794.

It was previously shown that high dose treatment with haloperidol (HAL) for 4 months induces synaptic rearrangements in layer VI of rat medial prefrontal cortex (MPF-VI), where the cortical dopamine projection terminates. In the present study a quantitative electron microscopic analysis of MPF-VI was carried out to determine the effects of low dose, long-term administration (1 yr) of HAL and clozapine (CLOZ) on the ultrastructure and arrangement of synapses. No change was found in the size of axon terminals, dendritic profiles or synaptic vesicle density. On both shafts and spines of CLOZ-treated animals, there was a decreased number of asymmetric synapses, while those with symmetric thickenings or no membrane specializations are increased. HAL-treated animals showed similar changes only on shafts. These various alterations occurred most frequently on larger caliber shafts and spines. These data suggest that low dose, long-term neuroleptic treatment may induce shifts among excitatory and inhibitory synaptic elements, and such shifts may provide important information about the interaction between neuroleptics and intrinsic components of MPF-VI. Supported by MH00423, MH31154, MH41440 & MH00378.

109.11

LATENT INHIBITION AS AN ANIMAL MODEL OF ANTIPSYCHOTIC DRUG ACTION L.A. Dunn*, G.E. Atwater*, G.W. Christison* C.D. Kilts. Dept. of Psychiatry, Duke Univ. Med. Ctr., Durham, NC 27710.

Latent Inhibition of a conditioned emotional response (CER) is a quantitative measure of selective attention. LI has been shown to be deficient in schizophrenic patients and to improve with antipsychotic medication (Baruch et al, J. Ment. Dis., 176:598-606, 1988). We have assessed the pharmacologic isomorphism of LI in rats with the clinical pharmacology of schizophrenia. Unless otherwise stated, all drugs were administered i.p. daily for 7 days. Drug and vehicle treated rats were placed individually into darkened test cages. Half were preexposed 20 times to cage illumination as a CS, and half were not preexposed. All groups were conditioned with 2 CS-US pairings. The US consisted of a 1 sec., 0.75ma. scrambled footshock. The following day CER, as measured by interruption of drinking in response to CS presentation, was recorded. LI was enhanced by haloperidol 0.3 mg/kg after 7 or 14 daily treatments, but not after a single acute dose. Haloperidol doses of 0.3 and 0.03 mg/kg enhanced LI, while doses of 0.003 and 3.0 mg/kg had no effect. Haloperidol enhancement of LI was unaffected by co-administration of the anticholinergic agent trihexyphenidyl. Enhancement of LI is exhibited by a broad range of antipsychotic drugs including fluphenazine, chlorpromazine, thiothixene, thioridazine, mesoridazine, and metoclopramide. The effect is specific to antipsychotic drugs as pentobarbital, imipramine, chlordiazepoxide, tihexyphenidyl, and promethazine all failed to enhance LI. LI exhibits striking parallels to the clinical pharmacology of schizophrenia in terms of dose response, latency to onset of effect, effect of anticholinergics, and drug sensitivity and specificity. (Supported by the Scottish Rite Foundation).

INTERACTION OF HALOPERIDOL AND (+) SKF 10,047 DETECTED BY THE BRAIN WAVE FACTOR SCAN. K.L. Marquis, R.P. Gussio*, M.G. Webb* and J.E. Moreton. Dept. of Pharmacol. & Toxicol. Univ. of Maryland School of Pharmacy, 20 North Pine St., Baltimore, MD 21201.

The (+) isomer of SKF 10,047 (SKF), the prototypic sigma agonist, alters rat cortical EEG in a fashion which is distinct from that of the PCP selective ligand MK-801. Haloperidol (HAL), also a potent sigma ligand, blocks SKF discriminative stimulus effects (Steinfels et al., 1987), and thus may alter the EEG response to SKF. Female Sprague-Dawley rats, prepared with frontal-parietal cortical recording electrodes and intravenous cannulae, were treated with haloperidol (0.1 mg/kg i.v.) or saline 15 min prior to SKF (10 mg/kg i.v.). Cortical EEG responses were analyzed for 10 minutes following the second injection by transforming analog EEG to power density spectra. Spectral quantities estimating frequency and energy responses in specific frequency bands were subjected to univariate statistical and factor analyses. No demonstrable change was observed in the average power spectra and no significant differences were detected by t tests. Alternatively, several factors emerged that described the patterned variation of the signal induced by SKF following HAL as distinctly different from that of SKF alone. These data indicate the need for more sensitive quantitative methods of analysis for cortical EEG. The implications to the pharmacology of the sigma receptor are a subject for further study. (Supported by grant DA03173)

109.13

CONTINUOUS HALOPERIDOL INDUCES ORAL MOVEMENTS IN RATS WHICH HAVE A TARDIVE DYSKINESIA-LIKE FORM, WHEREAS WEEKLY HALOPERIDOL INJECTIONS INDUCE A PRIMED DYSTONIA-LIKE SYNDROME. G. D. Ellison and R. E. See. Department of Psychology, UCLA, 405 Hilgard Ave., Los Angeles, CA 90024

Oral movements (OMs) in rats administered chronic neuroleptics were repeatedly observed and also measured by a computerized video system. If "typical neuroleptics" such as haloperidol (HAL) are continuously administered, rats gradually show an increase in smooth, relatively small OMs; upon drug withdrawal, persisting increases in larger amplitude OMs are seen. FFT analysis in these animals indicates a shift in peak energy to 1-3 HZ (the same frequency shown by humans with tardive dyskinesia). A different type of OM pattern is observed when HAL is administered in weekly, large injections, similar to the "priming" studies used to induce dystonic reactions in monkeys. In this case OMs develop during chronic administration which are large in amplitude, rapid in slope of onset, and have a peak energy at 4-6 HZ. Atypical neuroleptics such as clozapine or raclopride do not induce these syndromes, but with each of these drugs distinctively different effects on OMs gradually develop. Drug regimen thus appears to play an important role in producing acute dystonic- versus tardive dyskinesia-like syndromes in rats.

IN VIVO RECEPTOR BINDING IN RAT BRAIN OF THE POTENTIAL ANTIPSYCHOTIC ORG 5222. J.A.D.M. Tonnaer, W.M.J.B. van Gemert*, Th. de Boer* and L.P.C. Delbressine* Scientific Development Group, Organon International B.V., 5340 BH Oss, The Netherlands.

ORG 5222 is a tetracyclic compound with an antidopaminergic potency comparable to haloperidol but superior to chlorpromazine and clozapine. Behavioral and neurochemical testing further indicated profound antiserotonergic properties and revealed potential antipsychotic activity of ORG 5222 with a reduced risk of extrapyramidal side effects. We studied the in vivo binding of [^{3}H]ORG 5222 (50 μCi; 4 μg/kg i.v.) to synaptic membranes in rats. Displaceable binding reached equilibrium within 1 hour and was stable for at least 3 hours. HPLC analysis indicated that more than 80% of radioactivity bound to the membranes consisted of intact [^{3}H]ORG 5222. The topography of [^{3}H]ORG 5222 binding sites was assessed by quantitative autoradiography 1 hour after i.v. administration. Displaceable binding was prominent in the choroid plexus (300 fmol/mg t.e.), high in the claustrum and layer IV of the cortical fields (60-120 fmol/mg), intermediate in dopaminergic projection areas (45-70 fmol/mg) and low in the hippocampal formation, thalamus and brainstem areas (<45 fmol/mg). This regional distribution of ORG 5222 binding in vivo shows a conspicuous overlap with the localization of 5-HT$_{1c}$, 5-HT$_2$ and, to a lesser extent, of DA receptors. The serotonergic interactions may play a role in the antipsychotic action of ORG 5222.

109.15

EFFECTS OF THE NOVEL DOPAMINE AUTORECEPTOR AGONIST PD 118717 ON THE ACTIVITY OF SUBSTANTIA NIGRA DOPAMINE NEURONS. C.L. Christoffersen and L.T. Meltzer. Depart. of Pharmacology, Parke-Davis Pharmaceutical Research Division, Warner-Lambert Co., Ann Arbor, MI 48105.

PD 118717 (7-[3-[4-(2-Pyrimidinyl)-1-piperazinyl]-propoxy]-2H-1-benzopyran-2-one sulfate) binds to dopamine (DA) D-2 receptors and is active in biochemical tests of DA autoreceptor agonist activity (Pugsley et al. this meeting) and in behavioral studies shows selectivity for the DA autoreceptors versus postsynaptic DA receptors (Williams et al., this meeting). In the present experiments we compared the effects of PD 118717 with those of apomorphine and (-)-3-PPP on the firing activity of substantia nigra DA neurons recorded extracellularly in chloral hydrate anesthetized male S-D rats. IP administration of PD 118717 produced a dose-related inhibition of DA neuron firing. The maximal inhibition at 20 mg/kg IP was approximately 80% of the baseline firing rate. In contrast, apomorphine (1 mg/kg IP) and (-)-3-PPP (20 mg/kg IP) produced maximal inhibitions of 100% and 50%, respectively. PD 118717 inhibited DA neuron activity in rats depleted of DA by treatment with reserpine plus alpha-methyl-paratyrosine, indicating direct DA agonist actions. These data indicate that PD 118717 is a partial DA agonist, with greater intrinsic activity than (-)-3-PPP but less intrinsic activity than apomorphine.

109.16

IN VITRO AND IN VIVO NEUROCHEMICAL EFFECTS OF A DOPAMINE (DA) AUTORECEPTOR AGONIST PD 118717 IN RAT BRAIN. T.A. Pugsley, S.L. Myers*, L.C. Coughenour*, Y.H. Shih*, S.Z. Whetzel*. Dept. Pharmacol., Parke-Davis Pharmaceutical Res. Warner-Lambert Co., Ann Arbor, MI 48105.

We have previously reported that PD 116795 exhibits a selective DA action on presynaptic DA autoreceptors (Wise, L. et al. Soc. Neurosci. 13:359, 1987). In a continuation of these studies we have examined the effects of PD 118717 (7-[3- [4-(2-pyridimidinyl)-1-piperazinyl]propoxy]-2H-1-benzopyran-2-one sulfate), an analog of PD 116795, on DA autoreceptors regulating synthesis and release of DA. PD 118717 bound selectively to rat striatal DA-2 receptors in vitro and dose-dependently (1-30 mg/kg i.p. and p.o.) inhibited the gamma-butyrolactone (GBL)-enhanced rat striatal DOPA synthesis. These results together with behavioral data (Heffner, T., et al this meeting) showing a lack of effect of PD 118717 on normosensitive postsynaptic DA receptors indicates a selective action of this agent on DA autoreceptors. CI-954 decreased striatal DA synthesis in non-GBL treated rats, slowed the rate of utilization of brain DA, decreased striatal DA metabolism and increased rat serum corticostersone levels, findings consistent with DA autoreceptor agonist action. No effect on the synthesis and turnover of norepinephrine was found up to 20 mg/kg i.p. indicating a selective action of PD 118717 on DA neurons. These results indicate that PD 118717 is a orally active DA autoreceptor agonist.

109.17

BEHAVIORAL EFFECTS OF THE NOVEL DOPAMINE AUTORECEPTOR AGONIST PD 118717. **A.E. Williams*, J.N. Wiley* and T.G. Heffner. (SPON: D.A. Downs). Dept. of Pharmacology, Parke-Davis Pharm. Res. Div., Warner-Lambert Co., Ann Arbor, MI 48105.**

PD 118717 (7-[3-[4-(2-pyrimidinyl)-1-piperazinyl]-propoxy]-2H-1-benzopyran-2-one sulfate) is a dopamine autoreceptor agonist as determined in neurophysiological and neurochemical tests. PD 118717 inhibits spontaneous locomotion in mice and rats, consistent with activation of presynaptic brain dopamine receptors. Relative selectivity for pre-vs postsynaptic dopamine receptors is demonstrated by the lack of locomotor stimulation at large multiples of behaviorally-active doses in normal and reserpine-treated rats and by a 20-fold separation between doses that cause locomotor inhibition and those that cause stereotypy. In line with presynaptic dopamine agonist effects, PD 118717 reduces the locomotor stimulation caused by amphetamine, a drug that releases dopamine from central neurons. Absence of postsynaptic dopamine antagonist effects is suggested by the failure of PD 118717 to block climbing induced by the direct-acting dopamine agonist apomorphine. Like other dopamine agonists, PD 118717 increases locomotion in rats with supersensitive dopamine receptors following depletion of brain dopamine by 6-hydroxydopamine. PD 118717 is active after oral dosing and its effects persist for 4 hours. These results indicate that PD 118717 is an orally-active brain dopamine autoreceptor agonist.

109.18

U-68553B, A NOVEL DOPAMINE AUTORECEPTOR AGONIST WITH CHRONIC ACTIVITY. R.A.Lahti, M.F.Piercey, D.L.Evans*, K.J.Carrigan*, G.L.Neff*, C.Barsuhn*, G.Vogelsang*. CNS Diseases Research, The Upjohn Company, Kalamazoo, MI 49001.

Schizophrenia may be due to an overactive dopamine system and since autoreceptors regulate the activity of these neurons a selective autoreceptor agonist may reduce the symptoms of schizophrenia. A clinical study using NPA demonstrated the utility of this approach, but tolerance developed to its clinical effect.

U-68553B, a dihydrophenalene, is a potent autoreceptor agonist in: the GBL model, reducing HVA and plasma prolactin, and in reducing the firing rate of VTA dopaminergic neurons. In receptor binding studies, U-68553B had an IC50 of 11.0 nM at the D2 receptor, 270 nM at the 5-HT2 receptor, 7.0 nM at the 5-HT1A receptor, and was relatively weak at various adrenergic receptors. Following 2 weeks of administration, U-68553B was not found to develop tolerance in the GBL model, or HVA suppression, whereas apmorphine did develop some degree of tolerance to HVA. U-68553B was active in both the limbic and striatal areas.

These data suggests that U-68553B is a potent dopamine autoreceptor agonist in both the limbic and striatal areas, and does not appear to develop tolerance upon chronic administration.

109.19

NEUROLEPTICS: PREDICTION OF ANTIPSYCHOTIC RESPONSE. F.P. Zemlan, D.L. Garver and O.J. Thienhaus. Dept. of Psychiatry, Univ. Cincinnati Sch. Med., Cincinnati, OH 45267-0559

The purpose of the present study was to identify clinical, diagnostic or drug response variables which predict antipsychotic response to neuroleptic treatment in schizophrenic patients. Consenting inpatients (N=40) received a 14 day fixed dose neuroleptic trial with patient symptoms quantified three times per week employing the modified NHSI. Responders (N=25) were discharged after 15 ± 2 days of hospitalization, for nonresponders (N=15) neuroleptic was altered as clinically indicated. Stepwise regression analysis indicated that 84% of the variation in length of hospitalization was accounted for by the number of pharmacotherapy alterations required for symptom remission ($F=207.76;df=3,36;p<0.0001$). Bayesian analysis indicated that clinical response could be predicted for 65% of the patients after 3 days of neuroleptic treatment from combined thought disorder and auditory hallucinations scores, while by Day 7, response could be accurately predicted for 80% of the patients employing the same clinical symptoms.

Most predictive tests employed in medicine demonstrate a prediction accuracy of about 70% to 90%, similar to that presently reported for a 7 day neuroleptic trial to predict clinical response. It is suggested that the length of hospitalization for schizoprenic patients may be decreased by decreasing the length of time a clinician prescribes pharmacotherapy that subsequently proves not effective.

109.20

ADDITION OF DOPAMINE ANTAGONISTS IN FLUVOXAMINE-REFRACTORY OBSESSIVE COMPULSIVE DISORDER. C.J. McDougle, M.D.*, W. K. Goodman, M.D., L.H. Price, M.D., P.L. Delgado, M.D., J.H. Krystal, M.D., D.S. Charney, M.D., G.R. Heninger, M.D., Yale Univ. Dept. of Psychiatry, 34 Park St., New Haven, CT 06508.

The efficacy of serotonin (5-HT) reuptake inhibitors, e.g. clomipramine and fluvoxamine (FVX), in Obsessive Compulsive Disorder (OCD) suggests that 5-HT dysregulation may be involved in the treatment and pathophysiology of OCD. However, as many as 50% of OCD patients do not improve with 5-HT reuptake inhibitors. OCD in this subgroup of unresponsive patients may involve neurochemical abnormalities different from or in addition to 5-HT dysfunction. In this study, a dopamine (DA) antagonist was added to ongoing treatment in OCD patients refractory to FVX ± lithium. Methods: 17 patients with OCD (DSM-III-R) unresponsive to FVX ± lithium (mean ± S.D. duration = 10.9 ± 3 weeks) had DA antagonist (pimozide equivalents=6.5 ± 5.4 mg/day) added to their regimens for 2-8 weeks (mean, 4.7 ± 1.9 weeks). Yale-Brown Obsessive Compulsive Scale (Y-BOCS) scores before and after addition of DA antagonist were used to assess outcome. Clinical Global Improvement (CGI) ratings were also made. All cases were blindly reviewed to determine whether comorbid tic-spectrum disorders or schizotypal personality disorder (SPD) predicted a response to DA antagonist addition. Results: Nine of 17 (56%) patients were judged responders (CGI = "much" or "very much improved") after combined DA antagonist - FVX ± lithium treatment. Addition of DA antagonist was associated with a highly significant decrease (36%) in Y-BOCS scores (mean ± S.D. = 9.1 ± 8.9; p<.001). Seven of 8 (88%) patients with comorbid tic-spectrum disorders or SPD were responders, whereas only 2 of 9 patients without these comorbid diagnoses were responders (p=.02). Conclusion: This study documents the efficacy of DA antagonist addition in OCD patients refractory to treatment with FVX ± lithium. Comorbid diagnoses of tic-spectrum disorders or SPD, in which DA dysregulation has been postulated, were more frequently associated with a positive DA antagonist response. These data suggest that both 5-HT and DA systems may contribute to the pathophysiology of obsessive-compulsive symptoms in some patients.

109.21

ACUTE EFFECTS OF WY-47,846 AND RELATED COMPOUNDS ON SEROTONERGIC AND DOPAMINERGIC NEURONS. **C.W. UZZLE*, D.E. JONES* AND J.T. HASKINS.** Wyeth-Ayerst Research Princeton, N.J. 08543-8000

Wy-47,846 (3a,4,4a,6a,7,7a-hexahydro-2-[4-[4-(2-pyrimidinyl)-1-piperazinyl]-butyl]-4,7 ethenocyclobut [f] isoindole-1,3,(2H)-dione), a compound with preclinical anxiolytic activity, was examined to determine its effects on the neuronal activity of both 5-HT and DA neurons. The effects of Wy-47,846 on 5-HT neurons of the dorsal raphe were compared to those of 8-OH-DPAT and gepirone while the effects of Wy-47,846 on A9 and A10 DA neurons were compared to those of buspirone. Standard neurophysiological methods were used for recording. The rank order of potency of these compounds for inhibiting 5-HT neurons was 8-OH-DPAT > gepirone = Wy-47,846 (ID50's = 1.9, 28.9 and 31 µg/kg, i.v., respectively). The activation of A9 and A10 DA neurons by Wy-47,846 and buspirone was similar although buspirone was slightly more potent in both areas. These findings indicate that the putative nonbenzodiazepine anxiolytic, Wy-47,846, has effects on 5-HT and DA neurons similar to those of other nonbenzodiazepine anxiolytics.

109.22

SEROTONERGIC AND DOPAMINERGIC INVOLVEMENT IN THE FEEDING INDUCED BY BUSPIRONE, GEPIRONE AND IPSAPIRONE. P.J. Fletcher* and M. Davies* (SPON: T.B. Wishart). Neuropsychiatric Research Unit, MR Bldg., University of Saskatchewan, Saskatoon, Sask., Canada, S7N 0W0.

The possible roles of 5-hydroxytryptamine (5-HT) and dopamine (DA) systems in mediating the increased feeding induced by buspirone, gepirone and ipsapirone were investigated. Following peripheral injection each compound dose-dependently increased 1h food intake in free-feeding rats. Depletion of brain 5-HT with PCPA prevented eating induced by gepirone (2.5mg/kg) and ipsapirone (2.5mg/kg), but not by buspirone (1mg/kg). Microinjection of gepirone (0.2µg) and ipsapirone (0.04 and 0.2µg), but not buspirone (0.04-5µg), into the dorsal raphé nucleus (DRN) significantly increased food intake, presumably by inhibiting the activity of DRN neurons, thereby reducing forebrain 5-HT neurotransmission. Pretreatment with haloperidol (0.1mg/kg, 30 min) attenuated eating induced by the peripheral administration of all three compounds, indicating that DA is involved in mediating the increased feeding responses. Increased striatal DA activity results in general behavioural activation, which under certain conditions is observed as enhanced feeding. This mechanism may account for the feeding induced by buspirone, gepirone and ipsapirone, since these drugs have been shown previously to increase striatal DA turnover. In the cases of gepirone and ipsapirone induced feeding an indirect action involving inhibition of serotonergic DRN afferents may be involved. However a direct interaction with DA receptors may underlie the effect of buspirone.

109.23

REGIONAL CEREBRAL GLUCOSE METABOLISM IN THE RAT AS A CORRELATE OF THE ONSET AND BLOCKADE OF RAT VCMs

J. Dale, H. Kaneda, O. Shirakawa, L. Goodman, C.A. Tamminga, S.E. Bachus, (SPON: W.T. Carpenter), Maryland Psychiatric Research Center, Deparment of Psychiatry, University of Maryland, Baltimore, MD 21228

The evalution of regional cerebral glucose metabolism (RCGM) in the haloperidol-treated rat may suggest the brain areas which mediate development and blockade of vacuous chewing movements (VCMs). Sprague Dawley rats were treated for 1,3,6, and 12 months with water (W), haloperidol (H), haloperidol plus progabide (H+P), and progabide (P), with H at 1.5 mg/kg/day and P at 100 mg/kg/day. Quantitative glucose metabolism using 14C-2-deoxyglucose and autoradiography were carried out in rats from each group; multiple brain areas were examined for glucose utilization using the Sokoloff method. After 6 months, H increased RCGM in the caudate (H:96.6 (10.6) mg Glu/100 gm tiss/min; W:86.5 (3.47), p<.05; mean (SD). P increased RCGM in medial prefrontal cortex (P:96.5 (7.4); W:80.9 (7.8); p < .005); P also increased RCGM in hippocampus (P:62.8 (3.6); W:54.1 (5.2), p < .005). This effect in caudate is similar to the chronic neuroleptic effect on glucose metabolism in man (PET/FDG technique) but different than the acute H effect in previous rat studies. Areas whose RCGM correlate with the VCMs after 12 months of treatment will be reported.

109.24

DISSOCIATION OF ALTERED STRIATAL GAD ACTIVITY FROM VACUOUS CHEWING MOVEMENTS. S.E. Bachus, L. Goodman*, J.Dale*, H.Kaneda & C.A.Tamminga. Maryland Psychiatric Res. Ctr., Baltimore, Maryland, 21228.

The use of vacuous chewing movements (VCMs), which develop after chronic neuroleptic exposure, as an animal model for tardive dyskinesia[1] allows regional biochemical analysis to generate hypotheses for testing in the human condition. Both reduced nigral GAD activity[1] and increased striatal GAD activity with unchanged nigral GAD activity[2] have been reported to accompany VCMs in rats after chronic haloperidol (H) exposure. Production of VCMs by H is blocked by concurrent administration of the GABA agonist progabide (P)[3]. We have examined whether biochemical alterations occur in basal ganglia GABA pathways which correlate with onset of, or are reversed by blockade of VCMs.

Male Sprague-Dawley rats were treated for 6 mo. with water (W), H (1.5 mg/kg/day po), P (100 mg/kg/day po), or H+P. GAD activity was measured radioenzymatically[4] after specific brain regions were dissected.

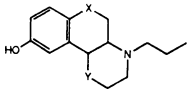
Nigral GAD activity was not changed after 6 mo. of H, despite the development of VCMs. While striatal GAD activity was not increased by H alone, it was elevated by H+P treatment (.24 ± .01 µmol/mg protein/hr) relative to W (.20 ± .01, p<.025) or P (.20 ± .01, p<.05). The ratio of striatal/nigral GAD activity was also increased by H+P (.23 ± .02) relative to W (.17 ± .01, p<.005) and P (.17 ± .01, p <.005). Neither nigral GAD activity (r=-.36) nor striatal GAD activity (r= .25) was significantly correlated with individual variability in VCMs in H-treated rats. Thus, elevated striatal GAD activity can persist despite the blockade of enhanced VCMs after chronic H, and this change does not correlate with VCMs, suggesting that it is not directly causally related to VCMs.

[1]Gunne & Häggström, Psychopharm 81:191,1983. [2]Mithani et al., Psychopharm 93:94, 1987. [3]Shirakawa et al. Soc Neurosci Abst. 1989. [4]Sims & Pitts, J Neurochem 17:1607, 1970.

109.25

GABA AGONIST ACTION ON HALOPERIDOL-INDUCED VACUOUS CHEWING MOVEMENTS

O. Shirakawa*, H. Kaneda*, J. Dale*, N. Kaneda*, L. Goodman*, S.E. Bachus, C.A. Tamminga, (SPON. B. Kirkpatrick)
Maryland Psychiatric Research Center, University of Maryland, P.O. Box 21247, Baltimore, MD 21228.



Vacuous Chewing Movements (VCMs) are an animal analogue of the human motor disorder tardive dyskinesia (TD). VCMs are slow in onset, nonsuppressible by atropine, continue after neuroleptic cessation, and have a prevalence in rats of 63% after 3-6 months of treatment. The pathophysiology of TD, and perhaps these VCMs, may include both dopamine (DA) system changes, and GABA system hypofunction. In an attempt to demonsrate a prophylactic effect of GABA agonists in VCMs, we have treated rats with water alone (W), haloperidol alone (H), progabide alone (P), and haloperidol plus progabide (HP). Sprague Dawley rats were fed H (1.5 mg/kg/day) in their drinking water and P (100 mg/kg/day) in their food for 1,3,6, and 12 months. VCMs/2 minutes were analyzed regularly by blind raters. After 6 months of treatment the 4 groups show significantly different rates of VCMs/2 minutes: 1.54 ± 0.43 for W; 9.81 ± 1.5 for H; 4.12 ± .93 for H+P; 0.97 ± .37 for P. Progabide to inhibited the onset of haloperidol-induced VCMs. Moreover, the P-treated animals do not merely show "dyskinesia" suppression but actual lack of onset as we have determined from an additional progabide-withdrawal experiment. These data would suggest that progabide and perhaps other GABAmimetic compounds can prevent the development of TD.

109.26

DOPAMINE AUTORECEPTOR AGONIST PROPERTIES OF (+)-trans-3,4,4a,10b-TETRAHYDRO-4-PROPYL-2H,5H-[1]-BENZOPYRANO-[4,3-b]-1,4-OXAZIN-9-OL AND ENANTIOMERS.

L.D. Wise*, H.A. DeWald*, T.G. Heffner, J.C. Jaen*, L.T. Meltzer, T.A. Pugsley (SPON: J.G. Marriott). Parke-Davis Pharmaceutical Research Division, Warner-Lambert Co., Ann Arbor, MI 48105

PHNO and CGS 15855A possess potent DA autoreceptor agonist activity. We have now synthesized and evaluated the dopaminergic properties of the trans-3,4,4a,10b-tetrahydro-4-propyl-2H,5H-[1]-benzopyrano-[4,3-b]-1,4-oxazin-9-ol (PD 125530) and its enantiomers, compounds which combine the structural features of the above compounds.

PHNO • X = CH_2, Y = O
CGS 15855A X = O, Y = CH_2
PD 125530 X = O, Y = O

Both PD 125530 and its (+)-enantiomer, PD 128907, bound to DA D_2 receptors, and in rats attenuated gamma-butyrolactone-stimulated brain DA synthesis, decreased firing of substantia nigra DA neurons, and selectively inhibited exploratory locomotor activity, a profile consistent with a DA autoreceptor agonist mechanism of action. However, the (-)-enantiomer, PD 128908, lacked activity. Thus, like PHNO and CGS 15855A, PD 125530 is a potent DA autoreceptor agonist, and this activity resides in one enantiomer.

109.27

INTERACTION BETWEEN THE POTENTIAL ANTIPSYCHOTIC CI-943 AND AMPHETAMINE.

T.G. Heffner, F.W. Ninteman*, A.E. Williams* and J.N.Wiley*. Dept. of Pharmacology, Parke-Davis Pharm. Res. Div., Warner-Lambert Co., Ann Arbor, MI 48105.

CI-943 (8-ethyl-7,8-dihydro-1,3,5-trimethyl-1H-imidazo [1,2-c]pyrazolo[3,4-e]pyrimidine) is a novel antipsychotic candidate that is not a dopamine receptor antagonist (Soc. Neurosci. Abst. 13:459-460,1987). In addition to reducing conditioned behavior and apomorphine-induced climbing, we reported previously that CI-943 does not block stereotyped behavior caused by apomorphine or amphetamine but can augment the locomotor stimulant effect of amphetamine in rats (Soc. Neurosci. Abst. 14:370,1988). Further studies indicate that CI-943 does not augment locomotor stimulation caused by amphetamine in rats habituated to the test environment, a paradigm that enhances the ability to detect stimulation. High doses of CI-943 reduce amphetamine locomotor stimulation in habituated rats. Moreover, CI-943 does not augment the increase in hypothalamic self-stimulation responding or Sidman avoidance responding caused by amphetamine, but instead attenuates the stimulant effects of amphetamine in these tests. CI-943 also does not enhance amphetamine-induced stereotyped behavior in rats. These results indicate that while CI-943 does not cause dopamine antagonist-like blockade of amphetamine-induced stereotyped behavior, neither does it enhance the psychostimulant effects of amphetamine in animals.

STRESS, HORMONES AND THE AUTONOMIC NERVOUS SYSTEM

110.1

HUMAN VASOPRESSIN (AVP) AND ADRENOCORTICOTROPIN (ACTH) RESPONSES TO STRESSFUL SENSORY INPUT: INDIVIDUAL DIFFERENCES AND ADAPTIVE RESPONSES.

R.L. Kohl and D.S. Calkins.* Universities Space Research Association and Krug International; Space Biomedical Research Institute, Johnson Space Center, National Aeronautics and Space Administration, Houston TX 77058.

Plasma levels of AVP and ACTH were determined in human subjects before and after exposure to stressful Coriolis stimulation on a rotating chair assembly (Kohl, R.L., Aviat. Space Environ. Med., 58:125, 1987). Subjects made head movements out of the plane of rotation until stimulation of vestibular systems induced advanced nausea and autonomic system dysfunction (i.e., motion sickness). Pre- and posttest levels of AVP were linearly correlated ($r = 0.561$, $p<0.05$). The amount of stimulation tolerated before nausea occurred was significantly correlated with the subjects' ability to mobilize AVP (Kruskal-Wallis 1-way ANOVA, $p<0.04$), but not with resting levels of AVP or ACTH. The coefficient of variation determined from six measurements of resting levels of AVP was inversely correlated with susceptibility to stressful motion ($p<0.006$). After five consecutive daily exposures to nausea, a significant diminution of postnausea AVP and ACTH occurred. Corelease of AVP and ACTH in response to nausea followed a linear relationship ($p<0.05$). These findings suggest the participation of the paraventricular hypothalamic nucleus in endocrine and autonomic responses to stressful sensory input and indicate that individual differences and adaptive responses involving these endocrine systems may offer predictive and etiologic insights into the autonomic dysfunctions observed.

110.2

STRESSFUL INTERVIEW ELICITS RISE IN PLASMA VASOPRESSIN AND RENIN ACTIVITY.

J.L. Meyerhoff, M.A. Oleshansky, G.P. Chrousos, E.H. Mougey and C. Calogeras*. Dept. Med. Neurosci., Walter Reed Army Inst. of Res., Wash., DC 20307 and Devel. Endo. Br., NICHHD, Bethesda, MD 20892.

Release of hormones from the anterior pituitary might be affected by several neurohumors known to increase in the circulation in response to stress. A stressful 30 min interview increased plasma levels of vasopressin (VP), epinephrine (EPI), norepinephrine (NE), and plasma renin activity (PRA), as well as cyclic AMP, ACTH, β-endorphin (β-EP), β-lipotropin (β-LPH) and prolactin (PRL). These increases occurred within 7 min of beginning the interview and were quite robust: VP (40%), EPI (200 %), NE (170%), PRA (123%), cyclic AMP (57%), ACTH (59%), β-EP (79%), β-LPH (42%) and PRL (46%). Plasma levels of atrial naturetic factor were unaffected by the stressful experience. Two of the stress-responsive circulating substances have been reported to affect the release of ACTH: VP and EPI. VP stimulates ACTH release from pituitary cells in vitro, and is believed to be released from the median eminence into the portal blood to stimulate corticotrophs in vivo. Our finding of stress-induced increases in circulating VP suggests that VP is also released from posterior pituitary during stress and may augment stress-induced CRF-mediated release of ACTH. Since angiotensin II (AGII) is reported to be a secretogogue for ACTH, and PRA is involved in the synthesis of the precursor for AGII, PRA might indirectly contribute to ACTH release.

110.3

CHANGES IN THE ELECTROGASTROGRAM AND THE ONSET OF EXCESSIVE WHEEL RUNNING IN RATS DURING ACTIVITY-STRESS. N.S. Morrow and S.W. Kiefer. Dept. of Psychology, Kansas State University, Manhattan, KS 66506.

To examine the relationship between changes in gastric function and the elevation of wheel running during activity-stress, surface recordings from the stomach (the electrogastrogram) were recorded. Initially, the stomachs of 14 rats were translocated so that the stomach was located just beneath the abdominal skin. Rats were then divided into an activity group (n = 7) and a home cage group (n = 7). Following baseline measurements, all rats were fed for 1 h each day. The electrogastrogram (EGG) was recorded daily. Results indicated that changes in the frequency and amplitude of EGG potentials were both predictive and correlated with increases in activity and ulceration. Home cage control rats did not exhibit changes in the EGG and did not become ulcerated. It is suggested that changes in gastric factors may influence the development of excessive wheel running.

110.4

ONTOGENY OF BEHAVIORAL AND HORMONAL RESPONSES TO STRESS IN PRENATALLY STRESSED MALE RAT PUPS. L.K. Takahashi, E.W. Baker*, and N.H. Kalin. Dept of Psychiat., Univ. of Wisc. Med. Sch., and VA Med. Cntr., Madison, WI 53705.

We reported that prenatally stressed 14-day-old rat pups (PS) showed marginal increases in stress-induced analgesia but elevated plasma ACTH (Physiol. Behav. 1988, 42:325). This study examines, in both 14- and 21-day-old male pups, effects of prenatal stress on occurrence of ultrasonic distress calls, freezing behavior, analgesic reactions, and plasma ACTH. Sprague-Dawley rats were shocked every other day during pregnancy. PS pups (n=12-15) were compared to home cage controls (HC, n=11-15) in 10-min tests that assessed responses to: 1) separation from the litter; and 2) foot shock. At 14 days, PS pups emitted fewer ultrasonic calls, showed lower stress-induced analgesia, and had higher plasma ACTH than HC pups ($p<.05$ or less). At 21 days, number of ultrasonic calls, duration of freezing, and level of analgesia were similar between groups. However, plasma ACTH again differed between PS and HC pups, with the latter exhibiting a significant elevation after shock exposure ($p<.05$). Differences in hormonal responses to stress, shown in early life of PS pups, reflect altered hypothalamic-pituitary-adrenal regulation which may be linked to the expression of stress-induced behavior.

Supported by NIMH grant MH-43986.

ONTOGENY OF DEFENSIVE BEHAVIORS AND HORMONAL ACTIVATION IN INFANT RHESUS MONKEYS. N. H. Kalin, S. E. Shelton*, and J. Turner*. Psychiatry Lab., VA Hospital; and Dept. of Psychiatry, Univ. of Wis., Madison, WI 53705

Infant rhesus monkeys (20- to 52-wk-old) emit frequent coo vocalizations when separated from their mothers. If a human enters the room and does not engage the infant in eye contact (NEC), it freezes. However, staring (ST) at the infant induces barking and hostility (Science 243:1718, 1989). This study examined the ontogeny of these responses in 0-2, 2-4, 5-7, and 9- to 12-wk-old infants (8 per group). With separation, 0-2 wk-old infants displayed distress, but failed to modulate their responses as the parameters of the threat changed. Two- to 4-wk-old infants froze during NEC, but during ST did not selectively respond with increased barking. Five- to 7-wk-old infants froze very little and did not increase their barking during ST. The 9- to 12-wk-old infants responded much like the older infants in our previous study, *i.e.*, NEC selectively induced freezing and ST selectively induced barking. ACTH levels were higher in the 9-12 wk-old group, whereas GH levels were elevated in the 0- to 2-wk-old infants. Separation increased levels of both hormones, but significant increases in ACTH did not occur before 5 wk of age. Thus, different developmental time courses exist in the rhesus monkey for defensive behaviors and stress-induced ACTH and GH secretion.

110.6

THE EFFECT OF PRENATAL STRESS ON THE HIPPOCAMPUS IN RATS. H. Uno, B. Schroeder*, P. Alsum*, L. Takahashi and N. Kalin. Wisconsin Regional Primate Research Ctr. and Dept. of Psychiatry, UW-Madison.

Our previous studies have revealed that prenatal stress in rats induced in offspring increased stress-induced secretion of ACTH and corticosterone. The hippocampal neurons are known to regulate the hypothalamic-pituitary-adrenal axis and the pyramidal neurons in the CA3 and 2 contain a high concentration of glucocorticoid receptors. In the present study, 28-day-old rats from 24 litters (16 stressed and 8 control, males and females) were perfused through the heart with 10% neutral buffered formalin. The hippocampal sections were embedded with glycol methacrylate resin and cut 3 microns thick with a glass knife, then stained with cresyl violet. The most pronounced change was found in the CA3 region; approximately 75% of prenatally stressed pups showed a 10-20% reduction of pyramidal neurons and the dendritic processes were poorly developed compared to those in control brains. In the other regions of the hippocampus, the pyramidal neurons in the CA1 and the dentate granular neurons showed no striking difference between stressed and control brains. These results suggest that the CA3 pyramidal neurons are most vulnerable to the effect of prenatal stress. Perhaps an increased level of glucocorticoids induced by stress during pregnancy led to developmental changes in the hippocampus of offspring. Our earlier work showed that prenatal administration of dexamethasone induced neuronal damage in the CA3 neurons of rhesus fetal brains.

α- AND β- ADRENERGIC RECEPTORS AND TELEMETERED AUTONOMIC RESPONSES TO SOCIAL STRESS. W. Tornatzky*, K. A. Miczek (SPON: J. Ellingboe) Psychology Department, Tufts University, Medford, MA 02155

Animals react to social stress with defensive and submissive behavior as well as with increased cardiovascular activity and core temperature. To evaluate the involvement of adrenergic receptor systems and anxiolytics in the heart-rate (HR), core temperature (TC) and behavioral reaction of a rat that is exposed for 1 hour to the threats by an opponent, clonidine (0.01 to 0.1 mg/kg i.p.), a centrally acting α2-receptor agonist, β-blockers and benzodiazepines were administered. The acute social stress situation consisted of brief physical agonistic interactions until the experimental rat was forced into a prolonged submissive supine posture, emitted ultrasounds and, subsequently, exposure to the opponent's threats, while being shielded from physical contact by a wire mesh. HR and TC of these individually housed Long-Evans rats (300g) were monitored by a PC-based telemetry system (Mini-Mitter Dataquest III) throughout the light/dark cycle. A stable circadian pattern developed within 7 days after implant of the telemetry sender with mean values of 350 beats/min and 37.6oC during the dark period; decreasing by 30-60 b/min and 0.4-1oC respectively during the light period. Physical interaction with the resident induced large elevations above dark cycle mean values (+150 b/min for HR and +1.8oC for TC). During the following threat period TC remained elevated. The HR declined to a level which was similar to the elevated HR (+50 b/min) measured during activity bouts. Clonidine (0.01-0.1 mg/kg) prevented the increase in HR and TC during the 1 h agonistic interaction dose-dependently. The 0.1 mg/kg dose restored the baseline levels, and did not prevent defensive postures and ultrasounds. Diazepam (3, 6, 10 mg/kg) attenuated the increase in TC, and also decreased defensive upright postures. Threat during social conflict results in massive autonomic reactions that appear to depend on central adrenergic receptors.

110.8

BLOOD PRESSURE VIA TELEMETRY DURING SOCIAL STRESS IN FREELY MOVING RATS. W.P.Meehan*, W.Tornatzky* and K.A.Miczek (SPON: D.Lindsley). Dept.Psych., Tufts Univ., Medford, MA 02155.

Daily variations in blood pressure (BP) and changes in BP due to social stress were recorded from freely moving rats. Implantable transmitters (Mini-mitter, OR) with a catheter inserted into the aorta allowed the remote recording of systolic and diastolic BP, heart rate (HR) and coarse motor activity. Rats were housed individually for baseline measures and, for social stress, they were placed as intruders into the cage of a rat selected for its aggressive behavior ("resident"). The 1 h test began with unrestricted physical interaction with the resident until the intruder displayed a submissive supine posture (30 to 180 s). Then, a wire cage was placed over the intruder to prevent futher physical contact by the resident. Baseline BP was 125/80 (HR=350) at rest and increased to 135/90 (HR=400) during activity. These periods of activity occurred at regular intervals and no differences in BP or HR were noted between lights on and off. BP during physical interactions with the aggressive rat was 165/115. In the protective wire cage, BP remained elevated at ca. 145/95 mm Hg and returned to baseline in the home cage. Clonidine (0.06 mg/kg) attenuated the stress-induced increase in BP. In summary, BP and HR were found to increase in response to non-stressful activity within the home cage of the rat and more so in response to aggression and threat of attack by another rat.

DIFFERENTIAL CARDIOVASCULAR EFFECTS OF FOOTSHOCK AND AIRPUFF STRESSORS IN WISTAR-KYOTO AND SPONTANEOUSLY HYPERTENSIVE RATS. R.F. Kirby, C.H. Woodworth, G.G. Woodworth* and A.K. Johnson. Dept. of Psychology and The Cardiovascular Center, Univ. of Iowa, Iowa City, IA 52242.

Cardiovascular responses to noxious and non-noxious stressors were compared in the present study with and without peripheral beta-adrenoceptor mediated-vasodilatory mechanisms blocked. Adult male WKY and SHR were implanted with carotid artery catheters for recording of arterial pressure and heart rate and jugular vein catheters for administration of vehicle or the beta-2 adrenoceptor antagonist. After recovery, animals were exposed to their first stress episode of 5 acute trials of either footshock (0.5 mA, 0.5 sec) or airpuff (15 psi, 100 ms) with each trial separated by 1 min. Animals were tested to the other stressor two days later with the drug treatment they had not previously been exposed to. Order of the stressors and drug treatment were counterbalanced between days. Both stressors led to immediate pressor responses that decreased across trials, but the responses were greater to airpuff than to footshock. However, blood pressure and heart rate rose gradually across footshock trials but remained stable between each airpuff trial. The effect of beta-2 adrenoceptor blockade was to increase the duration of the pressor response to both stressors. These results indicate that unique cardiovascular response patterns occur to airpuff and footshock stress but both involve activation of beta-2 adrenoceptors.

110.10

SPONTANEOUSLY HYPERTENSIVE AND WISTAR-KYOTO RATS SHOW BEHAVIORAL DIFFERENCES BUT CARDIOVASCULAR SIMILARITIES IN TACTILE STARTLE. C.H. Woodworth, R.F. Kirby, G.G. Woodworth* and A.K. Johnson. Depts. of Psychology and Statistics, and The Cardiovascular Center, Univ. of Iowa, Iowa City, IA 52242.

Concurrent behavioral and cardiovascular responses to tactile startle were investigated in SHR and WKY with and without blockade of peripheral vasodilatory mechanisms with a beta-2 adrenoceptor antagonist. These data were collected as part of a study comparing cardiovascular responses to noxious and non-noxious stressors (see Kirby et al., Soc Neurosci Abstr, 1989). Although SHR showed significantly greater motor responses to 100- msec, 15-psi airpuffs than WKY, there were no strain differences in pressor responses or tachycardia measured immediately or 30 sec following airpuff stimuli. Both strains showed significant habituation of motor and pressor responses and increasing tachycardia over 5 consecutive startle trials (60- sec ITI). Motor and HR responses changed more rapidly in WKY than SHR. Prior treatment with the beta-2 adrenoceptor antagonist ICI 118,551 (0.5 mg/kg, iv) had no effect on either behavioral or cardiovascular responses to airpuff stimuli in either strain, although motor responses habituated more slowly in ICI-treated rats than in vehicle controls.

DIABETIC RATS DISPLAY A HEIGHTENED STRESS AND ANXIETY RESPONSE TO THE OPEN FIELD AND ELEVATED PLUS MAZE. Q. Ahmad[1], S. Farag[1] and Z. Merali[1,2]. [1]Psychology and [2]Pharmacology, University of Ottawa. Ottawa, Ontario, Canada, K1N 9A9.

This study assessed the anxiety and stress responses of the insulin treated male Spontaneously Diabetic Rat (SDR) (4-6 months diabetic), matched non-diabetic and genetically distinct controls to: 1) the open field (OPFD); 2) the elevated plus maze (EPM) following either vehicle or the anxiolytic, Chlordiazepoxide (CHLOR 2.0, 4.0, 6.0 mg/kg; i.p.). 30 min after treatment, the rats were placed in the OPFD for 10 min, followed by 10 min in the EPM. In the OPFD, CHLOR induced a dose-dependent increase in locomotion, of similar magnitude, in all groups. In all groups, CHLOR dose-dependently increased the number of entries into the center (anxiogenic) area of the OPFD. This response however, was significantly attenuated in the SDR. In the EPM, CHLOR dose-dependently increased the time spent in the open (anxiogenic) arms. Again, this response was significantly attenuated in the SDR. In conclusion, the SDR show a heightened stress response and blunted sensitivity to the anti-anxiety effects of CHLOR, across 2 different stress and anxiety assessment paradigms.

MEDIAL FRONTAL CORTEX LESIONS ELIMINATE ULTRASONIC VOCALIZATIONS DURING STRESS IN THE RAT

E.J. Neafsey and R.J. Frysztak, Department of Anatomy, Loyola University Stritch School of Medicine, Maywood, IL 60153

During stress rats emit ultrasonic vocalizations (USV). Since in primates the anterior cingulate gyrus has been linked to production of the distress call (MacLean and Newman, BR 450,111, 1988), we examined the effect of lesions of the rat medial frontal anterior cingulate cortex (MFC) on USV emitted during tone-footshock classical conditioning and during presentation of the tone stimulus alone on extinction trials following conditioning. Bilateral lesions of the prelimbic and infralimbic regions of the medial frontal cortex of 13 male Sprague-Dawley rats were made by stereotaxic injection of 0.4 ul of N-methyl-D-aspartate; sham lesions were made in 13 other animals. After several weeks to several months of recovery, all SHAM animals emitted USV during tone-footshock conditioning and during subsequent tone presentation alone, while only 1 of 13 MFC-lesioned rats emitted any USV during these procedures. These results replicate those seen in primates following similar lesions (MacLean and Newman, ibid.). Supported by Loyola BRSG funds.

STRESS PRODUCES AN ACUTE AND LONG-TERM ENHANCEMENT OF THE ACOUSTIC STARTLE RESPONSE: A ROLE FOR ENDOGENOUS OPIOIDS. Collins, D.L.*, Mickley, G.A. and Cohen, S.J.* (SPON: J.L. Ferguson). BHS, AFRRI, Bethesda, MD. 20814-5145.

Intermittent (but, not continuous) footshock causes an analgesia mediated by endogenous opioids. Since opiates can alter acoustic startle responding, this experiment measured the startle amplitude of Sprague Dawley rats following either intermittent or continuous footshock. Rats in the former group, but not the latter group, exhibited significantly enhanced startle response amplitudes compared with control (i.e., non-shocked) rats. The startle amplitude of rats receiving intermittent footshock (but, not continuous footshock) was significantly reduced by naloxone (1 mg/kg, i.p.). In a follow-up test (conducted 27 days after the initial shock) rats that had been exposed to either intermittent or continuous footshock stressors demonstrated greater startle response amplitudes than control rats, and reduced their initial spontaneous activity in a novel environment. These data suggest that, following certain stressful conditions startle hypersensitivity may be long lasting and mediated by endogenous opioids.

110.14

STRESS INDUCED CHANGES OF ALPHA-2-RECEPTORS IN THE LOCUS COERULEUS. G.K. Weiss*, A. Voltura*, D. Savage, C. Lucero*, T. Hoffman*, & D. Karnaze* A. Ratner. Univ. of New Mexico Sch. of Med., Albuquerque, NM 87131,

Stress is known to activate the central noradrenergic (NA) system. Presynaptic alpha-2-adrenergic receptors act to suppress NA activity. Thus, adaptation to stress may involve changes in these alpha-2-receptors. This study examines the effect of various periods of mild stress on alpha-2-receptors in the Locus Coeruleus (LC). Adult male rats were placed in a cold room (4 C) and switched to a new novel environment every 30min. Control rats were kept in their home cage (24 C). Autoradiographic measurements of alpha-2-receptors within the LC were made by incubating tissue sections with the specific alpha-2-antagonist, H^3-Idazoxan. Computer assisted microdensitometry was used to determine specific binding. A significant increase in alpha-2-receptor binding was seen 1hr after stress. After 4hrs of stress, binding was significantly decreased. Exposure to the same stress procedure for 4hrs per day over a 4 day or 10 day period showed no change in binding. These results indicate that a mild short term stress can alter the binding of Idazoxan to alpha-2-receptors in the LC. The increase at 1hr may act to down regulate LC activity, while the decrease at 4hrs could lead to enhanced LC activity. The lack of change, after long term stress may be due to adaptation to the stressor, since corticosterone levels in these animals were not found to be increased.(Supported by NIH NS23262 and MBRS RR08139).

110.15

SYMPATHO-ADRENAL EFFECTS ON INHIBITORY RESPONSES TO STRESS IN RATS. P.Terry* and P.Salmon* (SPON: J.D.Feigenbaum). Dept. of Psychology, Univ. Coll. London, Gower St., London WC1E 6BT, U.K.

These experiments investigate the ways in which disruptions of the sympatho-adrenal system influence the growth and amelioration of inhibitory responses to stress. Sympatho-adrenal function was disrupted by beta-blocking drugs, by neurotoxic sympathectomy, and/or by adrenal demedullation. Behavioral inhibition by frustrative nonreward (extinction of rewarded running) was retarded by acute i.p. injection of the beta-blocker propranolol. Adrenal demedullation reproduced this effect of beta blockade, but neurotoxic sympathectomy (by 6-hydroxydopamine) facilitated inhibition. These two interventions in combination tend to cancel out. The results suggest a functional dissociation between the two components of the sympatho-adrenal system with regard to the inhibitory effects of stress.

110.16

CONTINGENCY, EMOTIONALITY AND NALOXONE-INDUCED ANALGESIA (NIA). C.X. Poulos*, A.D. Le*, D. Knoke* and H. Cappell* (SPON: Y. Israel) Dept. of Psychology, Univ. of Toronto and Addiction Res. Foundation of Ontario, Toronto, Canada.

Recently, we and other investigators have independently reported that repeated administration of naloxone (N) can produce analgesia. The present experiment was designed to examine the possibility that NIA might be a form of stress-induced analgesia. During acquisition, 2 groups of rats received N (5 mg/kg) and 2 groups received saline (S). One drug group and one S group were given a hot-plate test 20 min after injection (N-contingent and S-contingent). The other 2 groups received hot-plate tests 24 hrs following injection (N-noncontingent and S-noncontingent). Pawlick latency was used as an index of pain sensitivity. After 23 acquisition trials, all rats were injected with N and tested on the hot-plate. Only the N-contingent showed significant NIA. On the next test day, rats were given their usual injection substance and 15 min later they were placed in an open field box. The N-contingent group had the highest level of freezing as well as defecation. These findings showed that NIA per se is contingent upon painful stimulation during opiate blockade and that NIA might be mediated by heightened emotionality, which is similarly contingent.

PLASMA AND TISSUE CONCENTRATIONS OF CATECHOLAMINES AFTER DIFFERENT TYPES OF STRESSES IN RATS: NALOXONE EFFECTS. H.M.Rhee. Dept. of Pharmacology, Oral Roberts University School of Medicine, Tulsa, OK 74137.

Stresses are known to be responsible for sympathetic overdrive with an elevated level of plasma catecholamines. To investigate the role of opioid receptors in immobilization, heat, and exercise stresses, young adult male Sprague-Dawley rats were surgically implanted with arterial and venous catheters two days before the stress. Immobilization stress was applied in a rat restrainer. Heat stress was given under an infrared lamp (39°c) for 5 minutes. Other rats were forced to run on a treadmill for 3 weeks with a gradual increase in the speed as well as in the duration of running time. Blood pressure and heart rate were continuously measured before, during, and after the stress. Plasma and tissue catecholamines were analyzed using HPLC with EC detector. All stresses increased blood pressure and heart rate significantly. Naloxone did not prevent the rise of blood pressure and heart rate after the immobilization. Naloxone had little effect on plasma catecholamines after the immobilization, but it increased them after the heat stress. Naloxone had no effect on either total cholesterol or high density lipoprotein. The data suggest that different types of stresses selectively release catecholamines, which is regulated by opioid receptors, particularly under stressful conditions.

110.18

NEUROENDOCRINE AND BEHAVIORAL CORRELATES OF ACTIVITY-INDUCED ANOREXIA IN THE RAT L. Shih*, J. R. Glowa and A. Riley Clinical Neuroendocrinology Branch, NIMH, Bethesda, MD 20892 and Psychopharmacology Laboratoory, Depart. of Psychology, The American University, Washington DC 20016.

Rats were individually housed and allowed to acclimate to home cages, with free access to food and water and daily intake monitored. Based on wgts over the last three of five acclimatization days, rats were divided into two groups with similar wgts, and put into a home cage with (running group) an attached running wheel which was locked or without (control group) a running wheel. Both groups were then subjected to a nine-day regimen of limited access (1-hr) to food with wgt and consumption monitored. After that period, (running) rats were allowed to run 22.5 hrs/day; both groups were weighed daily at 4:00 p.m. and fed 25-30 g at 4:30 and allowed to consume as much as possible for 1 hr. This procedure was followed for 30 days. The animals were then weighed, sacrificed (with blood taken for ACTH and corticosterone analysis) and the brain quickly removed for molecular probe analysis. Significant differences in ACTH and corticosterone occurred between the two groups, and there was a profound, but not life-threatening, weight loss in the running group. These data are consistent with the notion that there is a positive relationship between activity and stress hormone levels, and a negative relationship between these variables and the ability to maintain weight. As similar effects occur with human anorexia patients, behavioral procedures related to adaptation should be examined clinically.

110.19

STRESS-INDUCED INCREASES IN FOREBRAIN CHOLINE AND GLUTAMATE SYNAPTOSOMAL UIPTAKE IN AGED RAT STRAINS. G.M. Gilad, V.H. Gilad and Y. Tizabi[1]. Neuropsychiatry Branch, NIMH Neurosciences Center at St. Elizabeths, Washington, D.C. 20032; [1]Dept. of Pharmacology, Col. Med., Howard Univ., Washington, D.C. 20059.

The activity of septohippocampal cholinergic neurons undergoes adaptive changes in response to stressful stimuli. These changes are more pronounced in inbred Wistar Kyoto (WKY) rats that are behaviorally more reactive to stressors and have a shorter life span than Brown Norway (BN) rats. Moreover, degeneration of these neurons which may be accompanied by reduced hippocampal choline uptake, occurs earlier in the WKY strain. Here we report the effects of 2 hr restraint stress on choline and glutamate uptake in aged (24 mo.) rats of these strains. After stress, choline uptake was increased slightly in the hippocampus (~15%) and by as much as 80% in the frontal cortex. With one exception—unchanged choline uptake in aged WKY hippocampus—no strain or age differences were noted in this stress-response. Glutamate uptake, measured in the hippocampus and septum, increased ~3 folds in both regions independent of strain or age. We conclude: 1) an initial increase in choline uptake after acute stressful stimuli is a hallmark of the stress-response of basal forebrain cholinergic neurons, and 2) a large increase in glutamate uptake (re-uptake) occurs after 2 hr of restraint stress and its characteristics should be subject to further studies.

110.20

EFFECTS OF IONIZING RADIATION ON ISOLATED AND GROUP-HOUSED MICE. M.R. Landauer*, H.D. Davis*, D.M. Maier*, T.B. Elliot* & G.D. Ledney*. (SPON: D.R. Livengood) Behavioral Sciences & Experimental Hematology Depts., Armed Forces Radiobiology Research Institute, Bethesda, MD. 20814-5145.

The effects of group housing on radiation-induced lethality were examined in male Swiss-Webster mice exposed to 9-12 Gy gamma photons. Isolated mice survived significantly longer (1.5 days) than animals housed in groups of 10, although there was no difference in the LD50s. Haloperidol, which antagonizes amphetamine-induced aggregate toxicity, failed to attenuate radiation-induced lethality. The radiation-induced aggregate toxicity effect was maintained in grouped animals regardless of cage size (39 vs 98 sq cm/mouse) or age (3-9 months). Pre-radiation (isolated, grouped) and post-radiation housing conditions (isolated, grouped & returned to same group [stable], or grouped & introduced to new group [unstable]), were examined. Animals grouped pre-radiation (10.5 Gy) survived longer than mice isolated pre-radiation. Mice housed in stable groups post-radiation survived longer than those in unstable groups. Oral administration of the antibiotic, Pefloxacin, increased survival time in both isolated and grouped (unstable) animals. Isolated mice in both control and antibiotic conditions survived longer than grouped animals. It was concluded that the radiation-induced aggregate toxicity effect may be mediated by the transmission of pathogenic organisms and/or the stress associated with post-radiation grouping.

111.1

DEVELOPMENT OF THE HUMAN THALAMUS: GOLGI ANALYSIS OF PULVINAR NEURONS. N.Zečević and J.Mojsilović. Dept.Neurophysiology, Institute for biological research, University of Belgrade, 11 000 Belgrade, Yugoslavia.

Development of the human pulvinar was analysed on Golgi impregnated brains from 7 fetuses, 12 to 34 gestational weeks (gw). Brain tissue was obtained after legal abortions The posterior and lateral area of the thalamus was considered as the place where prospective pulvinar neurons could be found at early ages. Neurons were bipolar and branched bipolar at 12gw, while at 14gw first multipolar neurons appeared. At 16gw number of multipolar neurons increased and two subtypes could be observed: bush cells and sparsely branched multipolar cells. In later ages (34gw) both subtypes had either small (<20μm) or large (often 30-40μm)maximal diameter (Dmax) of the soma. Parameters measured: total dendritic length (TDL), area and Dmax of the soma, number of dendritic segments, average segmental length- increased several times in the period examined. The largest increase was observed from 24-34gw, when TDL increased 3 times. In conclusion, major pulvinar neuronal types are well differentiated by 24gw. Acceleration of maturation between 24 and 34 weeks coincides with development of pulvinar projections to peristratal cortex.

111.2

GOLGI STAINING METHOD REVEALS THAT LESIONS TO CHOLINERGIC BASAL FOREBRAIN NUCLEI IN NEWBORN MICE RESULT IN ABNORMAL DIFFERENTIATION OF NEOCORTICAL PYRAMIDAL CELLS. C.F. Hohmann, K. Kwiterovich*, M.L. Oster-Granite and J.T. Coyle. Depts. of Psychiatry, Physiology and Neuroscience, The Johns Hopkins School of Medicine., Baltimore, MD 21205.

We have previously reported abnormal cortical morphogenesis following lesions to the nucleus basalis magnocellularis (nBM) area in newborn mice. Such lesions resulted in a transient (>85% at PND4/5; 35% at PND14; 20% at PND30), ipsilateral depletion of cholinergic markers in neocortex paralleled by an apparent retardation of cortical cell differentiation, as revealed by Nissl stain. Most affected were the pyramidal neurons of layer V which undergo differentiation during the first postnatal week, the time of maximal cholinergic depletion in cortex. We are now using the Rapid Golgi method in an effort to define and quantify the abnormal morphogenesis of layer V pyramidal neurons ipsilateral to the nBM lesion.

BALB/CByJ pups received unilateral nBM lesions at the day of birth and were sacrificed on PND7 and PND14, respectively, and processed for Rapid Golgi staining. Hemispheres ipsi- and contralateral to the lesion were sectioned coronally on a vibratome, slide mounted separately and analyzed blindly using a Glaser/Van der Loos Image Combining Computer Microscope [ICCM]. Our results show that the average perikaryal size of layer V pyramidals is significantly reduced ipsilateral to the lesion. The size differential between ipsi- and contralateral cells is larger at PND7 than at PND14, confirming previous impressions that the severity of morphological disturbances attenuates with age and recovery of cholinergic innervation. However, ipsilateral PND14 pyramidal neurons continue to display qualitatively and quantitatively abnormal dendritic morphology, including increased apical dendritic branching, paucity of spines and other morphological features otherwise found in more immature or genetically abnormal mice. Abnormalities of cellular morphology, similar to those reported here, have also been observed in autopsy samples from Down Syndrome and other mental retardation syndromes.

111.3

EXTRATHALAMIC AFFERENT INNERVATION OF THE CEREBRAL CORTEX IN THE NEONATAL RAT. H.C. Fibiger and K. Semba. Div. of Neurological Sciences, Dept. of Psychiatry, Univ. of British Columbia, Vancouver, B.C., Canada V6T 1W5

In addition to thalamocortical projections, the cerebral cortex receives inputs from a variety of subcortical structures including the basal forebrain, hypothalamus, and brainstem. There is some evidence that during development these cortical afferent fibers grow into the cortex at different times. Furthermore, some afferents appear to "wait" in the subplate, while others do not. However, currently available data on cortical ingrowth are limited to selective populations of afferents. In the present study, we investigated the status of cortical innervation by individual extrathalamic afferents in the neonatal (postnatal day 1) rat using retrograde transport of WGA-HRP. Three representative cortical regions were selected for detailed studies: the primary somatosensory (vibrissal region), visual, and medial prefrontal cortices.

Following WGA-HRP applications to the somatosensory or the visual area, retrogradely labelled neurons were seen in the respective specific thalamic nuclei, as well as in topographically appropriate regions of the magnocellular basal forebrain, and the locus ceruleus. However, no or very few cells were labelled in the raphe nuclei or hypothalamus, both of which are closer to the cortex than is the locus ceruleus. These results indicate that not all extrathalamic afferent fibers have grown into all cortical regions in the neonatal rat, and that the differential timetable cannot simply be explained by different times of origin of the afferent source neurons as previously shown in our laboratory, or their distances from the cortex.

FATE MAP OF FUTURE ENTORHINAL AND PERIRHINAL CORTEX IN THE EMBRYONIC MOUSE. C.D. Claypool*, B.W. Coltman*, C.F. Ide. Biology Department, Tulane University, New Orleans, LA 70118.

Our long term goal in this project is the prenatal removal of cortical afferents which might influence the development of target cells found in the hippocampus and dentate gyrus. Our first experiment involved determining the location of the entorhinal primordium in the embryonic day 15.16 (E15.16) cortex. Using exo utero surgical methods, we placed small DiI crystals in different cortical regions of the E15.16 embryo. At post-natal day 1 (P1), brains were fixed in 4% paraformaldehyde, cut via vibratome into 200 um sections, and examined with fluorescent microscopy (n=10). The entorhinal cortex was mapped to the far postero-lateral region of the E15.16 cortex. Clear projections to the hippocampus and the alveus were present by P1, as well as evidence of communication with the dentate gyrus. The perirhinal cortex was mapped to the region just anterior to the entorhinal region. Fibers from this region were shown to project into the alveus and through the anterior commissure. Axons from cells in the olfactory bulb were also stained and present in the perirhinal region. We are now removing these regions in E15.16 embryos to determine trophic effects cortical afferents have on development of target areas. Supported by NIH 1 F33 NS08594-01.

111.5

MORPHOLOGICAL IDENTIFICATION OF TACHYKININ-CONTAINING NEURONS IN THE DEVELOPING NEOCORTEX OF THE CAT. M.K. Boylan*, and R.S. Fisher. (SPON: C.L. Wakefield). MRRC and Dept. of Anatomy and Cell Biology, UCLA, Los Angeles, CA 90024.

Tachykinins (Tks, including substance P, substance K and neuromedin K) are produced by neocortical (Cx) neurons during fetal development in the cat and are frequent postnatally. Morphological identification of Tk-producing neurons has not yet been performed. In order to demonstrate the cellular origin of Tks in the developing Cx, immunohistochemistry was combined with a single slice Golgi/gold-toning procedure in the Cx of fetal (F56) and postnatal (P1, P30 and P90) cats. Golgi/gold-toning revealed the somatodendritic morphology of Tk-positive neurons; axons were not apparent. At F56 and birth (P1), immature pyramidal-like and nonpyramidal neurons contained Tk immunoreactivity. In the P30 and P90 Cx, spiny and sparsely spiny nonpyramidal (stellate) neurons were double labeled. These were present in layers III-VI. Pyramidal neurons were occasionally double labeled and were distributed in layers II-III and V-VI. These developmental results are in contrast to previous reports of Tks in the adult Cx indicating that Tk-producing neurons were strictly nonpyramidal and sparsely spiny or aspiny. The results of the present study suggest that pyramidal neurons transiently express Tk immunoreactivity during development. Also, spiny nonpyramidal cells are prevalent postnatally but may represent neurons that subsequently lose dendritic spines. Supported by USPHS Grants NS 24596 and HD 05958.

111.6

DEVELOPMENT OF A CHEMICALLY DEFINED MEDIUM FOR ORGANOTYPIC TISSUE SLICE CULTURES. J. Edmond*, C.M. Annis, R.T. Robertson and J. Yu. Department of Biochemistry, Mental Retardation Research Center, University of California, Los Angeles, CA 90024, and Departments of Anatomy and Neurobiology and Physical Medicine and Rehabilition, University of California, Irvine, CA 92717.

The organotypic tissue slice culture technique (Gahwiler, *TINS*, 1988) provide an excellent system for the analysis of axonal connectivity and neural development. However, the study of molecular mechanisms of axonal and neural development necessitates the use of a chemically defined culture medium. We report here the development of a medium, EOL 1 defined medium, which meets these needs. The medium is based on a deficient DMEM/ Ham's F-12, which is supplemented with several stable and unstable additives necessary for proper neural function and metabolism. Several of the more important medium additives are creatine, fumarate and D(-)-hydroxybutyric acid. Organotypic slice cultures from several brain regions, including cerebral cortex, hippocampus and basal forebrain, grow well in this defined medium and can be maintained for periods of time in excess of four weeks. Studies of normal morphology along with histochemical and immunocytochemical characterization of these cultures demonstrate that this defined medium allows for a high degree of cytoarchitectural maintenance while preserving many normal neurotransmitter and neuropeptide distributions.

112.1

A PARTIALLY PURIFIED MUSCLE FACTOR(S) INDUCES TYROSINE HYDROXYLASE EXPRESSION IN CULTURED NEURONS FROM VARIOUS BRAIN REGIONS IN RAT.

L. Iacovitti and L. Lyandvert, Div. Neurobiology, Cornell Univ. Med. Coll., NY, NY 10021

We have previously demonstrated that a soluble muscle-derived factor(s) (MDF) induces novel expression of the catecholamine (CA) enzyme tyrosine hydroxylase (TH) in cultures of embryonic rat cerebral cortex and greatly amplifies CA traits in cultures of CA neurons from substantia nigra. In this study, we examined whether MDF similarly affects 1) other brain neurons, 2) peripheral neurons and 3) neurons of differing age. Brain cells from striatum, cerebellum, collicular plate, and spinal cord of embryonic day (E) 14-17 rats and peripheral neurons from dorsal root (E14 DRG) and superior cervical (E21 SCG) ganglia were dissociated and maintained in culture either on control media or media supplemented with partially purified MDF. As in cortex, control cultures of other non-CA brain neurons contained a low percentage of TH neurons which was dramatically increased by addition of MDF. Induction was greatest in striatal cultures (Control: 431 $\pm$ 78 vs. MDF: 22,542 $\pm$ 769 TH neurons) with up to 40% of total neurons expressing TH. Although striatal neurons were MDF-responsive at all ages tested, cerebellar and collicular neurons could not be induced after E17. In ^{3}H-thymidine labeling studies, in all regions, only postmitotic neurons expressed TH. In contrast to brain neurons, peripheral neurons were not induced by MDF; DRG cultures did not contain more TH neurons nor did MDF increase TH activity levels in SCG cultures. We conclude that MDF promotes TH expression in certain classes of brain but not peripheral neurons. These studies suggest that the transmitter phenotype of neurons throughout brain is highly plastic during the critical time just following withdrawal from the cell cycle.

112.2

DIFFERENTIAL EFFECTS BETWEEN SERUM AND MUSCLE EXTRACT ON MOTONEURON SURVIVAL AND NEURITE EXTENSION.

B.H.J. Juurlink*, D.G. Munoz and R.M. Devon* (SPON: J.R. Doucette). Departments of Anatomy, Pathology and Oral Biology, University of Saskatchewan, Saskatoon, Canada, S7N 0W0.

Motoneurons were isolated according to the procedure of Dohrmann et al., 1986 [Develop. Biol. 118: 209-21] and grown on polyornithine coated glass coverslips [~60 cells/mm^2] in a medium consisting of DMEM/F12 containing the N1 supplements minus putrescine [CDM]. Horse serum [5% v/v] and/or muscle extract [50µg/ml] were added to the CDM for various experiments. The muscle extracts were prepared from E8, E11, E18 and P3 chick legs.

When grown in CDM alone no neurons survived longer than two days. The addition of only serum to CDM allowed the survival of 12% of neurons at 4 days and 4% at 8 days; however, neurite formation did not occur. Addition of muscle extract alone to CDM also allowed a similar number of neurons to survive but in addition promoted neurite formation. Neurons surviving longer than 4 days exhibited extensively developed neurites. The combination of adding both muscle extract and serum to CDM resulted in the survival of a much larger fraction of neurons [30% at 4 days and 18% at 8 days]. Furthermore, all neurons that survived 4 days or longer had very extensively developed neurites. There were no differences amongst the various muscle extracts tested in their ability to allow the survival of motoneurons and no marked differences in their ability to promote neurite formation. (Supported by the ALS of Canada)

112.3

THE FATE OF FGF IN THE OPTIC TRACT.

I.A. Ferguson, J.B. Schweitzer, and E.M. Johnson, Jr. Dept. of Pharmacology, Washington University, St. Louis, MO 63110 and Dept. of Pathology, University of Tennesse, Memphis TN 38163

^{125}I-FGF was injected intraocularly into adult rats and found to be internalized and anterogradely transported from the eye, through the optic nerve, to the contralateral lateral geniculate body and contralateral superior colliculus. ^{125}I-FGF was not retrogradely transported from superior colliculus to retina. Anterograde transport was blocked by excess unlabelled FGF and dependent on intact tertiary structure: Denatured, biologically inactive FGF was not transported. ^{125}I-NGF was not transported. Transport was not heparinase sensitive but was blocked by wheat germ agglutinin, arguing that high-affinity FGF receptors mediate transport. Time course studies showed the fastest transport rate of ^{125}I-FGF to be 3 mm/hour. In pulse label studies, radioactivity was lost from the superior colliculus with a half-life of 22 hours. Autoradiography of brain sections demonstrated that radioactivity was confined to retinal ganglion cell projections suggesting that it was not released from axons. Autoradiograms of optic tract tissues separated on SDS PAGE showed that ocular FGF is proteolytically degraded primarily after being exported from the eye.

Supported by NINDS grants: NS 25122 and NS 01230.

112.4

GINSENG SAPONINS : INFLUENCE ON GROWTH CONE OF FETAL MOUSE SPINAL CORD IN VITRO.

X.Y. Shen, S.M. Kuo*, S.C. Chang* and Z.L. Hao*, Dept. of Anatomy, Shanghai Medical University, Shanghai 200032, People's Republic of China.

Ginseng, the roots of Panax ginseng C.A. Meyer, has been used in traditional Chinese medicine for thousands of years. Much evidence has suggested that ginseng saponins may play a role in the regulation of neurotransmission. The authentic sample of ginsenosides is derived from Shanghai Institute of Pharmaceutical Industry. Primary organotypical cultures of 17 D fetal mouse spinal cord were done as usual (Shen,1985,1988). Each experiment was performed with five groups, one of which was a control group while the others contained 25, 50, 100 and 200 µg in 1 ml of the regular medium. The proliferative effect of neurites was consecutively observed at 2, 3 and 4 days in vitro under phase-contrast microscopy and some ultrastructural studies were also used. The criteria used for the evaluation of this activity is based on the neurite length as well as the total number of neurites produced by the explant. We found that the growth cones in 50-100µg/ml added groups were obviously enhanced when compared with other groups. The results suggest that ginsenoside of ginseng root has a promoting effect on neurite extension.

112.5

TROPHIC EFFECT OF OLFACTORY PROTEINS DEPENDS ON DNA SYNTHESIS.

M.P. Lambert, S.Hua*, and W.L. Klein. Dept. of Neurobiology and Physiology, Northwestern University, Evanston, IL 60208.

Previous work has shown that rat basal forebrain cultures respond to soluble olfactory proteins with increased survival and differentiation. Confirming this trophic effect using the MTT assay, we found that cells grown with olfactory bulb extract(OLBX) showed 100% survival for at least 48 hrs. By contrast, cells in control cultures showed 50% mortality after 6 hrs. In testing possible mechanisms for the response, we found that OLBX promoted DNA synthesis, with an initial (first 23 hr) 3H-thymidine incorporation rate that was double control values. Fetal calf serum(FCS) also promoted thymidine uptake but, as the effect was additive with that of OLBX, it appeared to act on different cells . To ascertain if DNA synthesis was necessary for the trophic effect of OLBX, aphidicolin was used to inhibit DNA polymerase I. During the first 1-5 culture days, aphidicolin not only inhibited thymidine uptake but completely inhibited the ability of OLBX to promote survival. In contrast, addition of aphidicolin after 7 or 9 culture days caused little morphological change in cultures, although it halted thymidine incorporation. These data support the hypothesis that olfactory bulb proteins increase survival of cultured neural cells by maintaining mitosis through a critical window of development. (Supported by NIH grant NS23348 to WLK)

112.6

THE DEVELOPMENT OF MESENCEPHALIC DOPAMINERGIC NEURONS *IN VITRO* IS AFFECTED BY NEUROTROPHIC ACTIVITIES DERIVED FROM NEURAL CELL LINES.

J. Engele, D. Schubert#, and M.C.Bohn. (Spon: D.L. Barker). Dept. of Neurobiology and Anatomy, University of Rochester, Rochester, NY. and #The Salk Institute, San Diego, CA.

Neurotrophic factors play a crucial role in neuronal differentiation and regeneration. To identify growth factors which affect the development of dopaminergic neurons, conditioned media (CM) were prepared as possible sources of neurotrophic activities from various cell lines, including a neuronal cell line B103, glial lines B49 and C6, PC12 pheochromocytoma and a microglia-like line R33 derived from a nickel sulphate induced eye tumor. CM were assayed for effects on high-affinity dopamine uptake and survival of dopaminergic neurons grown in low density cultures (80,000 cells/cm^2) of dissociated embryonic day 14.5 rat mesencephalon. In both the absence and presence of 0.5% horse serum, B49- and JScl1-CM produced a dose-dependent increase of ~250% in the number of tyrosine hydroxylase-immunoreactive (TH-IR) neurons after 8 days in vitro. In cultures treated with CM from the other cell lines, smaller, but significant, increases were observed. Moreover, the R33- and PC12-CM, but not the other media, also elicited a significant increase in (^{3}H) dopamine uptake per TH-IR neuron. These differential effects suggest the presence of at least two neurotrophic activities capable of influencing the maturation of central dopaminergic neurons.

112.7

SOLUBILIZATION OF A SPINAL CORD MEMBRANE MOLECULE THAT STIMULATES TYROSINE HYDROXYLASE ACTIVITY IN CULTURED SYMPATHETIC NEURONS. V. Wong & J.A. Kessler, Depts. Neurology & Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461.

Neuronal contact with other cell membranes and with extracellular matrix (ECM) plays an important role in regulating neuronal growth and development. Effects of cell contact on neurotransmitter expression (e.g. substance P, acetylcholine, catecholamine) have been demonstrated in various cell types including sympathetic, spinal cord, striatal neurons, and PC12 and chromaffin cells. We found that treatment of cultured sympathetic neurons with membranes prepared from adult rat spinal cord stimulated levels of tyrosine hydroxylase (TH) enzymes activity and TH mRNA. The TH-stimulating molecule(s) is differed from the previously characterized cholinergic stimulating molecule (MANS; Wong & Kessler, PNAS 84:8726, 1987), also isolated from spinal cord membranes, in that it could not be extracted from membranes by high salt treatment. Solubilization of spinal cord membranes required 0.1% Triton X-100, a non-ionic detergent, suggesting that the TH-stimulating molecule(s) contains an integral membrane moiety. When cultured sympathetic neurons were treated with the Triton extract, TH activity was stimulated 2-fold, while choline acetyltransferase (CAT) activity was unaltered. The remaining membrane pellet also stimulated TH levels, suggesting incomplete solubilization by Triton. Further studies are underway to identify a more effective detergent for solubilizing spinal cord membranes, and to characterize this TH-stimulating molecule.

112.8

SAFETY OF INTRATHECAL (i.t.) INSULIN IN RABBITS. C.K. Haun, G. Goubran*, W.K. Engel & I. Tan*. Depts. of Anatomy & Cell Biology and Neurology, University of Southern California School of Medicine, Los Angeles, CA 90033.

In pre-clinical safety-testing prior to its direct i.t. application to the abnormal human CNS, insulin was infused continuously into the lumbosacral CSF space, permitting high concentrations of insulin to bathe the CNS. Doses of up to 6 U/kg body wt./day were well tolerated for up to 4 wks. In 29 male NZ White rabbits (3-3.5 kg) under general anesthesia, a PE-10 catheter was inserted into the sub-arachnoid space at vertebrae L7-S1; its tip lying at the S2-3 vertebral level. The catheter was connected to an Alzet 2ML2 minipump (5ul/hr.) via a PE-60 extender. The pump was implanted in a s.c. pocket, and changed every 2 wks. It contained crystalline porcine or human-recombinant insulin, up to 122.5 U/ml in artificial CSF, with glutamic acid, 5-7 mg/ml, to prevent insulin aggregation. The animals survived well, exhibited normal behavior, and gained weight, providing they ate normally; their blood glucose did not change significantly from pre-operative levels (90-170 mg/dl). Rabbits that failed to eat suffered hypoglycemic convulsions and died despite post factum i.v. or s.c. glucose injections. (Doses of 10, 25 or 50 U/kg produced lethal hypoglycemia despite eating.) This study predicts CNS safety of dose-controlled i.t.-administered insulin in patients, but indicates the need to maintain blood glucose adequate to prevent hypoglycemia.

112.9

ENKEPHALIN IMMUNOREACTIVITY IN ORGANOTYPIC CULTURES OF DEVELOPING RAT CEREBELLUM: EVIDENCE FOR TRANSIENT OPIOID EXPRESSION IN VITRO. J.G. Osborne* and K.F. Hauser (SPON: L. Yurkewicz). Dept. of Anat. and Neurobiol., Univ. of Kentucky Sch. of Med., Lexington, KY 40536-0084.

Enkephalins are reported to transiently appear within the neuronal progenitor cells of the cerebellar external granule layer (EGL), and are hypothesized to modulate EGL cell growth *in vivo* (Zagon et al., *Science*, 227: 1049, 1985). Enkephalin immunoreactivity (IR) was examined within cerebellar explant cultures to better understand the mechanisms governing opioid expression during development. Cerebella from male, neonatal Sprague-Dawley rats were isolated from the brainstem, dissected into 8 explants per cerebellum, and maintained *in vitro* for 1, 4, 7, 14, or 28 days as organotypic explants in 22 mm wells or in Maximow chambers. The distribution of enkephalin IR (antisera from Dr. B.E. Maley) was explored in 4% paraformaldehyde fixed, whole-mount explants. Controls, using antisera preabsorbed against both met- and leu-enkephalin, lacked staining. Based on morphology and distribution within the explant, enkephalin IR was present in Golgi cells and smaller immature EGL cells. With progressive development, detectable enkephalin IR was not seen in mature granule, stellate or basket neurons, which are derived from EGL progenitors, indicating that enkephalin IR present in EGL cells is lost during maturation. However, some EGL cells were not enkephalin immunoreactive, suggesting that other local factors also affect enkephalin IR in EGL cells. The loss of enkephalin IR by neurons derived from the EGL suggests that enkephalin expression by EGL cells is developmentally regulated, and that the decline in expression is normally mediated by local mechanisms present within the maturing cerebellum. Supported by NIH RR05374, and PSP and UKMC Res. Funds (Univ. of KY).

112.10

OPIOIDS DIRECTLY MODULATE THE GROWTH OF MIXED-GLIAL CULTURES: SUPPRESSION OF ASTROCYTE PROLIFERATION BY MET-ENKEPHALIN. A. Stiene-Martin* and K.F. Hauser, Dept. of Anat. and Neurobiol., Univ. of Kentucky Sch. of Med., Lexington, KY 40536-0084.

Opioid peptides have been reported to inhibit the proliferation and differentiation of neural cells. This study examined the action of methionine-enkephalin (ME) on the growth of astrocytes in mixed-glial cultures. Primary cultures of mixed-glial cells were isolated from the cerebral hemispheres of 1-day-old mice. After 24 h *in vitro*, at least 6 wells/group were continuously treated with basal growth media alone (controls), ME (1 μM), ME (1 μM) plus naloxone (3 μM), or naloxone (3 μM) alone. Cultures were examined at regular intervals, and counts were made of absolute numbers of cells in unstained preparations. To determine whether ME selectively influences astrocyte DNA synthesis, mixed-glial cultures were treated with 0.24 μCi [^{3}H]-thymidine for 16 h. Combined [^{3}H]-thymidine autoradiography and GFAP immunocytochemistry were performed. When compared to controls and naloxone-treated groups, ME caused a statistically significant decrease in both total cell numbers and in the mitotic index of type I astrocytes (GFAP+ flat cells) after 4 days *in vitro*. However, type II astrocytes (GFAP+ process-bearing cells) were not affected. The data indicate that ME selectively suppresses the growth of a morphologically distinct subpopulation of astrocytes in mixed-glial cultures, and that the action of ME is opioid receptor specific-since its action was reversed by naloxone and naloxone alone had no affect. This supports the general hypothesis that opioids influence brain maturation by modulating neural cell proliferation, and suggests for the first time that glia may be a direct target for opioid action during neural development.

Supported by NIH RR05374, and PSP and UKMC Research Funds from the Univ. of Kentucky.

112.11

ANALYSIS OF PREPROENKEPHALIN mRNA EXPRESSION IN THE DEVELOPING RAT CEREBELLUM BY *IN SITU* HYBRIDIZATION. K.F. Hauser, J.G. Osborne*, S.L. Sanders*, T.E. Curry*, and M.H. Melner*[1] (SPON: A.G. Gona). Depts. of Anat. and Neurobiol., and of Ob./Gyn., Univ. of Kentucky Sch. of Med., Lexington, KY 40536 and [1]Oregon Reg. Primate Res. Ctr., Beaverton, OR 97006.

Enkephalin immunoreactivity (IR) is reported to be transiently present within germinative cells of the developing rat cerebellar external granular layer (EGL), and is hypothesized to modulate EGL cell proliferation (Zagon et al., *Science*, 227: 1049, 1985). To determine whether preproenkephalin mRNA expression is responsible for the transient appearance of enkephalin IR, as well as to identify the possible cellular sites of opioid gene expression in the developing cerebellum, preproenkephalin mRNA expression was examined by *in situ* hybridization in the developing cerebellum. Adult and postnatal day 1, 3, 6, 11, 12, 16, 21, 28 and 35 male Sprague-Dawley rats were anesthetized and sacrificed by intracardiac perfusion with 4% paraformaldehyde in phosphate buffer. Frozen sections were hybridized with an [^{35}S]-labeled cRNA probe specific for preproenkephalin mRNA. Preproenkephalin mRNA was not detected in cerebellar cortical neurons from postnatal days 1-6; although, occasional heavily-labeled cells were observed in the choroid plexus of the IVth ventricle, in the pia after day 3, and in nuclei in the brainstem. On day 11, Golgi cells were moderately labeled and this pattern remained consistent in older rats and adults. However, under the present hybridization conditions, preproenkephalin mRNA was not detected in the germinative cells of the EGL. Thus, the transient appearance of enkephalin IR in EGL cells appears to be unrelated to increased levels of preproenkephalin mRNA expression by these cells. Supported by NIH BRSG RR05374, and PSP and UKMC Research Funds (Univ. of KY).

112.12

LAMININ EXPRESSION IN DEVELOPMENTAL RAT BRAIN: A QUANTITATIVE IN SITU HYBRYDIZATION STUDY USING IMAGE ANALYZER. C. T. Cheng, F. C. Zhou, and C. H. Lee Depts. Anatomy and Pathology, Indiana Univ. Sch. Med. Indianapolis, IN46223

Laminin promotes neurite outgrowth of cultured neurons (Davis et al., TINS 8:528, 1985) and guides fiber growth of grafted neurons in the rat brain (Zhou and Azmitia, J. Chem. Neuroanat. 1:133, 1988). Recently, we have studied the distribution of the laminin mRNA in the rat brain at different developmental stages by in situ hybridization (Cheng et al., Abst. Soc. Neurosci. 14, 73, 1988). Currently, we performe a quantitative study of the laminin mRNA in rat brains by computerized autoradiographic image analyzer.

Brains from Sprague-Dawley rats of 18 days embryo (E18), postnatal day 7 and 29 (P7 and P29) were used for the study of the distribution of laminin mRNA by in situ hybridization. A 50-base oligonucleotide which hybridizes to the B2 chain of laminin mRNA was labeled with alpha-^{35}S (or ^{32}P)-dATP at 3' end and used to detect laminin mRNA. The density of radioreactive silver granules were analyzed by image analyzer and showed quantitative changes in cells of various brain regions during different stages of development .

At the same stage (P7) of development, a regional difference in the density of silver granules was observed: meningeal cells> cortical neurons> cerebellum/purkinje cells > CA3/pyramidal cells. As compared with ages, the densities of silver granules in the meningeal cells are low in E18 and reached their highest level at P7 and P29, whereas the densities of silver granules in the cortical neurons were increased from E18 to P7 and decreased by P29. These results indicate that the laminin expression in different rat brain areas have changed quantitatively during the development, which is in consistent with our previous immunocytochemistry study. Sponsored by NIH grant 23027.

112.13

INTRANEURONAL LAMININ(LM)-LIKE IMMUNOREACTIVITY IN HUMAN CENTRAL NERVOUS SYSTEM. H.Suzuki*, T. Yamamoto#*, H. Konno*, Y. Iwasaki*, Y. Ohara*, H. Yamamoto**, (SPON: K. Kurata##). *Dept. Neurological Sciences, ##Dept. Physiology, Tohoku Univ. Sch. of Med., Sendai, 980 Japan. #Dept. Neurology, Fukushima Medical College, Fukushima, Japan. **Dept. Cell Biology & Anatomy, North Western Univ. Sch. of Med., Chicago, IL.

Several recent studies have revealed the existence of laminin-like immunoreactivity(LLI) and their mRNA signals in CNS neurons of the rodent(T. Yamamoto, J. Neurol. Sci., 1988;84:1, T. Manthorpe, Abstr. ,18th Annual Meeting, S.N., 1988;149.13, C.T. Hu, Abstr.,18th Annual Meeting, S.N., 1988;149.14). We Report here the presence of intraneuronal LLI in the human brain and their distributions. Laminin affinity column-purified rabbit antibodies raised against human placental LM were applied to the sections from the formalin-fixed human brains. In addition to the expected staining of basal lamina of the capillaries and pia matter, distinct LLI was observed in neurons of the hippocampal pyramidal and dentate granular layers, amygdala, septal nuclei, basal forebrain, striatum, neocortical layers(I-III and VI), anterior and dorsomedial nuclei of the thalamus, and supraoptic nucleus. A small number of the neurons in the ventrolateral and reticular nuclei of the thalamus were also immunoreactive. The cortical layers(IV and V), cerebellum, red nucleus, subthalmic nucleus, pallidum, and motor neurons in the brainstem and spinal cord were devoid of immunoreactions. The distributions are in essence similar to those in rodents. Although the signigicance of LLI in neurons remains to be clarified, the differential distribution of the LLI suggests the neuronal system-specific roles imposed on the intraneuronal laminin-like molecule(s).

112.14

DOES THE DISTRIBUTION OF GANGLIOSIDES IN NEURONAL MEMBRANES DEPEND ON UNDERLYING CYTOSKELETAL COMPONENTS? I.H. Fentie*, S.P. Mahadik[1] and F.J. Roisen (SPON: C. Shields). Dept. of Anat. Sci. & Neurobiol., Univ. of Louisville, Sch. of Med., Louisville, KY 40292 and [1]NY State Psychiatric Inst. NY, NY 10032.

Compelling evidence has been accumulating which suggests that gangliosides play a regulatory role in both in vitro and in vivo neuronal development. Recently, we employed immunocytochemistry to examine the topographical distribution of the ganglioside GM1 on murine Neuro-2a cells using high resolution SEM and STEM. Frequently, the colloidal gold markers were seen distinctly aligned along the perikaryal and neuritic surfaces. This linearity implied that endogenous molecules of GM1 were bound to an underlying cytoskeletal component. To examine this possibility and to determine the nature of the underlying cytoskeletal anchorages, we applied cytoskeletal disruptive and stabilizing agents to Neuro-2a cells prior to immunolocalization of GM1 with mAb to GM1 labeled with colloidal gold. Preliminary studies suggest that conditions which limit microfilament formation (cytochalasin D) seem to reduce the linear arrays on the perikaryal surfaces. The relationship of these alignments to microtubules is being probed with colchicine and taxol. Attachment of surface molecules to underlying cytoskeletal anchorages could provide a means of regulating membrane fluidity and receptor efficacy. USPHS grant NS24524.

112.15

MORPHOLOGICAL EFFECTS OF EXOGENOUS GM1 GANGLIOSIDE ADMINISTRATION IN INTACT ANIMALS. L. Lescaudron* and D.G. Stein. Brain Research Laboratory, Rutgers Univ., Newark, NJ 07102.

We previously demonstrated that chronic GM1 ganglioside injections (17 days) do not affect the behavior of intact (sham-operated) rats studied on open-field, Morris water-maze and passive avoidance tasks (Bitran et al.,Soc.Neurosci.Abstr.,494.6, 1988). However, a significant decrease in ventricle size (-35%) and number of Ach-E-positive neurons (-11%) in the nucleus basalis magnocellularis (NBM) was observed in GM1 as compared to saline-injected animals. This suggests that GM1 gangliosides may have a toxic effect on cholinergic neurons. To examine this, we counted Ach-E- positive neurons in the lateral (LS) and medial (MS) septal nuclei in the same animals. No difference in the number of Ach-E positive neurons was observed in LS and MS between the two groups of animals. Next, in the NBM, we observed decreases in cell body size of Ach-E stained neurons ($p<0.007$). There was also a reduction in the number of Ach-E-positive neural processes (probably dendrites)($p<0.02$). However, on Nissl-stained sections, no difference was observed in cell packing density and in size of the cells within the NBM. Taken together, these data suggest that GM1 ganglioside injections reduce the number and/or activity of the Ach-E in some neurons within the NBM. A densitometric analysis performed in the frontal (FC) and fronto-parietal cortex (FPC) and the hippocampus (HP) showed a reduction of Ach-E staining by -7.7% in the FC and -15% in the FPC and no difference in the HP (relative to white matter) in GM1 treated rats as compared to saline controls. In conclusion, chronic injection of GM1 gangliosides produces a decrease in Ach-E labeling both in the NBM and cerebral cortex suggesting a modification of the cholinergic function in these structures.

GM 1 MODIFIES ADRENAL CHROMAFFIN CELLS "IN VITRO". G.Perez*,A.Posse*,V.Lauria* and J.A.Colombo. (SPON:E. Adler-Graschinsky). Unidad de Neurobiologia Aplicada (CEMIC-CONICET), Buenos Aires. Argentina.

The possibility of modifying viability rates and growth of neural cells prior to transplantation may represent a valuable tool for the improvement of their efficiency in attempting neural cell transfer.Among other trophic factors gangliosides affect neural growth. Under "in vitro" conditions we tested the effects of ganglioside GM1 (FIDIA) on cell morphology and adhesivity to a polylysine substrate. Adrenalchromaffin cells were enzymatically and mechanically dissociated from immature (PN 10) or adult rats, and seeded on polylysine-coated coverslips or 35 mm plastic dishes in DMEM-F 12. Incubation was carried out at 37°C and a mixture of 95% air/CO2. Twenty four hours after seeding, GM1 was added to each dish, in triplicates, to a final concentration of 10 -3, -5 and -7 M. Cell changes were registered daily. Addition of GM1 10 -3 to either immature or adult chromaffin cells resulted in a dramatic increase in cell size within 24 hs. after initiation of treatment, with a concomitant decrease in cell numbers adherent to substrate. Such changes were not apparent at 10 -7 M. Interaction between GM1 and NGF will be reported.-

This work was performed under grant support from the National Research Council of ARgentina (CONICET).

GM1 GANGLIOSIDE-INDUCED RECOVERY OF STRIATAL DOPAMINE LEVELS IN MPTP-TREATED ANIMALS IS INFLUENCED BY AGE AND EXTENT OF INITIAL INJURY. J.S. Schneider and C.F. Gross*. Dept. of Neurology, Hahnemann Univ. School of Medicine, Philadelphia, PA. 19102.

The present studies were performed to examine the effects of 2 variables-age and extent of injury-on the ability of GM1 ganglioside to stimulate recovery of striatal dopamine (DPM) levels following MPTP-induced damage to the DPM system. The effects of age were examined in C57 Bl mice. Mice aged 8 wks. to 12 months were given MPTP (18-30 mg/kg s.c., 2 times daily for 5 days). Some mice were then given 4 or 8 wks. of GM1 (30 mg/kg/day i.p.). Mice older than 6 mos. did not show any significant increase in striatal DPM levels with GM1 treatment in contrast to highly significant increases observed in 8-10 wk. old mice. Tyrosine hydroxylase immunohistochemistry suggested that older mice exposed to MPTP might have had more extensive substantia nigra cell loss than did younger mice. We have also observed that cats exposed to relatively low amounts of MPTP (and with mild to moderate motor deficits) have a larger magnitude increase in striatal DPM levels after GM1 treatment than cats given larger MPTP doses (and with initially severe motor deficits and extensive DPM depletions). These results suggest that increased age and extensive nigral cell loss are factors which decrease the restorative effects of GM1 ganglioside on striatal DPM levels in this model. POSSIBLE ROLE OF A PUTATIVE RPE-CELL TROPHIC FACTOR(S) IN PHOTORECEPTOR CELL RESCUE IN RCS DYSTROPHIC RATS. H.J. Sheedlo, L. Li and J.E. Turner. Department of Anatomy, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, NC 27103.

Normal retinal pigment epithelial (RPE) cell transplants have been shown to prevent photoreceptor cell (PRC) degeneration in retinas of 26 day-old Royal College of Surgeons (RCS) dystrophic rats (Li and Turner, 1988). This study revealed PRC rescue in areas distant from the RPE-cell graft site and under membrane debris, suggesting effects by putative trophic factors. The following studies were undertaken to determine if RPE cells release factors which affect PRC survival in dystrophic retinas. In one study medium conditioned by RPE cells (RPE-CM) from Long Evans rat pups was injected into the subretinal space of 26 and 27 day-old RCS dystrophic rats. Examination of the injected retinas 10 and 15 days later revealed a outer nuclear layer (ONL) thickness significantly greater than in noninjected retinas. Also, no outer segments (OS) were observed in retinas of 36 day and older RCS dystrophic rats; however, areas beneath the RPE-CM injection site showed OS as well as longer inner segments (IS). To further support the existence of trophic factors, normal RPE cells were transplanted into the vitreous and choroid of 26 day-old RCS dystrophic rats. At 60 days in grafted retinas, the ONL thickness was significantly increased when compared to 60 day control retinas. Although the PRC rescue effects were not as dramatic as shown by subretinal RPE-cell transplantation, IS and OS were detected. It is possible that RPE cell factors are able to affect the ONL by passing through the inner retina and Bruch's membrane. Biochemical analyses of RPE-CM and other injection studies are currently being performed. Supported by NEI EY-04337.

THE POLYPEPTIDE THYMOPOIETIN INDUCES PROCESS FORMATION IN PC12 CELLS. R. Cohen*, S. Geertsen*, T. Audhya*, G. Goldstein*, and M. Quik (SPON: B. Esplin) Dept. Pharmacol., McGill Univ., Montreal, Canada & Immunobiol. Res. Inst., Annandale, NJ.

Thymopoietin (Tpo), a peptide isolated from thymus, induces thymocyte differentiation. Tpo also binds to the nicotinic α-bungarotoxin (α-BGT) receptor in electroplax and brain. The present work shows that Tpo interacts with the α-BGT site in PC12 cells; Tpo resulted in a dose dependent inhibition of binding (IC50 = 3 nM). The effect of Tpo was also determined on cellular morphology in PC12 cells in culture as evidence exists that the α-BGT site may have a role in growth functions. Addition of Tpo to the cells in culture resulted in an enhanced formation of processes (≥ 25 um in length), which was dose and time dependent. Tpo-induced process extension occurred as early as 1 day after exposure to the peptide and increased with continued time in culture; for instance, after 5 days exposure, an increase (2 fold) in process extension was observed with 1 nM Tpo, which was maximal (100 fold) with 100 nM Tpo. These effects were not observed with splenin, a peptide identical to Tpo except for 1 amino acid substitution. The effects of Tpo appeared distinct from those of NGF. Thus Tpo, a peptide which interacts at the α-BGT site, can induce process formation in PC12 cells. The relationship between these events remains to be determined.

PROPERTIES AND BIOLOGICAL ACTIVITY OF AN *APLYSIA* LECTIN. M.P. Wilson*, G.M. Carrow, and I.B. Levitan, Graduate Dept. of Biochem., Brandeis Univ., Waltham, MA 02254.

The plant lectin concanavalin A (Con A) has a variety of effects on *Aplysia* neurons, including enhancement of neurite outgrowth in primary cell culture (Lin and Levitan, Science, 237:648, 1987). It is possible that there are endogenous lectins in *Aplysia* with similar biological activities. The gonads from *Aplysia depilans* have been reported to contain a lectin (*Aplysia* gonad lectin, AGL) which has been purified and partially characterized (Gilboa-Garber et al, FEBS Letters, 181:267, 1985). We have purified a galactose-inhibitable AGL from *Aplysia californica* and found it to be a disulfide linked dimer with a native molecular weight of 75 KD. It is found exclusively in gonads and eggs and has N-terminal amino acid homology with the plant lectin phytohemagglutinin-E, another galactose-inhibitable lectin. In preliminary experiments, AGL appears to enhance neurite outgrowth from *Aplysia* neurons in primary culture. Using ligand blotting, we have found that ^{125}I-AGL binds to three low molecular weight proteins from nervous system membranes. These proteins, which comprise a subset of those to which ^{125}I-Con A binds, have been purified. The amino acid sequences of these putative AGL receptors may provide clues about the mechanism of action of AGL on *Aplysia* neurons.

DOPAMINE RELEASE IN THE FRONTOPARIETAL CORTEX: EFFECTS OF NIGRAL NEUROKININ STIMULATION. M.S.Reid* M.Herrera-Marschitz*, M.Goiny*, U.Ungerstedt* (SPON: R.A.Yokel) Dept. of Pharmacology, Karolinska Institute, Stockholm, Sweden.

Using an in vivo microdialysis technique, we have found that dopamine is detected in perfusates collected from the frontoparietal (sensorimotor) cortex and striatum of rats (dopamine: 0.7 ± 0.2 nM, n=10; 11 ± 2 nM, n=10, respectively). The cortical and striatal dopamine levels were strongly reduced (0.07 ± 0.06 nM, n=4; 0.7 ± 0.4 nM, n=4, respectively) following deafferentation induced by mesencephalic 6-hydroxydopamine injection (Herrera-Marschitz M. et al. Neuro. Lett., 97:266-270, 1989). Presently, we have found that dopamine release in the cortex and striatum could be stimulated by an injection of d-Amphetamine (2.0 mg/kg s.c.) (466 ± 174%, n=4; 1168 ± 161%, n=4, respectively). Furthermore, intranigral injections of substance P (0.07 nmol/0.2 µL) could also stimulate dopamine release in the cortex and striatum (106 ± 41%, n=4; 32 ± 13%, n=4, respectively).

INFRARED DIC-VIDEO MICROSCOPY OF LIVING BRAIN SLICES
H.U. Dodt*, H. Pawelzik* and W. Zieglgänsberger (Spon. R. Gerstberger). Clinical Neuropharmacology, Max-Planck-Institute of Psychiatry, Munich, FRG

To analyse complex neuronal networks such as in the neocortex, a correlation of neuroanatomical and neurophysiological data is necessary. In the present study we tried to visualize single neurons in an in vitro slice preparation. We exploited a nearly neglected property of the brain slices, namely their translucence. For this purpose a newly developed brainslice chamber with a coverslip bottom was mounted on an inverted microscope (Zeiss Axiovert) equipped with differential interference contrast (DIC) optics. The slice could thus be inspected from below. The image was projected on the target of a video camera and displayed on a TV monitor. The Hamamatsu videosystem used allows analog and digital contrast enhancement and background subtraction. As the DIC optics provide optical sectioning, cells in brain slices of 200-250 µm could be visualized to a depth of 50-100 µm if illuminated with light of λ>700 nm. The contrast enhancement provided by the video system proved to be crucial for visualization of unstained single cells in slices of this thickness. The method was applied to hippocampus and neocortex of the rat. Intracellular and field potentials elicited by orthodromic stimulation were recorded with standard electrodes to show the viability of the preparation.

In the neocortex pyramidal and nonpyramidal neurons could be differentiated. Dendritic bundling of assemblies of pyramidal cells was clearly visible with medium magnification (20X-40X objectives). The use of a high power objective (63X, N.A. 1.4) allowed the visualization of varicosities and of nuclear heterochromatin. With appropriate use of a micromanipulator a multibarrel electrode could be positioned close to neurons of interest.

In combination with extra- and intracellular recordings the optical technique described here should allow the investigation of functional connections between morphologically identified cell types in the neocortex.

INDUCTION OF LTP BY ACTIVATION OF CORTICOCORTICAL INPUTS TO THE MOTOR CORTEX: INTRACELLULAR RECORDINGS AND LABELING.
A. Keller, A. Iriki* and H. Asanuma.
The Rockefeller University, New York, NY 10021

In an attempt to identify cortical circuits related to motor learning and memory, motor cortical neurons in which LTP is induced were studied intracellularly. Twelve young adult cats were anesthetized with Nembutal, and several microelectrodes implanted in the somatosensory cortex (area 2) and the association cortex (areas 5a & 5b) for intracortical microstimulation. Intracellular recordings were obtained from neurons in the motor cortex using a glass pipette filled with 5% biocytin. Stable recordings of short-latency EPSPs in response to stimulation through one of the electrodes were obtained from 19 cells; 10 cells received short-latency input from area 5, and 9 from area 2. Tetanic stimulation (200Hz; 20s; 30µA) was then delivered through the responsible electrode, and amplitude of EPSPs to test stimulation before, and after tetanic stimulation were compared. Following tetanic stimulation, mean EPSP amplitudes were significantly increased in 17 cells. The cells were then labeled by intracellular injection of biocytin; most of the labeled cells were pyramidal neurons, whereas only 3 neurons were sparsely-spiny, nonpyramidal cells. All labeled cells were in layers II or III of the motor cortex. The results suggest that LTP can be induced in the motor cortex by activation of various CC pathways, and in both pyramidal and nonpyramidal cells. Supported by NIH #NS-10705 & F32NS08626

LTP IN CAT MOTOR CORTEX CAN BE INDUCED BY ACTIVATION OF THALAMOCORTICAL AFFERENTS ONLY WHEN COACTIVATED WITH CORTICOCORTICAL INPUTS.
A. Iriki*, C. Pavlides*, A. Keller and H. Asanuma.
The Rockefeller University, New York, NY 10021

We have previously shown that tetanic stimulation of the sensory cortex (SI) produces LTP in motor cortical neurons, whereas tetanization of the ventrolateral (VL) nucleus of the thalamus does not (Brain Res. 1987, 413:360). In the present study we investigated LTP in the cat motor cortex using intracellular recording techniques, under nembutal anesthesia. Motor cortical neurons in which short latency EPSPs were produced by stimulation of both SI and VL were first identified. Then, simultaneous tetanization was delivered to SI and VL. This procedure resulted in an increase in amplitudes of EPSPs produced by test VL stimulation. This associative LTP was produced only when the rise time of EPSPs evoked by stimulation of SI and VL was similar, suggesting that both afferents synapsed on motor cortical neurons in close proximity to each other. All of these neurons were located in layer III of the motor cortex. The results suggest that this associative LTP in the motor cortex constitutes a basis for the acquisition and retention of motor skills. Supported by NIH Grant NS 10705.

ORIGIN AND FUNCTION OF HORIZONTAL LAYER I AFFERENTS TO RAT SI NEOCORTEX.

Lawrence J. Cauller* and Barry W. Connors.
Section of Neurobiology, Brown University, Providence, RI 02912.

Horseradish peroxidase (HRP) applied topically to the pia of anesthetized rats penetrated layer I and was transported retrogradely to the posterior thalamus and 2 ipsilateral cortical areas: the frontal agranular motor area, and the second somatosensory area. Thus, principal targets of SI outputs are also the source of its layer I inputs. This resembles the laminar pattern of forward and backward projections in the sensory cortical systems of monkeys and cats (Pandya and Yeterian, 1985). Transport of the fluorescent tracer DiI from a site in layer I in fixed hemishpheres revealed, after 4 weeks, a dense plexus of layer I fibers radiating 2-4mm in all directions.

A vertical cut was made through slices *in vitro*, sparing a bridge containing only the horizontal pathway in layer I (HLI). HRP injected into layer I on one side of the bridge showed that the HLI pathway does not originate from the collaterals of local neurons. Stimulation of layer I on one side evoked an early current sink restricted to layer I on the other side, at distances > 1mm horizontally. These HLI-evoked responses were reversibly blocked by the glutaminergic antagonist kynurenic acid (2mM). HLI-evoked EPSPs of up to 50ms duration were recorded intracellularly from pyramidal neurons in layers III and V; cells were identified with biocytin injections. While some layer V pyramidal cells within 1mm did not respond, others with profuse distal tufts of apical dendrites were excited up to 4mm away.

Supported by NIH NS01271 and NS25983.

CORTICOMOTONEURONAL POSTSPIKE EFFECTS IN AVERAGES OF UNRECTIFIED EMG ACTIVITY. G.W. Botteron* and P.D. Cheney. Dept.. of Physiology, Univ. of Kansas Med. Ctr., Kansas City, KS 66103.

To examine the extent to which clear postspike effects (PSEs) can be detected in spike triggered averages of unrectified EMG activity and to test the possible utility of this method, we compared postspike effects in rectified and unrectified EMGs from 44 corticomotoneuroal (CM) cells yielding 293 cortical cell - target muscles pairs (CMPs). Of the 293 CMPs tested, 110 showed clear PSF in averages of rectified EMG activity. Of these 110, 49 also showed clear postspike effects in simultaneously computed averages of unrectified EMGs. Twenty four CMPs showed clear postspike suppression (PSS). Remarkably, twelve of these 24 CMPs yielding suppression also showed clear PSEs in averages of unrectified EMGs. Thirteen CMPs showed clear PSEs in averages of unrectified EMGs but failed to show clear effects in corresponding averges of rectified EMGs. Simulations were used to confirm these findings and to investigate various interpretations. In conclusion, we have shown that clear PSEs associated not only with facilitation but also suppression can be detected in averages unrectified EMG activity. (Supported by NSF grant BSN-8216608 and NIH grant NS25646.)

SYNAPTIC INTERACTIONS BETWEEN NEIGHBORING NEURONS IN THE PRIMATE MOTOR CORTEX M. Matsumura*, D.-F. Chen* and E.E. Fetz, Regional Primate Research Center and Dept. of Physiology and Biophysics, University of Washington, Seattle, WA, 98195 USA.

To analyze synaptic interactions between primate motor cortex neurons we calculated spike-triggered averages (STA) of intracellular membrane potentials in a monkey anesthetized with halothane. Intracellular recordings were made with a glass micropipette while extracellular spikes were recorded from neighboring cells with a carbon-fiber electrode attached to a pipette for ionophoretic application of glutamate. Neurons could be identified by antidromic responses to pyramidal tract stimulation, response to natural stimulation and relative cortical location. To date we obtained simultaneous intra- and extracellular recordings from 118 pairs of neurons separated by less than 0.5 mm. 83 of the STAs showed broad depolarizing potentials straddling the trigger, indicating that both neurons received common synaptic input (mean amplitude ± SD = 800 ± 570 μv). 34 pairs showed postsynaptic potentials with onsets after the trigger, indicating the presence of a serial connection (often in combination with common input); these PSPs had onsets of 1.3 ± 1.0 ms, and amplitudes of 260 ± 200 μv. The types of synaptic interactions and their magnitude could be modulated by different forms of stimulation. Activating the cells by application of glutamate and by stimulation of receptive fields both reduced the relative amplitude of common input potentials, compared to those obtained with spontaneous activity.

113.8

INTRACORTICAL CONNECTIVITY OF CAT MOTOR CORTEX EVALUATED BY SPIKE-TRIGGERED AVERAGING AND CROSS-CORRELATION. P. Zarzecki, D.C. Gordon and E.E. Fetz Dept of Physiol, Queen's Univ, Kingston, Ontario, Canada; Dept of Physiol and Biophys, and Regnl Primate Res Ctr, Univ Wash, Seattle, WA, USA.

We studied the synaptic connections between neighboring motor cortex neurons in anesthetized cats by recording simultaneously with two electrodes. Intracellular (IC) recordings were made from 31 neurons. Extracellular (EC) spikes recorded by the second electrode were used to trigger averages of membrane potentials of IC neurons. For most of the more than 60 pairs of neurons analyzed so far, spike-triggered averages showed broad psps straddling the EC trigger spike. This is evidence of common synaptic input to the EC and IC neurons. Psps delayed after the trigger were interpreted as serial synaptic connections. There were eight serial epsps, ranging from 30 to 300 μV in amplitude, and two ipsps.

To assess the efficacy of the epsps, the IC neurons were made to discharge by current injection, and the EC and IC discharges were cross-correlated. Only one of the epsps produced a clear correlogram peak, confirming that cross-correlation underestimates the extent of intracortical connectivity.

Supported by the MRC of Canada and the US NIH.

RELATIONSHIPS BETWEEN SIMULTANEOUSLY RECORDED MOTOR CORTEX NEURONS IN PRIMATES. E.M. Schmidt and J.S. McIntosh. NIH, NINDS, Lab. of Neural Control, Bethesda, MD 20892.

One method of studying the organization of the motor cortex is to examine the firing patterns of closely spaced neurons during a controlled task and also during small perturbations that reveal sensory input to the neurons under study.

A Rhesus monkey was trained to flex and extend the wrist in response to movement of a visual target on a video monitor. The monkey's hand was held in a molded form coupled to a torque motor which produced a simulated spring load. The monkey was required to match a wrist-movement coupled cursor to a target for a period of at least one second to receive a reward. Halfway through the random duration hold period, a 50 ms torque pulse was applied to perturb the wrist in either a flexion or extension direction. After training, under pentobarbital anesthesia and sterile operating conditions, a recording chamber was implanted over the arm area of the contralateral precentral cortex, along with a head restraint device.

Thus far, the firing patterns of 42 pairs of simultaneously recorded neurons (each pair recorded with the same electrode) have been examined. At least one neuron of the pair was related in some fashion to the task. In half of the pairs the relationship was either similar (S) (29%), or reciprocal (R) (21%). In the remaining half, the relationship was complex (36%) or not related (14%). The sensory input was examined in all of the cells and only 25 pairs responded. The responses were similar in 2 pairs of S-cells and 1 pair of R-cells. The responses were reciprocal in 3 pairs of S-cells and 2 pairs of R-cells. In the remaining 17 pairs the responses were complex.

From this preliminary sample of closely spaced cortical neurons, 86% were task related. However, less than 1/3 have similar task related activity and only 17% have similar sensory input.

113.10

NEURAL ENCODING OF MOVEMENT PARAMETERS IN AREA 5 IN THE MONKEY. P. Burbaud*, C. Doëgle*, Ch. Gross*, and B. Bioulac. Lab. de Neurophysiologie, CNRS UA 1200, Université de Bordeaux II, 146 rue Léo Saignat, 33076 Bordeaux (France).

Electrophysiological and clinical studies have shown that area 5 of the parietal cortex is implicated both in the integration of complex proprioceptive inputs from area 2 and in the control of arm movement (Hyvarinen J. Springer Verlag (Eds) NY, 1982). Using unit recording techniques in the monkey, two populations of neurons have been described: somaesthetic-like neurons and neurons which exibit early movement-related changes in spike frequency (Seal et al., Brain Res. 250, 229-243, 1982). In this work, we studied the neuronal encoding of cinematic parameters of the movement (onset, duration, velocity) by area 5 neurons. For neurons showing changes in neuronal activity prior to the movement, the **stimulus or movement**-related activity has been investigated using two different statistical methods. It is concluded that these populations of neurons with different functional properties might represent the cellular substract of the somatognosic and the somatopraxic function ascribed to area 5 of the associative parietal cortex.

114.1

INTRINSIC CONNECTIVITY OF MOTOR CORTEX IN OLD WORLD MONKEYS. George W. Huntley and Edward G. Jones. Department of Anatomy and Neurobiology, University of California, Irvine, CA. 92717.

The intrinsic connectivity of the forearm and digit representations in the precentral cortex (areas 4 and 6) of macaque monkeys was examined using intracortical microstimulation (ICMS) followed by small extracellular HRP injections at defined sites. Multiple representations of movement about a single joint were found in both areas. Representations involving distal musculature were located nearest the central and arcuate sulci; more proximal representations were located between the two sulci. Small HRP injections were then made into one of several sites in area 4 from which the same movement could be elicited by low-threshold ICMS. The depth of the injection site varied. Axonal trajectories were reconstructed with a camera lucida; sites of termination within the precentral gyrus were then correlated with cortical locations physiologically identified using ICMS. From all injection sites, long processes were traced which extended both anterior and posterior to the injection site, and gave rise to foci of terminations which in certain instances joined sites with similar representations. The dimensions of the foci and their distance from the injection site varied both with the size of the injection and with the layer in which the injection site was located.

ORGANIZATION OF PRIMARY MOTOR CORTEX OF ADULT MOUSE AS STUDIED BY MICROSTIMULATION AND RETROGRADE TRACING TECHNIQUES. C.X. Li* and R.S. Waters (SPON: R.P. White). Dept. of Anatomy & Neurobiol., Univ. of Tenn., Memphis, Col. of Medicine, Memphis, TN 38163.

Our understanding of motor organization of rodent motor cortex has derived, in large part, from previous investigations in rat. In this report, we describe the organization of primary motor cortex in mouse and compare our findings with those previously reported in rat.

Experiments were carried out on 27 mice. Animals were anesthetized with Ketamine and placed in a modified stereotaxic apparatus. In 21 animals, the primary motor and somatosensory cortices were exposed and covered with warmed silicon oil. Microstimulation consisting of trains of cathodal pulses (0.2 ms duration; 300 Hz; 100-mA maximum intensity) was delivered to the cortex through tungsten-in-glass microelectrodes. Movement and threshold for activation were recorded. All electrode penetrations were marked on a high quality photograph of the cortical surface. Following mapping, the brain was removed, frozen, sectioned at 60 mm, and stained with cresyl violet. In 6 animals, HRP was injected into the cervical enlargement of the spinal cord. Animals were sacrificed 72 h after injection, brains removed, and tissue processed according to the method of Graham and Karnovsky (1966).

Microstimulation: The map of primary motor cortex consisted of a single representation of the body. Motor responses were activated from both agranular and granular cortex. The forelimb representation consisted of a flexor, extensor, and overlapping hindlimb zone.

HRP: Following injection of HRP, labeled neurons were observed in three discrete cortical regions. The most extensive labeling was found in frontal and parietal cortices where two foci of different density were interconnected by a more sparsely labeled area. Two smaller regions of labeling were also identified in lateral cortex.

The motor organization in mouse is similar to that described in rat and suggests a common plan of rodent motor organization. (Supported by NSF Grant BNS 85-16076)

114.3

TOPOGRAPHY OF CONNECTIONS TO PRIMARY MOTOR CORTEX(M-I) OF MACAQUES. M.F. Huerta and T.P. Pons. BioStructure and Function, Univ. Conn. Hlth. Ctr., Farmington, CT 06032; Lab. Neuropsych., NIMH, Bethesda, MD 20982.

The use of multiple tracers within a single animal is a powerful way to demonstrate topography of neural connections. In this study the topography of sources of inputs to physiologically defined regions of M-I were determined. In three monkeys (M. mulatta) intracortical microstimulation was used to define topographic sectors of M-I. Single injections of different tracers (fast blue, diamidino yellow, fluorogold, latex microspheres and/or tritiated amino acids) were then placed into separate movement representations of M-I. Thalamic connections include the oral ventral posterior lateral nucleus (VPLo) and the oral ventral lateral nucleus (VLo), with the facial and forelimb sector of M-I being connected with medial and lateral parts of both VPLo & VLo, respectively. The forelimb sector of M-I is connected with lateral postarcuate cortex, whereas the facial sector is connected with adjacent, more lateral, parts of this cortex; the facial sector of M-I is bilaterally connected with the rostral supplementary motor area, while the forelimb zone of M-I is bilaterally connected with immediately caudal parts of the same area. Connections with other structures were also observed. Our findings indicate that a topograghical pattern of connections with M-I is more obvious in some areas and nuclei than in others, which confirms and extends previous anatomical and physiological results.

PREMOTOR AREAS ON THE MEDIAL WALL OF THE HEMISPHERE: CORTICOSPINAL PROJECTIONS TO CERVICAL AND LUMBOSACRAL CORD. S.Q. HE*, R.P. DUM and P.L. STRICK. VA Med. Ctr. and Depts. of Neurosurg. & Physiol., SUNY-HSC @ Syracuse, Syracuse NY, 13210.

We have recently presented evidence that the medial wall of the hemisphere in macaques contains 3 premotor areas which are somatotopically organized and project directly to the spinal cord. One of these regions is the supplementary motor area (SMA) in a medial portion of area 6. The 2 other regions lie in the cingulate sulcus- one in area 23c, termed the caudal cingulate motor area (CMAc) and the other in area 24c, termed the rostral cingulate motor area (CMAr).

We examined the somatotopic organization of these areas more directly by injecting different fluorescent tracers into lower cervical and lower lumbar segments of the spinal cord in macaques. We found that the regions in each of the premotor areas which project to lower cervical segments did not overlap substantially with the regions that project to lower lumbar segments. In fact, the overlap observed in the premotor areas was comparable to what is seen in the primary motor cortex of the same animals. Few double labeled neurons were observed and these were found in regions of overlap. Our results support the concept that the premotor areas on the medial wall of the hemisphere contain arm and leg representations which are as distinct as those in the primary motor cortex.
Support: VA Med. Res. Serv. and Rehab. R&D; USPHS 24328, 2957.

114.5

PREMOTOR AREAS ON THE MEDIAL WALL OF THE HEMISPHERE: INPUT FROM VENTROLATERAL THALAMUS. J.W. HOLSAPPLE* and P.L. STRICK (SPON: D.S. Hoffman). VA Med. Ctr. and Depts. of Neurosurg. & Physiol., SUNY-HSC @ Syracuse, Syracuse, NY 13210.

We have examined the inputs from the ventrolateral thalamus to the caudal cingulate motor area (CMAc) using retrograde transport of wheat germ agglutinin conjugated to horseradish peroxidase (WGA-HRP). Small injections of tracer were placed into portions of the CMAc lying on either the dorsal or ventral banks of the cingulate sulcus in 4 monkeys (macaca nemestrina). We have focused our analysis on regions of the CMAc which are reciprocally connected with the 'arm area' of the primary motor cortex.

Following tracer injections into the dorsal bank of the CMAc, rostral portions of VLo contained the largest number of labeled neurons in the ventrolateral thalamus. In contrast, following an injection into the ventral bank of the CMAc, the largest number of labeled neurons was found in portions of VLc. None of our injections resulted in substantial labeling of thalamic neurons in the anterior nuclear group. Therefore, it is unlikely that the CMAc is a part of 'limbic-related' cortex. On the other hand, VLo and VLc are major sites of termination for pallidal output in the ventrolateral thalamus. Thus, our results suggest that the CMAc is a cortical target for the 'motor' component of basal ganglia output.

COMPARISON OF OUTPUT EFFECTS FROM SINGLE PULSE AND REPETITIVE INTRACORTICAL MICROSTIMULATION APPLIED TO MOTOR CORTEX IN PRIMATES. G.L. Widener and P.D. Cheney. University of Kansas Medical Center, Kansas City, KS 66103.

Although electrical stimulation has been widely used to identify the sign and strength of motor output from various brain areas, there has been no systematic comparison of different stimulation methods in terms of the motor output effects they yield. Therefore, we compared the effects of single pulse and repetitive intracortical microstimulation (ICMS) on muscle activity at 20 corticomotoneuronal (CM) cell sites in monkeys performing an alternating wrist movement task. CM cells were identified using spike triggered averaging (STA) of rectified emg activity (Fetz and Cheney J. Neurophysiol. 44: 751, 1980). Single pulse ICMS (S-ICMS) consisted of a series of biphasic pulses at a frequency of 10 to 20 Hz whereas repetitive ICMS (R-ICMS) consisted of a train of 10 biphasic pulses at a frequency of 330 Hz. At 10 μA, peak magnitues expressed as a percent of baseline for S-ICMS and R-ICMS were 56% and 265% respectively. Muscle field and muscles showing the greatest effect were used to characterize the pattern of output distribution. At 95% of sites, the muscles with the greatest effect from S-ICMS matched those with the greatest postspike effects (STA). For R-ICMS, the match was poorer (65%). Muscle field overlap between STA and S-ICMS was 70% compared to 53% for STA and R-ICMS. S-ICMS yielded lower thresholds for effects than R-ICMS at 7 sites, 5 sites had equal thresholds and at 2 sites thresholds were lowest for R-ICMS. We conclude that output effects obtained with either S-ICMS or R-ICMS are similar to those of the corresponding postspike effects but that S-ICMS is clearly superior in revealing basic features of underlying ouput organization. AREAL DISTRIBUTION OF CORTICAL NEURONS PROJECTING TO THE BRAINSTEM AND SPINAL CORD IN RATS. X.-G. Li, S.L. Florence and J.H. Kaas. Vanderbilt Univ., Nashville, TN 37240.

The present experiments were designed to determine the locations of corticospinal and corticotrigeminal neurons relative to the pattern of cytochrome oxidase dense patches that reveal the somatotopic organization of S-I in rats. Unilateral injections of 1% WGA-HRP were made in the ventral horn of the cervical or lumbar enlargement or into one of the trigeminal nuclei of anesthetized adult rats. We conclude: (1) Corticofugal projections originate from neurons throughout granular S-I. Injections in the lumbar enlargement labeled neurons throughout the lower limb and caudal trunk representations, injections at the cervical cord labeled the upper limb and adjacent trunk representations, and medullary injections labeled representations of the head and face. (2) Other projection neurons formed a somatotopic pattern in the dysgranular zones inserted in and around granular S-I. (3) Large numbers of projection neurons in a somatotopic pattern in presumptive M-I were found following injections at all sites including the lumbar enlargment. (4) Projection neurons were found lateral to S-I in S-II and/or the parietal ventral area (PV) and in perirhinal cortex. (5) Other projection neurons were found in the frontal cortex rostral to M-I. The results indicate that at least six cortical regions contribute to the corticospinal-trigeminal systems in rats. (Supported by NS16446.)

THE EFFECT OF LIMB POSITION ON ELECTROMYOGRAPHIC ACTIVITY EVOKED BY ELECTRICAL STIMULATION IN RAT MOTOR CORTEX

J. Wang, R. Kim* and J.P. Donoghue, Center for Neural Science, Brown University, Providence RI 02912

We have found that motor cortex (MI) representation patterns are modified rapidly following nerve transection (Sanes et al., '88). Alterations in afferent input to MI may serve as a cue for MI reorganization in these cases. To begin to investigate the role of afferent feedback on MI organization, we examined the effect of different elbow positions on the amount of muscle activity (EMG) evoked in the biceps and triceps muscles following electrical stimulation in MI. In ketamine anesthetized rats biceps and triceps EMG evoked by intracortical electrical stimulation (30 msec pulse trains, 333 Hz, 10-60 μA) was recorded after the elbow was fixed in an extended or flexed position. The amount of EMG (recorded through percutaneously inserted intramuscular wires) was measured as the integral of the average of 10 cortical stimuli at 1 and 2x threshold, and at 45 μA. A total of 64 sites yielding either forelimb or whisker movements was sequentially tested with the elbow placed in extended, flexed and again in extended position in 4 rats. The biceps EMG evoked from MI showed a consistent relationship to elbow position. In the extended position, the amount of biceps activity recorded at each site was, on average, more than 3X larger than that recorded in flexion. The average threshold to evoke biceps EMG in the extended position was about 40% (16.5±1.2 μA) lower than in the flexed position. The amount of EMG and EMG thresholds were near original levels when the limb was again returned to the extended position. The generally absent or weak triceps response made it impossible to evaluate position effects in this muscle. Stimulation in the MI vibrissa representation showed no significant effect of elbow position on whisker movement thresholds. At some sites the biceps threshold was lower than the whisker threshold when the elbow was at extension, but not when flexed. These results show that limb position can affect the amount of muscle activity evoked by electrical stimulation and suggest that afferent feedback of muscle length may modify the effect of MI output. They further demonstrate that limb position must be rigorously controlled when constructing maps of MI based on electrical stimulation techniques. (Supported by NS 25074).

ANATOMICAL SUBSTRATES FOR SHIFTING SOMATOTOPY IN RAT MOTOR CORTEX. S.A. Lee*, S.J. Bonasera*, D.L. O'Donoghue and D.R. Humphrey. Laboratory of Neurophysiology, Emory University, Atlanta, Ga., 30322.

Studies have shown that amputation of the forelimb (FL) in the neonatal rat produces an expansion of vibrissae (VB) motor areas into what would have been FL motor cortex (Donoghue and Sanes, PNAS, 84: 1123). One factor that might contribute to this finding is an overlap in the distributions of cortical cells projecting to bulbar VB and spinal FL motor control nuclei, an overlap which might not be revealed by microstimulation maps that emphasize lowest threshold responses. To study this possibility, we first mapped the FL and VB control areas in adult rats. Fluorogold dye was then injected into the reticular formation where the corticobulbar fibers that control the VB terminate, and Fast Blue dye was placed into the grey matter of the cervical (C5) spinal cord. Marking lesions allowed us to correlate the cortical stimulation map with the distributions of labeled neurons observed histologically in the same animals. Both types of labeled cells overlapped across the stimulation defined boundary between the VB and FL motor areas. Thus, an anatomical substrate exists even in normal animals that might account for some of the motor cortex 'plasticity' observed after neonatal manipulation of the controlled motor periphery. (Supported by NIH Grant NS 20146).

SIMILARITIES AND DIFFERENCES IN THE LAMINAR ORGANIZATION OF CORTICOCORTICAL CONNECTIONS IN RAT AS COMPARED TO MONKEY. T. W. Deacon, D.-W. Wang* and A. Carpenter*. Biological Anthropology, Harvard University, Cambridge, MA 02138.

In macaque and squirrel monkey neocortex there are systematic laminar patterns distinguishing different classes of corticocortical connections. Reciprocal connections between many cortical areas exhibit an asymmetric pattern of termination in which one projection's terminations predominate in middle cortical layers iiic-iv originating from cells that predominate in layer iii whereas terminations of its reciprocal counterpart predominate in layers i and vi originating from cells predominating in upper layer v. We have investigated corresponding reciprocal patterns in rat neocortex using the anterograde-retrograde transport of WGA-HRP and the anterograde transport of tritiated amino acids. We find similarities and striking differences with respect to typical monkey patterns. For example, similarities include layer vi and layer i termination patterns of frontal motor projections to parietal areas and from secondary to primary areas in all modalities. However, in contrast to monkey findings, projections from parietal to frontal areas terminate predominantly in layer i and to a lesser extent in ii and upper layer iii but not middle layers, and primary sensory areas project to adjacent secondary areas into upper layer v and layer iv but also apparently to layer i. Retrogradely labeled cells of origin for most corticocortical projections nearly always predominate in upper layer v and to a lesser extent layer iii, however, labeled cells are also observed in layer ii in most areas. Layer ii cells are not thought to have interareal connections in monkey brains. These data indicate that corticocortical laminar connection patterns are not simply generalizable across mammalian orders, but that some features may be common and others derived independently.

Pelvic Floor Muscles. Definition of Cortical Output by Intracortical Microstimulation. D. Filipini* and B. Dubrovsky. McGill University Montreal, Quebec H3A1A1.

We investigated the output organization of pelvic floor muscles control in the primary motor cortex of cats under nembuthal anesthetia (30 mg/kg i.p.). Emg activity of the external anal sphincter (EAS) and levator ani (LA) muscles was recorded and taken as the index of response to cortical stimulation.

Initially anodal surface stimulation with a silver ball was given to determine the locus of interest (tail and lower axial muscles). Secondly focal depth stimulation by means of low current intracortical microstimulation (ICMS) was used to activate individual muscular groups. Glass-coated tungsten microelectrodes with exposed tips of 10-20 μm were used to deliver trains of cathodal current. Trains of 40 ms duration at 400 Hz with pulses of 0.2 ms and 10-50 μA intensities were used to elicit muscular responses. Activation of LA and EAS was obtained when electrodes were positioned with a posterior angulation of 30° in the depth of an area extending over the middle part of the posterior sigmoid gyrus 4.9 mm posterior to the cruciate dimple (fig.). Mirror area in the other hemisphere elicited same responses. Latencies varied between 12 and 25 ms following the train. Lowest thresholds for LA (7±3 μA) and EAS (9±2 μA) were obtained at 5mm deep from the site of penetration. Exploration of areas in the vicinity produced contraction of tail and hip muscles.

Histological reconstruction of lesions delivered at different sites of activation corresponded to the middle part of the dorsal bank of the cruciate sulcus (fig.) which is hidden from the surface. Our results show that:

1)LA and EAS have bilateral representation in primary motor cortex of the cat

2)neuronal populations controlling both muscles are specifically placed and partly enclosed by zones controlling tail and proximal hindlimb musculature.

PATTERNS OF CONNECTIVITY IN RAT ORBITAL CORTEX. R.L. Reep, A. Wallach*, V. King* and J.V. Corwin. Depts. of Neuroscience and Physiological Sciences, J-144, Univ. Florida, Gainesville, FL 32610; Dept. of Psychology, Univ. New Orleans-Lakefront, New Orleans, LA 70148.

Previously we have demonstrated bilateral reciprocal connections between ventrolateral orbital cortex (VLO) and medial agranular cortex (AGm). Unilateral lesions of these cortical areas produce multimodal neglect. In order to further elucidate the neuronal circuitry pertinent to neglect, we have studied the connections of VLO, as well as the adjacent medial (MO) and lateral (LO) orbital areas, using retrograde and anterograde tracers.

Most of MO has cortical connections with anterior cingulate cortex bilaterally, insular cortex, and the ventral subiculum. Ventral MO and VLO have reciprocal connections with AGm bilaterally, posterior parietal cortex, and area Oc2MM of visual association cortex. Cortical connections of LO are limited to insular cortex. All three orbital fields have commissural connections with the homotopical area contralaterally.

Thalamic afferents to orbital cortex involve primarily the gelatinosus, ventromedial, and mediodorsal (MD) nuclei. Nucleus gelatinosus neurons projecting to VLO are located in the central portion of the nucleus, while those to MO and LO are arranged around the periphery. A heavy input to MO and LO arises from the ventromedial nucleus, but VLO receives none. All three orbital fields receive mediodorsal nucleus afferents, from partially overlapping portions of central, dorsolateral and posterior MD.

Amygdala connections are extensive with MO, and involve the basolateral, basomedial, cortical and amygdalo-hippocampal areas. VLO has moderate connections with the basolateral nucleus; LO with the anterior basolateral and lateral nuclei. Caudate projections are topographically arranged.

FORELIMB FLEXION EVOKED BY MOTOR CORTEX OR PYRAMID STIMULATION IN RATS IS DUE TO THE LARGEST PYRAMIDAL TRACT AXONS. C.A.Chapman* and J.S.Yeomans (SPON:P.Li). Dept. Psychology, Univ. Toronto, Canada, M5S 1A1.

Double pulses were delivered to the motor cortex forelimb area, or ipsilateral pyramid, and the maximum flexion of the contralateral forelimb measured at the wrist. The movements increased as the C-T intervals increased from 0.4-1.0 ms in pyramid sites, and increased at C-T intervals from 0.6-2.0 ms in cortical sites, suggesting longer refractory periods for cortical substrates. In cortical sites, as the C-T interval was increased from 4-20 ms, the movements decreased gradually to the single-pulse level, due to decreasing temporal summation. When C pulses were delivered to the cortex and T pulses to the pyramid, the movements increased at C-T intervals from 0.8-2.5 ms. When the C pulses were delivered to the pyramid and the T pulses to the cortex, the movements increased at slightly longer C-T intervals, due to the longer refractory periods in cortex, but estimated conduction times (0.5-1.0 ms) between the two sites were similar. This suggests that collision occurred between orthodromic and antidromic action potentials in the pyramidal tract axons responsible for the limb flexion. The large collision-like effect suggests that the largest pyramidal tract axons (conduction velocities of roughly 13-30 m/s) are responsible for most of the forelimb flexion in pentobarbital anesthetized rats.

114.14

UNILATERAL AND BILATERAL EFFECTS OF UNILATERAL FRONTAL AGRANULAR CORTEX LESIONS ON VISUAL REACTION TIME PERFORMANCE, PAW USE AND SOMATO-SENSORY NEGLECT IN THE RAT. V.J.Brown* and T.W.Robbins, Dept. of Exp. Psychology, Cambridge University, Downing Street, Cambridge, CB2 3EB, U.K.

The effects of unilateral aspirative lesions of medial agranular frontal cortex (AGm) were compared in three separate tests of sensorimotor integration. In an automated visual reaction time task with low stimulus response compatibility rats were trained to respond to brief visual stimuli presented unpredictably to either side of the head by making a nose poke response on the side opposite to that on which the stimulus occurred. Spatial response bias and reaction time to the visual stimuli were recorded (Carli et al., *Nature*, 313:679, 1985). The same rats were also trained to reach for food pellets (Whishaw et al., *Brain*, 109:805, 1986) and were tested for their removal of sticky patches applied bilaterally to the radial aspect of their forepaws (Schallert et al., *Pharmacol. Biochem. Behav.*, 18:753, 1983).

The animals showed a postoperative bias to the ipsilateral side on all tests. This had stabilized by 1 month, leaving deficits apparent in paw use and on the reaction time task. This latter task was found to be acutely sensitive to deficits following the lesion, with long lasting effects (3+ mths) on spatial response bias. In contrast to the ipsilateral side bias, the lesioned rats showed lengthened reaction times bilaterally, unlike previously reported effects of either unilateral striatal or unilateral AGm lesions in rats.

As the AGm lesion includes the region thought to be homologous to the supplementary motor area (SMA) in man, this bilateral effect on reaction time may parallel similar bilateral effects on motor performance of unilateral lesions of the SMA (Goldberg, *Behav. Brain Sci.*, 8:567, 1985). The effects on spatial response bias resemble those seen following unilateral striatal lesions and are consistent with the concept that cortico-striatal loops mediate behavioral functions of these related areas.

DYNAMIC NETWORKS DERIVED FROM SINGLE NEURONAL RECORDINGS IN PERFORMING MONKEYS. Erwin B. Montgomery, Jr., Department of Neurology and Neurological Surgery (Neurology), Washington University School of Medicine, St. Louis, MO. 63110.

A method described previously derives network models of neuronal interactions (patterns of connection strengths) from single neuron recordings in performing monkeys (Montgomery, Abs. of the 11th meeting of the Euro. Neurosci. Assn., 1988). A series of simultaneous equations are constructed relating the discharge frequencies of a target neuron (F_t) and driver neurons (f_1 through f_n) of the form

$$F_t = a_1 * f_1 + \ldots + a_n * f_n + c$$

where a_1 through a_n reflect connection strengths and c, the target neuron excitability. Since the discharge frequencies of the target and driver neurons are experimentally determined, the target neuron excitability and connection strengths can be mathematically determined.

One implication is the "connect period" where one neuron may influence another for a limited time period. Furthermore, multiple "connect periods" may be strung together to produce a dynamic network which determines behavior. This study determined connection strengths between putamen neurons in overlapping segments through the course of a behavior in performing monkeys.

Results show connection strengths vary through the time course of behavior suggesting a dynamic network. Thus, the driver neuron contribution to a target neuron is the product of discharge frequency and connection strength which may vary with connections to different target neurons and within the time course of the behavior. A dynamic network may provide a syntactical structure which some have argued to be missing in current concepts of network function (Fodor and Physlysn, Cognition 28:2849-2857, 1988).

115.2

THE ACTIVITY OF STRIATAL NEURONS CHANGES DURING THE INITIATION OF HAND MOVEMENTS MADE IN RESPONSE TO VISUAL AND VIBRATORY CUES. T.W. Gardiner and R. J. Nelson, Dept. of Anatomy and Neurobiology, College of Medicine, Univ. of Tennessee, Memphis, 875 Monroe Ave., Memphis, TN 38163.

The activity of striatal neurons was recorded while Rhesus monkeys made identical wrist flexion and extension movements in response to either vibratory or visual cues. Animals were rewarded with fruit juice for correct performance during these self-paced tasks. Vibratory cues consisted of palmar vibration (low-amplitude sine wave at 27, 57 or 127Hz) delivered to the control handle of the apparatus. Visual cues consisted of changes in the lamp display that also signaled the current wrist position. Visual and vibratory-cued trials were presented randomly in blocks of ten trials with the same movement being required in response to each of the sensory cues. Of the 108 presumptive striatal neurons recorded, 83 were task-related. Of these, 19 (23%) responded to the onset of sensory stimuli: 10 to vibratory stimuli, 3 to visual stimuli and 6 to both. Seven of 15 vibratory responsive neurons were tested and did not respond to the stimuli when the monkeys were instructed not to move after stimulus onset. Sixty-four neurons showed pre-movement activity changes. Whereas 12/64 showed late changes in activity, 52/64 (~80%) exhibited early activity changes (>80msec) before movement onset. Of the movement-related neurons, 24/64 (~37%) showed directional bias and responded differentially depending upon the direction of the subsequent movement.

These findings suggest that some vibratory responsive striatal neurons are conditionally responsive to these stimuli when they trigger movement. In addition, the significant percentage of movement-related cells showing activity changes that preceded movement suggests that the striatum may play a role in the initiation of planned motor behaviors as well as its more accepted role in the execution of the movements themselves. This study met NIH guidelines for animal utilization.

115.3

A COMPARISON BETWEEN PRIMATE CAUDATE NUCLEUS AND PUTAMEN SINGLE UNIT ACTIVITY IN A PRECUED REACHING TASK. D.Jaeger, S.Gilman and J.W. Aldridge, Dept. of Neurology, Univ. of Michigan, Ann Arbor, MI 48104

There is growing evidence that the caudate nucleus (Cd) is concerned with the cognitive aspects of a motor task whereas the Putamen (Pu) is concerned with movement execution. To test this hypothesis, single unit activity was recorded from the Cd and Pu of the left hemisphere of a monkey during a task which required contralateral or ipsilateral reaching movements to touch one of a set of 4 target knobs on each side. Stimulus lights, mounted on each target knob, cued the target for each trial. In addition, a subset of stimulus lights was flashed as a precue for 2 s before the go-cue. The location of the flashing lights precued partial to complete information about the target position of the next movement. Of 149 Pu and 100 Cd units analyzed with respect to contralateral target reaching movements, 58% of Pu and 19% of Cd units were activated during the movement. The average spike rate increase in Pu responses was twice that of Cd and better aligned to movement onset. Pu responses were typically dependent on movement amplitude and direction. The onset of 46% of these responses was simultaneous with movement onset while 44% of the responses had an early component preceding movement onset by as much as 1 second. Of 39 Pu and 22 Cd units analyzed with respect to ipsilateral target reaching movements 38% of Pu and 14% of Cd units were activated during movement execution. Unit responses in Cd were typically related to the presentation of sensory cues and the response onset preceded the cue onset in most cases. For 24% of Cd and 7% of Pu units such an anticipatory cue response was found with respect to the precue, which was a cue without an immediate motor demand to the animal. The results of this study support the hypothesis that Pu activity is tightly linked to limb movement and that movement control is organized bilaterally to some extent. Early Pu responses indicate that this structure is involved in movement planning as well as execution. Cd unit activity on the other hand is rarely linked to limb movement and the predominance of anticipatory cue responses indicates that it may be related to attentional switching in predictable sequential tasks and to the processing of cognitive task requirements. NIH grants NS19613, NS07222.

115.4

THE TIMING OF CHANGES IN PALLIDAL DISCHARGE IS CORRELATED WITH MOVEMENT TIME. M. Anderson and R.S. Turner*, Depts. of Physiol. and Biophys. and Rehab. Med. and Reg. Primate Res. Center, Univ. of Washington, Seattle, WA. 98195

The discharge of many neurons in the globus pallidus of monkeys changes during an arm-reaching movement, and when the normal pallidal activity is interrupted, the movement time (MT) is prolonged. Does the discharge of these neurons at particular times predict or reflect movement time?

This question was addressed by a trial-by-trial analysis of the discharge of 40 pallidal neurons whose discharge was task-related and could also be modified by "passive" movement around one or more joints of the arm. The linear correlation between the number of spikes and the movement time was evaluated for each 50 ms bin during before and after the movement. For 35 of the 40 cells, there was a correlation at the $p<.05$ level between the number of spikes and the MT for one or more 50 ms bins, and for 19 of these, the correlation was significant at the .001 level. The pattern of correlations across time showed that for only 3 cells was the correlation significant at the time of the peak change in firing. Instead, significant correlations were usually positive during the onset of a period of decreased firing or on the falling phase of a burst and negative at the end of a decrease in firing. Significant changes usually occurred near the end of the movement.

These data indicate that it is the timing of changes in pallidal activity that is most strongly related to the duration of the movement.

115.5

ACTIVITY OF PALLIDAL NEURONS DURING REACHING MOVEMENTS UNDER THREE CONDITIONS OF SPATIAL AND TEMPORAL CUING. R.S. TURNER* and M.E. ANDERSON (SPON: A. RUSSELL)

Depts. of Physiol. and Biophys., Rehab. Med., and Reg. Primate Res. Center, Univ. of Washington, Seattle, WA 98195

Clinical evidence and the study of SNr cells during eye movements suggest that the BG are especially involved in movements made in the absence of immediate sensory cues, e.g. visually precued or self triggered movements. We would expect to find larger changes in cell activity, and/or more GP cells related to a particular movement when it is performed under precued or self triggered conditions. We have addressed this hypothesis by recording GP cell activity in monkeys performing reaching movements under 3 task conditions. The monkey moves its hand across a slightly inclined work surface from a central start position to one target LED in an array offering 8 possible target directions and 3 possible distances from center. Sensory targeted and triggered: A target LED is illuminated and trigger tone sounds simultaneously. The monkey is rewarded to move to the target within 0.8 s. Visually precued/Sensory triggered: A target lights briefly, up to 1.5 s. before the trigger tone sounds. The monkey must wait until the trigger tone sounds before moving to the then invisible target position. Visually targeted/Self triggered: One target LED is continuously lit during a block of trials, but no trigger tone sounds. The monkey must hold at the start position for at least 1.5 s. before moving to the target position. Among the 203 GP cells studied under more than one condition, 57 could be driven by manipulation of the contralateral arm. Preliminary analysis shows that of these 'arm' cells, 11 had larger responses during precued trials, and 11 had larger responses during sensory targeted and triggered trials. There is thus no initial support for the simple interpretation of the above stated hypothesis.

PATTERNS OF SENSORIMOTOR INTEGRATION IN THE PRIMATE NEOSTRIATUM: PRIMARY SOMATOSENSORY CORTEX (SC) AND MOTOR CORTEX (MC) PROJECT TO COEXTENSIVE TERRITORIES IN THE PUTAMEN. M. Fotuhi, V.E. Koliatsos, G.E. Alexander, and M.R. DeLong. Departments of Neuroscience and Neurology, The Johns Hopkins University, School of Medicine, Baltimore, MD, 21205.

Previous findings in our laboratory (Alexander et al., Soc. Neurosci. Abstr. 14:720, 1988) have indicated that the arm areas of the supplementary motor, arcuate premotor, and motor cortex project to adjacent but non-overlapping regions of the putamen. In combination, these three motor and premotor areas appear to include most of the arm territories of the putamen.

To determine the relationship between the terminal fields of SC and MC projections to the putamen, we carried out a double anterograde tracing study in two monkeys. The arm regions of SC and MC of one hemisphere received multiple small injections of wheat germ agglutinin-horseradish peroxidase and tritiated amino acids, respectively. Terminal fields labelled from both sets of injections extended over long rostrocaudal domains of the putamen in a discontinuous distribution. Patches of the MC terminals overlapped extensively with patches containing terminals from the sensory SC. In contrast to the segregation of terminal fields from the precentral motor and premotor areas, the present data indicate that selected pre-and post-rolandic areas converge upon the same region of the neostriatum.

115.7

STIMULUS-LOCKED CHANGES IN NEURONAL ACTIVITY IN THE SUPPLEMENTARY MOTOR AREA (SMA), MOTOR CORTEX (MC), AND PUTAMEN OF THE MONKEY. M.D. Crutcher and G.E. Alexander. Dept. of Neurology, Johns Hopkins Univ. Sch. of Med., Baltimore, MD. 21205.

We have previously described neuronal activity in the SMA, MC, and putamen related to 'high level' aspects of the preparation and execution of visually guided limb movements. These studies used rhesus monkeys trained to perform a set of visually guided, delayed step-tracking tasks. During the course of those experiments, we noticed cells whose changes in activity were more closely related to the time of occurrence of the visual stimulus that triggered the movement than to the time of onset of the movement. To examine this more closely, a correlational analysis was used to determine whether changes in single-cell activity in the SMA, MC and putamen were stimulus- or movement-locked. Approximately one-third of the onsets of movement-related activity were stimulus-locked in all three motor areas (SMA, 38% (N=123); MC, 28% (N=166); Putamen, 31% (N=231)). Moreover, in each of these areas approximately one-half of the cells with preparatory activity showed stimulus-locked offsets of activity (SMA, 57% (N=67); MC, 43% (N=40); Putamen, 51% (N=53)). During the preparation and execution of visually guided limb movements the brain must translate information concerning the location of the target into appropriate patterns of muscle activation. These stimulus-locked changes in neuronal activity may represent the earliest stages of this stimulus/response transformation. Alternatively, they can be viewed as neural correlates of the initiation or 'triggering' of these highly overlearned limb movements. In either case, the fact that stimulus-locked changes in neuronal activity were seen often, and with comparable frequency, in all three structures suggests that relatively 'high' levels of motor processing are distributed across multiple components of the motor system. (Supported by NIH grant NS - 17678).

115.8

SERIAL VS. PARALLEL PROCESSING WITHIN THE PRIMATE BASAL GANGLIA-THALAMOCORTICAL 'MOTOR CIRCUIT'. G.E. Alexander and M.D. Crutcher. Dept. of Neurology, Johns Hopkins Univ. Sch. Med., Baltimore, MD 21205.

The problem of controlling visually guided limb movements can be divided analytically into sequential levels of processing that successively determine: a) target location; b) limb trajectory; c) joint kinematics; d) joint torques; and e) muscle activations. Whether the motor system employs such a serial approach, rather than parallel processing, is not known. This issue was addressed in the present study. Monkeys were trained to perform a set of motor tasks that dissociated behavioral variables related to three of the analytically defined motor processing levels (a,c,e). We recorded task-related neuronal activity in the supplementary motor area (SMA, 222 cells), motor cortex (MC, 202 cells) and putamen (317 cells). All are components of the basal ganglia-thalamocortical 'motor circuit'. We found that multiple levels of processing ('target', 'joint' and 'muscle') were represented by neuronal activity within the 'motor circuit', which argues against a direct mapping of target coordinates onto muscle activation patterns. Target-level representations were more prevalent than joint-level representations during the preparation for movement, while the pattern was reversed during movement execution. This suggests that 'higher' levels of processing are emphasized during movement *preparation*, with a shift toward 'lower' levels during *execution*. That multiple levels of processing were represented in all three structures indicates that motor processing is spatially distributed and not strictly localized or hierarchically segregated. The relative timing of onsets and offsets of task-related activity suggested a cascade of influences leading from SMA and MC to putamen. Nevertheless, both within and across structures, there was strong evidence that multiple levels of motor processing proceed concurrently, that is, *in parallel*, during both the preparation and execution of visually guided arm movements. (Supported by NIH grant NS 17678.)

SOMATOTOPY IN RAT STRIATUM MAPPED WITH ^{14}C DEOXYGLUCOSE AUTORADIOGRAPHY. L.L. Brown, S. Salinas and S.M. Feldman. Dept. of Neurology, Albert Einstein Coll. of Med. Bronx, NY 10461.

Primary sensory (SI) corticostriate projection patterns in cat show a patchy somatotopic organization in the dorsolateral striatum (Malach & Graybiel, 1986). Is somatotopic information also segregated in the rat striatum and can it be mapped functionally? Twelve adult rats were prepared for quantitative ^{14}C deoxyglucose studies and stroked with a nylon bristle which exerted a 2.5 gm force on either the forelimb, trunk or hindlimb. Serial sections were collected throughout the striatum. Autoradiograms were analyzed with an image analysis system which produced isodensity maps of the ten highest grey levels above threshold. Distinct patches were observed in the dorsolateral striatum at several anterior-posterior levels, unlike controls and the contralateral striatum. In one area, patches were observed regardless of body region stimulated. In other regions, forelimb patches were ventral and lateral to trunk and hindlimb patches. The data suggest that somatotopic information is both segregated and integrated by the striatum in the rat.

FORELIMB-CORRELATED AND VIBRISSAE-CORRELATED SINGLE UNIT ACTIVITY IN THE DORSOLATERAL STRIATUM OF THE AWAKE, FREELY MOVING RAT. R.M. Carelli, J. Crescitelli*, P. Schriever* and M.O. West. Dept. Psychology, Rutgers Univ., New Brunswick, NJ 08903.

We have previously demonstrated somatic representations in the dorsolateral striatum of the rat (Neurosci.Abstr. 14: 76, 1989). The objective of the present study was to further evaluate sensory characteristics of two types of striatal units: forelimb-correlated and vibrissae-correlated neurons. Long-Evans male rats (300g) were chronically implanted with a detachable microdrive for recording in the lateral striatum (+2.0 to -2.0 mm A-P, 3.5 to 4.5 mm M-L, and 3.0 to 6.0 mm D-V from Bregma). The first study examined the response latency of forelimb-correlated units. Electrical pulses (0.1-1.0 mA, 0.2 msec) were delivered randomly (1-10 sec intervals) through a bipolar stainless steel wire routed subcutaneously to the contralateral forelimb. Preliminary results showed a mean latency to striatal discharge of 10.5 msec (n=6). Forelimb-correlated SI cortical units in the same recording track exhibited a mean latency of 6.0 msec (n=3). In the second study, sensorimotor aspects of vibrissae-correlated units were examined. Water-deprived rats were trained to obtain water reinforcement by making a nose-poke through a notch containing a photocell beam, which involved vibrissae contact with the notch. Computer-synchronized videotape recordings (60 frames/sec) allowed the construction of peri-event histograms showing correlations between neural and behavioral events. Preliminary results suggest that vibrissae-correlated units fire rhythmically, in phase with vibrissae beating during voluntary movement (4-6 cycles/sec). Ongoing studies are examining the relationship between these rhythmic discharges and sensory discharges related to notch contact. Supported by NSF BNS-8708523, DA 04551 and PHS RR 07058-21.

PUTAMEN NEURONAL ACTIVITY ASSOCIATED WITH WRIST MOVEMENT UNDER DIFFERENT BEHAVIORAL CONDITIONS. Samuel L. Liles, Dept. of Physiology, Louisiana State Univ. Med. Ctr., New Orleans, LA 70119.

Two monkeys were trained to extend or flex the wrist in a horizontal arc in response to visual cues. A panel containing two rows of light-emitting diodes (LEDs), 32 LEDs in each row, was located in front of the monkey. The lower row provided a visual display related to wrist position, while visuo-spatial targets were presented in the upper row. Three different behavioral conditions were tested: (i) simultaneous presentation of the "go" stimulus and the visuo-spatial target; (ii) presentation of the visuo-spatial target as a prestimulus cue which remained lighted after the "go" stimulus to provide a visible target for movement; and (iii) presentation of the prestimulus cue briefly (extinguished 1-3 sec prior to the "go" stimulus), so that subsequent wrist movement was made to a "remembered" target position. Electromyographic recordings were made from 14 different muscles to verify that the patterns of muscle activity were comparable during wrist movement under these three different behavioral conditions.

The major finding is that 31 neurons in a sample of 72 exhibited enhanced tonic or phasic discharge rates during trials involving movement to a remembered target position compared to discharge rates in which the target was visible. (Supported by NIH Grant NS-22275).

TRAINED CIRCLING BEHAVIOR INDUCES FIRING RATE CHANGES IN STRIATAL AND VENTROMEDIAL THALAMIC NEURONS IN FREELY MOVING RATS. P. Patino *, M. Garcia-Munoz and C. R. Freed. SPON: (Evelyn Kriek). Depts. of Med. and Pharm., Univ. of Colorado Health Sci. Ctr., Denver, Co, 80262.

The unilateral lesion of the dopaminergic nigrostriatal pathway causes postural asymmetry and dopamine agonist induced circling behavior. Our laboratory has reported that forced locomotion increases the firing rate of nigral dopamine cells. We have now studied firing changes in the medial lateral or ventral lateral striatum (ST) and ventromedial thalamus (VMT) during trained circular locomotion. VMT receives afferents from substantia nigra pars reticulata and constitutes one of the main output pathways for this circling behavior. Rats were trained to run on a circular disk treadmill for water reward and then implanted with Parylene C coated stainless steel wires for single unit chronic recording in ST or VMT. Some units were identified antidromically in ST from SNR. Basal firing rates in ST ranged from 0.2 to 2.5 hz and respond to changes in motor activity. Many (50%) cells in ST increased their firing rates to contralateral locomotion, a few ipsilateral (2%) and a few to bilateral (25%) while others did not change firing with movement (23%). In comparison to the ST, changes in firing rate in VMT are smaller, bilateral in more cases (30%), and there are more non movement related units (26%). We have seen movement related changes in firing in ST and VMT some of which are lateralized.

ROLE OF VISUAL INFORMATION IN MONKEY PUTAMEN DURING OPERANT FEEDING MOVEMENT. M.Fukuda, T.Ono, H.Nishijo* and E.Tabuchi*, Dept. Physiol., Fac. Med., Toyama Med. and Pharmaceu. Univ., Sugitani, Toyama 930-01, Japan

We recorded single unit activity from the monkey putamen to study processing of visual information during operant feeding behavior. We divided the behavior sequence into four phases; visual, bar press, procurement, and ingestion. Of 489 neurons recorded, 119 (24.3%) responded in at least one of the four phases. Of these, 51 (10.4%) responded during the visual phase, 62 (12.7%) during bar press, 26 (5.3%) during procurement and 27 (5.5%) during ingestion. Most of the neurons that responded during bar press and procurement were probably related to movement, extension and flexion of the hand. Some neurons responded to visual stimuli, food and/or nonfood objects. For example, some neurons responded strongly at the sight of preferred food, but weakly at the sight of non-preferred food, and did not respond to nonfood. These responses depended on special situations of motor demands such as waiting, or preparing for movement, but not on reflex movement or automatic movement. These results suggest that differential responses in the putamen to visual stimuli might be related to some cognitive functions such as visual discrimination, habit, or motor control required for task execution.

CUE & MOVEMENT RELATED RESPONSES OF PALLIDAL AND NEOSTRIATAL NEURONS IN THE RAT DURING A TARGETED HEAD MOVEMENT. A.C. Moretta*, T.W. Gardiner and S.T. Kitai (SPON: L. Johannsen). Dept. Anatomy & Neurobiol., College of Medicine, Univ. Tenn. Memphis, Memphis, TN 38163.

Neuronal responses related to limb movement and to sensory cues that trigger locomotion have been described previously in the neostriatum (STR) of the rat. We have examined neuronal activity in both the STR and globus pallidus (GP) of rats performing a head movement task. Rats were trained to hold their heads centered and then to move to a left or right target in response to a sensory cue. Single-unit recordings obtained from 14 GP units and 11 STR units showed alterations in their firing patterns during this task. Six GP units and 5 STR units altered their activitiy in association with the cue for movement. Changes in activity associated with the subsequent movement were observed for 24 of the 25 units. Most movement-related responses (10 in GP, 5 in STR) were directionally specific. These results suggest that responses associated with the head movement are prevalent in both GP and STR and that neuronal activity in these structures is at least qualitatively similar to that observed in other species. 115.15

EFFECT OF ETHANOL ON MANY-NEURON ACTIVITY IN RAT NEOSTRIATUM DURING LOCOMOTOR BEHAVIOR. R.-S. Lee, N. Shimizu*, and D.J. Woodward. *Dept. of Cell Biol. and Anat., The Univ. of Texas. Southwestern Med. Ctr. at Dallas, TX 75235.*

The objective of the present study was to clarify the following: (1) how ethanol affects the general activity of neostriatal neuronal circuitry in rats, (2) how ethanol affects context dependent behavior of neostriatal neurons at different stages of the experience of treadmill (TM)-induced locomotion. Long-Evans rats (n=21) were prepared for chronic recording with 20 microwires (25 or 45 μ), which were implanted into neostriatum. Rats were trained to walk on a treadmill (30 sec on / 30 sec off). A tone served as a cue for the onset of TM. The spontaneous activity of multi-channel single units (2-6) in neostriatum was recorded extracellularly. Some neostriatal neurons were recorded daily for 2-7 weeks. The firing rate of many neostriatal neurons elevated during TM-on phase. The results demonstrated that: (1) The normally elevated unit activity during TM was suppressed by ethanol (0.8-1.4 g/kg, i.p.) on most neostriatal neurons recorded with microwires chronically, consistent with previous study that used tungsten electrodes (Soc. Neurosci. Abst. Vol. 14, 718, 1988). (2) Heterogeneous responses to ethanol were demonstrated in simultaneously recorded neostriatal neurons. The responses of some cells were unaffected or even increased, while those of the other neurons decreased. (3) Furthermore, the firing rate or pattern of neuronal activity of TM trained rats changed remarkably over 30 sec on-off intervals in which several trials expressed high activity with occasional shifts to very low or no neuronal activity after ethanol. Overall, ethanol suppressed the response of increased activity on most neostriatal neurons during TM exercise. We postulate that in the TM trained rat after ethanol there emerges a labile context "mode" switch which yields changes similar to those produced during transitions found between activity patterns in mode of " familiar" versus "novel" TM cycle intervals. *(Supported by AA-3901, DA-02838, Biol. Humanics Found.)*

REACTION TIME STUDIES IN MONKEYS WITH DAMAGE TO THE NIGROSTRIATAL DOPAMINERGIC SYSTEM. E. Trouche and P. Apicella. LNF 3, CNRS, 13402 Marseille Cedex 9, France.

In this study, we investigated the effects of striatal dopamine (DA) depletion on monkeys' reaction time (RT) performances. For this purpose, Papio papio baboons with 6-hydroxydopamine (6-OHDA)-induced lesion of the nigrostriatal DA system were tested with a variety of motor tasks involving either rapid accurate forelimb reaching towards a visual target or a similar movement with no target. In some tasks, the subjects had to choose the appropriate movement when the signal to move was given (choice RT) by a visual starting signal, the spatial location of which was randomly varied on the test panel. The results show that injections of 6-OHDA into the substantia nigra, even those resulting in small (40 to 60 %) to moderate (60 to 80 %) striatal DA depletion, disrupted the RT performances whatever the testing procedure used. The increase in RT does not seem to have been modified by the complexity of the programmed motor response or the amount of preparation for movement. This may indicate that premovement central neural processing was not impaired in the monkeys studied here. On the other hand, the extent of the lengthening of the RTs depended on the position of the trigger signal in the visual field, which shows that the severity of the movement initiation impairment can depend on the sensory context.

STRIATAL EXCITOTOXIC LESIONS CAUSE DYSKINESIAS AND CHOREA-LIKE MOVEMENTS FOLLOWING APOMORPHINE ADMINISTRATION IN NON-HUMAN PRIMATE (Papio papio). O. Isacson, P. Hantraye, D. Riche and M. Maziere. Dept. Neurology, Harvard Med. Sch., McLean Hospital, Belmont, MA 02178, CNRS, and C.E.A. Dept. de Biologie, F-91906 Orsay, France.

We have categorized the dyskinesias induced by 0.5-2.0 mg/kg apomorphine 1-82 weeks following subtotal excitotoxic lesions of the caudate-putamen in baboons (Papio papio). In parallel with behavioral studies, in vivo positron-emission tomography (PET) using labelled bromolisuride was used to assess striatal degeneration. Post-mortem histological results were compared with the dyskinetic profile in each animal. The dyskinesias appeared within 7 days after the unilateral ibotenic-acid lesion and only after pharmacological activation. The motor symptoms included dystonia, chorea-like movements, head-dyskinesia, oro-facial dyskinesia and rotation. PET-scans revealed a 30-60% reduction of the dopamine receptor ligand binding in the caudate-putamen, depending on extent of neuronal loss in this area. Post-mortem morphological analysis indicated a striking similarity with the regional neuronal and axon-sparing lesions seen in Huntington's disease, although interneurons were not spared. Our results show that a unilateral excitotoxic caudate-putamen lesion in non-human primates can produce dyskinesias, PET and post-mortem pathology not unlike that seen in Huntington's disease.

KINEMATIC DEFICITS IN PARKINSON'S DISEASE VARY AS A FUNCTION OF MOTOR TASK Nadine P. Connor, James H. Abbs and Greg S. Turner, Speech & Motor Control Lab., Waisman Center, Univ. of Wisconsin, Madison, WI 53706.

During rapid goal-directed arm movements, Parkinson's Disease (PD) subjects typically show a disproportionate reduction in peak velocity for a given movement amplitude and an increased movement duration. However, these manifestations of bradykinesia may be confounded by task variables, such as novelty or use of visual guidance. Consistent with this hypothesis, recent research suggests that these movement disturbances may not generalize to well-learned, natural movements performed without visual guidance.

This study compared jaw opening movements in six male PD subjects with those of age/sex matched controls under two conditions: 1) rapid visually-guided jaw movements toward discrete targets and 2) non-visually guided movements for speech. During visually-guided jaw movements, PD subjects manifested the same deficits previously reported for the proximal arm; namely, reduced peak-velocity/amplitude ratios relative to normal and increased duration. In contrast, these measures were not different from normal during speech movements of comparable amplitude. These results suggest that the PD motor impairment must be viewed as a complex, task-dependent disorder influenced by a variety of factors, including the degree to which sensory information is available and utilized. Supported by NIH Grants NS-13274, HD-03352, and NS-16373.

115.19

TURNING EVOKED BY STRIATAL OR CORTICAL STIMULATION: LONG "REFRACTORY PERIODS" DUE TO TRANSYNAPTIC COLLISIONS. J.S.Yeomans and K.E.Buckenham*, Dept. Psychology, University Toronto, Canada, M5S 1A1.

Frequency thresholds for turning were reduced at C-T intervals of 0.6-4.0 ms. in both cortical and striatal sites. In several sites, thresholds were also reduced at C-T intervals of 10-50 ms, which is too long to be attributed to axonal refractoriness. This late recovery was associated with large electrode tips (r=+.67) and high currents (r=+.38). When C pulses were presented via the cortical electrode and T pulses via the striatal electrode, frequency thresholds for turning decreased at short C-T intervals (0.6-4 ms). When C pulses were presented via the striatal electrode and T pulses via the cortical electrode, frequency thresholds for turning decreased at long C-T intervals (10-50 ms). This asymmetric collision suggests that one-directional synapses are interposed on the descending pathway between cortex and striatum. The size (10-40%) and C-T intervals of the late asymmetric recovery in the collision experiment were almost the same as the size and C-T intervals of the late recovery in the striatal refractory period data. The striatal electrodes showing late recovery are proposed to activate both presynaptic and postsynaptic axons. The late recovery is attributed to recovery from transynaptic action potentials occurring 10-50 ms after the C pulses.

BASAL GANGLIA AND THALAMUS II

116.1

ORGANIZATION OF PRIMATE VENTROLATERAL THALAMUS: MICROEXCITABILITY AND SENSORIMOTOR PROPERTIES. J. Ashe', J.L. Vitek', M.R. DeLong and G.E. Alexander. (SPON: R.T. Richardson). Johns Hopkins Univ., Baltimore, MD 21205.

Anatomic and physiologic studies have demonstrated that the cerebellum and basal ganglia project to different subnuclei within the ventrolateral thalamus, and these in turn project to separate cortical areas. To further characterize this region of thalamus, and to establish whether ventrolateral thalamic subnuclei have distinctive physiological properties, we carried out the following study. African Green monkeys were conditioned to permit a detailed sensorimotor exam that included passive joint rotation, muscle palpation, tactile stimulation and the elicitation of active movements of the limbs and orofacial structures. Electrode penetrations were made in parasagittal planes by an anterior oblique approach. Neuronal activity was sampled throughout each penetration and microstimulation (maximum current: 45 μA) was carried out at 250 μ intervals.

Discrete movements of the contralateral face, arm and leg, were evoked by microstimulation over a region of the thalamus, that was largely coextensive with VPLo. The pattern of microstimulation effects, and the distribution of neuronal sensorimotor response properties, revealed clear evidence of somatotopic organization.

Areas of the ventrolateral thalamus corresponding to regions that receive basal ganglia input showed little microexcitability. In contrast, areas in which microstimulation effects were prominent, appeared to correspond to regions receiving cerebellar input. The microexcitability seen in VPLo may be related to its strong functional connection to motor cortex.

116.2

ORGANIZATION OF PRIMATE VENTROLATERAL THALAMUS: NEURONAL RELATIONS TO ACTIVE AND PASSIVE LIMB MOVEMENTS. J.L. Vitek', J. Ashe', M.R. DeLong, G.E. Alexander. (SPON: D. Hanley). Dept. of Neurol., Johns Hopkins Univ., Baltimore, MD 21205.

This study was undertaken to examine the functional properties of neurons in ventrolateral thalamus in order to: 1) test the hypothesis of segregated basal ganglia and cerebellar thalamocortical circuits and 2) clarify the differential role of ventrolateral thalamic subnuclei in motor performance.

African Green monkeys were trained to perform a visuomotor step-tracking task requiring elbow flexion and extension. Torque perturbations sufficient to displace the forearm were randomly interspersed with the movement trials and monkeys were trained to permit passive somatosensory exams.

Approximately one-half of the movement-related neurons (48/95) showed unidirectional responses. Examination of the sensorimotor response properties of these unidirectional cells revealed 25 whose response properties were restricted to active and/or passive movement about the elbow or shoulder.

Elbow or shoulder specific cells located in more antero-medial penetrations (8/25) discharged only during active arm movements and all but two gave no response to torque perturbations. In contrast, shoulder (2/25) or elbow (15/25) specific cells located in more postero-lateral penetrations were responsive to both passive sensory examination and torque perturbations. The relative number of torque-responsive cells increased and the torque response latency decreased in more lateral penetrations. In the most lateral sites many of the torque response latencies were in the 7-15 ms range. Cells in this region may act to relay short latency proprioceptive input to the motor cortex. The functional differences observed between antero-medial and postero-lateral regions of ventrolateral thalamus may be explained by differential inputs to these areas from the basal ganglia and cerebellum, respectively.

116.3

CHRONIC STIMULATION OF THE VIM THALAMIC NUCLEUS SELECTIVELY INHIBITS THE PARKINSONIAN AND ESSENTIAL TREMORS IN HUMAN PATIENTS. A.L. Benabid, P. Pollak*, D.M. Gao*, L. Jeaugey*, D. Hoffmann*, C. Feuerstein. Dept. of Clin. and Biol. Neurosciences, INSERM U-318, Joseph Fourier Univ.of Grenoble, 38700 La Tronche, FRANCE.

During stereotactic procedures in non anesthetized patients suffering from Parkinson disease or essential tremor, suppression of the tremor was obtained by acute test stimulation of the nucleus ventrointermedius of the Thalamus (VIM) at high (130 Hz) frequency. This was then used as a treatment in 20 patients: VIM was chronically implanted with DBS electrodes connected to an Itrel Medtronic stimulator. Stimulation at 65 Hz was not efficient. In all patients, the tremor was consistently suppressed and the effect was maintained for as long as 2 years although the intensity of the stimulation had to be increased within acceptable limits. This increase actually reached a stable level after three months. Additionnal L-DOPA, when needed for akinesia, enhanced the effect of thalamic stimulation. Side effects were not observed at the intensities necessary for tremor suppression but when the voltage was increased, paresthesias were induced and, for even higher intensities, cerebellar dysmetria. Bilateral implantation was performed in 5 patients and in 3 the implantation was performed on the contralateral side of a previous thalamotomy. No neuropsychological deficit was observed following these bilateral procedures and old patients were successfully submitted to this procedures without complications. The mechanism of this effect is not fully understood but could be due to an inhibition of a retroactive loop in the same manner thalamotomy does. The reversibility of the effect, its possible adaptation to the particular circumstances of each patient makes this procedure very flexible and this should replace the thalamotomy in the regular surgical treament of the parkinsonian tremor. However, this effect is selective and does not work as spectacularly in other types of tremor, for which new targets, if any, should be found. Experimental approaches (including micro and semi-microelectrodes electrophysiological recordings in Macacus Monkeys and in human patients) are in progress to understand the mechanism and the characteristics of this highly efficient therapeutic effect.

116.4

DiI AS AN *IN VIVO* AND *IN VITRO* TRACER IN BASAL GANGLIA AND OTHER SYSTEMS. S. Milošević*, A.F. Sadikot, M.-C. Bélanger* and A. Parent. (SPON: L.J. Poirier) Lab. of Neurobiol, Fac. of Med., Laval Univ., Québec.

The fluorescent carbocyanine dye 1',1-dioctadecyl-3,3,3',3', tetramethylindocarbocyanine perchlorate (DiI) was used for a variety of *in vivo* and *in vitro* applications in rat CNS. Brains were cut on cryostat, freezing microtome, or vibrotome, and kept for up to 2 months in phosphate buffer saline (PBS) or PBS-30% sucrose solution, with no apparent differences in quality of fluorescent labelling. The striatonigral system was used to study applicability to anterograde and retrograde axonal transport *in vivo*. Effective injection sites limited to 50-150 microns were possible using micropipettes filled with DMSO solution of DiI either implanted into brain to allow passive diffusion, or using iontophoresis. Following injections into striatum, axon terminals and cell bodies were noted in substantia nigra at as early as 20 hours. Optimum transport of dye occurs within 5-10 days, although survival times up to 4 months also resulted in excellent labelling. Combination with tyrosine hydroxylase immuno-histochemistry gave good results in the substantia nigra. *In vitro* experiments included application of crystals into embryonic brain tissue and blood vessels of adult cerebral cortex. Application of DiI to cerebral vessels results in profuse axonal labelling but no cell labelling was seen with diffusion times as long as 4 months. However, following application of DiI to adult cortical surfaces labelling of cell bodies was observed due to uptake of dye by thick apical dendrites. In embryonic tissue, excellent axonal labelling was obtained following application of DiI, with retrograde labelling of cell bodies in visual and olfactory systems.

116.5

DIFFERENTIAL PROJECTIONS OF CENTRE MEDIAN AND PARAFASCICULAR NUCLEI IN SQUIRREL MONKEY. A.F. Sadikot and A. Parent, Lab. of Neurobiol., Fac. of Med., Laval Univ., Québec, Canada.

Efferent projections of the centre median (CM) and parafascicular (PF) thalamic nuclei were examined in 3 squirrel monkeys (*Saimiri sciureus*), using anterograde transport of lectin-conjugated horseradish peroxidase(WGA-HRP) in one case and *Phaseolus vulgaris*-leucoagglutinin (PHA-L) in two cases. Striatal distribution of calbindin-28K, prosomatostatin, tyrosine hydroxylase and acetylcholinesterase was examined on a few sections from each case to delineate patch-matrix compartments. Efferents to the striatum are principally distributed to the matrix compartment. The putamen receives a dense projection from the CM, which is organized in the form of bands in the dorsolateral putamen, becoming patchy at more caudal levels. Striatal inputs from the Pf are found more rostrally, supplying principally the ventromedial putamen, ventrolateral caudate and tail of the caudate, lateral nucleus accumbens, and olfactory tubercle. Both pallidal segments receive inputs from CM and Pf nuclei; CM efferents terminate preferentially in the external segment, whereas Pf efferents preferentially supply the internal segment. Other basal forebrain areas receiving parafascicular inputs include the septum, islands of Calleja, ventral pallidum, nucleus basalis of Meynert and amygdala. Projections from the CM or Pf nuclei are also seen in the hypothalamus, substantia nigra, ventral tegmental area, retrorubral field, deep layers of the superior colliculus, and peribrachial tegmentum. The results suggest that in the primate, the CM nucleus projects principally to motor areas of the basal forebrain, whereas the Pf nucleus projects principally to limbic-associative areas.

116.6

EVIDENCE FOR COLLATERALIZATION OF THE PROJECTION FROM PARAFASCICULAR NUCLEUS TO GLOBUS PALLIDUS AND CAUDATE-PUTAMEN IN THE RAT. A.E.Kincaid, S.W.Newman, A.B.Young and J.B. Penney, Jr. Dept. of Anat. and Cell Bio. and Dept. of Neuro. Univ. of Michigan Medical School, Ann Arbor, MI 48109.

The parafascicular nucleus (PF) of the thalamus, one of the intralaminar nuclei, is known to project to the caudate-putamen (CPu), subthalamic nucleus (STN) and cortex (Cx), but has not been shown to project to the globus pallidus (GP) of the rat. We have presented evidence for a projection from the PF to the GP of the rat. To test the hypothesis that the axons from PF to GP are collaterals from the PF to CPu projection, we injected fluorescent retrograde tracers into the GP and CPu. Adult, male Sprague-Dawley rats received iontophoretic injections of Fluoro-gold (FG) into GP and pressure injections of rhodamine-filled microspheres in CPu. Four days later, animals were perfused and their brains processed for microscopy. Slides were viewed on a fluorescence microscope and double-labeled neurons were identified on the same section; FG-labeled cells under UV light excitation, and rhodamine-labeled cells under green light excitation. A substantial population of double-labeled neurons were noted in the PF following these injections. Not all neurons that project to the GP and the CPu from the PF, as determined by our injections, were double-labeled. Supported by NIH NS20629 to SWN and NIH NS19613 to ABY and JBP.

BASAL GANGLIA $GABA_A$ AND BENZODIAZEPINE RECEPTORS AFTER IBOTENIC ACID LESIONS OF INTRALAMINAR THALAMUS. K. O'Mara*, A.B. Young and J.B. Penney (SPON: M.B. Bromberg). Dept. of Neurology, University of Michigan, Ann Arbor, MI 48109.

The rat parafascicular thalamic nucleus provides a major input to striatum. We have found compensatory $GABA_A$ and benzodiazepine receptor changes in basal ganglia after lesions of striatum (Pan et al., J. Neurosci. 3:1189, 1983), substantia nigra (Pan et al., J. Neurochem. 45:1396, 1985) and cortex. To study the effects of parafascicular lesions, 10 μg in 1 μl of ibotenic acid was infused over 8 min 20 sec at 2.9 mm caudal, 6.0 mm ventral and 1.0 mm lateral to bregma into the parafascicular nucleus. Eight weeks later autoradiographic saturation assays of $GABA_A$ (15 - 90 nmol [^{3}H]muscimol) and benzodiazepine (2.5 - 25 nmol [^{3}H]flunitrazepam) receptors were performed on striatum, globus pallidus, entopeduncular nucleus, substantia nigra and ventromedial/ventrolateral thalamus. No changes were found in B_{Max} or K_d of either ligand in any region. These findings suggest that parafascicular input does not greatly influence striatal GABAergic output.

Supported by NS 19613.

116.8

DIRECT STRIATO-THALAMIC PROJECTIONS IN NEONATAL RATS. M.S. Nishihama*, M. Takada, T. Moriizumi* and T. Hattori.Dept. of Anatomy, Univ. of Toronto, Toronto, Ontario M5S 1A8, Canada.

In the course of investigation on the development of the basal ganglia-related neuronal connections, we have found direct projections from the striatum to the thalamus in neonatal rats. Following WGA-HRP injections into the core of the striatum at postnatal day 0 (P0), anterogradely labeled axon terminals were observed ipsilaterally in the ventrolateral (VL), ventrobasal (VB), centrolateral (CL) and parafascicular (Pf) thalamic nuclei at P1. By contrast, WGA-HRP deposits in the overlying cortex as control labeled terminals only in the VB. Moreover, thalamic injections of a fluorescent retrograde tracer Fluoro-gold (FG) at P0 resulted in perikaryal labeling in the ipsilateral striatum at P1. These FG-positive cells were aggregated in a mosaic fashion similar to the patchy distribution characteristic of perinatal striato-nigral projection cells (J. Neurosci., 7:1969, 1987). Thus, the present data provide evidence that the neonatal rat striatum has efferents projecting outside the basal ganglia (at least to the VL, CL and Pf of the thalamus). Since no available studies have previously suggested the existence of direct striato-thalamic projections in the adult, this novel pathway might transiently appear during development. Supported by the MRC of Canada.

116.9

THALAMIC AFFERENTS FROM THE ENTOPEDUNCULAR NUCLEUS IN THE DOG. B.A. Hannah* and S.T. Sakai (SPON: J. Krier) Department of Anatomy, Michigan State University, East Lansing, MI 48824.

As part of our ongoing studies on the organization of the motor control pathways, the present study investigated the distribution of the entopeduncular (EP) efferents to the canine thalamus using the autoradiographic (ARG) tracing technique. A series of tritiated amino acid injections were made into the EP in anesthetized dogs. Labeled fibers were observed emanating from the EP toward the thalamus within the ansa lenticularis and the fasciculus lenticularis. Silver grains were observed throughout a wide extent in the ipsilateral thalamus including the ventral anterior nucleus (VA) and the ventromedial nucleus (VM). Heavy ARG label was observed in the lateral habenular nucleus (HL) and the centromedian (CM) and parafascicular (Pf) nuclei. In addition, labeled fibers were observed in the massa intermedia distributing to the contralateral VM, CM and HL.

It is of interest that the pallidothalamic regions of VA, VM and the caudal intralaminar nuclei labeled in the present study appear to coincide in location with the thalamic regions known to project to area 6 in the dog (Stanton et. al. 1986). Moreover, comparison of the present results with our data on the canine nigrothalamocortical projections suggest that area 6 may receive ascending inputs from two basal ganglia sources: the entopeduncular nucleus and the substantia nigra.

THE DISTRIBUTION OF THE NIGROTHALAMOCORTICAL PROJECTIONS IN THE DOG: A COMBINED HORSERADISH PEROXIDASE AND AUTORADIOGRAPHIC STUDY. S.T. Sakai Department of Anatomy, Michigan State University, East Lansing, MI 48824.

The purpose of the present study was to determine the extent to which the canine area 6 thalamocortical projections receive inputs originating from the substantia nigra (SN). In the anesthetized dog, a series of tritiated amino acid injections were made into the SN . At the same time, a series of horseradish peroxidase (HRP) injections were made into area 6. The HRP labeled area 6 thalamocortical neurons were found to be coextensive with nigrothalamic autoradiographic (ARG) label in the ventral anterior nucleus (VA), ventromedial nucleus (VM), mediodorsal nucleus (MD) and parafascicular nucleus (Pf). However, HRP labeled cells were also observed in the ventral lateral nucleus (VL) in a region where no ARG label was observed. In addition, both VA and VM contained areas of dense ARG label where no HRP filled cells were observed. While these results suggest that area 6 receives indirect input from the SN via the thalamus, comparison of these results with our previous data obtained from the cerebellothalamic and pallidothalamic projections suggest that area 6 may also receive inputs originating from these additional sources. Finally, the possibility remains that an additional cortical target of the nigrothalamic projections exists. This region may include the prefrontal cortex. In the monkey, Ilinsky et. al. (1985) demonstrated nigrothalamic afferents to the prefrontal cortex as well as the supplementary motor area and the frontal eye fields.

NEURONAL AND SYNAPTIC ORGANIZATION OF THE VENTRAL ANTERIOR NUCLEUS PARS MAGNOCELLULARIS (VAmc) OF THE MACACA MULATTA THALAMUS. I.A. Ilinsky and K. Kultas-Ilinsky, Dept. of Anatomy, Univ. of Iowa Coll. Med., Iowa City, IA 52242.

The magnocellular subdivision of the ventral anterior nucleus is recognized only in primates. It receives nigrothalamic projections throughout its extent and is reciprocally connected with the prefrontal cortex (Ilinsky et al., JCN 236:315-330, 1985). No data are available on physiological characteristics or ultrastructural organization of this nucleus and its functional significance remains obscure. The goal of this study was to provide neuroanatomical data on organization of neuronal circuitry in the VAmc. A variety of techniques including antero- and retrograde HRP labeling, EM-autoradiography and GAD-immunocytochemistry were used. Two major cell types were identified: thalamocortical projection neurons (PN) and small GAD-positive cells, apparently local circuit neurons (LCN). The major input to PN was from nigral afferents distributed to the soma and all levels of dendritic arbor with the heaviest concentration on secondary branches and bifurcation sites. These boutons formed symmetrical synapses and were all GAD positive. PN somata received also sparse indirect cortical input mediated by GABAergic dendrosomatic synapses and symmetrical synapses from boutons of unknown origin on axon hillocks and initial axonal segments. Corticothalamic terminals provided major input to PN tertiary dendrites with only some boutons contacting secondary dendrites directly and indirectly through LCN dendro-dendritic synapses. Two additional very sparse populations of synaptic boutons of unknown origin were observed on distal PN dendrites. LCN received mainly cortical and very sparse nigral input on their distal dendrites plus a symmetrical synapse from a large bouton of unidentified origin on soma. The results suggest the prevalence of inhibitory input from various sources on PN without obvious strategically placed excitatory input which could drive these cells. Supported by NS RO1 24188.

AUTORADIOGRAPHY OF GABA AND BENZODIAZEPINE RECEPTORS IN THE MONKEY MOTOR THALAMUS. K. Kultas-Ilinsky, J. Kallsen*, S. Tewfik*, L. Freedman and I.A. Ilinsky. Dept. of Anat., Univ. of Iowa, Iowa City, IA 52242.

Quantitative receptor binding autoradiography technique was used to study subtypes of GABA and benzodiazepine receptors in projection zones of basal ganglia and cerebellar afferents to the thalamus in two species of subhuman primates: Macaca Rhesus and Erythrocebus pates. The binding assays were carried out as described by Kultas-Ilinsky et al. (1987, Brain Res., 459:1-16) using [^{3}H]-muscimol ([^{3}H]MUS), [^{3}H]-flunitrazepam ([^{3}H]FLU)], [^{3}H]-baclofen and [^{3}H]-bicuculline. Consistently saturable specific binding was obtained only with [^{3}H]FLU and [^{3}H]MUS. Bicuculline (10 μM) inhibited [^{3}H]MUS binding by 30-50% in different nuclei but enhanced [^{3}H]FLU binding (17-30%). Enhancement of [^{3}H]FLU binding by 10 μM GABA was more pronounced (20-40%). No substantial differences between the two monkey species were detected in the distribution and binding parameters of receptors. In both, the highest number of [^{3}H]FLU and [^{3}H]MUS binding sites was found in the nigrothalamic projection zone (VAmc). In the nuclei receiving pallidal (VAdc and VApc) and cerebellar (VL) input the Bmax values for both ligands were lower. Binding affinities were comparable in all nuclei analyzed (KD = 2-3 nM for [^{3}H]FLU and KD = 36.9 nM for [^{3}H]MUS). When compared to our previous data on the GABA receptor binding in the cat motor thalamus several differences could be noted. The most significant: the higher concentration of both binding sites in the nigral projection zone compared to pallidal, little difference between thalamic nuclei with respect to [^{3}H]MUS/[^{3}H]FLU binding site ratio, and overall lower [^{3}H]MUS binding affinity. The differences in GABA receptor distribution between the feline and primate thalami may be related to differences in topography of subcortical afferents and neuronal organization of the nuclei in these species. Supported by NSRO119280.

THERMAL DEPENDENCE OF INDUCTION AND EXPRESSION OF LONG-TERM POTENTIATION IN THE HAMSTER HIPPOCAMPAL SLICE. M.P. Thomas*, M.S. Krelstein*, and J.M. Horowitz, Animal Physiol., Univ. Calif. Davis, CA 95616. (SPON: P.Pappone)

The mechanisms involved in the induction of long-term potentiation (LTP) differ from those involved in its maintenance. We investigated the thermal sensitivity of the induction process and the initial expression of LTP. We prepared hippocampal slices from hamsters as described previously (Thomas et al. J. therm. Biol. 11:213, 1986) and measured field PSP initial slopes in response to Schaffer collateral/commissural fiber stimulation. Bath temperature was varied via an external water bath. LTP was reliably evoked above 25°C by high-frequency pulse train stimulation, and could not be evoked below 20°C. However, when a high-frequency train was delivered to slices at a bath temperature of 20°C and the slice subsequently warmed to 25°C, LTP was observed relative to control responses recorded previously at 25°C. Furthermore, when LTP was elicited at a bath temperature of 25°C, it persisted when the slices were cooled to 20°C (determined by comparing post-tetanic responses with control responses recorded previously at 20°C). In summary, the first experiments show that when the temperature is held at 20°C the process is initiated but then arrested. The second set of experiments show that once expressed at a higher temperature, the synaptic enhancement persists when the tissue is cooled. [NSF grant BNS-88-19973.]

ULTRASTRUCTURAL AND IMMUNOHISTOCHEMICAL OBSERVATIONS ON A PROJECTION FROM THE MAGNOCELLULAR BASAL NUCLEUS TO THE THALAMIC RETICULAR NUCLEUS IN RATS. by L.L. Porter and C. Asanuma. Department of Anatomy, USUHS, Bethesda, MD, 20814 and Laboratory of Neurophysiology, NIMH, Poolesville, MD, 20837.

We have examined some details of the projection from the caudal magnocellular basal nucleus (cMBN) to the thalamic reticular nucleus (TRN) in rats. Axons of this pathway are known to give rise to clusters of boutons apposing TRN somata and 'en-passant' beads upon TRN dendrites.

The terminal boutons of the cMBN ⇒ TRN pathway were examined at the EM level following PHA-L injections into the cMBN. Following the immunohistochemical processing, many PHA-L positive terminal profiles are apparent within the TRN. Labeled axonal terminals frequently synapse upon both somata and proximal dendrites of TRN neurons, with symmetric membrane specializations. These may, therefore, differ from the ChAT positive synapses within the TRN which are asymmetric and terminate upon distal dendritic processes.

Following WGA-HRP injections into the TRN, neurons were identified within the cMBN that are both retrogradely labeled and positive for GABA. Such doubly labeled neurons occur in the same general cMBN region as ChAT positive neurons that project to the TRN.

Thus, a portion of the cMBN ⇒ TRN projection synapses directly upon the somata and proximal dendrites of TRN neurons with symmetric membrane specializations, and some of the cells giving rise to this projection are GABAergic. We infer from these observations that at least a portion of the cMBN ⇒ TRN projection is GABAergic. Since GABA iontophoresis inhibits TRN spike activity presumably by increasing chloride ion permeability (McCormick, D.A., & Prince, D.A., *Nature* 319: 402, 1986), this pathway may, in part, serve to directly 'shunt' the excitability of TRN neurons at their somata and proximal dendrites. Further work is needed to understand the physiology of this projection and its relation to thalamic gating functions.

NEURAL CONNECTIONS OF THE SUPRACHIASMATIC NUCLEUS WITH MIDLINE THALAMIC NUCLEI B.G.Orpen, Z.Woskowska*, M.O.Miceli and M.Steiner. St.Joseph's Hospital Research Institute, and Dept.of Psychiatry and Biomedical Sciences, McMaster University, Hamilton, Ontario, Canada.

The suprachiasmatic (SCN) and adjacent hypothalamic nuclei project to several midline thalamic nuclei. The thalamic nuclei project in turn to the limbic system and striatum, and are thus in a position to modulate circadian time-keeping information. We used the neural tracer, horseradish peroxidase-wheat germ agglutinin (HRP-WGA), to study in more detail the afferent and efferent neural connections of the midline thalamic nuclei in the golden hamster, Mesocricetus auratus, with particular emphasis on connections with the SCN and adjacent hypothalamic nuclei.

Hamsters injected with HRP-WGA were sacrificed after 24-48 hours. The brains were then processed using tetramethyl benzidine histochemistry. Five subjects sustained small, confined injections in the paratenial (PT) and paraventricular (PVT) thalamic nuclei. The remaining five animals sustained larger thalamic injections, which incorporated much of the anterior-posterior and lateral extent of the PT and PVT, and, in some instances, the paracentral and reuniens thalamic nuclei. Control injections included the immediately dorsal cortex, septum-fornix and the adjacent bed nucleus of the stria terminalis.

After confined injections, only a few labelled cells and terminals were observed in the SCN; after larger injections, many labelled SCN cells, but only a few terminals were observed. This pattern suggests that each SCN cell projects to only a small area in the PVT and/or PT. Labelling was uniformly distributed in the anterior SCN, but was confined to the ventral and lateral portions of the mid- to posterior SCN. These findings will be discussed in relation to labelling of other potential components of the circadian rhythm system.

ADAPTIVE CHANGES IN BINAURAL TUNING OF NEURONS IN THE OPTIC TECTUM OF BARN OWLS RAISED WITH ALTERED EXTERNAL EARS. J.F. Olsen* and E.I. Knudsen (SPON: T. Iismaa). Dept. Neurobiol., Stanford Univ., Stanford, CA 94305

Experiments in which barn owls were raised with monaural earplugs have shown that the auditory space map in the optic tectum can be modified in response to altered cues for sound localization (Knudsen, 1983). Here we show that the tuning of tectal neurons to interaural differences in time (ITD) and intensity (IID), measured directly with dichotic stimuli, is altered adaptively when owls are raised with abnormal external ears. The direction-dependent sensitivities of the ears were changed radically by removing the ruff feathers and preaural flaps before they grew in. After the owls reached adult size, ITDs and IIDs were measured with microphones in the ear canals. Although ITDs varied with azimuth, as found in normal owls, the change in ITD with azimuth was faster than normal for frontal source locations (out to 40° azimuth), and was slower than normal peripherally. This abnormal pattern of ITD variation correlated with an adaptive change in ITD tuning of tectal neurons: For bimodal units with visual receptive fields within the frontal 40°,best ITDs changed faster with visual best azimuth in ruff-cut owls than in normal owls. In normal owls, IID cues vary primarily with source elevation. In ruff-cut owls, IID cues varied primarily with azimuth, and spanned an abnormally small range. Unit tuning to IID was altered in ruff-cut owls: In general, best IIDs varied with best azimuth but not with best elevation, a pattern opposite to normal. However, for units that had best azimuths within 15° of the vertical meridian, best IID varied with best elevation. Thus, despite severely altered cues, units that represent the vertical meridian developed a nearly normal pattern of IID tuning. NIH grant R01 NS 16099-09.

117.2

CALLOSAL AND THALAMOCORTICAL TERMINAL FIELDS IN PRIMARY AUDITORY CORTEX OF DEVELOPING RATS. R. T. Robertson, K. A. Gallardo* and J. Yu. Depts. of Anatomy and Neurobiology and Physical Medicine and Rehabilitation, University of California, Irvine, CA 92717.

We have examined the areal and laminar distributions of callosal and thalamocortical terminal fields in primary auditory cortex of developing rat pups. Infant Sprague-Dawley rat pups, 6-11 days of age, were anesthetized and injections of 10% HRP were made unilaterally in auditory cortex. Following survival periods of 1-2 days, animals were perfused and frozen sections were processed for HRP or AChE histochemistry. Callosal terminal fields were identified by anterograde transport of HRP; thalamocortical terminal fields were identified by endogenous AChE activity.

Injection sites within primary auditory cortex (cortical area 41) were identified by strong retrograde labeling of neurons in the ipsilateral ventral medial geniculate nucleus. In animals sacrificed before postnatal day 10, contralateral auditory cortex showed widespread retrograde and anterograde HRP labeling; the areal pattern overlapped extensively with AChE staining. However, HRP labeling was most pronounced in cortical layers II/III and V while AChE labeling was most pronounced in layer IV. In animals sacrificed after day 12, anterogradely transported HRP also occurred in layer II/III and V, but the areal pattern appeared patchy, occuring mainly in regions other than those displaying prominant AChE staining. These data indicate that after an initital "exuberant" phase, callosal terminal fields reduce to complement the geniculocortical terminal fields in auditory cortex.

RAPID MITOCHONDRIAL RESPONSE TO COCHLEA REMOVAL IN CHICKEN BRAIN STEM AUDITORY NEURONS. G.E. Hyde* and D. Durham. Hearing Development Labs, RL-30, U. of W., Seattle, WA 98195

Removal of excitatory input to second order auditory neurons (n. magnocellularis, NM) in the chicken brain stem results in rapid *increases* in the activity of mitochondrial enzymes as early as 6 hours after cochlea removal. Light microscopic results of histochemical staining for cytochrome oxidase (CO) suggest that mitochondria may also be redistributed within the neuronal soma as a result of cochlea removal. An ultrastructural study was done on chicks surviving 6 hours or 14 days after unilateral cochlea removal at 10 days of age. Vibratome sections of the brain stem were incubated for CO histochemistry followed by preparation of thin sections. Because the cochlear ganglion cells project to the ipsilateral NM, the contralateral NM was used as a within-animal control.

Six hours following cochlea removal, neurons in the ipsilateral NM show *proliferating* mitochondria. Stereologic measurements show at least a 53% (±4% S.E.M.) increase in mitochondrial surface density in ipsilateral NM neurons compared to contralateral neurons. In addition, a greater percentage of cristae within the proliferating mitochondria contain CO reaction product. A small sub-population of NM neurons ipsilateral to cochlea removal shows neither mitochondrial proliferation nor increased CO staining; these neurons also exhibit polyribosome dissociation as described by Rubel et al. (Soc. Neurosci. Abstr. 14:1117, 1988). At 14 days survival, there is a *decrease* in the number and CO staining of mitochondria in NM neurons ipsilateral to cochlea removal. At this time, the number of lipid-containing vacuoles, which may represent products of mitochondrial degradation, is increased within the ipsilateral NM neurons. (Supported by PHS grants NS26521, NS07246, NS24518)

DEVELOPMENT OF ACTION POTENTIALS OF EMBRYONIC CHICK COCHLEAR GANGLION CELLS *IN VITRO*. R. Batra and K. Book*. Dept. of Anatomy, Univ. of Conn. Health Cntr., Farmington, CT 06032.

Earlier studies have shown that embryonic neurons from a sensory ganglion can produce action potentials mediated by a combination of sodium and calcium ions, or by sodium alone. In some cases, a transition from sodium-calcium to sodium action potentials occurs during development. The present *in vitro* study of the cochlear ganglion of the chick provides evidence that ganglion cells with sodium-calcium action potentials and those with sodium action potentials coexist at intermediate stages of development. Intracellular recordings were made from cochlear ganglion cells of white leghorn embryos explanted during the period when cochlear nerve fibers begin to innervate hair cells (embryonic day 9-15, Hamburger-Hamilton St. 35-41). The neurons were grown for various lengths of time *in vitro* prior to recording.

In response to a positive step of current (50-300 pA), an explanted ganglion cell exhibited its characteristic action potential, which could be of one of two types. The first type of action potential had a rapid rise followed by a broad plateau that could last tens of milliseconds. It resembled action potentials produced by a combination of sodium and calcium currents. The second type consisted of a rapidly rising spike that was brief (~1-3 ms) and resembled action potentials produced by sodium currents alone. Greater steps of current produced a burst of action potentials in some cells, but others always fired only one action potential at the onset of the step. Ganglion cells did not fire action potentials spontaneously.

The two types of action potentials may represent two different populations of neurons or the same population at different stages of development. To distinguish these possibilities, we are presently recording from cochlear ganglion cells explanted later in development and from the cells of the cochleo-vestibular ganglion at the earliest stages of differentiation.

117.5

VISUAL OR AUDITORY DEPRIVATION PREVENTS THE EMERGENCE OF AN ELECTROPHYSIOLOGICAL MAP OF AUDITORY SPACE IN THE GUINEA PIG.
D.J. Withington-Wray* & M.J. Keating* (SPON: Brain Research Association). National Institute for Medical Research, London NW7 1AA, UK.

Multi-unit electrophysiological recording from the superior colliculus of the guinea pig shows that the emergence of an auditory space map follows a protracted postnatal course. Spatially diffuse auditory responses are present on the first day after birth (DAB). Localized response areas and a topographic map do not appear until 32 DAB. Animals were reared from birth in either total darkness or in a chamber providing continuous omnidirectional white noise and mapped between 34-67 DAB. They showed no evidence of an auditory space map and their responses were similar to those of normal animals shortly after birth. The results of experiments in which the sensory deprivation was limited to particular developmental periods indicate that, for both visual and auditory peturbation, the period from 26-30 DAB represents a critical susceptible period. These data are compatible with the view that the normal elaboration of the auditory space map requires coincident visual and auditory sensory input.

117.6

DEVELOPMENTAL SHIFT OF THE TONOTOPIC ORGANIZATION OF THE CHICK AUDITORY CORTEX ANALOGUE.
P.Heil and H. Scheich. Inst. Zoology, Techn. Univ., 6100 Darmstadt, F.R.G.

A developmental shift of the place coding of sound frequencies along the basilar papilla has been proposed as one solution of the discrepancy between the morphological maturation of the cochlea, which starts at the base and proceeds to the apex, and the physiological and behavioral ontogeny of hearing, initiating at low and progressing to higher frequencies (Rubel, E.W., in Handbook of Sensory Physiology IX:135, 1978). If with age no rewiring of the frequency-specific projections occurs along the auditory system, concomitant developmental shifts of tonotopic organizations should be demonstrable in higher auditory centers. We therefore mapped the tonotopic organizaion of field L, the chick auditory cortex analogue, using the (14C)-2-deoxyglucose (2DG) technique. Methods of stimulation and quantitative densimetric analysis were described elsewhere (Heil, P. and Scheich, H., Exp. Brain Res. 58:532, 1985). In each of the three postnatal ages examined (P0, P7, P27) there was a clear tonotopic gradient. But during this first postnatal month basically all 2DG-isofrequency contours shifted continuously and significantly (up to 8%) to relative positions, where formerly lower frequencies were represented. These results are likely to indicate changes in best frequencies of individual neurons. Furthermore, this first demonstration of a developmental change in the place coding of sound frequencies at the forebrain level raises the question of constancy of perceptual correlates with age.

A PROPOSED MECHANISM FOR HYPERPLASTIC GROWTH OF THE OLFACTORY RECEPTOR SHEET IN GROWING RATS.
E. Meisami, M.A. Paternostro and M.J. Sichlau*. Dept. of Physiology, Univ. Illinois, Urbana, IL 61801.

Rat olfactory epithelium (OE) grows continuously by hyperplastic expansion and thickening (Meisami, Dev. Brain Research, 46: 9-19, '89). From birth to day 90, OE surface area increases 23x, total number and surface density of olfactory receptor neurons [ORN] increase 26x and 1.8x; OE thickness 1.5x. Total numbers of basal and supporting cells increase as well but their density per unit OE surface area remains unchanged. We propose that OE hyperplastic growth occurs by two mechanisms: first, a horizontal growth accompanied by a proliferative division of basal cells; this is the major source of expansion and hyperplasia. Second, a vertical growth, caused by a differentiative division of basal cells, resulting in ORN accretion and OE thickening. Morphometric and topological analyses reveal that OE growth between days 1 to 90 occurs across both septal and turbinal surfaces (10x and 30x, respectively). Relative contribution of turbinate OE to total OE increases from 69% at birth to 82% at day 90. At all ages, about 90% of total OE is found in the heavily turbinated middle and posterior olfactory regions, even though absolute amount of growth in these areas is very marked, compared to anterior areas. The results indicate a "ballooning" pattern of growth in all OE areas.

IDENTIFIED MAMMALIAN OLFACTORY RECEPTOR NEURONS IN CELL CULTURE.
P.Q. Trombley† and G.L. Westbrook. †Dept. Biology, Univ. of Oregon, & Vollum Institute, Oregon Health Sciences Univ., Portland, OR.

Recent studies in vivo suggest that the glomerular layer of the olfactory bulb, the site of olfactory receptor neuron (OR) input to Mitral cells, shows significant alterations during olfactory learning. Thus detailed physiological studies of this excitatory synapse could be of importance to an understanding of synaptic plasticity in this brain region. In order to examine this synapse, we have first established primary cultures of OR cells and examined their voltage-dependent conductances. OR cells were identified by retrograde transport of rhodamine labelled latex beads. Beads were injected into the olfactory bulbs of 2-5 day postnatal rats; 48 hours after injection, the olfactory epithelia were dissociated and plated on a confluent layer of olfactory bulb astrocytes.

ORs could be identified morphologically as small bipolar cells with a fine axon on one end and a thick dendritic process on the other, some with cilia. These cells were stained by antibodies against neuron specific enolase, while a smaller proportion were stained by antibodies against olfactory marker protein (OMP); most OMP(+) cells also contained rhodamine beads suggesting that these were mature OR cells. Whole-cell recordings from both fluorescent-labelled and unlabelled OR cells after 3-25 days in culture were similar. In physiological saline, the apparent input resistance was 1-10 GΩ and the OR cells fired a single action potential in response to depolarizing current injection. The spike was abolished by 100 nM TTX. Under voltage clamp, depolarizing steps from -80mV revealed: 1) a fast inward current with steady-state inactivation which was TTX-sensitive and Cd-insensitive 2) a slow persistent inward current in 10 mM Ba which was TTX-insensitive and washed out over 1-2 minutes (with 1 mM ATP /0.1 mM GTP in the pipette); 3) a persistent outward current activated at steps positive to -10mV which was blocked by 25mM TEA or intracellular Cs, but unaffected by 100 µM Cd. No transient outward current or Ca-K current(s) were seen under these conditions. Supported by NIH and the McKnight Foundation.

117.9

INFLUENCE OF OLFACTORY PLACODE TRANSPLANTS ON THE DEVELOPMENT OF THE OLFACTORY BULB IN *XENOPUS LAEVIS*.
C.A. Byrd and G.D. Burd. Dept. of Molecular and Cellular Biology, University of Arizona, Tucson, AZ 85721.

Olfactory receptor cell axons may play an inductive role in the development of the olfactory bulb (OB). When an extra olfactory placode is added to *Xenopus* embryos, the OB that develops appears to be larger than normal (Stout and Graziadei, 1980). To determine how the primary afferents affect development in this system, we quantified afferent innervation to and neuron number in the OB. Olfactory placodes were transplanted into *Xenopus* embryos (stages 28-32) so that the resulting epithelium would innervate the OB. Animals with successful transplants (i.e. those with a nerve innervating the OB) were sacrificed just before metamorphosis. The transplanted tissue developed into a closed epithelium that contained the same cell types found in normal olfactory epithelium--basal cells, receptor cells, and two types of supporting cells. Axon counts were performed to determine the number of axons innervating the OB in normal and transplant animals. We found that animals with a transplant did not have more afferents innervating the OB, even though there was an extra nerve. The possibility that there are more afferents in transplant animals earlier in development is being explored. We also counted the cells in the mitral cell/external plexiform layer (MCL/EPL) in normal and transplant animals in an effort to determine whether the output neurons (mitral/tufted cells) are influenced by the transplant. Preliminary results suggest that the transplant can cause an increase in neuron number in the MCL/EPL, but it does not have an effect in all cases.

THE DEVELOPMENT OF ELECTRO- AND MECHANORECEPTORS IN EIGENMANNIA IS INDUCED BY INNERVATION OF EPIDERMAL CELLS.
H.A.Vischer and W.Heiligenberg. SIO, Neurobiol. Unit, UCSD, La Jolla, CA 92093.

Gymnotiform fish of the genus Eigenmannia were induced to spawn under laboratory conditions. In order to visualize outgrowing nerves of the anterior lateral line ganglion (ALLG), primordial cells of the ALLG were labeled with the fluorescent dye DiI in embryos (2-3 days after spawning, 55-75 somites). Labeled rami of the anterior lateral line nerve (ALLN) were ablated 12-48 hours later with a short (t<500 ms), high-intensity (U>1500V) electric current pulse applied through an Indium-filled electrode. In a significant number of cases (90%; n=15), no lateral line receptors developed in those areas which are normally innervated by the lesioned rami. In another set of experiments, more than 90 cells were labeled iontophoretically with Lysinated Rhodamine Dextran in the vicinity of the ALLG primordium in a total of 30 embryos, 2-3 days old. 4-8 days later, traces of the marker could only be found in neural crest-derived cells, such as melanophores, but not in any lateral line receptor cells. We conclude: 1) Cephalic mechano-and electroreceptors have no placodal origin and 2) innervation is essential for the formation of anterior lateral line receptors.

117.11

CRUSTACEAN PROPRIOCEPTOR ORGAN RETAINS NORMAL SENSORY RESPONSES IN CULTURE. H. B. Hartman, S. N. Wright* and R. L. Cooper. Department of Biology, Duquesne Univ., Pittsburgh, PA 15282 and Biocenter, Univ. of Basel, CH 4056 Basel, Switzerland.

The crustacean proprioceptor, the propus-dactylus organ (PD), can be maintained in culture in either crab serum with gentamicin added or in defined medium at 11°C for at least 10 days without loss of patterned sensory activity. Blood from Dungeness crabs Cancer magister was pooled, then chilled to form a clot which was discarded. Serum was sterilized by filtration. The defined medium consists of crab saline, L-15 medium Leibovitz, BSA, gentamicin, and HEPES buffer adjusted to 950 mOsm/l at pH 7.3 which was sterilized by filtration.

The PD organ distal cuticular protuberance and proximal tendon were pinned firmly to the bottom of a Sylgard-lined glass Petri dish with the elastic strand stretched between them to approximate its normal rest length. Survival of the sensory neurons in the two media was assayed in the following manner. Action potentials were recorded daily from selected identified movement sensitive neurons (both ESC and RSC), the entire position nerve, and a nerve containing a subset of movement sensitive neurons over a period of 10 days. The responses quantified by the statistical index eta^2 remained normal for the test period. PD organs from early juvenile crabs where sensory hyperplasia is known to occur (Hartman and Cooper, in preparation) are being cultured and examined for growth cone formation. Supported by NSF Grant BNS-8700506 to H.B.H.

MORPHOLOGIC AND ELECTROPHYSIOLOGIC CHARACTERISTICS OF RAT NODOSE GANGLION NEURONS CO-CULTURED WITH CAROTID BODY CELLS J. Alcayaga* and C. Eyzaguirre (SPON: P. Zapata). Dept. Physiol., Univ. Utah Sch. Med., Salt Lake City, UT 84108

Nodose ganglion (NG) neurons and carotid body (CB) cells obtained by enzymatic dissociation were plated on poly-lysine, collagen, or fibronectin-coated dishes and cultured in Medium 199, MEM, or F-12 supplemented with 10% FBS, 10% HS, 20 mM HEPES and NGF (15 ng/ml). Co-cultures were made either in one step or CB cells were added to NG neurons previously treated with cytosine arabinoside (3.7 μM) for 3 days. Cultures were maintained for up to 26 days at 37°C in a 5% CO_2-air environment. Conventional intracellular recordings were made during superfusion with 5% CO_2 in O_2-equilibrated Earle's saline.

NG neurons maintained in Medium 199 or MEM were mainly round; only few cells presented short neurites (<50 μm). However, 2% of neurons grown in F-12 had longer neurites (50-1500 μm). In co-culture, many NG neurons showed neurites (>70 μm) regardless of the media. The soma diameter was 20-40 μm in all cases. Neurons cultured alone had passive electric properties similar to those previously reported but no spontaneous activity. In co-culture their passive properties remained similar but spontaneous action potentials, sometimes preceded by slow depolarizing potentials, occurred in 14% (5/36) of them. Thus, CB cells seem to induce morphological and physiological changes in cultured NG neurons although the nature of this influence needs to be elucidated. Supported by grant NS05666.

A POST-NATAL INCREASE IN AMPLITUDE OF THE T-TYPE Ca^{2+} CURRENT AND THE APPEARANCE OF BURST FIRING IN FRESHLY ISOLATED RAT SENSORY NEURONS G. White,* D.M. Lovinger,* and F.F. Weight (SPON: K.L. Zbicz), Section of Electrophysiology, NIAAA, Rockville, MD 20852.

An afterdepolarizing potential (ADP) generated by a T-type Ca^{2+} current produces burst firing in neurons isolated from adult rat dorsal root ganglia (DRG) [White et al., Soc. Neurosci, Abst: 14, 297,1988]. The amplitude of the T-current in adult neurons is much larger than reported for cultured embryonic or neonatal DRG neurons. To determine if this difference in current amplitude is present prior to culturing, we recorded electrophysiological responses in DRG neurons freshly isolated from 1 day-old, 12 day-old and adult rats using the whole-cell patch-clamp technique. The frequency of occurance of an ADP was the same across all age groups (≈55% of the neurons); however the amplitude of the ADP increased with age as did the frequency of observations of ADP-associated burst-firing (>80% of neurons from adult rats[n>50], 43% from 12 day-old rats [n=18], and 0% from 1 day-old rats [n=22]). Voltage-clamp experiments revealed that the amplitude of the T-current (corrected for cell capacitance) was also greatest in neurons from adult rats (29.8 pA/pF, n=22), smaller in neurons from 12 day-olds (8.7 pA/pF, n=18) and smallest in neurons from 1 day-olds (4.4 pA/pF, n=18, $p<.05$, Kruskal-Wallis). These observations suggest that the post-natal increase in T-current density contributes to the development of burst-firing.

BIOCHEMICAL AND PHARMACOLOGICAL CORRELATES OF DEVELOPMENT I

118.1

DEVELOPMENT OF CENTRAL α_2-ADRENORECEPTORS IN THE SHEEP: A PHARMACODYNAMIC APPROACH. RK Zoltoski, JC Rose*, and CE Dunlap, III. Bowman Gray School of Medicine of Wake Forest University, Winston-Salem, NC 27103.

Guanabenz (GB), a centrally acting α_2-adrenergic agonist, lowers blood pressure in hypertensive rats and human patients and normotensive dogs. The effects of this drug on fetal cardiovascular function are not known. Therefore, we undertook experiments to test the hypothesis that GB produces similar cardiovascular effects in the fetal lamb compared with the maternal ewe.

Changes in fetal and maternal mean arterial pressure (MAP), heart rate (HR), amniotic fluid pressure (AFP), and GB plasma levels were determined in chronically catherized pregnant ewes and their fetal lambs of known gestational ages. Fetal lambs were divided into two groups, 100-115 and 120-135 days of gestation.

Following maternal administration of 2 mg GB iv, a biphasic response of maternal MAP was observed; a large increase in MAP (10±2 torr at 0.5 min), due to stimulation of peripheral α_2-adrenoreceptors, followed by a sustained decrease (-12±4 torr at 5 min) lasting 40 mins. A decrease in HR was noted at 1 min (-16±6 bpm) and lasted 75 mins (-15±2 bpm). GB also increased AFP which artifactually raised MAP in both groups of fetal lambs; however, following correction of MAP for the increase in AFP, no change was detected. A reflex-like decrease in fetal HR occurred (-39 to -53 bpm at 3 mins), but this response was not sustained. Plasma level measurements indicated that there was a rapid decline in GB from the maternal compartment ($t_{1\backslash 2\alpha}$=3 min, $t_{1\backslash 2\beta}$=58 min) and equilibration into the fetal compartment did not appear to occur. When 0.1mg/kg GB was administered to the fetal lamb, an increase in fetal MAP (12-14 torr at 1 min) occurred, but no decrease in pressure, up to 2 hours, was noted. HR in these lambs appeared to be reflexly decreased due to the increase in pressure (-31 to -32 bpm at 1 min). No changes in maternal MAP, HR, or AFP were seen.

We conclude that GB diffuses poorly across the placental barrier into the fetal lamb from maternal circulation, and that the central α_2-adrenergic hypotensive actions are not expressed in fetal lambs, as they are in adult sheep.

N-METHYL-D-ASPARATATE RECEPTOR ACTIVATION IS REQUIRED FOR DEVELOPMENTAL EXPRESSION OF THE CAT-301 ANTIGEN. Robert G. Kalb and Susan Hockfield, Section of Neuroanatomy, Yale University, New Haven, CT 06510

Neuronal activity in early postnatal life can have a profound influence on the development of neuronal properties. The N-methyl-D-aspartate (NMDA) class of glutamate receptor has been implicated in this process, but the molecular events which follow receptor activation and lead to alterations in neuronal characteristics are largely unknown. We have used monoclonal antibody Cat-301 to identify a chondriotin sulfate proteoglycan whose expression requires NMDA receptor activation during early postnatal life. The Cat-301 antigen is a good candidate for NMDA-regulated expression because previously we have shown that its expression on motor neurons in the hamster spinal cord depends on neuronal activity during a circumscribed period in postnatal life.

Neonatal hamsters were administered a range of doses of the NMDA-receptor antagonist MK-801 from postnatal day 7 (P7) to P21. Normally all sciatic motor neurons are Cat-301 positive by P14. In MK-801-treated animals, Cat-301 expression on motor neurons was inhibited in a dose-dependent manner. Two other motor neuron antigens were unaffected by MK-801 treatment. Adult animals treated with MK-801 for two weeks continued to express Cat-301 on all motor neurons. These results demonstrate a temporally-restricted period in motor neuron development during which the expression of the Cat-301 antigen is sensitive to NMDA receptor blockade. The Cat-301 antigen provides a positive molecular marker for NMDA-mediated development of motor neurons.

DEVELOPMENT OF CHOLINERGIC TERMINALS IN RAT STRIATUM AS VISUALIZED BY [^{3}H]HEMICHOLINIUM-3 AUTORADIOGRAPHY. H.K. Happe and L.C. Murrin. Dept. of Pharmacology, Univ. of Nebraska Med. Ctr., Omaha, NE 68105.

Cholinergic terminals can be quantitatively analyzed at the light microscopic level by use of [^{3}H]hemicholinium-3 (HC-3) autoradiography. HC-3 binds with high affinity and specificity to the high affinity choline transport site, a specific marker for cholinergic neurons. We characterized HC-3 binding (Sandberg & Coyle, Brain Res. 348:321, 1985) to slide mounted tissue sections from 5, 10, 15 and 21 day old rats. Binding is saturable (K_D = 10 nM), reachs equilibrium by 20 min at RT, is sodium-dependent and is inhibited by choline. Specific HC-3 labelling of tissue sections increases 3-fold between 5 and 21 days of age. Quantitative autoradiographic analysis finds a 6-fold increase in HC-3 binding in certain regions of striatum over this same time period. There is a 4-fold lateral to medial gradient in the body of the striatum in all animals 5 to 21 days of age. There is also a large rostral to caudal gradient in receptor density. The head of the striatum is relatively homogeneous in labelling. The shell of the accumbens and the olfactory tubercle are also heavily labelled. A striosomal pattern is apparent in caudal portions of the striatum at 5 days of age, coincident with patterns for mu opiate receptors and acetylcholinesterase. By 21 days of age this striosomal pattern of HC-3 labelling is no longer apparent. Supported by NS23975 and a McDonald Fellowship.

118.4

EFFECTS OF NEONATAL 6-OHDA LESIONS ON DOPAMINE RECEPTORS, DOPAMINE AND DOPAC IN STRIATUM. L. Arqueros* and L.C. Murrin. Dept. of Pharmacology, Univ. Nebraska Md. Ctr., Omaha, NE 68105.

As a basis for studies on the importance of dopaminergic input to the development of other neuronal systems in the striatum, we carried out a detailed study on the effects of 6-hydroxydopamine (6-OHDA) lesions on the development of markers for the dopamine system. Two-day old rat pups were administered desmethylimipramine (20 mg/kg i.p.) and 60 min later 50 μg of 6-OHDA was injected into each lateral ventricle in a volume of 5 μl over 5 min followed by a 5 min wait. From 4 to 30 days of age dopamine (DA) and 3,4-dihydroxyphenylalanine (DOPAC) were undetectable in striatum of most pups and means were <1% of controls, indicating no recovery of DA. Norepinephrine levels in hippocampus were unaffected and were reduced 30-40% in striatum. D1 receptor number is unchanged at 4 days of age but is reduced by 30% in 15 and 30 day animals. D2 receptor number remains statistically unchanged from 4 to 30 days of age. These data suggest that D1 and D2 receptors are affected differently in development by DA terminals and presumably DA release. This further supports the idea that the development of these two receptors is regulated by different mechanisms. Supported by NS23975 and the Burroughs Wellcome Fund.

DIVERSE DEVELOPMENTAL PATTERNS OF RECEPTOR BINDING IN RAT NEOCORTEX. J.L. Fuchs. Dept. of Biol. Sciences, Univ. of North Texas, Denton, TX 76203.

This study investigated the ontogeny of receptor binding in relation to underlying features of the rat neocortex. Autoradiographs of in vitro labeled sections were prepared from Long-Evans rats ages P0 through adult. While all of the ligands examined showed developmental changes in laminar distribution, some also showed radial transitory patterns associated with identified cortical areas. The only radial pattern extending through all laminae was that of [^{125}I]α-bungarotoxin binding, which labeled all primary sensory cortical areas as early as P2-4. Radial patterns for other ligands emerged 1-4 days later, but were confined to laminae IV and the V-VI border. [^{3}H]Muscimol was dense in area 17, SI and areas anterior to SI, [^{3}H]imipramine marked SI, area 17 and TeI, and [^{3}H]nicotine labeling was heaviest in area 17. Other ligands, including [^{3}H]QNB, [^{3}H]flunitrazepam and [^{3}H]phorbol 12,13-dibutyrate, did not reveal obvious distinctions between cortical areas. The observed radial differences were maximal around P8-12 and then "faded" during the 3rd week so that little if any contrast remained between adjacent areas in adults. The present survey is compatible with a heterogeneous, dynamic picture of developing neocortex in which various neurotransmitter systems gain and recede in prominence as they vie with each other for cortical territory.

DOPAMINE RECEPTOR ONTOGENY IN MOUSE CNS TISSUES. B.D. Perry, M. Wainwright*, L. Won, A. Heller and P.C. Hoffmann. Depts. Psychiatry, Pharmacol/Physiol Univ Chicago, Chicago, IL 60637

As part of studying determinants of D-1 and D-2 dopamine receptor expression we have examined 125I-SCH 23982 (SCH:D1) and 125I-Spiperone (SPIP:D2) binding sites in developing mouse brain regions (caudate: CS; cortex: CX ros. mesenceph. teg.: RMT). At embryonic day 16 (ED 16) specific binding sites for both ligands are detectable (for each, Bmax approx. 0.05 fmol/mg prot.). The ligands have lower affinities for these sites than in mature CNS (e.g. SCH Kd for ED 16 CS 4.0 nM and 0.4 nM in 28 day postnatal). The density of sites increases steadily through 28 day postnatal. This is the first report that we are aware of that examines prenatal ontogeny of D1-receptor binding sites. These studies will facilitate examination of the developmental determinants of phenotypic expression of dopamine receptors.

FUNCTIONAL EFFECTS OF PRENATAL COCAINE EXPOSURE. L.A. Freed, T.A. Fico, H.E. Hughes and D.L. Dow-Edwards. Lab of Cerebral Metabolism, Dept of Neurosurgery, SUNY-Health Science Center, Brooklyn, NY 11203 and Department of Developmental Psychobiology, NY State Psychiatric Institute, NY, NY 10032.

Infants prenatally exposed to cocaine are reported to have neurobehavioral deficits. Recent animal studies have suggested direct effects of cocaine on brain development. Following exposure to cocaine during critical periods of postnatal development in the rat (days 1-10 or days 11-20), we found long-lasting changes in functional activity in several brain regions (Dow-Edwards, et al., Dev. Brain Res. 42:137, 1988) and (Soc Neurosci abstr, 290.15, 1988). We have now quantified (^{14}C) 2-deoxyglucose patterns in rat brain following prenatal cocaine exposure and correlated these findings with D_1 and D_2 receptor binding.

Wistar rats were mated and housed under standard laboratory conditions. Dams received either 0 or 60 mg/kg cocaine-HCL po, from gestional day 8 through 22. Pair-feeding and surrogate fostering techniques were used. At 58-64 days of age, local rates of glucose utilization were determined in only the male offspring (1/litter) using the deoxyglucose method of Sokoloff et al. (J. Neurochem. 28:987, 1977). Selective tritiated D_1 and D_2 receptor ligands were used to correlate altered dopamine receptor concentrations autoradiographically in discrete brain regions in these same animals. Compared to metabolic responses in females receiving cocaine during the neonatal period, prenatal cocaine appears to produce minimal alterations in patterns of brain metabolic activity in male offspring.

118.8

REGIONAL DEVELOPMENT OF DOPAMINE AND MUSCARINIC RECEPTORS IN RAT BRAIN. J. K. Rowlett*[1], M. A. Rice*[2], S. A. McDougall*[1], M. T. Bardo[1] and N. W. Pedigo.[2] (SPON: J. F. Zolman[1]). [1]Depts. of Psychology, [2]Pharmacology and Anesthesiology, Univ. Kentucky, Med. Ctr., Lexington, KY 40536.

The purpose of the present study was to characterize muscarinic and dopamine-1 (D-1) binding sites in the developing rat anterior striatum, medial prefrontal cortex and hippocampus-entorhinal cortex. Ages were based on those commonly used in behavioral ontogeny studies: 11, 17, 28, and 35 days after birth. ^{3}H-SCH 23390 (0.2-2.0 nM) in the presence or absence of 10 or 100 uM (+)-butaclamol, was used to define D-1 binding, with mianserin (100 nM) added to mask serotonin-1C sites. ^{3}H(-)quinuclidinyl benzilate (^{3}H-QNB; 20-500 pM) in the presence or absence of 10 uM atropine was used to define muscarinic binding. Saturation studies were done at equilibrium for each age and region. D-1 receptors reached adult levels between 17 and 35 days after birth, whereas muscarinic receptor density generally increased throughout development. For example, adult levels of D-1 binding in striatum were 2393 ± 45 fmol/mg protein, but binding in 11, 17, 28 and 35 day old rats was 68, 69, 138 and 130% of adult, respectively. Striatal levels of muscarinic binding were 5203 ± 763 fmol/mg protein in adults and 45, 55, 81 and 66 % in the neonatal rats. Significant differences were due to increased receptor concentration without age-related changes in receptor affinity. The differential development of muscarinic and D-1 receptors may account for behavioral differences between neonatal and adult rats.

118.9

IMMUNOSUPPRESSION BY PRENATAL DIAZEPAM.
M. Schlumpf, *H.R. Ramseier, W. Lichtensteiger, *G. Seiler and **J.B. Baumann. Institute of Pharmacol. and *Inst. of Immunol. and Virol. Univ. Zürich and **Kantonsspital Basel, Switzerl.

When administered between gestational day (GD) 14 and 20 diazepam (1.25 mg/kg) as well as clonazepam (0.25 mg/kg, s.c.), a selective ligand for the central benzodiazepine (BDZ) receptor, suppressed cellular immune responses in male and female Long Evans rat offspring, i.e. the lymphocyte proliferative response to allogeneic and polyclonal stimuli. Treatment of the pregnant animal with the peripheral type agonist Ro 5-4864 did not consistently affect immune responses in offspring, although peripheral BDZ receptors are present in fetal brain and periphery. The involvement of the central type benzodiazepine receptor suggests a neuroendocrine link. However corticosterone plasma levels in fetuses at GD 20, 1 hour after the last drug injection, were significantly decreased only in females, whereas the immune depression was seen in both sexes. At PN 4 female pups but not male had significantly increased plasma hormone levels. The postnatal rebound of plasma corticosterone might have contributed to the immunosuppressive effects but seemingly represents not a main factor in suppression of T cell responsiveness.

118.10

DEVELOPMENTAL EXPRESSION OF ENKEPHALIN CONTAINING SYSTEMS IN THE RAT BRAIN.
T.T. Quach, C. Llorens-Cortes*, J.C. Schwartz*, R.J. Wyatt, A.M. Duchemin INSERM U. 109, 2ter rue d'Alésia, 75014 Paris (France), NIMH St Elizabeths Hospital, Washington D.C. and School of Medicine, Ohio State University.

The expression of the gene encoding for enkephalin (Enk) was studied pre- and post-natally in rat brain with a pre-pro-Enk specific cDNA probe to quantitate mRNA. In addition, specific RIAs were used to measure the levels of met-enkephalin and of Tyr-Gly-Gly (YGG), its principal metabolite. Poly A^+ enriched RNA from rat brain was analyzed for the presence of Enk-mRNA by agarose gel electrophoresis, followed by transfer to mitrocellulose and hybridization to a ^{32}P-labeled Enk-cDNA probe. Brain pre-pro-Enk mRNA detectable by embryonic day 14 represented more than 30 % of adult levels. It increased continuously until post-natal day 28 when it reached maximal concentrations. In young adult rats, level was decreased. Enk and YGG immunoreactive peptides detected in the samples from embryonic day 12, represented respectively 0.05 % and 0.78 % of the adult level. Marked development of peptides was seen only post-natally with a rapid increase occurring within the first 2 weeks after birth. The highest contents of the peptides were present in young adult rats.

118.11

THE DEVELOPMENT OF THE OXYTOCIN RECEPTOR IN RAT FOREBRAIN: CHEMICAL NEUROANATOMY AND BEHAVIORAL CORRELATIONS.
T.R. Insel, L. E. Shapiro*, and D. Dang*. Section on Comparative Studies of Brain and Behavior, Laboratory of Clinical Science, NIMH, Poolesville, MD 20837.

The ontogeny of oxytocin receptors in rat forebrain was studied using the selective oxytocin receptor antagonist, ^{125}I-d(CH_2)$_5$[Tyr(Me)^2,Thr^4,Tyr-NH_2^9]OVT ([^{125}I]-OTA). With *in vitro* receptor autoradiography, binding was noted on the first postnatal day in dorsal subiculum and thalamus. From postnatal days 5-18, intense labeling was evident in posterior cingulate cortex, dorsal subiculum, lateral septum, and the CA1 subfield of hippocampus. Of these regions only the lateral septum expressed oxytocin receptors in adult brain. Competition studies on coronal sections through posterior cingulate, septum, and dorsal subiculum at P10 demonstrated that transient binding sites in these areas were indeed oxytocin selective (OXY>AVP>V_1>V_2). Results from saturation studies on cingulate membranes from 10-day-old pups agreed favorably with previous reports of the kinetics of [^{125}I]-OTA binding to adult oxytocin receptors, K_d = 0.099 nM in P10 cingulate cortex vs. 0.073 nM for adult ventral subiculum (Elands et al., 1987). In contrast to these evanescent developmental sites, oxytocin receptors in the bed nucleus of the stria terminalis and the ventromedial nucleus of the hypothalamus only appeared in adulthood, presumably in response to the surge of gonadal steroids at puberty.

To determine if oxytocin receptors during development were functionally responsive to exogenous peptide, oxytocin was administered intracerebroventricularly to pups at ages 5-7 days. Injection of oxytocin (0.1 µg) resulted in an 80% decrease in the rate of ultrasonic calls following social separation without altering locomotor activity. This effect was blocked by co-administration of the selective oxytocin antagonist, [d(CH_2)$_5$Tyr(Me)^2, Orn^8]-vasotocin, at a dose which lacked intrinsic effects.

These results demonstrating a marked, transient increase in the expression of oxytocin receptors during development and a decrease in the response to social separation following oxytocin administration, suggest a unique role for this peptide during development.

118.12

ONTOGENY OF α_2 RECEPTOR SUBTYPES IN RAT BRAIN.
H.K. Raymon and F.M. Leslie, University of California, Irvine, CA. 92717.

Monoamines may play a neurotrophic role in early ontogenesis by regulating cell differentiation in monoamine receptive cells. To investigate possible sites of noradrenergic action in development, the ontogeny of α_2 adrenoceptor subtypes and norepinephrine (NE) uptake sites were examined in rat brain using *in vitro* autoradiography. Brain sections from developing rats were incubated with [^{3}H]desmethylimipramine (DMI), which labels NE uptake sites, in the absence and presence of 10 µM nortriptyline to define nonspecific binding. α_2 binding sites were defined with either [^{3}H]idazoxan (which labels the total population of α_2 binding sites) or [^{3}H]rauwolscine (which labels only a subpopulation of α_2 binding sites). Specific binding was defined as the difference in binding in the absence and presence of 10 µM phentolamine. [^{3}H]DMI uptake sites are present at postnatal day (PND) 1 in the septum and the anterior olfactory nucleus. By PND 4, binding sites are visible in several areas, including the bed nucleus of the stria terminalis, septum, the vertical limb of the diagonal band and anterior cingulate cortex. The α_2 receptor subtypes show a differential distribution during development. [^{3}H]Idazoxan binding sites are visible at PND 1 in the anterior olfactory nucleus, the frontal cortex, the caudate-putamen, several thalamic nuclei and the hippocampus. In contrast, [^{3}H]rauwolscine binding sites are not seen in the thalamus on PND 1, indicating a differential distribution of sites. They are, however, seen in other areas labeled by [^{3}H]idazoxan. Preliminary data indicate that there is a transient, laminar distribution of rauwolscine binding sites in cerebellum by PND 14, which disappears by PND 21. This suggests that the rauwolscine binding sites may play a role in cerebellar development. Developmental processes in regions which exhibit [^{3}H]DMI uptake sites and α_2 receptor binding may be under the influence of endogenous NE systems. In addition, the differential appearance of the α_2 binding sites is consistent with the existence of α_2 adrenoceptor heterogeneity. *Supported by NIH NS 19319 and NIH 1F31MH09737.*

118.13

OPEN FIELD ACTIVITY IN OFFSPRING OF DIAZEPAM-TREATED MALE MICE.
A. Márquez-Orozco*, M. C. Márquez-Orozco*, M. Ramos-Avila* and R. A. Prado-Alcalá (SPON: B. Ortega). Embryol. Dept. and Physiol. Dept., Med. Sch, Natl. Univ. of México, México, D.F., México 04510.

To assess if diazepam (DZP) administered to males produces motor impairments to their offspring, male CD-1 mice were given DZP (2.7 mg/kg, i.p.) daily during six weeks. Immediately afterwards they were mated with females. Five months after birth, the litters (males and females) were tested in an open field (100 x 100 x 20 cm, divided into 9 squares of equal area). Litters of saline treated males were also studied. They were habituated for 5 min, and the number of crossings between squares was measured during the next 5 min. All mice derived from DZP-treated males displayed a significantly higher exploratory behavior than the control mice. In other groups of the same characteristics as the ones described, scopolamine (SCOP, 6 mg/kg) or saline solution was injected (I.P.) 5 min before habituation: in all cases SCOP induced an increase in motor activity. These results suggest that DZP administered to males before mating, may produce behavioral alterations in their offspring.

118.14

ULTRASTRUCTURAL ALTERATIONS IN THE RETINA OF MICE FETUSES PRENATALLY EXPOSED TO DIAZEPAM.
M.C. Márquez-Orozco, A. Márquez-Orozco and V. Gazca-Ramírez. (Spon: H. Brust-Carmona). Embriol. Dept. Sch. of Med. Natl. Univ. of México, México 04510, D.F, México.

Diazepam accumulation during gestation in the retinas of mice fetuses delays cellular differentiation. We investigated if diazepam causes ultrastructural changes that could account for this delay. Three groups of gestating mice of the CD-1 strain were injected, i.p., between the 6th and 15th day of gestation, either with single daily doses (2.7 mg/kg b.w.) of diazepam (D), the vehicle (V), or 0.9% saline solution (S). On the 16th day, the mice were sacrificed by beheading, the fetuses removed, and perfused intracardially with 1% paraform-aldehyde and 2.5% glutaraldehyde, the eye globes were postfixed in OsO_4 and embedded in epoxic resin. Histological sections were contrasted with uranyl acetate and lead citrate and observed under a transmission microscope Zeiss EM-10. Nuclear density per area was greater in the D fetuses than in the S and V fetuses ($p < 0.05$). Chromatin was atipically distributed in the nuclei, the rough endoplasmic reticulum showed distended cisternae; the Golgi Complex, the mitochondrias, and the polyribosomes were more abundant; the photoreceptors' microvilli were disorganized. These ultrastructural changes were not observed in groups V and S. The greater nuclear density and the alterations of the cytoplasmic organelles could reveal disruptions in cell multiplication.

118.15

A FLOW CYTOMETRIC ANALYSIS OF DEVELOPMENTAL CHANGES IN $GABA_A$ RECEPTOR FUNCTION IN EMBRYONIC CHICK SPINAL CORD CELLS. A. Prasad*, S.V.Smith*, G.D. Lange and J.L. Barker, (SPON: H. Lansdell). Laboratory of Neurophysiology, NINDS, NIH, Bethesda, MD 20892.

Suspensions of acutely dissociated spinal cord cells from chick embryos were incubated with a voltage-sensitive oxonol dye and analyzed using flow cytometry. In a series of experiments, the Na^+/K^+ ionophore gramicidin was added to oxonol-stained cell suspensions, while varying the ionic conditions. The analysis of these results provided a basis for correlating changes in oxonol fluorescence, as measured by flow cytometry, with changes in cellular membrane potential.

Membrane potential responses to GABA and muscimol, a $GABA_A$ agonist, were probed in cells from animals ranging in age from embryonic day 3 (E3) to E13. There was a major subpopulation of cells scattering a significant amount of light, which, beginning at E4, depolarized in response to muscimol and GABA. By E12 however, much higher doses of agonist were routinely required to produce any shifts in oxonol fluorescence.

Both types of agonist-induced shifts were blocked by bicuculline, a competitive antagonist at $GABA_A$ receptors and picrotoxin which blocks a $GABA_A$ receptor coupled chloride conductance at the channel rather than the receptor level. We are investigating the possibility that some of the properties of $GABA_A$ receptor-coupled choride channels which emerge early in embryogenesis on spinal cord cells are transformed during development.

118.16

$GABA_A$ RECEPTOR-MEDIATED RESPONSES IN RAT HIPPOCAMPAL CELLS CHANGE THEIR PROPERTIES DURING DEVELOPMENT. J.L.Barker, M.L.Fiszman*, E.A.Novotny* and G.D.Lange Laboratory of Neurophysiology, NINDS, NIH, Bethesda, MD 20892.

Embryonic and early postnatal rat hippocampi were papain digested in order to obtain cell suspensions suitable for analysis in a fluorescence-activated cell sorter (FACS). Oxonol (DiBa-C4(3)), a voltage-sensitive indicator dye, was used to detect membrane polarization changes.

In embryonic hippocampal cell suspensions nanomolar concentrations of GABA and muscimol depolarized all cells scattering significant levels of light in a dose-dependent manner with a threshold concentration of 10nM. This effect was prevented by preincubation with bicuculline or picrotoxin. In hippocampal cell suspensions obtained from 5-7 day old pups $GABA_A$ agonists depolarized one subpopulation and hyperpolarized another. The threshold concentration to induce this effect was ten times higher than in prenatal preparations. At all the ages tested (-)pentobarbital failed to modulate GABA-induced responses. However, it did induce a GABA like effect with concentrations ranging from 50 to 200μM. This effect was blocked by bicuculline or picrotoxin.

Our results indicate that there is a change in the responses to $GABA_A$ agonists as well as in their affinity during development. The low effective concentrations of the agonists suggest that a high affinity state of the receptor is functionally operative in early stages of development.

118.17

THE DEVELOPMENTAL EXPRESSION OF GABA PRECEDES GAD IN THE RAT SPINAL CORD. T.N. Behar*, A.E. Schaffner, S. Nadi and J.L. Barker, (SPON: M. Freed) LNP, LN, NINDS, NIH, Bethesda, MD 20892.

Developing rat spinal cord was analyzed for the presence of GABA and GAD by immunocytochemistry and HPLC. Levels of GABA determined biochemically paralleled the development of a GABAergic phenotype in acutely dissociated cells. GABA was first detected by HPLC and indirect immunofluorescence at embryonic day (E)13. The concentration of GABA and the number of GABA+ cells began to increase at E15. By E19 the level of GABA reached 200 nmoles/mg protein and remained at this level through postnatal day (PN) 5. During the same period the number of GABA+ cells increased to 15-30% of the total cell population. Double labeling with anti-neurofilament (NF) antibodies revealed that the GABA+ cells were also NF+. Over the period E15 through PN7, the number of NF+ cells expressing GABA increased dramatically such that by PN7 >50% of the NF+ cells were GABA+. The pattern of GABA staining also changed during development. Initially, GABA was diffusely distributed throughout the cytoplasm and processes of the cells. A more punctate pattern was evident in some cells at PN7 and by PN21 virtually all GABA+ cells displayed the punctate pattern of GABA staining. GAD was first detected by immunofluorescence at E21 in 1% of the cells and initially appeared in a perinuclear patchy pattern. GAD expression increased such that by PN 14, 50% of the GABA+ cells were also GAD+. At PN21 all GABAergic cells were GAD+ and comprised 5% of the total population. When various regions of the cord at E17 were dissociated and stained for GABA, there was a distinct rostral to caudal and ventral to dorsal gradient of GABA expression. Detection of GABA before GAD suggests that GABA is synthesized through an alternative pathway, such as polyamines, and that GABA may play a role in differentiation or morphogenesis of the spinal cord.

METABOLISM OF DOCOSAHEXAENOIC ACID (DHA) IN BRAIN AND RETINA IN NEONATAL MOUSE. **F. Cai* and N.G. Bazan (SPON: K. Kratz). LSU Eye Center and Neuroscience Center, New Orleans, LA 70112.**

DHA is a fatty acid that is uniquely and rapidly accumulated during synaptogenesis and photoreceptor membrane biogenesis. Its physiological role and metabolism are still unclear. The synthesis of DHA, and its supply to brain and retina, were studied using ^{14}C-linolenic acid (18:3), given intraperitoneally (IP) or orally to 3-day-old mice. Mice were killed from 10 min to 4 h later. Liver (L), serum (S), brain (B), retina (R), and gastrointestinal (GI) tissue were removed for lipid analysis, and analyzed by TLC into different lipid classes and by HPLC for conversion of 18:3 to DHA. ^{14}C in lipids appeared in S and L within 10 min after IP injection, peaked at 30 min, and then declined. Oral ^{14}C peaked at 60 min in GI. Thirty min after oral administration, 67% of the ^{14}C was in phospholipids (PL) in B, and 62% in R; in L most of the ^{14}C in triacylglycerols (TG) remained as 18:3, but in PL at 2 h 40% of the 18:3 in TG had been converted to DHA and 10% to 22:5, an intermediate in DHA metabolism. In B only 10% of the ^{14}C was 18:3 at 1 h, while 20% was 20:5 and 6% was 22:5. These results suggest that DHA is synthesized in liver (as 22:6-PL) and supplied to neuronal membranes via the bloodstream. (Supported by NIH EY04428)

NEURAL-IMMUNE INTERACTIONS: STRESS

119.1

GLUCOCORTICOID BINDING IN IMMUNE TISSUES IS LESS AFFECTED BY STRESS LEVELS OF CORTICOSTERONE COMPARED TO BRAIN. A.H. Miller*, R.L. Spencer, M. Stein, B. McEwen (SPON:S. Barclay). Mt. Sinai Med. Cntr., NY,NY 10029 and Rockefeller Univ., NY,NY 10021.

Glucocorticoids may be important in neural-immune interactions. Therefore, Type I and II glucocorticoid receptor (GR) binding was measured concurrently in thymus,spleen,hippocampus (HC) and pituitary (PIT) after various neuroendocrine manipulations. Sprague-Dawley rats were divided into 3 treatment groups (N=3 per group): 1) 16 hr adrenalectomy (ADX), 2) intact/no stress and 3) intact + 1 hr restraint stress. For ADX rats, Type I binding was absent in thymus and low in spleen relative to HC and PIT. Type II binding in ADX rats was highest in thymus, intermediate in spleen and lowest in HC and PIT. After restraint, Type I binding was absent in spleen and HC and very low in PIT. Compared to intact rats, Type II receptor level of stressed rats was significantly reduced in HC but unchanged in thymus, spleen and PIT. Likewise, the Type II Kd in HC after stress was greatly increased compared to nonstressed rats. A much smaller elevation in Kd was noted in thymus,spleen and PIT after stress. In sum, stress levels of corticosterone appear to have a lesser effect on GR binding in thymus, spleen and PIT than in HC.

119.2

EFFECTS OF HANDLING ON IMMUNE REACTIVITIES OF BALB/C MICE

J.A. Moynihan*, G.J. Brenner*, D. Koota*, R. Ader*, and N. Cohen* (SPON: E. Caine) Depts. of Psychiatry and Microbiology and Immunology, University of Rochester, Rochester, NY, 14642

We have studied the specific and non-specific immunological consequences of psychosocial manipulation in an animal model. BALB/c.ByJ mice were picked up and held for 2 minutes/day for 2 weeks prior to being: injected intravenously with $1x10^5$ syngeneic Line 1 lung carcinoma cells; injected with intraperitoneally with 100 μg of the protein antigen keyhole limpet hemocyanin (KLH); or evaluated for splenic NK cell cytotoxicity and T cell proliferation. This handling protocol was consistently associated with the appearance of a significantly increased number of Line 1 metastases in the lungs of the handled animals relative to home caged unhandled controls (no differences were noted when animals were handled after tumor cell injection). This handling protocol was also associated with decreased IgG anti-KLH antibody responses. Glucocorticoid levels were higher 30 minutes after KLH injection than they were immediately before injection in the unhandled animals, but not in the handled mice. Finally, 2 weeks of daily handling has been consistently associated with decreased Con A-induced T cell proliferation, but not with increased in vitro NK cell cytoxicity.

119.3

STRESS MODULATES SENSORY EVOKED POTENTIALS FROM THE HYPOTHALAMUS, HIPPOCAMPUS AND SUPERIOR COLLICULUS. J. Casada*, R. Perry*, and N. Dafny. (SPON: R. Guynn) Dept. Neurobiol. and Anat., The University of Texas Medical School at Houston, 77225.

Stress has been shown to modulate immunity in experimental animals and in human subjects. The present experiment was designed to investigate whether single or repeated exposure to an acute stressor elicits changes in sensory evoked potentials recorded from brain sites implicated in neuroimmune modulation using freely behaving rats. Thirty male Sprague Dawley rats were permanently implanted with 120 μm stainless steel semimicroelectrodes in the dorsal hippocampus (DH), medial basal hypothalamus (MBH), and superior colliculus (SC). Animals were restrained for four hours per day on each of four consecutive days. Four sets of 32 averaged visual evoked responses were recorded on the day prior to the first restraint (control) and on the first and fourth day of restraint. Restraint generally elicited an increase in the amplitude of sensory evoked potentials recorded from the MBH, DH, and SC without changing the neuronal recovery function. A persistent increase in the averaged evoked potential amplitudes seen on both the first and fourth daily presentation of the stressor indicates that the animals did not adapt to the stressor as measured electrophysiologically.

119.4

CONDITIONED STRESSOR INDUCED ALTERATIONS OF IMMUNE FUNCTION: EFFECTS OF CONDITIONED EXCITATORY AND INHIBITORY STIMULI. DT Lysle, JE Cunnick, BJ Kucinski*, H Fowler* & BS Rabin. Depts. of Pathology and Psychology, Univ. of Pittsburgh, Pittsburgh, PA 15213.

Our research program is designed to investigate the effect of psychological stress, in the form of a conditioned aversive stimulus (CS) based on electric shock, on different compartments of the immune system. The present research used Lewis rats to evaluate the effect of a CS on the mitogenic response of lymphocytes from the blood, spleen, and lymph nodes. The blood and spleen lymphocytes showed suppression of mitogenic responsiveness to Con-A and PHA. In contrast, lymphocytes derived from the lymph nodes were unaffected by exposure to the conditioned stimulus. There was also a reduction of natural killer cell activity for spleen lymphocytes. The reduction in immunoresponsiveness of spleen and blood lymphocytes was not the result of a decrease in interleukin-2 (IL-2) production, as those cells produced normal levels of IL-2. We also have extended our assessments to include other forms of conditioning such as conditioned inhibition (i.e. a signal which predicts the absence of shock and thus inhibits fear by inducing relief or relaxation). We assessed whether a conditioned inhibitor would attenuate the suppression of lymphocyte responsiveness produced by a signal for the shock, or on its own enhance immune function.

119.5

THE EFFECT OF DIFFERENTIAL HOUSING ON ANALGESIA, TASTE AVERSION, AND NATURAL KILLER CELL CYTOTOXICITY IN TWO MOUSE STRAINS

K.S.Kelly, L.J. Grota, and R.Ader*. Dept. of Psychiatry, University of Rochester Medical Center, Rochester, NY, 14642.

Female Swiss Webster (SW) and C57Bl/6J mice were shipped at weaning, housed singly or in groups of five, and remained undisturbed for 10 weeks. The mice then received access to chocolate milk or water for 1 hr and were injected s.c. with morphine sulfate (150 mg/kg) or saline. Analgesia testing on the conditioning day yielded a significant morphine effect in both strains. SW mice exhibited a differential housing effect with group housed animals showing shorter response latencies. One week later, all mice were tested for taste aversion. Only the SW mice exhibited a conditoned aversion with no differential housing effect observed. A second conditioning trial was given the following week. Prior to the morphine injection, a main effect of housing was observed; individually housed mice consumed more chocolate milk. The taste aversion seen in SW mice had extinguished. A final test trial showed the conditioned taste aversion was not reinstated in SW mice; C57B1/6 mice still failed to show an aversion to the chocolate milk. Thus, this dose of morphine had a strain dependent effect on taste aversion. The weak aversion shown by SW mice extinguished in one trial and was not reinstated with a second conditioning trial. Finally, mice were sacrificed and spleens assayed for NK cell cytotoxic activity. Differential housing had a significant effect on NK cell cytotoxicity, with individually housed mice showing enhanced responses relative to group housed animals.

119.6

ROLE OF GLUCOCORTICOIDS AND CATECHOLAMINES IN THE MEDIATION OF SHOCK-INDUCED SUPPRESSION OF T-LYMPHOCYTE MITOGENIC RESPONSIVENESS. JE Cunnick, DT Lysle, H Fowler, and BS Rabin. Div. of Clinical Immunopathology, Dept. of Pathology, Univ. of Pittsburgh, Pittsburgh, PA 15213.

We have previously shown that presentations of mild-footshock to Lewis rats can suppress splenic and peripheral blood responses to non-specific T-cell mitogens. Although the mechanism(s) mediating the in-vivo suppression have not been identified, glucocorticoids and catecholamines are immunosuppressive in-vitro. Testing of adrenalectomized, sham operated and normal, unoperated rats demonstrated that adrenalectomy prevented the suppression of the mitogenic response of peripheral blood T-cells but only slightly attenuated the suppression of splenic T-cells. The beta-antagonists, propranolol and nadolol were both capable of attenuating the shock-induced immune suppression of splenic cells in a dose dependent manner. Furthermore, neither drug was able to attenuate suppression of the blood mitogen response.

These data indicate that, in-vivo, there are two distinct mechanisms mediating the suppression of T-cell responsiveness to mitogens in the spleen and the peripheral blood. As nadolol does not cross the blood/brain barrier, it suggests that the peripheral release of catecholamines is responsible for splenic immune suppression.

STRESS-INDUCED IMMUNOMODULATION: I. BASIC PARAMETERS. LR Watkins, M Fleshner*, DR Rager, DA Warren*, C Broussard*, D Bellgrau, SF Maier & M Laudenslager. Psych. Dept., U CO Boulder, CO 80309 HSC U CO Denver, CO 80204 & 80262.

This lab has previously reported that inescapable tail-shock can suppress in vivo IgG production against s.c. lyophilized keyhole limpet hemocyanin (KLH). In order to (a) study splenic rather than lymph node response & (b) attain temporally discrete in vitro spleen placque and in vivo IgM & IgG responses, we are now examining the antigenicity of i.p. and i.v. soluble KLH in rats. Plasma samples were obtained by tail bleed on days 3, 5, 7, 9, & 14 following KLH injection. Dose dependent elevations of anti-KLH IgM & IgG were found (ELISA) following 100, 500, & 1000 ug KLH. I.V. KLH produced larger increases in IgM & IgG than did equal doses of i.p. KLH. The IgM response was also far more temporally discrete following i.v. than i.p. KLH, with a sharp peak in IgM response occurring 5 days after i.v. KLH. Preliminary spleen placque assay results support these findings. Confirming and extending this lab's previous results, 100 inescapable tail shocks delivered immediately after 100 ug i.p. KLH led to significant decreases in anti-KLH IgM & IgG. Ongoing studies with i.p. and i.v. KLH are aimed at identifying the critical temporal relationship(s) between shock delivery and KLH administration required for immune alterations to occur. Once the critical period(s) is/are identified, the effect of escapable vs. inescapable shock will be examined and the potential role of pituitary-adrenal hormones assessed (see companion abstract). Supported by ONR00014-85K0211 and NSF BNS-8808840.

STRESS INDUCED IMMUNOMODULATION: II. PITUITARY-ADRENAL INFLUENCES.

M. Fleshner*, L. R. Watkins, M. L. Laudenslager & S. F. Maier (*upon D. M. Diamond*) Psych Dept. U CO Boulder, CO 80309 U CO HSC Denver, CO 80204.

Rats exposed to stressors show changes in immune function. One possible mechanism underlying these changes involves activation of the pituitary-adrenal axis. These studies investigate the role of ACTH and corticosterone (CORT) in stress-induced modulation of IgM and IgG production (described in Part II companion abstract). Because adrenalectomy induces widespread changes in physiological and neural function, we have avoided the potential confounds posed by this technique. Instead, three alternative methods for investigating pituitary-adrenal involvement are currently being pursued and each will be used to examine tail-shock induced immunosuppression. The first approach involves i.p. administration of dexamethasone (DEX) prior to shock. Using this method, we determined a dose of DEX that reduces stress levels of CORT as measured by RIA without significantly affecting the antibody response to s.c. KLH. The second method is intracerebroventricular (ICV) injections of DEX which, importantly, avoids directly exposing immune cells to this steroid. With multiple ICV injections prior to shock we found that CORT remained at basal levels during shock. A third method being developed involves surgical isolation of the adrenal glands followed by revascularization. This should allow the animal to release basal but not stress levels of steroids. An important advantage of these methods is that animals should be physiologically normal and have normal levels of circulating CORT at the time of clonal proliferation and antibody production when steroids seem important for immune function regulation. These techniques should allow us to clearly define the potential role of pituitary-adrenal factors in tail-shock induced immunomodulation. (N0014-85-K-0411 ONR, NSF BNS 8808840).

EVIDENCE FOR A CAUSAL RELATIONSHIP BETWEEN THE SUPPRESSIVE EFFECT OF STRESS ON NATURAL KILLER CELL ACTIVITY AND ENHANCED METASTATIC TUMOR GROWTH IN RATS S. Ben-Eliyahu, R. Yirmiya, R. P. Gale, and J. C. Liebeskind Dept. of Psychology, UCLA, Los Angeles, CA 90024

Acute stress can facilitate malignant tumor growth and can suppress the cytotoxic activity of natural killer (NK) cells. However, because stress can affect tumor growth in ways other than via the immune system, the causal relationships among stress, immune deficiency, and enhanced tumor growth are only suggestive. In this study, we used a malignant cell line, MABD106, which is syngeneic to Fischer 344 rats and was shown to be highly controlled by NK cell activity in vivo. Using a 2x2 design, Fischer 344 rats were injected with either naltrexone (s.c. 10mg/kg) or saline and were either subjected to intermittent forced swimming stress or were not stressed. In the first experiment, one hour after the end of the stress session rats were sacrificed, spleens were taken, and a 16 hour chromium release assay was used to measure splenic NK cytotoxic activity. In the second experiment, one hour after the end of the stress session rats were intravenously injected with 10^5 MADB106 cells in .5 ml PBS under halothane anesthesia. Twelve days later, lung surface metastases were counted. Stress significantly suppressed splenic NK cytotoxic activity against MADB106 and enhanced MADB106 metastatic growth in vivo. Naltrexone had no effect on either end point. Taken together with the previously established role of NK cells in limiting MABD106 lung metastases, this evidence supports causal relationships among stress, suppressed NK activity, and tumor development. (NIH grant NS07628)

RESTRAINT STRESS-INDUCED IMMUNOSUPPRESSION OF A LYMPHOKINE RESPONSE TO INFLUENZA VIRUS. J.F. Sheridan , N. Feng and B.S. Huneycutt (SPON: S. Travers). Depts. of Oral Biology, Medical Microbiology and Immunology, Ohio State Univ. Colleges of Dentistry and Medicine, Columbus, Oh. 43210.

Stress has been shown to inhibit a variety of immune responses in both experimental animals and humans. However, the health consequences of stress are still unclear. The purpose of this experimental study was to assess the effect of restraint-induced stress on the immune response to viral infection in the mouse. Mice (4 to 6 week old C57/B6, males) were infected intranasally with influenza A/PR8 virus. One group was stressed 16 hours (5:00 pm - 9:00 am) each day, for one day prior to infection and 14 days post infection. A second group was stressed for 6 hours (10 am - 4 pm) one week prior to infection and 14 days post infection. Control groups consisted of stressed, not infected and non-stressed, infected mice. Cells from lymph nodes and spleen were stimulated in vitro with influenza virus and the production of lymphokines, IL-2/IL-4, was measured. IL-2/IL-4 secretion in the stressed group was significantly reduced for both lymph node and spleen cells. The virus-specific response by mediastinal lymphocytes and splenocytes from the 16 hour stressed group was suppressed by 95.7% and 59%, respectively, when compared to the non-stressed group. Immunosuppression persisted at 25 days after termination of stress. Suppression of IL-2/IL-4 activity by 6 hour stress was not significant (20.6% for splenocytes) at 14 days after initiation of stress, while significant suppression was present two weeks after termination of stress.

119.11

DEVELOPMENT OF PRIMATE PSYCHOSOCIAL MODELS FOR NEUROIMMUNOMODULATION. W.B. Iturrian, J.L. Weed*, M.A. Hebert* and B.N. Bunnell. Pharmacology and Psychology Depts., Univ. Ga., Athens, GA 30602.

The objective was to develop nonhuman primate stress models correlating social, immune and neuroendocrine modulation strategies. We monitored cortisol; ACTH; PRL; PBL number; viability; and mitogen (PHA, Con A) responses as well as various aggressive, submissive and affiliative social behaviors. Social stress produced by adding a stranger into a group (N=42) depressed SIs acutely, with overshoot on day 4. The precise pattern varies with social rank and individual behavioral type. Increased aggressive and affiliative behaviors accompanied by reversals in rank increased the winner's Con A SI while the loser's decreased. Physical and social stressors caused complex biphasic cycles of immune status lasting weeks. Con A mitogen responses were related to social manipulation and behavior.

119.12

SOME LONG-TERM BEHAVIORAL AND IMMUNOLOGICAL EFFECTS OF BRIEF, EARLY MATERNAL SEPARATION IN NONHUMAN PRIMATES: PRELIMINARY OBSERVATIONS D.R. Rager*, M.L. Laudenslager, P.E. Held*, and M.L. Boccia*. Univ. of Colorado Health Sciences Center, Denver, CO 80204.

A number of well-documented behavioral and physiological changes occur acutely in response to maternal separation in nonhuman primate infants. These include behavioral agitation (increased activity and vocalization) followed by depression (decreased activity and social withdrawal). Physiological changes include alterations in heart rate, body temperature, EEG activity, and several measures of immune function. Preliminary data from our lab suggest that behavioral and immunological effects of early maternal separation may be observed up to 30 months later. The nature of these effects is dependent upon the particular macaque species studied. Additional pilot data regarding the ability of benzodiazepines (e.g., aprazolam) to modulate these long-term immunological changes will be discussed. (Supported in part by NIMH research grant MH37373 and a generous gift from the Upjohn Company).

119.13

EARLY SOCIAL ISOLATION IN RHESUS MONKEYS: LONG-TERM EFFECTS ON SURVIVAL AND CELL MEDIATED IMMUNITY. J.P. Gluck*, H. Ozer*, L.L. Hensley*, A. Beauchamp*, R.B. Mailman, and M.H. Lewis. (SPON: K. Suzuki) Biological Sciences Research Center and Departments of Psychiatry and Medicine, University of North Carolina, Chapel Hill, NC 27514, and Department of Psychology, University of New Mexico, Albuquerque, NM 87131

Considerable attention has been given recently to the effects of early life events on vulnerability to disease and psychiatric disorder. The behavioral effects of early social isolation in some non-human primates has been well documented. We have examined the survival rate and cell mediated immunity in a group of 18-23 year old rhesus monkeys, half of whom were socially isolated during their first 9 mos. of life. A comparison of survival rates indicated that the socially deprived monkeys had a significantly decreased survival rate, males being particularly vulnerable. Comparisons of the immunological phenotype between socially isolated and control animals were conducted on three separate occasions (the last following administration of the antigen tetanus toxoid) using monoclonal antibodies directed at human T-cell, B-cell, NK, LAK and macrophage phenotypes. A significant decrease in the ratio of helper to suppressor T cells was associated with early social isolation. A second effect of early social deprivation was a significantly increased percentage of natural killer (NK) cells. These findings, combined with preliminary data from functional studies, including mitogen stimulation and NK and LAK cell activity, provide important evidence to support the relationship between early psychosocial insult and life-long alterations in immune function. (Supported by PHS grant MH42938 and Center grants HD03110 and MH33127.)

EFFECTS OF SOCIAL SEPARATION ON T-CELL SUBSETS AND FECAL CORTISOL IN CEBUS MONKEY: RELATION TO NEUROTRANSMITTER ACTIVITY IN AMYGDALA. A. Kling, R. Lloyd, K. Tachiki, B. Ring*, and H. Prince*. Psychiatry Service, UCLA/VA Med. Center, Sepulveda, CA 91343, and American Red Cross.

We suggest that the influence of separation on the immune system may be mediated by the amygdaloid nuclei. Four Cebus monkeys (2 ♂ C. albifrons and 2 ♀ C. apella) were group-housed in an outdoor enclosure. We measured the T-cell subsets using flow cytometry during the social vs. separated condition. Samples obtained after two 3-5 day separations were compared with 5 samples during group housing. Blood and fecal samples for concentration of cortisol were obtained after each treatment condition. The major effects of social separation were an increase in the percentage of lymphocytes expressing a T-suppressor marker in all subjects. Further, the females showed an increase in T-helper percentages as well. Fecal cortisol concentrations were higher during separation compared to group housing and chair restraint. Subsequent analysis of brain neurotransmitters and metabolites obtained by microdialysis of the amygdala in the same subjects showed a robust and consistent increase in 5-HIAA and NE during separation. These findings suggest that social separation results in alterations of lymphocyte subsets along with an increase in brain serotonin and NE. This study was supported by the Joan B. Kroc Foundation and the Veterans Administration.

119.15

STRESSOR PREDICTABILITY AND IMMUNE FUNCTION. J. Irwin and N. Custeau*. Psychology Dept., Queen's University, Kingston, Ont. K7L 3N6, Canada.

The predictability of an aversive stimulus may be an important determinant of physiological or behavioral responses to stress. That is, when a light or tone signal precedes stressor onset, an organism may be able to adopt preparatory responses which buffer the aversive consequences of the stressor. Recently it was reported that this variable also influences stress-induced changes in immune activity, including mitogen-induced lymphocyte proliferation (Mormede et al, 1988). In the present study, the role of predictability in the mediation of stress-induced changes in Natural Killer (NK) cell activity was investigated.

NK activity was assessed in male C57BL/6J mice following exposure to 1 hr of intermittent inescapable footshock. For some animals shock onset was preceded by a 10 sec light CS (signalled shock), whereas for others, the light was not contiguous with shock onset (unsignalled). In addition, shock was presented either at regular intervals or on a variable interval schedule. Twenty-four hr later, splenic NK activity was assessed with a ^{51}Cr release assay. Compared to control animals, mice exposed to signalled shock at regular intervals exhibited a significant reduction of NK activity. Surprisingly, those in the unsignalled groups showed less NK suppression than those in the light-signalled shock group. It may be the case that the light was not sufficiently salient to predict shock onset. Alternatively, the warning signal and the temporal regularity of the shock may have added an increment of stress which is absent when stress is unpredictable. Nonetheless, these data do suggest that predictability may influence stress-induced alterations in immunity. (Supported by NSERC Grant U0569).

119.16

EFFECT OF BRIEF STRESSORS ON LYMPHOCYTE FUNCTION IN RATS: MECHANISTIC IMPLICATIONS J.P.Halper*, A.H.Miller*, C.Lackner*, B.Trestman*, F.Berkenbosh*, A.Santucci, V.Haroutunian, M.Stein. Mt. Sinai Med. Cntr., NY, NY 10029

Many studies have implicated that stressors lead to diminished lymphocyte function. However, little is known regarding the mechanism. The studies reported herein indicate that short periods of stress (2 minutes of intermittent footshock or 5 minutes of restraint) lead to diminished lymphocyte proliferation in response to mitogenic lectins. This defect in mitogenesis appears to occur at or beyond the level of Protein Kinase C (PKC), since mitogenesis in response to phorbol ester and ionomycin (which directly activate PKC) was also diminished. Brief stressors have the advantage of minimizing nonspecific effects associated with more prolonged or intense stress. Brief stressor effects on lymphokine production and lymphocyte subset distribution will also be presented.

119.17

INESCAPABLE FOOTSHOCK STRESS PROLONGS SURVIVAL IN MRL-LPR/LPR AUTOIMMUNE MICE

L.J. Grota, J.A. Moynihan*, S.G. Schmidt,* T.R. Schachtman*, N. Cohen* and R. Ader*. Depts. of Psychiatry and Microbiology and Immunology, University of Rochester, Rochester, NY, USA 14642

MRL-lpr/lpr mice develop autoimmunity that is characterized by production of autoantibodies to a wide spectrum of self-antigens; arthritis; and glomerulonephritis caused by both immune complex deposition in the kidneys and a T cell inflammatory response. They die beginning at approximately 20 weeks of age. Additionally, the MRL-lpr/lpr mice display massive lymphadenopathy due to the proliferation of a novel subset of T cells that are dull Thy 1^+ and Lyt 1^+.

We have demonstrated that footshock stress delivered 5 days/week beginning at 19 weeks of age consistently and significantly prolongs survival of MRL-lpr/lpr mice compared to both apparatus control and home cage control animals. A sigificant difference was found at 26 weeks of age, shocked animals having fewer deaths than controls (Chi-square analysis, $p<0.01$). In one such study, after 7 weeks of shock, 1/16 (6.25%) footshocked animals, 6/16 (37.5%) apparatus control, and 8/12 home caged (66.7%) had died

After 3.5 weeks of "therapy", animals were bled to measure corticosterone levels 15 minutes following the end of the shock session. Preliminary data indicate similar steroid levels in shock and apparatus control animals, suggesting that the difference in survival may not be mediated by the anti-inflammatory effects of steroids.

119.18

PSYCHOLOGICAL STRESS DOWN-REGULATES IL-1 PRODUCTION IN HUMAN MACROPHAGE/MONOCYTES. R. Glaser, A. Griffin, D. Bucci, J. Hillhouse, S. Kennedy, M. Kotur and J. Kiecolt-Glaser. The Ohio State University Medical Center, Columbus, Ohio 43210.

Work from our laboratory has focused on the interaction between the CNS and the immune system, and how psychological stress in humans can modulate this interaction. Since cytokines are important in cell-to-cell interactions, we have examined the synthesis of IL-1 by macrophage/monocytes in blood samples obtained from medical students taking examinations or from cell obtained approximately one month prior to the examination block (baseline). Supernatants from adherent cell cultures were assayed for IL-1 synthesis using the mouse thymocyte proliferation assay. We found that there was a significant decrease in IL-1 synthesis by cell cultures obtained at the time of examinations, as compared to the levels of IL-1 synthesized in cells obtained at baseline. We also found that this change was not related to the total number of macrophage/ monocytes in each sample. The results are consistent with previously published data from our laboratory and others, that psychological stress can down-regulate cellular immunity at several different levels.

NEURAL PLASTICITY IN ADULT ANIMALS: MOTOR SYSTEMS

120.1

SYNAPTIC REORGANIZATION IN THE MOTOR CORTEX INDUCED BY LESIONS OF THE DEEP CEREBELLAR NUCLEI. H. Asanuma, K. Arissian*and A. Keller. (SPON: E. L. White) The Rockefeller University. New York, NY 10021

We have previously reported that elimination of the thalamic input to the motor cortex induces proliferation of the corticocortical (CC) afferents in the motor cortex, at sites of synaptic contacts previously occupied by the thalamocortical terminals (Ichikawa et al., Brain Res., 437:131 1987). To determine whether similar plastic processes occur without synaptic vacancies, the deep cerebellar nuclei, which project to the motor cortex via the thalamus, were lesioned unilaterally in 7 adult cats. Operations were performed under Nembutal, and sterile conditions. Cerebellar lesions did not produce degenerative changes in the motor cortex. One month later, CC afferents from area 2 to the motor cortex were labeled by lesion-induced degeneration. Quantitative electron-microscopy revealed that sections of motor cortex contralateral to the cerebellar lesions contained significantly higher numbers of labeled CC terminals, and higher proportions of axospinous synapses, compared to control hemispheres. In addition, electrophysiological examination revealed that the polarity of evoked potentials induced by area 2 stimulation reversed in the depth of the motor cortex, whereas in control hemispheres there was no reversal. The results demonstrate that a functional, but not anatomical, elimination of input to the motor cortex can induce a reorganization of synaptic connections. Supported by NIH #NS-10705 (H.A.) & NRSA #1 F32 NS08626 (AK)

120.2

DENERVATION IN VITRO: CHANGES IN FUNCTIONAL PROPERTIES OF PERIPHERAL NICOTINIC ACETYLCHOLINE RECEPTOR (AChR). R. Rozental*, W. Randall* and E.X. Albuquerque. (Spon: S.R. Max) Dept. of Pharmacol., Univ. of Md. Sch. of Med., Baltimore, MD 21201.

Although the AChR is the best studied agonist-gated ion channel, some of its properties are still controversial. One question is whether the altered kinetic properties of the AChR observed after denervation are due to post-translational modifications or to expression of new transcription. Single fibers were dissociated from frog interosseal muscle, kept at 4°C, for a period of up to 14 days, and cell attached patch-clamp recordings were made at 10°C. After acute dissociation, ACh (0.4 μM) and (+)anatoxin (0.2 μM) induced channel openings with 30 pS conductance and voltage-dependent lifetimes. On the 2nd and 7th days after fiber dissociation, 2nd (18 pS) and 3rd (smaller than the previous) conductance states were observed. The channel lifetimes of the 2nd and 3rd conductance states were shorter than the 1st one described, and by 12–14 days, each one accounted for 33% of the total observed openings. Chronic treatment of the fibers kept at 4°C with cycloheximide (10 μg/ml) did not prevent the appearance of the two lower conductance states, yet inhibited all incorporation of ^3H-leucine into TCA precipitable protein. α-Bungarotoxin (5 μg/ml) blocked all currents. Thus, we conclude that: 1–protein synthesis may not be required for the expression of the above two lower conductance states. 2–these above channels are different from the "embryonic" type observed in the denervated muscle. 3–our results may represent the expression of different subconductance states of the same AChR. (Support: US Army Med. Res. & Dev. Comm. Contract DAMD17-88-C-8119 and NIH Grants NS25296 & NS26885).

120.3

MORPHOLOGICAL AND PHYSIOLOGICAL CORRELATES OF SYNAPTIC COMPETITION AT FROG NEUROMUSCULAR JUNCTIONS. R. Dunia and A.A. Herrera. Dept. of Biological Sciences, Univ. of Southern California, Los Angeles, CA 90089.

In the pectoral muscle of adult Xenopus (10-44g), half the fibers have two junctions. By recording curare-blocked EPPs from identified sites on these dually-innervated fibers, we found the following 3 innervation patterns: 1) those with the same axonal input innervating each of two distant sites (a/a), 2) those with different inputs innervating distant sites (a/b), and 3) those similar to type a/a, but with one of the two sites innervated by a second axon (a/ab). EPP amplitudes (corrected for input resistance and resting potential) measured at each site confirm previous reports that type a/a terminals produce larger EPPs than either type a/b or a/ab terminals. It has been hypothesized that these differences in synaptic efficacy are due to competitive interactions between axons of different motoneurons.

We are currently examining other aspects of synaptic transmission such as facilitation and depression at junctions of each type to more fully characterize the physiological consequences of synaptic competition. In addition, we are correlating the histological appearance of the identified junctions with innervation pattern to test whether competition induces enhanced structural remodelling. CHANGES IN THE SIZE OF LUMBAR MOTONEURONES AFTER ROSTRAL SPINAL CORD TRANSECTION. E. Eidelberg, L. H. Nguyen*, and M. Gutierrez*. Division of Neurosurgery, U. of Texas Health Science Center, San Antonio, Texas 78284

Rats were prepared by complete transection of the spinal cord at T_8-T_{10}, followed by retrograde labeling of soleus (SOL) and extensor digitorum longus (EDL) motoneurones by injection of WGA-HRP into each muscle (one muscle/side). We measured the crossectional area of the soma of densely labeled cells. There were no significant differences in the mean size of SOL vs. EDL cells in intact rats. The cells in both groups became significantly larger, even a few hours after the transection, but EDL cells returned to baseline size sooner than SOL cells. Pre-treatment with intraventicular puromycin, a blocker of protein synthesis, prevented the size increases. It seems possible that a rapid increase in protein synthesis may underlie the morphological changes.

MONOCLONAL ANTIBODIES TO NEONATAL HUMAN AND MOUSE CEREBELLUM. J. Raisanen,* L.B. Pickford,* D.N. Mayer* and R.V. Rouse. (SPON: M.E.Smith) Dept. of Pathology, Stanford Univ. School of Medicine, Stanford, CA.

The mammalian cerebellum has a highly ordered morphology which is composed of several distinct types of neurons and glia. Morphogenesis depends on the successive proliferation, migration and differentiation of primitive neuroectodermal cells of the metencephalon. Each of these stages is likely defined by a regulated expression of certain neural, glial and interstitial molecules. Identification of these molecules would, therefore, help to characterize these developmental processes. As an initial step, monoclonal antibodies to neonatal human (35 weeks gestational age) and Balb/c mouse (P10) cerebellum were generated using standard fusion methods. Generated antibodies were screened for binding specificity on acetone fixed, frozen sections of developing cerebellum.

In the human cerebellum, mouse monoclonal antibodies defined antigens specific to the molecular layer, to small blood vessels, Purkinje cells and cells of the dentate nucleus. Similar recognition patterns were observed in both neonatal and adult cerebellum and cerebrum. In the mouse, rat monoclonal antibodies included ones recognizing Bergmann and radial glia and glial endfeet on blood vessels. Others recognized nuclear membranes of many neural cell types and blood vessels throughout the brain. Further immunohistochemical and biochemical characterization of the molecules recognized by these antibodies is in progress. These molecules may be important in the anatomical or physiological development of the mammalian cerebellum.

MEMORY TRACES IN PRIMATE SPINAL CORD: CORRELATION WITH BEHAVIOR. J.R. Wolpaw, C.L. Lee, and J.S. Carp. Wadsworth Laboratories, NYS Dept Health, Albany, NY 12201.

Operant conditioning of the H-reflex, the electrical analog of the monosynaptic stretch reflex, changes the spinal cord itself (J Neurophysiol 61:563-572, 1989). Conditioned side-to-side reflex asymmetry is still present in the anesthetized animal three days after transection removes supraspinal influence. We compared the asymmetry in the awake behaving animal to the asymmetry that persists in the transected spinal cord.

Nineteen Macaca nemestrina underwent conditioning to increase or decrease triceps surae H-reflex in one leg. Then, each animal was deeply anesthetized, reflexes were measured in the transected spinal cord, and animals were sacrificed by overdose and perfused for anatomic study.

The conditioned reflex asymmetries present in awake behaving animals remained after transection isolated the spinal cord from supraspinal influence. Larger asymmetry in the behaving animal was associated with larger asymmetry in the transected spinal cord ($r=.75$, slope=.70, $p<.001$). This relationship suggests that the memory trace in the spinal cord accounted for most of the asymmetry seen in the awake behaving animal. Physiologic and anatomic studies (Carp et al and Lee et al, this volume) are evaluating the most likely site of this memory trace, the Ia synapse on the alpha motoneuron.

CHOLINE-ACETYL-TRANSFERASE (CHAT) DISTRIBUTION IN THE LUMBOSACRAL SPINAL CORD CHANGES FOLLOWING CHRONIC SACRAL ROOT RESECTION. A.M. Booth, S. Erdman* V. Erickson* M. Kawatani, J.R. Roppolo, S. Smerin and W.C. de Groat. Department of Pharmacology and Center for Neuroscience, University of Pittsburgh School of Medicine, Pittsburgh, PA 15261.

In the spinal cord CHAT, a marker for cholinergic neurons, is located in preganglionic cells in the intermediolateral nucleus, in motoneurons, and in some interneurons in the medial dorsal horn and the intermediomedial nucleus. These experiments examined the change in CHAT distribution following long term (more than one year) unilateral transection of the sacral dorsal and ventral roots in adult cats. Following fixation by intracardiac perfusion the tissue was frozen and cut at 42 μm. Localization of CHAT-like immunoreactivity used a rat monoclonal antibody and a double bridge, nickel intensified PAP process on free floating tissue. CHAT-like immunoreactivity in lesioned tissue was different in several regions of the lumbosacral cord. Most notable was a tangle of CHAT positive processes projecting into lamina VII and into the ventral white matter where they extended both rostrally and caudally. Quite unexpected were intensely labeled processes coursing from the S_1 intermediolateral and lateral ventral horn (lam VII & IX) toward the commissural region and into the dorsal columns and a group of processes extending along the lateral margin of the dorsal horn and into Lissauer's tract. These bundles of CHAT positive projections traveled both rostrally and caudally from S_3 to L_7. There was no change in size, number or intensity of labeling of CHAT containing neurons. These findings raise the possibility that axotomy of efferent cells increases the intensity of CHAT staining in the processes of these cells and/or that long term rhizotomy causes an expansion of the processes.

120.8

CHANGES IN PEPTIDE-IMMUNOREACTIVITY IN RAT DORSAL HORN FOLLOWING ELECTRICAL STIMULATION OF THE SCIATIC NERVE. C.M. Klein*, L.S. Sorkin, S.M. Carlton, K.Westlund and R.E. Coggeshall. (SPON: H.W. Burden). Dept. of Anat., MBI, Univ. of Texas Med. Br., Galv., TX 77550.

The purpose of this study was to examine changes in peptide-immunoreactivity in the L4-L5 dorsal horn following acute sciatic nerve stimulation. Three peptides known to be contained in primary afferent fibers were targeted:substance P (SP), calcitonin gene-related peptide (CGRP), and cholecystokinin-8 (CCK). Adult Sprague-Dawley rats were anesthetized (Nembutal), paralyzed (Gallamine) and the sciatic and tibial nerves on one side were exposed. The sciatic nerve was then electrically stimulated (1 Hz, 0.2 ms) for 20 mins.; the compound action potential was monitored from the tibial nerve. The C wave was present and did not diminish for the entire stimulation period. Immediately after stimulation, the rats were perfused with 3% paraformaldehyde, 3% glutaraldehyde, 0.1% picric acid in cacodylate buffer. The L4-L5 spinal cord segment was removed and processed for immunocytochemistry by the peroxidase anti-peroxidase method. Results show that immunoreactive staining for SP, CGRP and CCK in the medial half of the superficial dorsal horn was significantly decreased following acute stimulation of the sciatic nerve. This data suggests that electrical activity in primary afferent fibers causes depletion of peptides in their terminal distribution in the dorsal horn.

120.9

CHANGES IN PEPTIDE-IMMUNOREACTIVITY IN RAT DORSAL HORN FOLLOWING PLACEMENT OF SCIATIC NERVE STUMPS INTO SILICONE TUBES. R.E. Coggeshall, C.M. Klein, T.E. Sherburn AND S.M. Carlton. The Marine Biomedical Institute, Dept. of Anatomy and Neurosciences and Dept. of Phys. and Biophy., The University of Texas Medcial Branch, Galveston, Texas 77550.

Transection of large peripheral nerves is known to cause loss of dorsal root ganglion cells and of peptides in the dorsal horn. Recently we found that putting the stumps of a transected nerve in an impermeable tube avoided the cell loss. To test whether the tube also influenced the immunocytochemical staining, rat sciatic nerves were transected and the animals were placed into two groups; 1) simple nerve transections and 2) nerve transections treated by tubes. The data indicate that there is loss of immunocytochemical staining in the dorsal horn in the tubed animals but not as much as with the simple transections. If this is confirmed quantitatively and if cell numbers do not change (to be determined), the conclusion will be that transection of a peripheral sensory axon causes depletion of peptides in the central processes of dorsal root ganglion cells which is not correlated with the death of the cells. 120.10

SYNAPTIC REPRESSION IN THE CRAYFISH AFTER PARTIAL DENERVATION. L.L. Gould* and S.J. Velez (SPON: F. McCann). Department of Biological Sciences, Dartmouth College, Hanover, New Hampshire 03755

The superficial flexor muscle system of the crayfish Procambarus clarkii was used to study the effect of partial denervation on established synaptic contacts. The six motoneurons that innervate the 40 muscle fibers have their cell somas at precise locations within the abdominal ganglia. A portion of the third segment ganglia was cut and removed from cold-anesthetized animals at a location that removed the cell soma of three of the six neurons going into the muscle. The remaining cell somas (neurons 1, 3 and 5) were left in place, along with the nerve and the muscle fibers. At regular intervals after the surgery, the connectivity patterns generated by neuron 3 over the muscle surface were analyzed by recording jp's in phase with axonal spikes. In control animals, jp's ranging from 0.1 to 5 mV (generated by the spontaneous firing of the neuron) are easily recorded all over the muscle surface. In experimental animals, no jp's could be recorded at the 0.1 mV limit of resolution of our system even after eight weeks after surgery, yet they could be seen after stimulating the axon at 10 Hz or after cold treatment. Therefore, synaptic contacts are present but are not generating the normal postsynaptic jp sizes under physiological conditions. This suggests that the synaptic contacts from axon 3 are being repressed when some of the neurons that innervate the muscle are missing.

120.11

THE EFFECT OF PARTIAL DENERVATION ON ULTRATERMINAL SPROUTING IN THE EDL MUSCLE OF ADULT AND AGED RATS. J.L. Rosenheimer, Y.P. Xu*, and L.A. Trotter* Dept. of Physiol., Univ. of Wis., Madison, WI 53706.

In rat extensor digitorum longus (EDL) muscle end plates, there is an age-related decrease in nerve terminal number but an increase in ultraterminal sprouting, characteristic of muscle denervation. To see if the sprouting response following denervation would be affected by age, EDL muscles from 10- and 25-mos animals were partially denervated and end plates were examined 4 to 14 days after denervation.

There was a significant increase in ultraterminal sprouting after 4 days denervation in the 25-mos rats, but not until 7 days after denervation in the 10-mos rats. Sprouting frequency in 25-mos muscle end plates was 2x greater than in 10-mos muscle. However, the number of sprouts in 25-mos denervated muscles was only 1.3x greater than in 25-mos innervated muscles; in 10-mos denervated rats the number was 2.5x greater. Average ultraterminal sprout length was 2x greater in 25- compared to 10-mos muscles. In general, innervated end plates with sprouts and all denervated end plates had larger areas and fewer nerve terminals than innervated end plates without sprouts. The results suggest that aging at the neuromuscular junction is accompanied by changes reminiscent of functional denervation. Supported by NIH grant AG01572.

PROTEIN SYNTHESIS IS REQUIRED FOR LONG-TERM ADAPTATION OF TRANSMISSION AT NEUROMUSCULAR SYNAPSES. P.V. Nguyen* and H.L. Atwood. Dept. of Physiol., Univ. of Toronto, Toronto, M5S 1A8 Canada.

Previous work has established that chronic stimulation of the crayfish claw closer muscle's phasic motoneuron can induce a long-term adaptation (LTA) of its neuromuscular synaptic responses (J.Neurosci. 5:459-67). LTA is characterized by reductions in both initial EPSP amplitudes and synaptic depression. In the present study, these changes were evident 2 days after a 3-day conditioning regimen (2h/day,5 Hz). To determine if protein synthesis was required for LTA, we injected cycloheximide (CHX; 5ug/g), a protein synthesis inhibitor, into intact crayfish at various times relative to each conditioning period. CHX reversibly and maximally blocked protein synthesis for 2 hours following a single injection. Injection of CHX before each conditioning period significantly attenuated LTA, while injection during or after conditioning had no effect. Chronic CHX injection had no adverse effect on neuromuscular transmission in control animals. Thus, short-lived, pre-existing protein(s) may be required for neuromuscular LTA in the claw's phasic motoneuron.

DISTRIBUTION OF MYOSIN ISOENZYMES IN AGING SKELETAL MUSCLE OF MICE. K. Y. Saiki* and M. A. Fahim. Andrus Gerontology Center, University of Southern California, Los Angeles, CA 90089-0191.

To delineate morphological differences in aging skeletal muscle, the proportion of alkali-1 and -2 myosin light chains (MLC) in extensor digitorum longus (EDL) in young and old mice (C57BL/6NNia) were determined by immunocytochemical techniques. The EDL of 6 month old and 24 month old mice was either partially ablated (ABL) or the nerve innervating the muscle crushed (CN) to invoke partial denervation. Five weeks post-surgery fluoroscein-labeled antibody, specific for alkali-1 and -2 MLC showed a redistribution towards a greater proportion of alkali-1/alkali-2 MLC in both young and old CN-EDL with young muscle showing a higher ratio. ABL-EDL also demonstrated similar changes with old muscle, however, showing a higher ratio. Twitch tensions/unit mass of young CN-EDL decreased when compared with young controls while old ABL-EDL attenuated compared to old controls. This suggests that strength decrement may be associated along with other age related changes with the redistribution of alkali-1 and -2 MLC. Supported by NIH grant AG-04755.

DISSOCIATED CELL CULTURE OF ADULT RAT PELVIC GANGLION. W.D. Steers and J.B. Tuttle Urology and Neuroscience Univ of Virginia Hlth Sci Cntr, Charlottesville, VA 22908

Parasympathetic decentralization fails to block neuronal hypertrophy in rats with partial urethral obstruction. Thus, the alterations in function, morphology and electrophysiology found in this animal model for outlet obstruction appear to depend upon events in the target organ: the bladder. Methods were developed to test the hypothesis of target-derived trophic factor involvement in obstructive pathophysiology by examining growth factor action in cell culture. Dissociation protocol and medium formulation were optimized to culture neurons from pelvic ganglia 6 weeks following ligation or sham surgery. The adult rat neurons adapted to culture with only a 10-30% initial yield. Neuronal counts were confirmed by immunostaining for neuron-specific beta-tubulin (TuJ1). NGF (0.1 ug/ml) doubled initial survival. The retrograde fluorescent tracer diO, injected into the bladder 36 hrs prior to dissociation, labeled some cultured neurons indicating survival of the subpopulation innervating bladder. Neurons were immunoreactive for TH and NPY, indicating survival of a mixed cell population. Cultured neurons retained excitability, with voltage-sensitive Na^+ and K^+ currents serving action potentials. Thus, the adult rat pelvic ganglion is suited to studies of trophic interaction in vitro, and may be useful in providing further insight into plasticity of the adult peripheral nervous system.

GROWTH ASSOCIATED PROTEIN, B-50 (GAP43) IS PRESENT IN THE MAMMALIAN ENTERIC NERVOUS SYSTEM. K.A. Sharkey*, W. Tetzlaff*, P.J. Coggins*, H. Zwiers*, M. Bisby and J.S. Davison*. (SPON: G.E. Lucier) Dept. of Medical Physiology, University of Calgary, Calgary, Alberta, Canada.

B-50 (also known as GAP43) is a neuron-specific, membrane bound phosphoprotein whose synthesis is selectively enhanced during neural development, growth and conditions of neuronal plasticity. In the adult peripheral nervous system B-50-like immunoreactivity (B-50-LI) is normally present at low levels. However, there is an increase in B-50-LI after injury. The presence of B-50 has not been investigated in the mammalian enteric nervous system. Experiments were performed on adult rats. B-50-LI was localized in nerves throughout the wall of the intestine using affinity purified rabbit B-50 antibodies. Most striking was the dense immunoreactivity in the myenteric plexus. A few scattered endocrine cells were stained in the ileum. B-50-LI nerves were found in the longitudinal and circular muscle layers, both myenteric and submucous plexuses and in the peri-and sub-glandular and villus portions of the lamina propria. Numerous nerve cell bodies in both plexuses were lightly stained. In-situ hybridization with a cDNA probe to GAP43 revealed a positive signal in enteric neurons. In extracts of ileum a band of B-50-LI material was observed on Western blots. The role of B-50 in the gut has yet to be determined, but it is tempting to speculate that the adaptive ability of the gut after injury might be related to the presence of B-50 in enteric nerves.

120.16

POTENTIAL ROLE FOR NGF IN NEURONAL PLASTICITY AFTER BLADDER OBSTRUCTION. D.J. Creedon, W.D. Steers, and J.B. Tuttle.Depts Urology, Neuroscience, Physiology, Univ of Virginia Hlth Sci Cntr, Charlottesville, VA 22908

Urethral obstruction causes bladder enlargement associated with neuronal hypertrophy and functional changes in the reflex pathways controlling micturition. Since smooth muscle cells can secrete trophic substances that influence peripheral neuronal growth including nerve growth factor (NGF), neurotrophic factors may be involved in the pathophysiological sequence following obstruction. NGF (0.1 ug/ml) enhanced the survival of adult rat major pelvic ganglion (MPG) neurons in culture. This suggests at least a subset of MPG neurons remain responsive to NGF in the adult. Using a two-site ELISA to measure NGF, obstructed bladders produced 2X more NGF (ng per mg protein) than controls. In one experiment, the amount of NGF per mg protein was similar to controls, but the increased size of the obstructed bladder (wet wgt 684 vs. 75mg) resulted in 10X more total NGF in the enlarged organ. Since the number of neurons innervating the bladder following obstruction is unchanged, MPG neurons may access 10-20X more NGF following bladder enlargement. This change in NGF supply could mediate the neuronal hypertrophy and some aspects of adult reflex plasticity. The results suggest that regulation of target organ size and factor synthesis in response to functional demands may alter the supply of trophic material available to innervating neurons in the adult.

120.17

PRESYNAPTIC INFLUENCE ON POSTSYNAPTIC CHANNEL KINETICS IS LOCALIZED TO INDIVIDUAL SYNAPSES. L.M. Marshall. Dept. of Physiology, Univ. of North Carolina, Chapel Hill, NC 27599.

In the two types of principal neurons in frog sympathetic ganglia, B- and C-cells, a twofold difference in the mean open time of nicotinic synaptic channels accounts for the twofold difference in the decay rate of their fast excitatory postsynaptic currents (EPSCs). When B-cells are denervated and incorrectly innervated by preganglionic C fibers, B-cells acquire the slowly decaying EPSCs and long channel open times normally seen in C-cells only (Nature 317: 621, 1985). This study examined the EPSCs from B-cells that were denervated and reinnervated by both B and C preganglionic axons.

Dually innervated B-cells in the 9th and 10th paravertebral ganglia of adult Rana catesbeiana were examined by whole voltage clamp. In individual B-cells, stimulation of B preganglionic fibers evoked EPSCs with a fast decay, while C preganglionic nerves evoked EPSCs with a slow decay. These results suggest that presynaptic influence on synaptic channel kinetics is localized to the region of each synaptic contact (Supported by grant NS14899)

120.18

NEURON NUMBER INCREASES IN POSTMETAMORPHIC BULLFROGS: SYMPATHETIC GANGLIA. P.B. Farel and J.K. Baek*. Dept. of Physiol., Univ. N. Carolina, Chapel Hill, NC 27599.

In most species, body size continues to increase after the period of nervous system development is over. **How does the nervous system accomodate to the expanded target size?** We retrogradely labeled sympathetic neurons by applying HRP to the nerve trunk supplying the posterior thigh in bullfrogs ranging from 3.3-11.5 cm in length (n = 12). Labeled and unlabeled sympathetic neurons were counted in the three sympathetic ganglia that supply the leg. Serial reconstruction of labeled neurons demonstrated that no correction factor is needed for nucleolar counts.

The total number of neurons was strongly correlated with size (r = 0.75). Large frogs (10.5-11.5 cm, n = 4) had 2-4 times as many total neurons as small frogs (3.3-3.5 cm, n = 4) and 4-8 times as many HRP-labeled neurons.

Neurons are added to the sympathetic ganglia in adulthood and these added neurons send axons to the periphery. Experiments in progress are directed toward estabishing the generality, kinetics, and mechanism of the increase in neuron number.

120.19

NEURON NUMBER INCREASES IN POSTMETAMORPHIC BULLFROGS: DORSAL ROOT GANGLIA. P.G.R. St.Wecker* and P.B. Farel (SPON: D.L. McIlwain). Dept. of Physiol., Univ. N. Car., Chapel Hill, NC 27599.

To further our study of neuronal increase in the adult bullfrog, we retrogradely labeled lumbar DRG neurons by applying HRP to the posterior profundus nerve in bullfrogs ranging from 3.3-11.5 cm in length. Labeled and unlabeled neurons were counted in the three DRGs that supply the hindlimb. Serial reconstruction of labeled neurons demonstrated that split nucleoli occur in approximately 5% of counted neurons.

The total number of neurons was strongly correlated with body length (r = 0.88). Large frogs (10.5-11.5 cm, n = 3) had a mean (±SD) of 12,368±1,580 total neurons, versus a mean of 6,943±739 in small frogs (3.3-3.4 cm, n = 2). Counts of HRP-labeled neurons showed a similar ratio, with a mean count of 384±84 for large frogs and 226±40 for small frogs.

These data indicate that peripherally projecting neurons are added to the DRG in adulthood. These results are consistent with previous data on sympathetic ganglia, spinal motoneurons, and brainstem projection neurons in adult bullfrog.

121.1

BRAIN-BEHAVIOR RELATIONSHIPS IN AGING OBSERVED THROUGH QUANTITATIVE MAGNETIC RESONANCE (MR) IMAGING AND MEMORY MEASURES. J. Rawles*, E. V. Sullivan, K. O. Lim*, R. B. Zipursky*, and A. Pfefferbaum*. Stanford University School of Medicine, Stanford, CA and Veterans Administration Medical Center (116A3), Palo Alto, CA 94304.

Although declines in memory function and changes in brain morphology occur with normal aging, little direct evidence exits for a link between these two processes. This linkage was assessed by comparing quantitative measures of medial temporal-lobe integrity from MR scans with performance on memory tests in 8 young men (mean=24yrs) and 7 older men (mean=73yrs). We expected that scores of long-term memory (LTM) tests, subserved by medial temporal-lobe structures, would be negatively correlated with measures of temporal horn cerebrospinal fluid (CSF) in the older group.

MR quantification for this analysis comprised three specific measures (left, right, left+right temporal horn CSF) and one global measure (ventricular volume excluding the temporal horns)(Lim, et al., 1989, *Soc. Neurosci. Abstr.*). Memory assessment included tests of short-term memory (STM)(Wechsler Memory Scale [WMS] and block span) and LTM (delayed recall of WMS subtests).

The older group had significantly greater CSF volumes for all MR measures and scored significantly lower than the young group on four STM and two LTM tests. Scores of two LTM tests (stories and drawings), but of no STM test, correlated significantly with specific brain measures and with the global MR measure in the older group; no correlation was significant in the young group.

Thus, coupling structural imaging measures of circumscribed brain regions with tests of component processes of memory is a viable method for observing specific brain-behavior relationships in normal aging that transcend nonspecific deterioration commonly associated with the aging process.

121.2

EVIDENCE FOR ATYPICAL NEURAL ARCHITECTURES IN NEUROPSYCHOLOGICALLY NORMAL ADULTS. J.P. Brandt*, D. Tranel, H. Damasio, A.P. Tranel* and R.D. Jones. Div. of Behav. Neurol. & Cognitive Neuroscience, Dept. of Neurology, Univ. of Iowa Col. of Medicine, Iowa City, Iowa, 52242.

The development of aphasia following a right hemisphere lesion in dextral adults is extrememly rare. We conducted neuroanatomical and neuropsychological studies in 2 such adult males. Both had handedness quotients of +100 (complete right-handedness), and normal cognitive development and intellectual abilities. Also, both had typical anatomical asymmetries of auditory cortex, i.e., favoring the left. In the acute epoch after a lesion involving right primary and association auditory cortices, the subjects had (a) fluent, paraphasic speech, with profound disturbances of comprehension, repetition, reading, and writing, AND (b) anosognosia, left neglect, and visuoperceptive defects.

Handedness is generally used as a predictor of cortical functional dominance and has even been thought to be a factor in its development (indirectly via an asymmetry for motor control). The evidence here contradicts that notion and reveals that atypical neural architectures can occur in cognitively normal adults with typical anatomical asymmetries, even when characteristic indexes, e.g., sinistrality, ambidexterity, or developmental learning disorder, are entirely absent.

121.3

HUMAN EXTRACELLULAR STEREOTRODE ANALYSIS OF NEURONAL ENSEMBLE DYNAMICS DURING LANGUAGE TASKS. D.F. Cawthon*, G.A. Ojemann, E. Lettich*, D.F. Kalk*, and D.B. Percival* (SPON: A.B. Harris). Dept. Neurosurg.and Appl.Physics Lab., Univ. of Washington, Seattle, WA 98195.

With informed consent and under institutional rules, we have found modulation of normal human temporal lobe neuronal activity by language and memory tasks at nonessential sites during epilepsy surgery. Separation of action potentials of different neurons is critical for frequency analysis if one is interested in the dynamics of firing in an ensemble of cells, but could not be reliably accomplished by time-window discriminators from multiunit activity obtained by standard tungsten microelectrodes. We therefore adapted a "stereotrode" (McNaughton, B.L. et al. *J Neurosci Methods* 8: 391-397, 1983) which in our version has two stainless steel microwires (60μ diameter, 70μ apart) threaded through a 30G hypodermic shaft, used as reference. After recording, the location of the tips is marked thermally and alternating 20 μ sections are stained by Nissl or Fink-Heimer methods. Recordings were played back from FM tapes via National Instruments' A/D and DMA boards and software drivers into a Macintosh II computer, with additional software written in Pascal and then analyzed using PITTSA, a time series analysis package written in Lisp. Each cell's action potential appeared on both microelectrode channels but with different amplitudes due to different distances from the two electrode tips. Cells of nearly identical waveform were often indistinguishable on one channel, only to be revealed as separate by the other channel. A dual amplitude scatter plot yields 3 to 6 well-defined clusters, each corresponding to a different cell, as corroborated by differences between cell firing patterns with different linguistic tasks and by statistical cluster analysis techniques. Action potential duration can be examined as a third clustering parameter, in a 3D scatter plot. (Supported by NIH Grants NS21724, NS20482, NS17111 and NS07289 and by the Epilepsy Foundation of America.)

STIMULUS-SPECIFIC MEMORY DEFICITS AFTER THALAMIC LESIONS IN MAN. J.Ilmberger,W.Fries*,A.Danek*, Inst.Med.Psychology,Univ. of Munich, Munich,FRG.

It is well known that circumscribed lesions in the left or right temporal lobe lead to stimulus-specific verbal or nonverbal memory deficits. It is unclear whether this specificity also holds true for memory disorders due to thalamic lesions. One problem in testing is finding nonverbal stimulus material resistant to verbal encoding. Milner's (1973) recency test seems to offer an adequate solution to this problem.

We used a similar test consisting of serially presented stimulus cards; at regular intervals a question card was interposed. The subject had to indicate whether he had seen the two items on that card before and, if yes, in which order. Both a verbal (nouns) and a nonverbal (partial reproductions of abstract paintings) form of the test was administered to patients with uni- and bilateral thalamic lesions and a healthy control group. Bilateral lesions led to a high error score in both forms of the test; a left-sided lesion decreased verbal, a right-sided lesion nonverbal performance, indicating that the verbal -nonverbal distinction also is valid at the thalamic level.

EFFECTS OF AUDITORY ASSOCIATION CORTEX LESIONS ON THE PROCESSING AND RETENTION OF ACOUSTIC STIMULI IN MONKEYS. M. Colombo*, M. R. D'Amato*, H. R. Rodman, and C. G. Gross. Dept of Psychology, Rutgers University, New Brunswick, NJ, 08903 and Dept. of Psychology, Princeton University, Princeton, NJ, 08544.

Unlike previous studies that used auditory-visual or auditory-spatial delayed matching-to-sample (DMS) designs, we employed an auditory-auditory DMS task to examine the effects of auditory association cortex lesions on the short-term memory capacity of monkeys.

Three *Cebus apella* monkeys were preoperatively overtrained on closely similar visual and auditory DMS tasks with delays of .5, 4, and 32 seconds. Each then received a two-stage bilateral lesion, with testing after each lesion. The lesions included most of the superior temporal gyrus and upper bank of the superior temporal sulcus, and the anterior part of the lower bank of the lateral fissure.

Although visual DMS performance was completely unaffected by the auditory cortical lesions, auditory DMS performance suffered, particularly after the second operation. One monkey was able to match the acoustic stimuli but displayed a severe retention loss at all delays. The other two monkeys were unable to match the acoustic stimuli, even at the shortest delay. The fact that these subjects could discriminate tones less separated than the tones used in the matching task indicates that the matching deficit was not due solely to sensory impairment; rather, it reflects a deficit in higher-order processing of auditory information.

121.6

BEHAVIORAL DISTURBANCES IN THE DEVELOPING RHESUS MONKEY FOLLOWING NEONATAL LESIONS OF INFERIOR TEMPORAL CORTEX (AREA TE) RESEMBLE THOSE IN ATTENTION-DEFICIT HYPERACTIVITY DISORDER. P. M. Merjanian, J. Bachevalier, K. D. Pettigrew*, and M. Mishkin. Laboratory of Neuropsychology, NIMH, Bethesda, MD 20892.

Early damage to the limbic system in monkeys yields severe socio-emotional disturbances resembling those seen in autistic children (Merjanian et al., Soc. Neurosci. Abstr., 12:23, 1986 and 14:2, 1988). Although the 6 operated controls that had received early damage to area TE did not show these disturbances, they did display other behavioral abnormalities. Six monkeys had received area TE lesions (TE) neonatally, 6 were normals (N/TE) reared with monkeys from Group TE and 6 were normals reared with other normals (N/N). At 2 and 6 months of age, each animal from Group TE was paired in a play cage with its age-matched control (N/TE), and their behavior was observed for 12, 5-minute intervals on 6 days. Similarly, each N/N was paired with another N/N. At 2 months, the monkeys in Group TE were hyperactive, shifted more from one behavior to another, and showed more stereotyped behaviors than monkeys in either Group N/TE or Group N/N. In addition, animals in Group N/TE showed more aggressive behavior towards animals with TE lesions and had more temper tantrums than both other groups. Although these behavioral disturbances in both the operated animals and their unoperated controls were less severe at 6 months of age, they strongly resemble those of people with attention-deficit hyperactivity disorder and the responses of their peers.

121.7

RETROSPLENIAL CORTEX: POSSIBLE ROLE IN HABITUATION OF THE ORIENTING RESPONSE. S.E. Kwon*, S.E. Nadeau*, and K.M. Heilman, Dept. Neurol., Univ. FL, Gainesville, FL 32610.

A patient following a retrosplenial(RS) area lesion developed a propensity to attend contralaterally (Neurol., 38(suppl.1)1988). To learn if a RS regional loss was inducing this defect, unilateral RS and cingulum(CG) lesions in rats were reproduced by aspiration. Subjects were assessed preop and postop for orientation and habituation to bilateral simultaneous stimulation in 3 modalities; visual, tactile and auditory. At each session, independently tested, the orientation test was terminated upon completion of 5 trials per modality and the habituation test ended at habituation (4 consecutive response failures) or upon completion of 15 trials per modality.

Contralesional vs ipsilesional orientation was not significantly different suggesting no evidence of neglect. A significant delay in habituation to contralesional stimulation in postop weeks 2 and 3-5 was revealed by two-way ANOVA for its interactions ($p<0.01$) and its post-hoc comparison ($p<0.02$).

Our results suggest that RS-CG lesions are associated with a failure to habituate to contralesional stimuli. While the mechanism underlying this defect is unknown, this limbic region has close anatomic connections with areas such as the frontal lobe that are known to play a role in directional attention. Perhaps RS lesions release attentional networks from limbic control.

ACQUISITION OF SIGN LANGUAGE FOLLOWING LEFT HEMISPHERE DAMAGE AND APHASIA. S.W. Anderson, H. Damasio, A.R. Damasio, U. Bellugi, A.P. Tranel*, J.P. Brandt*, and L. O'Grady*. Div. Behav. Neurology & Cognitive Neuroscience, U. Iowa College of Medicine, Iowa City, IA 52242.

Because American Sign Language (ASL) shares principles of auditory-based languages but is based on visual-motor signs and has linguistic mechanisms unique to this mode of transmission, studying its processing after brain damage offers a new window into the neural basis of cognition. We describe a case-control experiment of the acquisition of ASL following a left temporo-parietal infarct which caused severe aphasia for English. This 28 year old man with no prior knowledge of sign language was able to acquire ASL lexicon at a rate equal to an age matched normal control. Specific signs were produced with great accuracy (words - 97%; letters - 96%; numbers - 100%), in striking contrast to a near complete inability to speak their word counterparts (less than 10% correct). These findings were replicated in another English-speaking man with left temporo-parietal damage and severe aphasia. The finding that specific semantic knowledge may be readily expressed by a visual-gestural symbolic system after damage to posterior language-related cortices and aphasia for English, indicates that such knowledge is represented independently of a verbal lexicon and does not depend on the posterior cortices necessary for normal verbal-auditory language.

121.9

KNOWING THAT "COLORADO" GOES WITH "DENVER" DOES NOT IMPLY KNOWLEDGE THAT "DENVER" IS IN "COLORADO." A.R. Damasio and D. Tranel. Div. of Behav. Neurol. & Cognitive Neuroscience, Dept. of Neurol., Univ. of Iowa Col. of Medicine, Iowa City, IA, 52242.

Patient Boswell, who is severely amnesic in both the retrograde and anterograde compartments, can provide the name of a state that a particular city is in, given the name of the city, e.g., given "Denver," he will respond "Colorado." By contrast, he is entirely unable to answer the request to name cities in Colorado, and is unable to provide even superficial information about the unique characteristics of the city of Denver. To investigate this phenomemon, we conducted two experiments. In the first (State Completion), Boswell was given 77 names of cities in the USA, and asked to provide the associated state name; the second (City Generation) required Boswell to provide names of cities, given the name of 27 states. For State Completion, Boswell's performance was quite accurate: he correctly supplied 41/77 (53%) state names and improved to 95% correct with forced choice. For City Generation, Boswell produced only 4 city names (on average, 0.15 cities per state). The dissociation indicates that the ability to complete a well learned verbal set (e.g., DENVER-COLORADO) given its first component, implies nothing about (1) the underlying verbal or nonverbal knowledge associated with either item in the set, or (2) their relationship to one another.

121.10

DEVELOPMENTAL PROSOPAGNOSIA: A NEW FORM OF LEARNING AND RECOGNITION DEFECT. D. Tranel and A.R. Damasio. Div. of Behav. Neurol. & Cognitive Neuroscience, Dept. of Neurol., Univ. of Iowa Col. of Medicine, Iowa City, IA, 52242.

In the course of our studies on learning and recognition, we have learned about individuals who complain of never having developed a normal ability to recognize the identity of human faces. The problem is first noted at school age and is severe, i.e., it is not a mere "difficulty" with face learning, and it is not a problem of "putting names to faces." It can often be circumvented by adaptive compensatory strategies, is relatively isolated, and is compatible with normal intelligence. We have termed the defect developmental prosopagnosia. Based on preliminary observations, we have identified several salient characteristics: (1) Male preponderance; (2) Preponderance of left-handedness; (3) Association with at least one other pattern recognition defect; (4) Intelligence at a level compatible with major professional achievement; (5) Presence of artistic abilities. There is no description of this defect in the neurological and neuropsychological literatures, the reason probably being that affected persons successfully disguise the defect, are considerably embarrassed by it, and cope with it effectively. In its general profile, developmental prosopagnosia has several characteristics of the acquired form of the disorder, i.e., the form of prosopagnosia that occurs with sudden onset following focal brain damage.

VISUAL EVOKED POTENTIALS (VEP) AND EVENT-RELATED POTENTIALS (ERP) IN TRAINED MONKEYS. A.Glover*, M.F.Ghilardi*, M.Basciani*, and I.Bodis-Wollner. VEP Laboratory, The Mount Sinai Sch. Med., New York, NY 10029 Using an "odd-ball" paradigm, we studied the VEPs and ERPs in 2 cynomolgus monkeys. Electrodes were at Fz, Cz and Oz, O'1 and O'2 (3 cm left and right of Oz, respectively) and in a primate chair and positioned 27 cm from a Tektronix 608 monitor. The size of the visual display was 17.3 deg., the stimuli were 2.5 cpd vertical ("target") or oblique ("non target") sinusoidal gratings. The mean luminance and contrast were 85 cd/m2 and 40%, respectively. Stimulus duration was 742 msec. Target stimulus probabilities of 0.5, 0.3 and 0.1 trials were studied. Trials were initiated by the monkeys by pressing and holding a lever. Lever release for the target resulted in fruit juice reward. In the fully-trained monkeys, discriminating accurately 95% of the time, the VEPs to either stimuli consisted of an initial negative potential at 53 msec followed by a positive peak (56 msec) and a succeeding negative-positive deflection (68 and 73 msec). The mean peak-peak amplitudes were: 14.0, 13.2, 11.1 and 10.2 uV, respectively. We obtained P300-like signals at the centro-parietal derivations only to the target stimulus. At 0.5 target presentation, the mean latency and peak-to-peak amplitude of P300 at Cz are 408 msec, and 25 uV,respectively. Eye movements recorded during the study had no relationship to P300-like potentials. Supported by N.I.H. grants NS 11631;EY01708;EY01867.

MEMORIZED OBJECTS MUTUALLY INTERFERE ON DELAY DISCHARGES FOR PICTORIAL SHORT-TERM MEMORY IN NEURONS OF PRIMATE TEMPORAL CORTEX. MIYASHITA,Y., SAKAI,K.* and HIGUCHI,S.* Dept. Physiol., University of Tokyo, School of Medicine, Tokyo 113, Japan.

Human short-term memory is limited in its capacity. No neural basis for this cognitive limitation has so far been discovered. We previously reported that, in the anterior ventral temporal cortex of monkeys, individual neurons exhibited sustained activity highly selective to a few of 100 colored fractal patterns during a visual working-memory task (Miyashita et al., Nature 331, 68-70, 1988). Now we have developed a listed delayed matching-to-sample task, in which several sample stimuli are successively presented and a match stimulus is given after a 16sec delay interval. Two monkeys (Macaca fuscata) were trained to memorize the sample stimuli and to decide whether the match stimulus was included in the samples. In all of the 20 tested neurons, the optimum discharge rate during the delay period was weaker when the monkeys memorized several stimuli at a time than it was when they memorized only one optimal stimulus. This result suggests that the capacity limitation of short-term memory originates from a limited memory representation rather than a bottleneck in a decoding process.

121.13

MACAQUES ARE AS SEVERELY IMPAIRED IN OBJECT-REWARD ASSOCIATION AFTER COMBINED ABLATION OF AREA TE AND THE SUPERIOR TEMPORAL SULCUS AS AFTER AMYGDALO-HIPPOCAMPAL ABLATION. J.A. Weinstein*, R.C. Saunders, and M. Mishkin. Laboratory of Neuropsychology, NIMH, Bethesda, MD 20892.

Following amygdalo-hippocampal (AH) removals, macaques are severely impaired on a variety of trial-unique object-reward association tasks (Phillips and Mishkin, Soc. Neurosci. Abstr. 10: 136, 1984.) Attempts to fully reproduce this impairment by disconnecting the limbic system from its visual inputs by means of inferior temporal lesions (of either area TE, area TEO, or both combined) consistently failed (Spiegler and Mishkin, Soc. Neurosci. Abstr. 5: 323, 1979). Here we investigated the possibility that the preserved visuo-limbic interaction observed in that study reflected preserved transmission of information through the depths and upper bank of the superior temporal sulcus (STS). Monkeys (Macaca mulatta) with either TE, TE+STS, or AH lesions, and their unoperated controls (N), were retrained on a trial-unique object-reward association task (Gaffan, Learn. and Motiv. 10: 419-444, 1979). At all list lengths (1, 2, 3, 5, and 10) Groups TE+STS and AH, but not TE, were severely and equivalently impaired relative to Group N. The results suggest that, for purposes of object-reward association, visual information can be transmitted to the limbic system via either area TE or STS.

121.14

RETROGRADE AMNESIA AFTER NEOSTRIATAL LESIONS IN MONKEYS: PRESERVED NON-MATCHING RULE AND IMPAIRED OBJECT MEMORY. E.C. Gower and S. Jacobson. VAMC, Boston MA 02130.

The design of this experiment separated a test of procedural memory from a test of preoperatively acquired object information using the non-matching-to-sample (NMTS) recognition memory task. Cynomolgus monkeys learned NMTS with one set of objects, and relearned it using a different set of objects. Three monkeys with ibotenic acid lesions of the caudate nucleus were only mildly retarded in reacquisition compared with 4 normal monkeys. A subsequent test combined long-term memory trials for preoperatively encountered objects with short-term memory trials for a list of recently presented objects. Here the experimental group demonstrated normal immediate memory for the first list sample, a significant decline in performance for the 2nd and 3rd items in the list, and a dramatic deficit on trials requiring the recognition of familiar objects last seen 3-6 months previously. For these trials, the range of normal performance was 76-83% correct choice of the novel object, in contrast to 53-66% correct for the experimental monkeys. The latter still represented above-chance performance however ($X^2_3 = 15.85$, $p<.01$). This pattern of results parallels the dissociation of preserved task-related procedural information from a significant loss of memory for events observed in human retrograde amnesia. 121.15

A BEHAVIORAL COMPARISON OF TWO MODELS OF DEMENTIA-AMNESIA IN THE RAT. C. T. Dickson* and C. H. Vanderwolf. Dept. of Med. Physiology, Univ. of Calgary, Calgary, Alberta T2N 4N1, and Dept. of Psychology, Univ. of Western Ontario, London, Canada N6A 5C2.

Two animal models of human dementia and/or amnesia have been proposed recently: 1) combined lesions of the hippocampal formation and amygdala; and 2) joint blockade of ascending serotonergic and cholinergic projections to the cerebral cortex. To compare these models, groups of rats prepared with 1) stereotaxic lesions of the ventral hippocampus and the amygdala; 2) intra-brain stem injections of 5,7-dihydroxytryptamine (DHT, 25 ug/ul, 0.5 ul in each of 4 sites); 3) p-chlorophenylalanine (PCPA, 500 mg/kg/day, i.p. X 3) plus scopolamine (5 mg/kg, s.c.); and 4) control treatments, were tested on: a) an open field; b) a swim-to-platform test; and c) a Lashley III maze. DHT impaired maze performance, especially after scopolamine, and PCPA plus scopolamine virtually abolished swim-to-platform performance, but combined hippocampal-amygdala lesions had little effect on either of these tests. All 3 treatments increased open field activity to varying degrees. From this it can be concluded that blockade of central serotonergic activity, especially when combined with scopolamine treatment, results in a more severe impairment of behavior than do lesions of the hippocampus and amygdala. (Supported by funds from NSERC)

IMPAIRMENT ON A PRETRAINED SPATIAL NONMATCH-TO-SAMPLE TASK IN AN ANIMAL MODEL OF HUMAN DIENCEPHALIC AMNESIA. R. L. Knoth, Department of Psychology, Chapman College, R. G. Mair, Department of Psychology, University of New Hampshire, Durham, NH 03824, S. A. Rabchenuk, Department of Psychology, Dartmouth College, P.J. Langlais, San Diego, VAMC.

The post-thiamine deficient (PTD) rat is an animal model for human Wernicke-Korsakoff's disease. The primary symptoms of human Korsakoff's disease are retrograde and anterograde amnesia. Behavioral testing of PTD animals has demonstrated global anterograde learning and performance deficits in a variety of discrimination and memory tasks (Mair et al., Behav Brain Res., 27, 223-239; Knoth et al., Neurosci Abstr., 14, 1230). No experiment however, has adequately examined retrograde deficits in these animals.

The purpose of this experiment was to examine retrograde memory deficits using a pretrained spatial NMTS task. A total of 24 animals were trained to 90% correct responding on NMTS in daily sessions of 25 trials. Following pretraining, 16 animals underwent thiamine deficiency. Following recovery, 11 experimental and 8 control animals were retested on NMTS. PTD animals performed significantly worse than controls on Day 1 of behavioral retesting. Both groups, however, showed improved performance over the next 15 training sessions.

These results support the assumption of retrograde memory deficits in PTD animals.

121.17

EFFECTS OF IBOTENIC ACID LESIONS OF THE HIPPOCAMPAL CA1 FIELD ON A DELAYED NON MATCHING TO PLACE TASK IN MICE. BERACOCHEA, D.,CHO, Y. and JAFFARD, R., Lab. Psychophysiologie, CNRS URA 339,Univ. Bordeaux I,33405 TALENCE FRANCE.

We have investigated the role of the CA1 hippocampal area on a delayed-non-matching to place task (DNMTP; 8-arm radial maze) and determined whether preoperative training might influence post-operative performance.Mice were first trained on the DNMTP rule to a criterion of 85% correct responses then submitted to memory testing. The memory test was divided into a study phase and a test (choice) phase. The time-interval between the visit to a target arm and subsequent recognition was either free (0 sec or 30 sec) or occupied by forced visits to other arms (1, 3 or 5 arms) according to a mixed design. Results showed that animals trained before CA1 lesions required twice as many trials as controls to master the DNMTP rule. They subsequently exhibited only a slight transient impairment of memory performance in the more difficult condition (5 interposed arms). Performances were not impaired by delays. Animals trained post-operatively were as rapid as controls in reaching the DNMTP rule criterion, but were unable to perform correctly in the mixed design procedure whatever the conditions. Our results weigh in favor of a differential effect of CA1 lesions on post-operative memory performance as a function of preoperative training.

A RAT MODEL OF MEDIAL TEMPORAL LOBE AMNESIA: NONRECURRING-ITEM DELAYED NONMATCHING-TO-SAMPLE. D.G. Mumby*, J.P.J. Pinel, and E.R. Wood*. Dept. of Psychology, Univ. of British Columbia, Vancouver, B.C., V6T 1Y7.

The study of the neural bases of memory and amnesia has been greatly facilitated by the development of a monkey model of medial temporal lobe amnesia: the nonrecurring-item delayed nonmatching-to-sample paradigm. We have adapted this paradigm for use with rats. Performance of intact rats (n=14) at retention intervals of up to 120 s was comparable to that commonly reported for monkeys; the rats scored approximately 93%, 90%, 84%, and 82%, at retention intervals of 3-s, 15-s, 60-s, and 120-s, respectively. Aspiration lesions of the hippocampus had only slight effects on performance. When amygdalar lesions were subsequently added, performance was dramatically reduced at retention intervals longer than 15 s, but was unaffected at shorter intervals. These results suggest that there is considerable continuity among humans, monkeys, and rats in the neural basis of recognition memory, and in so doing, they illustrate the potential of the rat model in its investigation.

121.19

ISCHEMIA-INDUCED DAMAGE TO THE RAT HIPPOCAMPUS PRODUCES DEFICITS IN NONRECURRING-ITEM DELAYED NONMATCHING-TO SAMPLE. E.R. Wood*, D.G. Mumby*, J.P.J. Pinel, and A.G. Phillips. Dept. of Psychology, Univ. of British Columbia, Vancouver, B.C., V6T 1Y7.

Rats subjected to transient forebrain ischemia induced by bilateral carotid occlusion combined with hemorrhagic hypotension develop irreversible neuronal loss limited to the CA1 region of the hippocampus (Mudrick, L.A., et al., Prog. Brain Res., 78:87-93, 1988). Evidence suggests that selective damage to this brain area produces memory deficits both in humans (Zola-Morgan, S., et al., Neurosci., 6:2950-2967, 1986) and in monkeys (Bachevalier, J., and Mishkin, M., Neuropsychologia, 27:83-105, 1989). Ischemic rats and sham-surgery controls were tested on a nonrecurring-items delayed nonmatching-to-sample task (Mumby, D.G., Pinel, J.P.J., & Wood E.R., this meeting). This test is analogous to tests that are sensitive to medial temporal lobe damage in humans and other primates. Ischemic rats took longer to reach criterion (at least 21/25 correct on two consecutive sessions) than controls (725 trials vs 350). Once criterion had been achieved the interposition of 15-, 30-, and 60-s delays between the sample and the test produced significant performance deficits. These findings suggest that the performance deficits produced in humans and monkeys by selective CA1 cell loss can be modelled in the rat.

121.20

SEVERE IMPAIRMENT ON CONCURRENT OBJECT DISCRIMINATION FOLLOWS CEREBRAL ISCHEMIA IN RATS. L.A. Rothblat, J.R. Graham* and T. Zheng*, Dept. of Psychology, The George Washington University, Washington, D.C., 20052.

It is now well established that restricted areas of the hippocampus, most notably the CA1 subfield, are especially susceptible to ischemic injury. Recent clinical findings suggest that such limited damage can result in severe and enduring amnesia. To further explore the relationship between ischemia, the hippocampus and memory, we trained rats which had been subjected 3 months earlier to an ischemic episode on a 4-pair visual concurrent object discrimination (COD).

Rats subjected to cerebral ischemia were severely impaired on COD. Ischemic animals required significantly more days to learn the discriminations (X=22.8, S.E.=2.5) than did normal (X=13, S.E.=1.1) or sham-operated controls (X=10.0, S.E.=1.7). In fact, 4 of 10 ischemic animals failed to reach criterion within 30 days. Further analysis indicated a significant correlation between degree of damage in the CA1 subfield and discrimination performance.

The present findings indicate that COD may be a particularly sensitive assay of hippocampal dysfunction. They also suggest that temporal lobe structures in rats may serve mnemonic functions which are qualitatively similar to those of human and nonhuman primates. Supported by ONR N00014-88-K-0227.

MK-801 REDUCES MORPHOLOGIC AND BEHAVIORAL SEQUELAE OF KAINIC ACID-INDUCED STATUS EPILEPTICUS. B.A. Stein, R.M. Sapolsky, J. Nagode *, H.P. Davis, & B.T. Volpe. Dept Biol Sci, Stanford Univ., Stanford CA 94305; Dept Psychol, Univ Colorado at Col Springs, 80933; Dept Neurol, Cornell Univ Med Ctr, White Plains, NY 10605.

The hippocampus is vital to learning and memory, and neuropathologic insults to the structure impair cognition. Various insults, including hypoxia-ischemia, hypoglycemia and seizure, appear to damage the hippocampus via excessive stimulation of the NMDA receptor by amino acid neurotransmitters. Thus, the degenerative consequences of these insults are diminished with NMDA receptor antagonists. It is not clear if only partial hippocampal protection (with receptor blockade) is sufficient to spare cognitive function. We test this possibility.

Rats were injected ip with either saline, or the excitotoxin kainic acid (KA; 10mg/kg) with or without treatment 20 minutes prior with the NMDA antagonist MK-801 (10mg/kg). Rats received 5 seizures in 15 days, recovered for 30 days, and were tested for 60 trials on a 12-arm radial maze with 7 arms baited. Rats were perfused and volumes of hippocampal damage. KA-alone rats sustained considerable damage, with $24 +/- 12 \times 10^5$ cubic microns of damage in their hippocampi. KA + MK-801 rats had 35% less damage than did KA-alone rats. The groups did not differ in seizure intensity or mortality rate.

The reduction in damage with MK-801 also spared cognition; saline and KA + MK-801 rats did not differ in working errors (reentry of a baited arm), reference errors (entry of an unbaited arm), or working-reference errors (reentry of an unbaited arm). KA-alone rats were impaired in all three categories ($p < .01$ in each case). Thus, even partial attenuation of hippocampal damage can protect cognitive function.

121.22

LESIONS OF THE PERIRHINAL CORTEX BLOCK FEAR-POTENTIATED STARTLE. J.B. Rosen, J.M. Hitchcock, M.J.D. Miserendino* and M. Davis. Dept. of Psychiatry, Yale Univ. Sch. of Med., 34 Park St., New Haven, CT 06508.

The acoustic startle reflex can be potentiated by presentation of a stimulus previously paired with a shock (i.e., fear-potentiated startle). Neuroanatomical, electrical stimulation and lesion studies have demonstrated that this potentiation involves a direct projection from the central nucleus of the amygdala to the acoustic startle pathway. However, little is known about brain areas which may activate the amygdala during fear-potentiated startle. The present study sought to determine cortical areas which may be critical for fear-potentiated startle using a light as a conditioned stimulus.

Rats were trained to be fearful of a light by pairing it with shock. The following day, five groups of 7-10 rats were lesioned in one of the following areas: the visual (including areas 17, 18a, 18b, and retrosplenial cortex), frontal (including parietal and cingulate cortices), medial prefrontal, insular, or perirhinal cortices. Six days later, rats were tested for fear-potentiated startle by presentation of an acoustic startle stimulus alone or in the presence of the light conditioned stimulus. Fear-potentiated startle was markedly attenuated only in rats with perirhinal cortex lesions. Subsequent experiments determined that lesions of only the rostral part of the perirhinal cortex (as defined by Paxinos and Watson, 1986) were necessary to block fear-potentiated startle.

These results indicate that the perirhinal cortex (a multisensory association cortex that has direct projections to the amygdala), but not many other cortical areas, plays an important role in fear-potentiated startle using a visual conditioned stimulus. Neuroanatomical tracing will be performed to elucidate the perirhinal afferents and efferents that may be important for fear-potentiated startle.

121.23

IBOTENIC ACID LESIONS OF RETROHIPPOCAMPAL AREA: EFFECTS ON BEHAVIOUR SLEEP/WAKING PATTERNS AND EEG. Hagan J.J., Verheijck E., Spigt M.H. and Ruigt G.S.F. (SPON F. JENCK). CNS Pharmacology, ORGANON B.V. OSS, 5340 BH - The Netherlands.

The effects of bilateral ibotenic acid injections in the entorhinal cortex of rats were studied. Following histology rats were divided into two groups: (RH) had lesions in subiculum, medial and lateral entorhinal cortex and posteroventral hippocampus: EC/SUB had a similar pattern but with no hippocampal lesion. Ache staining was increased in the molecular layer of the dentate gyrus. Place navigation learning was unaffected but EC/SUB animals were impaired when retrained to a new location. For a second set of experiments lesioned rats were implanted with cortical electrodes. Light period deep sleep was increased, REM sleep decreased and spindles increased in the EC/SUB group. REM sleep EEG peak frequency was reduced in RH rats and both groups showed reduced amplitude. During active waking both lesions reduced peak frequency and peak amplitude. No changes were found in deep sleep EEG. Both groups were nocturnally hyperactive but open field behaviour was unchanged. SHAM and RH rats, but not the EC/SUB group, reacted to a novel object with an increase in contact time. Partial excitotoxic lesions of the entorhinal cortex and subiculum cause subtle and selective impairments in behaviour and cortical EEG.

122.1

CIRCUITRY OF THE EXTENDED AMYGDALA: INTRODUCING THE USE OF FLUORESCENT DEXTRANS FOR RAPID, ANTEROGRADE AND RETROGRADE TRACT TRACING. L.C. Schmued* and L. Heimer. Dept. of Otol., Univ. of VA, Charlottesville, VA 22908.

This study introduces the use of two rhodamine conjugated dextran derivatives, RBD70K, and TMRD10K. Like the PHA-L technique, TMRD10K allows for a detailed visualization of anterogradely labeled fibers and terminals, is compatible with numerous other histochemical procedures, but does not require any histochemical processing. The ECAC (extended central amygdaloid continuum) is named for its best characterized component, the central amygdaloid nucleus. It also includes the lateral bed nucleus of stria terminalis, and portions of sublenticular substantia innominata. Injection of three different retrograde fluorescent tracers including RBD70K into the vagal complex, mesopontine tegmentum, and substantia nigra verified that all ECAC components project to these brainstem areas. It was also found that 2-5% of ECAC neurons with brainstem projections send axon collaterals to one or both of the other injected brainstem nuclei. Injection of retrograde fluorescent tracers into the vagal nuclei and substantia nigra, and the anterogradely transported fluorescent dextran TMRD10K into the mesopontine tegmentum, revealed ECAC cells with identified brainstem efferents relative to the location of the reciprocal afferents from the mesopontine tegmentum. Supported by NIH Grant NS17743.

UPTAKE, REPLICATION & TRANS-SYNAPTIC PASSAGE OF PSEUDORABIES VIRUS IN BRAINSTEM CIRCUITS. L. Rinaman[1], A. Robbins*, M. Whealy*, J. P. Card and L. Enquist*. The DuPont Co., Wilmington, Delaware, 19880 and [1]Institute of Neurological Sciences, University of Pennsylvania, Philadelphia, PA 19104.

Previously, we established that pseudorabies virus may be effectively used to define neural circuits in the rat brainstem which influence gastric function. Injection of virus into the stomach wall results in uptake, retrograde transport and replication of virions within motoneurons of the dorsal motor vagal nucleus (DMV). In addition, the virus passes trans-synaptically to infect second-order neurons which synapse upon the peripherally projecting motoneurons. In the present ultrastructural investigation, we have used two polyvalent antisera generated against either the entire virus or gIII, the major envelope glycoprotein, to gain further insight into the specificity of the trans-synaptic transport and to examine the replication and assembly of the virus within neurons. Both antisera identify virus within a di-synaptic brainstem circuit consisting of DMV motoneurons and interneurons in the adjacent nucleus of the solitary tract (NST). The most intense and complete labeling of this circuit is achieved with the whole virus antiserum, which identifies major forms of the virus. Dense immunoreactivity is characteristically associated with replicating capsids within both the cell nucleus and cytoplasm. All other forms of the virus in the cell cytoplasm and dendrites also exhibit dense immunoreactivity. Particular associations with the nuclear membrane, Golgi cisternae and smooth endoplasmic reticulum (SER) are apparent. Antiserum to gIII identifies only enveloped forms of the virus, and results in dense immunoreactivity related to the Golgi cisernae and SER. Immunoreactivity from both antisera is also densely concentrated at postsynaptic densities of motoneuron perikarya and dendrites. It is striking that only the whole virus antiserum detects virus within presynaptic afferents at these sites, suggesting that the virus loses its envelope as it passes through the synapse. These data provide considerable insight into the replication, assembly and trans-synaptic transport of pseudorabies virus in the nervous system and reiterate the usefulness of this neurotropic virus for studying neuronal circuits.

122.3

REVEALING DISYNAPTIC PATHWAYS BY COMBINING ANTEROGRADE DEGENERATION, RETROGRADE TRACING, INTRACELLULAR STAINING AND ELECTRON MICROSCOPY. E.H. Buhl#+*, W.K. Schwerdtfeger#* P. Germroth#* and W. Singer# (SPON: A. MacKay-Sim). #Max-Planck-Institute for Brain Research, 6000 Frankfurt 71, FRG; +Vision, Touch and Hearing Research Centre, University of Queensland, St. Lucia, Qld 4067, Australia.

Synaptic circuitry was investigated by combining retrograde tracing, intracellular staining, anterograde degeneration and electron microscopy in the same piece of tissue. This methodological procedure was successfully applied to disentangle a disynaptic neuronal chain, which originated in the olfactory bulb, was synaptically relayed in the entorhinal cortex and terminated in the ipsilateral hippocampus. Presumed entorhinal relay cells were retrogradely labelled from their hippocampal termination site by means of the fluorescent tracer Fast Blue. Subsequently, the marked projection neurones were intracellularly injected with Lucifer Yellow in fixed slice preparations. Following a simple photo-conversion procedure, dye filled cells were flat-embedded and processed for electron microscopy. The origin of presynaptic afferents to identified relay cells was revealed ultrastructurally after lesion induced anterograde degeneration of olfactory mitral cell axons. Due to its reliability, technical simplicity and a high degree of selectivity the new approach is considered an appropriate tool for unravelling neuronal networks.

LABELLING OF AXONS OF PASSAGE BY *PHASEOLUS VULGARIS* LEUCOAGGLUTININ (PHA-L) B. R. Schofield. Dept. of Neurobiology, Duke Univ. Med. Cntr., Durham, NC 27710.

Phaseolus vulgaris leucoagglutinin has emerged as an important tool for tracing neuroanatomical pathways. Its reported advantages include little or no uptake by axons of passage. I report here that such uptake can occur and can lead to extensive labelling in both anterograde and retrograde directions.

In guinea pigs, 2.5% biotinylated PHA-L was injected by iontophoresis (+5uA for 15 - 60 min) through glass micropipettes (12-25 um tip dia.) into the trapezoid body, the spinal trigeminal tract, or the inferior cerebellar peduncle. Five days later, the brain was fixed by perfusion and PHA-L was localized with avidin-biotin-peroxidase immunohistochemistry.

Injections in the spinal trigeminal tract labelled axons in the trigeminal nerve and axons and terminals in the principle and spinal trigeminal nuclei. After trapezoid body injections, labelled axons extended more than 13 mm to reach the contralateral inferior colliculus. Injections into the inferior cerebellar peduncle labelled fibers entering the cerebellum, as well as trigeminocerebellar cells in the spinal trigeminal nucleus.

These results suggest that the possibility of labelling axons of passage should be considered whenever PHA-L is used. Supported by NIH grants NS 08177 and NS 14655.

THE ASSOCIATION OF FRAGMENT C OF TETANUS TOXIN WITH THE NEURONAL MEMBRANE. E.A. Neale, L.M. Bowers*, H. I. Trenchard, and W.H. Habig*. Laboratory of Developmental Neurobiology, NICHD, NIH and Laboratory of Bacterial Toxins, FDA, Bethesda, MD 20892

Fragment C, the binding portion of the tetanus toxin molecule, can be used with a specific, non-neutralizing monoclonal antibody (18.2.12.6) as a neuronal label for fetal mouse neurons in cell culture (Neale et al., Soc. Neurosci. Abst. 14:547,1988). Dissociated neurons treated with the Fragment C/18.2.12.6 complex shortly after plating, and with fluorescent secondary antibody 24 hours later, show fluorescence extending to the tips of the growing neurites. Such staining could result from lateral diffusion of the complex along the membrane during growth, or from dissociation of the complex and reassociation with newly formed receptors. When neurons are plated into a culture already containing neurons pre-labeled with complex, and the culture is treated at a later time with secondary antibody, both populations of neurons appear fluorescent. Binding and staining data indicate that the presence of a neutralizing monoclonal antibody (18.1.7) in the medium during the interval between exposure to complex and to secondary antibody reduces the amount of cell-associated Fragment C/18.2.12.6. These experiments suggest that Fragment C/18.2.12.6 can dissociate from and subsequently rebind to the neuronal membrane. In contrast, a complex of tetanus toxin/18.2.12.6 cannot be detected on the neuronal surface after 2 hr and is visualized only inside the cell after detergent treatment. These results suggest that the initial processing of Fragment C by the neuron is different from tetanus toxin.

122.6

NEURONAL PROCESSING OF TETANUS TOXIN FRAGMENT C DIFFERS FROM PROCESSING OF THE HOLOTOXIN. H.I. Trenchard, S.C. Fitzgerald*, W.H. Habig*, and E.A. Neale. Lab. of Develop. Neurobiol., NICHD, NIH and Lab. of Bacterial Toxins, FDA, Bethesda, MD 20892

The use of Fragment C, the binding portion of the tetanus toxin molecule, as a neuronal marker raises questions about the processing of this ligand by the cell. We have studied the binding of ^{125}I-labeled tetanus toxin and Fragment C (FrC) in 3 wk old dissociated cultures of fetal mouse spinal cord. For all experiments, toxin or FrC was applied to cultures in a physiologic salts solution for two hours at room temperature, after which cultures were rinsed and returned, in growth medium, to the incubator (37°C, 10% CO_2). Culture fluid was removed at various times and the cells dissolved in 1% SDS for assay of cell-associated radioactivity and gel analysis of toxin degradation.

Bound FrC is released rapidly into the culture medium during the first 24 hr, while tetanus toxin dissociates more gradually. FrC which is released from cells during 2 or 16 hr following initial incubation will rebind to new cultures. Tetanus toxin, that has been bound and released, loses some ability to rebind. A non-neutralizing monoclonal antibody against FrC (18.2.12.6), when present during binding, increases the amount of FrC and tetanus toxin bound to cells, and appears to stabilize the association of FrC with the membrane. A neutralizing antibody (18.1.7), when present in the culture medium during the interval following the initial incubation, decreases the amount of cell-associated FrC. Neither antibody has much effect on bound tetanus toxin, suggesting a more loose association of FrC with the membrane. SDS gels reveal that toxin breakdown products are found in the culture medium and not in cells. However, toxin breakdown occurs only in the presence of cells and not in conditioned medium. This suggests that cells have degraded the toxin and excreted the products.

EVALUATION OF C-FRAGMENT OF TETANUS TOXIN TO TRACE GUINEA PIG CENTRAL SYMPATHETIC PATHWAYS. R.L. Meckler, R. Baron*, & E.M. McLachlan*. School of Physiol. & Pharmacol., New South Wales Uni., Kensington, NSW 2033, AUSTRALIA.

The C- fragment of tetanus toxin (TTC) has been evaluated as a tool for retrograde transsynaptic identification of pathways in the sympathetic nervous system using immunohistochemical methods. TTC injection into medial gastrocnemius (MG) muscle, in addition to its retrograde transport within somatomotor, sympathetic and sensory axons, was taken up and concentrated by terminal varicosities within pre- and paravertebral ganglia at all thoracolumbar levels, after post-injection times of 6 to 55 h. Staining was absent in chronically denervated sympathetic ganglia, demonstrating the specific association of the antigen with preganglionic varicosities. Preganglionic varicosities at all thoracolumbar levels were also labelled after TTC injection into the peritoneal cavity or into denervated MG, either of which failed to label somatic motor or sensory neurones. The results indicate that this tracer cannot be used to demonstrate sympathetic pathways within the central nervous system. The data may help explain the widespread involvement of the sympathetic nervous system in tetanus.

A MODIFIED TMB HRP REACTION FOR LM AND EM PATHWAY TRACING. R.J. Weinberg, S.L.Van Eyck, and A. Rustioni. Depts. of Cell Biology & Anatomy, and of Physiology, U of North Carolina, Chapel Hill, NC 27599.

Compromises must be made in HRP histochemistry among many factors, including sensitivity, specificity, tissue preservation, and identifiability of label. Reactions at low pH with TMB chromogen and nitroferricyanide stabilizer provide unexcelled sensitivity, but give high background and poor preservation. Stabilization with molybdate reduces background and improves preservation, but is less sensitive. Tungstate stabilization of TMB by the following protocol is particularly useful for anterograde tracing.

Tissue sections in glass vials are incubated at room temperature on a shaker for 10' in 1 ml of 0.1M phosphate buffer (pH 6.0) with 50 µl of 1% ammonium paratungstate (K&K) in H_2O and 25 µl of TMB (Sigma) 0.2% in EtOH. Add 1 µl of H_2O_2 and incubate 30'-1 hr. Rinse twice in buffer and dry on subbed slides. Pass through alcohols to xylene, mount with DPX. The reaction produces small blue-green crystals; under crossed polarizers, anterograde label is bright pink, and labeled cells are green. Thionin gives an excellent stain with little loss of label; counterstaining enhances visibility of the retrograde labeling, although anterograde labeling becomes less visible in darkfield. The tungstate-TMB method is also suitable for EM. Optimal results are achieved when grain size is reduced (by shortening incubation to ~15') and label is stabilized with DAB: Rinse sections well in pH 6.0 cacodylate buffer (add 1 ml 1M HAc to 13 ml .05M sodium cacodylate); incubate 8' in 1 ml buffer with 0.5 mg DAB, 20 µl 1% $CoCl_2$, and 2 µl 3% H_2O_2. Rinse well, osmicate, dehydrate, and embed in Epon-Spurr; thin sections are post-stained with uranyl acetate and lead citrate. Small flattened crystals of reaction product are clearly visible in dendrites, somata, and axon terminals. The protocol has been combined with post-embedding immunocytochemistry to demonstrate glutamate in primary afferent terminals in rat caudal trigeminal nucleus.

NEW APPLICATIONS FOR HORSERADISH PEROXIDASE-REACTIVE CHROMOGENS IN IMMUNOCYTOCHEMISTRY AND TRACT TRACING AT THE LIGHT AND ELECTRON MICROSCOPIC LEVELS. M.N. Lehman and R.B. Norgren, Jr. (SPON: P. Sanberg) Anat. and Cell Biol., Univ. of Cincinnati Med. Coll., Cincinnati, OH 456267

We have found that chromogens developed for HRP-tract tracing or peroxidase based immunocytochemistry (ICC) can be profitably utilized in other applications and in combination with other chromogens (Norgren & Lehman, J. Histochem. Cytochem, 1989). Diaminobenzidine (DAB) has been used for both tract tracing and ICC experiments. Other chromogens have been utilized primarily for either tract tracing or ICC. Recently, we have been investigating the properties of Indophane Blue (Viomedics). We have found that this chromogen can be used in tract tracing as well as avidin-biotin-peroxidase immunocytochemistry. Indophane Blue is sensitive enough to visualize anterogradely transported cholera-toxin-HRP in the visual system and appears to be more sensitive than DAB in this application, though not as sensitive as tetramethylbenzidine (TMB). An important advantage of this chromogen over TMB is that tissue sections can be processed at pH 6.0 rather than pH 3.3. The blue color of this chromogen is easily distinguishable from the brown DAB reaction product making it an excellent second label for immunocytochemistry. Electron microscopic observation suggest that Indophane Blue is electron dense. [Supported by NIH grants HD21968 and NS24292 (MNL)].

REACHING THE UNREACHABLE: USING THE CARBOCYANINE DYE DiI TO TRACE FIBRES IN THE RAT FETUS AND HUMAN BRAIN. Stuart Bunt, Husni Al-Goshae* and Greg Irwin*. Dept. of Anat. and Physiol., The University, Dundee, DD1 4HN, U.K.

The stable, highly fluorescent DiI embeds in lipid membranes and diffuses slowly to cover the cell envelope. As this diffusion can occur even in fixed material it enables visualization of fibre morphology and pathways in previously difficult or inaccessible sites. We place crystals of DiI (1, 1'-dioctadecyl, -3, 3, 3', 3'-tetramethylindocarbocyanine perchlorate) directly on the fibres to be traced and maintain the tissue in fixative at 37° or room temperature for up to six weeks. The dye has enabled us to observe ganglion cell axons in the human retina and we have successful examples from whole and 50-250um vibraslice sections of hippocampus, thalamus, neocortex, cerebellum, lateral geniculate body, superior colliculus and corpus callosum of adult human brains; a) from donated specimens held in 4% formalin for up to six months, b) postmortem specimens fixed in formalin within 12 hours of death and c) unfixed postmortem tissue obtained within 12 hours of death.

In E12-E15 rat embryos we have labelled growth cones of the first spinal axons. In E14 and E15 embryos most of these are club like endings between 3 X 8 um and 7 X 35 um. At earlier stages and in ventral tracts larger filopodial structures between 5 X 30 and 7 X 30, resembling the wider growth cones seen in vitro, are more common.

Preliminary Attempts at Retrograde Labelling and Culturing of Spinothalamic (ST) Neurons in Fetal and Postnatal Rats K. Thor, C. Pechura, V. Smallwood*, N. Silva, J. Barker NIH, Bethesda, MD 20892

We are attempting to establish long-term cultures of ST neurons that are retrogradely labelled with rhodamine beads (RB) by refining techniques for 1) culturing postnatal ST neurons and 2) *in utero* injections for labelling fetal ST neurons. Postnatal (PN) day 4-5 pups were injected with 200 nl RBs into the thalamus while under halothane anesthesia. 5 days later, the spinal cords were dissociated with various proteases and cultured in various media. In optimal cases, obtained using papain dissociation and culturing in media with 5% newborn calf serum, 3-5 RB-labelled neurons/plate survived for at least 9 days in culture. Postnatal neurons were more susceptible to dissociation damage than were embryonic cells, and recording was difficult. RB-labelled neurons did not develop to the same extent as unlabelled neurons. *In utero* RB injections into the brains of E17-E19 fetal rats were made in chloral hydrate-anesthetized dams, whose uteri were placed into a specially-designed stereotaxic holder. A needle (30g), inserted through the uterine wall and fetal skull, delivered 200 nl of RBs into the fetal brain. The uterus was returned to the peritoneal cavity and the abdomen sutured. At various times post-injection (1-3 days) the fetuses were removed, and their spinal cords were frozen for sectioning or dissociated for culturing. All of the dams survived with no complications (n=4), and 25% of the injected fetuses (n=20) developed normally. Numerous RB-labelled neurons were seen in the fetal brains and/or spinal cords, but these preliminary injections were not accurate. Refinement of coordinates should allow placement of the needle tip into the fetal thalamus *in utero* and eventual culturing of ST neurons. We thank C. Asanuma for advice on *in utero* injections.

IDENTIFICATION OF ISOLATED MAGNOCELLULAR NEUROENDOCRINE CELLS (MNCs) FROM THE HYPOTHALAMUS. M.L. Weiss and P. Cobbett Pharmacology & Neurosci. Prog., Michigan State Univ. E. Lansing, MI 48824

We wanted to stain selectively neuroendocrine cells from young adult rats following intravenous (IV) injection as others have done with HRP. In order to visualize dispersed, living cells, however, we needed to substitute HRP with a retrograde fluorescent tracer. Evans Blue (EB; 10%) was found to produce specific hypothalamic labeling similar to that of HRP, after injection into either subclavian or tail veins and a 1-2 day survival. Following EB treatment, small blocks of tissue containing the supraoptic nucleus were enzymically and mechanically dissociated and plated onto Con-A coated coverslips. Apparently healthy dispersed neurons were located using phase contrast microscopy; the majority of these cells contain EB. Visualization of the dye using epi-fluorescence did not appear to affect the phase brightness of neurons, even after long exposures to incident beam. We plan to confirm that the EB labeled MNCs contain neurophysin with immunocytochemistry. These results show that MNCs can be recovered and identified following dispersion, and suggest that it may be possible to electrophysiologically record from isolated, identified MNCs. IN VITRO LABELLING TO DEMONSTRATE CONNECTION BETWEEN HOST RETINA AND FETAL TECTUM OR CEREBELLUM GRAFTS IN ADULT RATS. R.V. Stirling, R.Aramant, M.Seiler and A.R. Adolph. Eye Research Institute, Boston, MA 02114

A previous study has shown that embryonic brain tissue can be grafted to adult rat retina (Aramant et al., Soc. Neurosci. Abstr. 14:1276). We have developed a technique to investigate how these grafts connect with the host retina. Pieces of E15 tectum or cerebellum were placed through an incision through sclera, choroid and retina into a retinal lesion site (posterior approach). Such grafts survive, develop and integrate with the host retina.

In vitro labelling with horseradish peroxidase allows the label to be placed selectively either to where extensions from the graft join the host retina or into the graft itself. Following a warm saline perfusion, the retina is removed from the sclera and flattened down onto a nylon mesh in a dish containing cold modified Ames medium (Langdon, pers. comm.), perfused with 95% 0_2 5% $C0_2$. HRP is applied using fine microelectrodes tipped with concentrated HRP. The retina is pinned down with a fine veil and left in the oxygenated solution at 28°C for 5-6 hrs. The retina is fixed between two coverslips for 1-2 hrs. at 4°C; it is processed affixed, vitreous up, to a glass slide with albumin/gelatin embedding medium using the ion intensified DAB reaction (Adams 1971). The retina can easily be removed for resectioning.

Using this technique, we have labelled cells in tectal grafts by HRP application to the host retina, and have seen fine fibers leaving the graft. These usually do not progress very far, often making hairpin turns back to the graft. Occasionally, fibers from the graft do enter the host where they make extended randomly oriented arbors in the outer part of the inner plexiform layer, with swellings which may indicate synaptic contact.

This whole-mount in vitro method is simple to use and yields complete filling of RGC's, and their axons, and has demonstrated connection between tectal grafts and host retina.

DISTINCT IDENTIFICATION IN VIVO OF TWO LABELED POPULATIONS OF GRAFTED MOUSE NEUROBLASTOMA CELLS USING RHODAMINE AND FLUORESCEIN LATEX NANOSPHERES. **B.A. Bonsack,* J.D. Macklis* and R. Madison,+*Dept. of Neurology and Program in Neuroscience, Harvard Medical School, Children's Hospital, Boston, MA and +Division of Neurosurgery, Duke Univ. Durham, NC**

Latex nanospheres with a wide range of incorporated chromophores were developed for selective labeling of neuronal subpopulations in vitro and in vivo. In vitro studies show some neuronal populations accumulate and store these nanospheres more avidly than non-neuronal populations. Neurons are retrogradely labeled by these nanospheres in vivo(1) Mouse neuroblastoma cells were chosen as a model system to show that separate populations of neural cells can be distinctly labeled, grafted in vivo, and distinguished from host cells and from each other.

Mouse neuroblastoma cultures were grown using standard methods, labeled in vitro with either rhodamine or fluorescein nanospheres by direct application of concentrated nanospheres, and washed. After 24 hours, cells were examined for label intensity, labeling efficiency, and viability. Rhodamine and fluorescein labeled cells were combined in single cultures and followed for one week. Cells from each initial culture remained healthy and uniquely labeled with eccentric granular fluorescence after coculturing; no double labeling was seen. In vivo grafts of two distinctly labeled cultures into overlapping regions of mouse neocortex demonstrate unique identification of cells from each graft. Preliminary studies suggest that mouse neocortical neurons can be similarly labeled, transplanted, and distinctly identified from multiple donor sources. Supported by NS26311, HDOO859, Alzheimer's Assoc., & Whitaker Fdn.

ULTRASTRUCTURAL EVIDENCE FOR GABA-ERGIC BRAINSTEM PROJECTIONS TO SPINAL MOTONEURONS. J.C. Holstege*(SPON: M. Godschalk) Anatomy Dept. Erasmus Univ. Rotterdam, P.O.Box 1738, 3000 DR Rotterdam, The Netherlands.

Several studies have shown the existence of serotonergic and non-serotonergic brainstem projections to spinal motoneurons. In the present study in rat it was investigated whether the non-serotonergic projections contained GABA. WGA-HRP was injected in the ventro-medial part of the lower brainstem. After perfusion, the L5 and L6 spinal segments were dissected, treated for TMB histochemistry, osmicated and plastic embedded. Immunogold postembedding immunocytochemistry was performed with a GABA antibody (a gift from Dr. R. Buys, Amsterdam). In the lateral motoneuronal cell groups 505 WGA-HRP labelled terminals were analysed at the ultrastructural level. Nearly 40% of these terminals were also labelled for GABA. 81% of the double labelled terminals were of the F-type, 12% were G-type (indicating possible co-existence of serotonin and GABA) and 7% were S-type. The results show the existence of a substantial GABA-ergic (inhibitory) brainstem projection to lumbar motoneurons. These projections may act as a gain setting system, thereby counteracting the serotonergic fibers in the control of the excitability of spinal motoneurons.

122.17

IMMUNOCYTOCHEMISTRY OF AFFERENTS TO HRP-LABELLED MOTONEURONS (MNs): SEQUENTIAL LIGHT AND EM ANALYSIS USING ACROLEIN FIXATION. M.S. Beattie, M.G. Leedy, and J.C. Bresnahan. Depts. of Surgery and Anatomy and Neurosci. Prog., Ohio State Univ., Columbus, OH 43210.

Acrolein (CH_2=CH-CHO) has been reported to be a superior fixative for EM immunocytochemistry (King, J. et al., J.Histochem.Cytochem.,31:62, 1983). We have employed this technique in combination with retrograde HRP.

HRP was applied to rat sciatic nerve; after 2 days, rats were perfused with 5% acrolein in PBS. Tissue was vibratomed and processed simultaneously for HRP and immuno-staining using antibodies to 5-HT, L-enkephalin (ENK), and dopamine-beta-hydroxylase (DBH), the ABC technique, and glucose oxidase. Plastic-embedded 60 um sections were used for LM analysis, then thin-sectioned for EM. Densely-stained DBH and L-ENK terminals in apposition to HRP-labeled MNs were evident through the depth of 60 um plastic sections. 5-HT label was inconsistent. EM showed stained synaptic appositions to HRP labelled MNs. The procedure should be useful for quantitative analyses of afferents to identified MNs, and provides excellent morphology in thick plastic sections. (NS10165)

DOUBLE LABELING OF CYTOCHROME OXIDASE AND GAMMA AMINOBUTYRIC ACID IN CENTRAL NERVOUS SYSTEM NEURONS OF ADULT CATS. X.G. Luo*, R.F. Hevner and M.T.T. Wong-Riley. Dept. of Anatomy & Cellular Biology, Med. College of Wis., Milwaukee, WI 53226.

The relationship between the levels of cytochrome oxidase (C.O.) and gamma aminobutyric acid (GABA) was investigated within single neurons by double labeling the two markers in the same section. Seven adult cats were used. Frozen brain sections were cut at 15 um and divided into two groups. One group was incubated with GABA immunogold-silver staining (modified from Holgate et al., J. Histochem. Cytochem., 31:938-944, '83) followed by indirect immunoperoxidase for C.O. (Hevner & Wong-Riley, J. Neurosci., in press). The second group was incubated for C.O. histochemistry (Wong-Riley, Brain Res., 171:11-28, '79) followed by immunogold-silver staining of GABA. Double staining was equally effective for both methods. The discrete black silver grains were clearly distinguishable from the brown enzyme reaction product within the neuronal cytoplasm. There was no evidence of cross reaction between the two primary antibodies in our experiments. These combinations enabled the demonstration of four different types of labeling within neurons in the same sections: C.O.+/GABA+, C.O.+/GABA-, C.O.-/GABA+, and C.O.-/GABA-. Neurons in the perigeniculate nucleus and basket cell terminals in the cerebellum were GABA positive and rich in C.O. Interneurons of the lateral geniculate nucleus as well as stellate and Golgi cells of the cerebellum were GABA-rich but poor in C.O. These results demonstrate that GABAergic neurons in the CNS can have either high or low levels of C.O. (Supported by NIH NS18122 and EY 05439 to MWR and MCW MSTP Fellowship to RFH).

NOVEL, LAMINAR- SPECIFIC IMMUNOSTAINING OF NEURONS IN LAYERS 1,2,3 AND 5 OF CAT VISUAL CORTEX. Mala Glenwright,* Maynard Morrison,*+ David Dobbie*+ and J.A. Matsubara (SPON: D.P. Phillips). Depts. of Ophthalmology, Anatomy and the Neurosciences, Univ. of Brit. Columbia, V5Z 3N9. Canada and + Dominion Biologicals, Dartmouth, Nova Scotia B3B1M1. Canada.

Recent advances in hybridoma technology have provided us with new markers for specific cell types and cell layers in the central nervous system. We report a new monoclonal antibody which recognizes neuronal populations in layers 1,2,3 and 5 in cat visual cortex.

Monoclonal antibody #73 7A4-2 (Dominion Biologicals, Limited) was raised against an antigen isolated from human blood cells and derived from overgrown tissue culture supernatant. While not yet fully characterized, it is specific for human blood group A. We screened this antibody, and others, on fixed tissue from cat and rat.

Animals were deeply anaesthetized and perfused transcardially using a series of standard fixatives. Sections were first incubated overnight in primary antibody (or in phosphate buffer for control sections), followed by standard procedures using the avidin-biotin method (Vector Labs). Vibratome sections yielded better immunostaining than frozen sections.

Monoclonal antibody #73 7A4-2 labeled neurons in supragranular layers 1,2 and 3 and in layer 5 in areas 17 and 18 of cat visual cortex. The cytoplasmic, but not the nuclear, compartment of both pyramidal and non-pyramidal cells in these layers were labeled. Among these cells, the larger pyramidal cells in layers 3 and 5 were significantly darker and more intensely stained than the other neurons. Furthermore, the apical dendrites of these cells exhibited exceptionally intense immunostaining. Diffuse labeling was present in adjacent cortical areas (cingulate cortex and area 19), but the strong, laminar specificity was confined to areas 17 and 18. No additional organizational features were observed in sections cut in the horizontal plane. (This work funded by MRC MA-9150 to J.M.).

"FLUORO NISSL GREEN": PURIFICATION AND FUNCTIONAL CHARACTERIZATION OF A NOVEL FLUORESCENT NISSL STAIN FOR NEUROANATOMIC TECHNIQUES. B. Quinn, Dept. of Brain & Cognitive Sciences, MIT, Cambridge, MA 02139.

Fluorescent neuroanatomical techniques, such as immunofluorescence and retrograde tracing with novel markers like Di-I, derive great utility from their specificity. However, this specificity can be a drawback as well, in that it may be difficult to achieve a detailed assessment of labeled neurons or axons in their cytoarchitectonic context. We have reported a protocol which led to a green fluorescent counterstain for neuronal perikarya (Quinn & Weber, Soc Neurosci 14:219.6, 1988). An enhanced synthesis and purification of this fluorochrome is now described, along with functional characterization. 200-400 mg of m-phenylene diamine (Sigma; Aldrich), 400 ul glycerol, and 200 ul acetic acid in 10 ml H2O are heated to boiling in a lab microwave, developing a lemon yellow color. The solution is diluted 20-fold with H2O and applied to a SepPak C18 disposable cartridge (Waters, Milford MA, No.51910). The cartridge is washed with 20 ml H2O and the fluorochrome eluted with 2 ml aliquots of 10-20-30-40-50% MeOH or acetonitrile. The most active fluorescent fraction, confirmed by spot illumination, is dried in a Speedvac vacuum centrifuge or by an N2 stream. We further purified the compound by C8-RP-HPLC, but it can be used brought up directly in buffered glycerol pH 7.5-8.0 (e.g., 100 mM Tris:Glycerol 1:1).

The SepPak-purified compound has a maximum absorbance of 434 nm and maximum emission at 517 nm, with respective half-intensity bandwidths of 54 and 46 nm (C. Earley, Dept. of Chemistry, MIT). Thus, it is excited by most fluorescein, and certain UV, filters; the emission peak is very close to FITC. It provides an excellent green counterstain to rhodamine, and to Di-I (S. McConnell et al., this meeting). Preferential perikarya staining is obtained above pH 7, and nuclear staining at acid pH. In a model on-slide system, staining was preferential for rRNA over protein; and like a classical Nissl stain, cresyl violet, staining of perikarya and nucleolus is attenuated by RNAse treatment. Although the earlier 1988 protocol was suggestive of the Skraup reaction, the reaction is active in the presence of polyalcohols from ethylene glycol to dextrose. The rapid, but low, yield is consistent with a contaminating reactant, although one candidate, m-nitroaniline, which would lead to chrysoidin-like azo fluorochromes, was inactive. Full structural characterization of this compound is in progress.

122.22

TRAUMA INDUCED GOLGI-LIKE STAINING OF DENDRITIC TREES. A.N.van den Pol and F.Gallyas*, Sect.Neurosurgery, Yale Univ.Sch.Med.,New Haven,CT. 06510.

A critical problem in neuroscience has been that of identifying damaged neurons immediately after moderate brain injury. We report here a new approach which allows the silver staining of the soma and dendritic tree, including spines, of traumatized neurons throughout the CNS. Unilateral brain injury in heavily anesthetized rats resulted in labeling only in the vicinity of the trauma, while non-traumatized contralateral loci showed no labeled neurons. The stain worked equally well on pig, mouse, and human brain, and labeled neurons injured by micropipette, pressure, toxic chemicals, and other means. Even with fixation starting as soon as 1 min after injury, neurons were labeled. For experimental neurocytology, selected neurons can be traumatized in vitro under microscopic control, allowing the stain to be used as a method for selectively labeling dendritic trees with a Golgi-like appearance as demonstrated in the hypothalamic paraventricular and suprachiasmatic nucleus. Unlike Golgi impregnations which generally start as an expansion from a single crystal in a given cell, many independent regions of metallic precipitation appear in traumatized dendritic trees. Subsets of neurons in regions of the brain such as the hypothalamus or hippocampus appear differentially sensitive to different types of insult or injury, allowing characterization of neurons based on dendritic tree and response to injury.

122.23

POSTNATAL MAMMALIAN MOTONEURONS IN CULTURE. C. Krieger* and S.U. Kim. Division of Neurology, Dept. of Medicine, Univ. of British Columbia, Vancouver, BC, V6T 1W5.

Investigations of cultured mammalian motoneurons have generally used embryonic material which has been retrograde labelled using fluorescent dyes. Embryonic neurons differ, however, from those in the adult animal in that they undergo a period of naturally occurring cell death. Since there is no significant postnatal cell death in neurons of the rat or mouse, investigations on neonatal motoneurons may be more relevant to understanding the pathophysiology of disorders affecting the adult mammalian motoneuron.

Under cold anaesthesia, neonatal rats or mice (1-6 days of age) were injected with Rhodamine isothiocyanate into the proximal muscle masses of the extremities. After 24 to 48 hours, spinal cords were removed, dissociated and the labelled cell fraction was enriched using fluorescence-activated cell sorting. Cells were plated onto poly-L-lysine coated coverslips or feeder layers of rat brain astrocytes. Some of these labelled motoneurons were capable of survival for more than 5 days in vitro and demonstrated neurofilament and neuron-specific enolase immunoreactivity.

Supported by the Canadian MRC and the ALS Society of Canada.

IMMUNOGOLD SILVER STAINING OF INTRACELLULARLY INJECTED SUPRAOPTIC NEURONS. LL. Smithson*, K.G. Smithson and G.I. Hatton. Neurosci. Prog., Michigan State Univ., E. Lansing, MI 48824.

Our studies have sought to integrate functional and structural properties of neuroendocrine cells by combining intracellular electrophysiology and injection of Lucifer Yellow CH (LY) with immunocytochemical (ICC) analysis (J. Neurosci. Meth., 10:59,1984). This procedure used an avidin biotin-HRP complex and 3,3'-diaminobenzidine (DAB) as a marker and while generally successful, one limitation has been the opacity of the ICC marker. Incompletely filled cells, such as those dye coupled to an injected cell, may be dim and sometimes rendered unidentifiable. To alleviate this problem we have evaluated another ICC marker, 5-15 nm colloidal gold. After dye injection, tissue is fixed, dehydrated, and embedded in polyethylene glycol. Serial sections (3-5 μm) are cut, and ICC is done on those sections containing portions of cytoplasm and/or the nucleus of dye filled cells following which the gold-labeled sections are silver intensified. This silver-intensified colloidal gold marker produces a punctate reaction product within the cytoplasm of an immunopositive cell. Unlike DAB, this reaction product results in little or no attenuation of the injected cell's LY fluorescence. The use of a silver-intensified colloidal gold marker should improve the reliability of this ICC procedure, especially for dimly fluorescent cells and allows positive identification of sections that contain only a small portion of the cell. Supported by NS 16942 and a fellowship from the Medical Scientist Training Program to KGS.

A TRIPLE-LABELING TECHNIQUE TO IDENTIFY AND REVEAL THE DETAILED MORPHOLOGY OF MOTONEURONS RECORDED IN VITRO. F. Viana*, L. Gibbs* and A.J. Berger (SPON: W. Spain). Dept. Physiol. & Biophys., Univ. of Wash., Seattle, WA 98195.

Techniques such as antidromic activation commonly used in vivo to characterize cells in a motor pool (motoneurons vs. interneurons) may not be possible in vitro. We devised a triple-labeling protocol to circumvent this problem in guinea pig hypoglossal nucleus (HN) studies. The retrogradely transported marker, rhodamine-dextran (RhD), was applied to the cut central end of the 12th nerve in the neck. After 2 days, brainstem slices (500 μm) were prepared and intracellular recordings obtained from HN neurons. After characterizing the cell physiologically, a mixture of 1.5% Lucifer Yellow (LY) and 1% biocytin (dissolved in 1M LiCl) was injected via iontophoresis into the cell. Slices were then fixed, frozen and sectioned at 80 μm and sections were examined using a fluorescence microscope; 91% (n=21) of LY-injected cells were recovered. Nineteen of these cells were double-labeled (fluorescence for both Rh and LY), thereby positively identifying them as HN motoneurons. After photomicrography, the sections were rehydrated and the biocytin visualized with streptavidin-biotin and diaminobenzidine as the chromagen. All LY-labeled cells then exhibited permanent HRP-like staining quality, allowing detailed reconstruction of somal, dendritic and axonal morphology. We conclude that: 1) RhD can be used as a retrograde marker for central neurons projecting to the periphery; 2) Biocytin injected with LY can provide permanent and detailed morphology of Rh-labeled central neurons. (NS 14857)

QUANTITATIVE MORPHOLOGICAL COMPARISON OF RAT DENTATE GRANULE CELLS INJECTED IN FIXED SLICES AND THOSE FILLED IN VITRO. **A.M. Felthauser* and B.J. Claiborne. Division of Life Sciences, University of Texas, San Antonio, TX 78285.**

Previous studies have shown that intracellular injections can be made in fixed cortical tissue (Neurosci. 28:3, 1989), but it is not yet known if neurons labeled using this method are adequately stained for quantitative analyses. Here we compare the dendritic structure of granule neurons injected with Lucifer Yellow in fixed hippocampal slices to the structure of granule cells filled with HRP in vitro and analyzed in our earlier work (Claiborne et al., in press). Hippocampi were removed from 7 Sprague-Dawley rats between the ages of 37 and 41 days. Transverse slices 400 um thick were cut on a tissue chopper, fixed for 45 min. in 4% para-formaldehyde, rinsed in buffer and mounted on gelatin-coated slides. Granule neurons in the dorsal blade were filled with Lucifer Yellow (2.5% in 0.5 M LiCl). Slices were re-fixed overnight, dehydrated in EtOH and cleared in methyl salicylate. Results showed that almost all dendrites extended to the pia, as is seen with in vitro injections, and that there were 29.6 ± .9 segments per cell (mean ± s.e.m.; n=16). This was not significantly different (t-test) from the 31.5 ± 1.0 segments seen in neurons (n=26) filled with HRP in vitro. These results indicate that neurons filled in fixed slices are adequately labeled for quantitative studies. (Supported by grants BNS 8709366 and AG 07141.)

A VERSATILE, HIGH-RESOLUTION, MULTI-USER IMAGE ENHANCEMENT AND ANALYSIS WORKSTATION FOR NEUROBIOLOGY. R.S. Nowakowski, M.D. Egger, H.M. Geller, J.P. Grierson, T. Liang,* and †J.A. Blumert*. Image Enhancement and Analysis Facility, Departments of Anatomy and Pharmacology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854, and †Silicon Graphics, Inc., East Hanover, NJ 07936.

In order to exploit recent advances in computer imaging technology, we have assembled a versatile, general-purpose, high-resolution imaging workstation for use by a diverse group of neurobiologists. We use a Silicon Graphics IRIS (Model 4D/70GT) Unix-based graphics workstation equipped with a digitizing and image analysis board (Androx ICS 400), a high-resolution (1024 x 1024 pixels) video camera (Dage 81), a color screen-printer (Seiko CH-5103) and software packages (Androx ICL and Synoptics Semper 6). Images can be displayed and analyzed in gray-scale (up to 1024 gray values) or in 24-bit color (over 16 million shades) at resolutions up to 1024 x 1024 pixels. An ethernet port allows rapid transfer of images to and from remote sites, including PC's.

Capabilities of our system include: 1) 3-dimensional display of neuron trees from Golgi-stained or HRP-filled neurons, 2) enhanced (digitized, averaged and histogram-stretched), high-resolution images of immunohistochemically-stained neurons in culture, 3) image-ratioing and cross correlations to demonstrate co-localization of multiple fluorophores, 4) automated counting of BUdR-labeled proliferating cells in the developing brain, and 5) 3-dimensional graphs of flow cytometry data.

Supported in part by NIH grant 1S10RR04019.

THE STEREOLOGY OF AUTORADIOGRAPHY: MEASURING THE SIZES AND DENSITIES OF TRITIUM LABELED CELL NUCLEI. S.J. Clark* J. Cynx. (SPON: D.R. Griffin). The Rockefeller University, Field Research Center, Millbrook, NY 12545

True cell size distributions and densities cannot be measured directly from tissue sections. Stereological models have been developed to correct this problem. Unfortunately, these models are not applicable to autoradiographically labeled nuclei.

Here we present equations which can be used in conjunction with stereological models of the "unfolding" type (e.g. Wicksell, S.D., Biometrica 17:84, 1925) to reconstruct the sizes and densities of autoradiographically labeled nuclei.

We show how these equations were developed, how they can be modified so as to be applicable to different experimental parameters, and the assumptions and limitations of the models. Finally, we illustrate the use of the model on data from a study of neurogenesis in the avian telencephalon (Nottebohm et al. in prep.).

A TRUE QUANTITATIVE FLUORESCENT MICROSCOPY SYSTEM FOR VOLTAGE SENSITIVE DYE. R. M. Dasheiff and D. S. Sacks* Veterans Admin. and Univ. of Pittsburgh Epilepsy Center, Pgh. Pa. 15213.

Fluorescent microscopy is a powerful imaging technique. There has been an increasing interest and need to measure actual dye concentration in a sample. Recently, fluorescent voltage sensitive dyes (VSD) have been used as a histological marker for the membrane potential in neural tissue. However, to maximize the utility of this technique, the absolute dye concentration needs to be calculated. The dye can both record and *save* the information about the state of depolarization or hyperpolarization in the tissue for latter analysis. The actual voltages can be calculated if the dye concentration can be accurately determined. In our experiments, diO-C_2-(5) is injected through the carotid artery and is accumulated into neural tissues. The brain is immediately removed, frozen, sectioned on a cryostat, and thaw-mounted onto microscope slides to produce a permanent and stable record. An epifluorescence microscope with a computer controlled scanning stage provides the image to a SITS camera. The entire cross section of the brain can be scanned and is analysed by creating a montage. The gain and high voltage of the camera is kept constant, and only the gating is used to compensate for high or low light levels. A uniformly fluorescent standard is used to subtract out inhomogeneities in the camera image caused by uneven lighting from the lamp, and shading effects in the camera. A set of VSD standards, of known concentration and thickness, is used to construct a calibration curve. By using this curve and the gate number, the "relative" intensity of fluorescence in the raw image is transformed into an actual dye concentration in the tissue. The voltage difference produced between the control and experimental conditions can then be calculated from the dye concentrations.

123.1

THE RELATIONSHIP BETWEEN STIMULUS-EVOKED METABOLIC ACTIVITY AND WGA-HRP LABEL IN THE VENTROBASAL THALAMUS OF MONKEYS. W. Ma[1] and S.L. Juliano[1,2]. [1] Dept. of Anatomy, USUHS, Bethesda, MD 20814; [2] Lab. of Neuropsychology, NIMH, Bethesda, MD 20892.

Earlier studies investigating the coincidence between cortico-cortical connections and stimulus-evoked 2-deoxyglucose (2DG) activity in the somatosensory cortex of monkeys indicated that the location of metabolic patches could be predicted by the presence of transported HRP patches, after injections into different somatosensory fields. This observation was more clearly true following injections into area 3b than following injections into area 1. In the present study, electrophysiological recordings were conducted to identify small fields of skin (RFs) that activated neurons at the recording site, when stimulated with a mechanical stimulator. These RFs were small and on glabrous skin. An iontophoretic injection of WGA-HRP was then made into the recording site. The injection sites were approximately 500-750 um in diameter. Two days later, each monkey (*Macaca fasicularis* or *Saimiri sciureus*) received an injection of 2DG while the stimulus identified in the recording experiment was delivered. Evaluation of the transported WGA-HRP and the stimulus-evoked 2DG activity in the VPL nucleus of the thalamus, revealed that the relationship between the 2 forms of label was similar to that found in the somatosensory cortex. That is, following WGA-HRP injections into cytoarchitectonic area 3b, the 2 forms of label were co-localized in VPL. Following injections into area 1, the 2 forms of label were not coincident, although both *patterns* of label were remarkably similar. This finding suggests that the information conveyed to the somatosensory cortex arises from separate populations of VPL neurons and that information projected to area 3b more clearly predicts the loci of evoked metabolic activity. Supported by NS-24014.

123.2

MODULAR ORGANIZATION OF THE THALAMIC VPM NUCLEUS IN MONKEYS. E. Rausell* and E.G. Jones (SPON: C. Avendaño). Dpt of Anatomy and Neurobiology, College of Medicine, University of California, Irvine, CA 92717.

The ventralis posterior medialis (VPM) nucleus of the monkey thalamus, which forms the relay for trigeminal inputs to the first somatic sensory area (SI) of the cerebral cortex, is divided into a series of elongated rod-like configurations of relay neurons. The rods are cytochrome oxidase (CO) positive and physiologically form the basis for the projection of modality and place specific information to column-like arrays of SI neurons (Jones et al. *Exp. Brain Res* 62: 438, 1986). The present study, in *M. Fascicularis* further characterizes the population of neurons in the rods and defines a second set of SI projecting neurons situated in different compartments of VPM. After defining the SI face areas of both sides by multiunit mapping, Fast Blue was either injected into the middle layers or applied directly to the cortical surface. The deeper injections led to retrograde labeling of cells in the CO positive rods, while superficial deposits affecting only layer I led to retrograde labeling of cells in medium and small celled zones of VPM that stain less strongly for CO. These zones are situated adjacent to the borders with the centre median and ventralis posterior inferior nuclei.

In parallel immunocytochemical experiments, the rod cells projecting to middle layers of SI were shown to stain positively for parvalbumin and with the monoclonal antibody CAT 301. The cells outside the rods and projecting to layer I were shown to stain positively for the 28 kd calcium binding protein, calbindin. Gaba immunoreactive interneurons are situated among both sets of cells and do not stain for parvalbumin or calbindin.

These results show that thalamic relay neurons project differentially upon layers of the SI cortex, as in the cat (Rausell and Avendaño, *Brain Res.* 347:165, 1985). In the monkey, these cells can be further characterized by the differential expression of calcium binding proteins.

123.3

Classes of thalamocortical relay neurons defined by differential immunoreactivity for calcium binding proteins in monkeys. E.G. Jones and S.H.C. Hendry Department of Anatomy and Neurobiology, University of California, Irvine, California 92717.

The distributions of neurons displaying immunoreactivity for parvalbumin and 28Kd calbindin were studied in the thalamus of Macaca fascicularis. Relay cells were identified by retrograde transport of fast blue from cortical injections and intrinsic neurons by GABA immunoreactivity in the same sections. Anterograde transport and degeneration studies also revealed parvalbumin or calbindin immunoreactivity in thalamocortical axons.

Thalamic nuclei are distinguished by different patterns of parvalbumin and calbindin immunoreactivity. In certain nuclei, e.g. in the anterior pulvinar nucleus, relay neurons stain for one only. In other nuclei that stain for both, the two calcium binding proteins can be found in separate relay neurons, e.g. in the intralaminar nuclei, or colocalized in some of the relay neurons, e.g. in some members of the ventral group. GABA is colocalized with parvalbumin in cells of the reticular nucleus but only in a few cells in the medial and lateral geniculate nuclei and in no cells in other nuclei.

123.4

COLLATERAL THALAMOCORTICAL PROJECTIONS TO AREAS 3b AND 1 OF SOMATOSENSORY CORTEX IN SQUIRREL MONKEYS: A FLUORESCENT DOUBLE LABELING STUDY. C.G. Cusick, S.L. Florence, P.E. Garraghty, and J.H. Kaas. Anatomy Dept., Tulane Univ. Med. School, New Orleans, LA 70112, and Psychology Dept., Vanderbilt Univ., Nashville, TN 37240.

Injections of the retrograde anatomical tracers WGA-HRP and ^{3}H-WGA into separate representations of the finger tips in somatosensory cortex of squirrel monkeys produce overlapping zones of label and double labeled cells in the thalamus (Cusick, et al., Somatosensory Res., 3:1, 1985). The present study was undertaken to determine if thalamic neurons project to both areas 3b and 1, and if branched projections include representations of the proximal fingers and palm as well as finger tips. Injections of retrograde fluorescent tracers fast blue and diamidino yellow, or fluorogold and rhodamine labeled microspheres, were placed in electrophysiologically identified representations of the proximal phalanges and digital pads in areas 3b and 1 in anesthetized squirrel monkeys (Saimiri sciureus). Overlapping and non-overlapping zones containing retrogradely labeled cells were revealed in the ventroposterior lateral, ventroposterior superior, ventropsterior inferior, and anterior pulvinar nuclei. Double labeled cells were identified in all four nuclei. The results suggest that branched projections terminate in areas 3b and 1 and include all parts of the hand representation.

123.5

ORIGINS OF THALAMIC PROJECTIONS TO LAYER I OF THE CEREBRAL CORTEX OF THE MONKEY. D.P. Friedman[1,2], Lin Li[1], and L.G. Ungerleider[1]. Lab Neuropsychology[1], NIMH Bethesda, MD, 20892 and Div Preclinical Res[2], NIDA, Rockville, MD, 20857.

We have previously described widespread projections from the region of the medial thalamus to layer I of the macaque cortex (Friedman et al., Soc Neurosci Abstr 13:251, 1987). To determine the nuclei of origin of these projections, we have made injections of retrogradely transported markers into large cortical regions in 8 rhesus and cynomolgus monkeys. All injections were performed under deep ketamine and barbiturate anesthesia while aseptic precautions were observed. After survival times of 2 days, the animals were again deeply anesthetized and perfused with 3% paraformaldehyde.

Injections into prefrontal, cingulate, temporal, parietal, and occipital regions all produced labeled cells in the midline nuclei and in the adjacent portions of the paracentral nucleus (PCN) and the magnocellular division of the ventral anterior nucleus (VA). However, both the density and distribution of this label differed depending on the site of the injection. Thus, whereas injections into prefrontal, cingulate, or parietal cortex led to labeling primarily in the midline nuclei, injections into the inferior temporal or prelunate gyrus led to sparse labeling on the midline, but impressive numbers of cells in VA and PCN.

The present results supply additional evidence that the midline nuclei have widepsread projections to cortex, but indicate that these nuclei may not supply the entire thalamic projection to layer I. Thalamic input to layer I of cortical areas in receipt of only sparse midline projections may arise instead in VA and/or PCN.

123.6

THALAMOCORTICAL RELATIONSHIPS IN THE VIBRISSA/ BARREL SYSTEM. P.W. Land and J.D. Yoskosky*, Dept. of Neurobiol., Anat. and Cell Sci., Univ. of Pittsburgh Sch. Med., Pittsburgh, PA 15261.

We investigated the topographic relationship between somatosensory cortical barrel columns and corresponding thalamic barreloids in rats using orthograde and retrograde transport of horseradish peroxidase (HRP). Electrophysiological recordings were used to target iontophoretic injections of HRP in lamina IV or VI of the posteromedial barrel subfield. Patterns of labeling in the medial division of the thalamic ventrobasal complex (VBm) were examined in sections cut parallel or orthogonal to the long axis of the barreloids. Injections into lamina VI or into the region of the V/VI border beneath a barrel labeled corticofugal axons that arborized throughout the corresponding thalamic barreloid. Divergent projections were more common "within a row" than "within an arc".

Both lamina IV and lamina VI injections led to labeling of neurons in the thalamus. Deep injections yielded labeled neurons throughout the extent of the barreloid corresponding to the injected barrel column. By contrast, lamina IV injections tended to produce labeled neurons primarily in the ventral lateral portion of VBm. These results indicate that each barrel column in rat provides cortical feedback to the barreloid providing the primary thalamic input, and perhaps to barreloids representing vibrissae in the same row. The data also suggest that, despite the morphological homogeneity of VBm neurons, cells in different parts of the nucleus may have distinct patterns of axonal termination in the somatosensory cortex. (supported by NIH grant NS 23047).

123.7

INTRINSIC CONNECTIONS OF RAT SmI BARREL CORTEX. N. D. Akhtar and P. W. Land, Dept. of Neurobiology, Anatomy and Cell Science, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA 15261.

Small iontophoretic injections of HRP placed into individual laminae of the rat somatosensory cortex were used to trace the inter- and intralaminar distribution of neurons projectiong to the target site. The overall distribution of retrogradely labeled neurons is similar whether injections are within a barrel column or between adjacent barrel columns. Following injections into lamina II/III, the majority of labeled neurons appear in lamina V. A few labeled cells also are present in lamina IV below the injection site. Injections in lamina V always produce labeled neurons in lamina VI, and in lamina II/III. In addition, larger infragranular injections that either extend to the region of the IV/V border, or include lamina VI result in some labeled neurons within lamina IV above the labeling site. In all cases, there is a column of labeled cells extending through the cortex. Injections in lamina IV, in particular, label a narrow column of cells primarily in the infragranular laminae. Finally, within each lamina a target site tends to receive more convergent projections from cells within the same barrel row than from adjacent rows. Our results demonstrate specific patterns of connectivity for individual laminae in rat SmI as has been reported for other sensory cortical regions. The tendency for connections between neurons representing vibrissae in the same row may contribute to a bias in the processing of sensory information in the barrel cortex. (Supported by grant MH09773)

123.8

CHARACTERIZATION OF ENSEMBLE PROPERTIES OF SIMULTANEOUSLY RECORDED NEURONS IN SOMATOSENSORY (SI) CORTEX. J. Chapin, M. Nicolelis*, C.-H. Yu*, and S. Sollot*, Hahnemann Univ., Phila, PA. 19102

The CNS accomplishes its actions through the joint activity of large numbers of neurons, yet standard neurophysiological analysis involves recording neurons only one at a time. To define network mechanisms of cortical processing, we have quantitatively characterized patterns of discharge among neurons simultaneously recorded through arrays of 25μ microwire electrodes in the SI cortex of awake, behaving rats. All neurons were initially classified according to classical criteria, such as cutaneous or proprioceptive receptive fields, motor-behavioral correlates, and functional connections defined by spike-triggered cross-correlation. Next, multivariate statistical techniques were used to characterize the "ensemble properties" of the neurons. Cluster analysis was used to define the "state-space" of the ensemble. The joint activity of the N simultaneously recorded neurons over certain time intervals (10-100 msec) were represented as points in N-space. Clusters of these points defined activity states corresponding to particular behavioral conditions, such as sensory stimuli, or to phases of limb movement. These multi-neuronal states yielded more accurate predictions of the behavioral condition than did any individual neuron. Factor analysis was used to identify the elemental factors underlying these activity states. Some factors were identified as representing particular types of sensory inputs, but others were correlated specifically with movement, or were "unexplained". Principal components analysis was used to define component factors which could account for most of the variance in the network over several behavioral conditions. As composites of the elemental factors these components represented emergent properties of the ensemble. They were also used as a reduced criterion set for subclassification of the recorded neurons. This was useful, for example, for subclassifying sensory neurons which possessed similar receptive fields, but which discharged differently during various behaviors. In summary, these approaches not only provided measurement and visualization tools appropriate for multi-neuronal studies, but also allowed a conceptualization of cortical physiology in terms of distributed activity across neurons. *Supported by PHS grants NS26722, AA06965, and AA00089.*

123.9

AXONAL PROJECTIONS IN MOUSE BARREL CORTEX. K.L. Bernardo, J.S. McCasland and T.A. Woolsey, Dept. Neurosurg., Div. Exp. Neurol. & Neurosurg. and McDonnell Center for Studies of Higher Brain Function, Washington University School of Medicine, St. Louis, MO 63110.

The distribution of retrogradely labeled **cell bodies** in barrel cortex following focal extracellular HRP injections directly into the barrel field is in columns of the same barrel row as that which was injected (Bernardo et al, '88). Quantitative conclusions were drawn from automated analyses of histological slides using a Grinell image processor, video camera and a microscope with a computer-contolled motorized stage.

We now describe the distribution of labeled **axons** in these materials, using the same automated image analysis system with new software designed to extract data about axonal trajectories instead of cell somata.

Results have been analyzed so far for injections confined to the supragranular layers within barrel cortex. In layer IV and in the infragranular layers of each cortex, axons project primarily ***laterally***, down the barrel row which was injected (e.g. C3 -> C4), as well as into the ***anterior*** adjacent barrel row (e.g. B -> C, C -> D, etc.). Presumably these projections serve to convey information to specific adjacent barrel columns. The different cell and axonal labeling patterns identify distinct **populations** of cortical neurons subserving different functions for integration of inputs from the whiskers.

123.10

LAMINAR INTERACTIONS IN RAT VIBRISSA/BARREL CORTEX SHI DI[1,2,3], CHRISTOPH BAUMGARTNER[1,4]* and DANIEL S. BARTH[1,2], *Departments of [1]Neurology and [2]Psychology, Univ.of California, Los Angeles, (U.S.A), [3]Mental Health Institute, Beijing Medical University (China) and [4]Neurological University Clinic, Vienna (Austria)*

The rat vibrissa/barrel cortex was studied as a model of sensory information processing. Previous receptive field and latency studies have suggested sequential processing among cortical laminae in barrel cortex. The present study applied the current source-density (CSD) analysis combined with principle component analysis (PCA) to analyze field potentials in rat vibrissa/barrel cortex evoked by mechanical whisker displacements. The potential complex consisted of biphasic fast components followed by long lasting slow waves. It began with activity in supragranular cells consisting of a source in layers I-II and a sink in layers IV-V, this was followed by activation of the infragranular cells with a paired sink and source in layers I-IV and V-VI, respectively. The slow wave sequences also began in the supragranular cells followed by infragranular neurons. We propose that the fast components reflect the sequential interlaminar depolarization processes, and the slow waves, the hyper- or repolarization processes. These results suggest that a basic neuronal circuit, consisting of sequential activation of the supragranular then infragranular pyramidal cells, gives rise to the field potentials evoked by physiological stimulation. This is consistent with our previous studies of direct cortical responses (DCR) and pathological discharges of penicillin focus.

123.11

REGULAR-SPIKING CELLS BUT NOT BURSTING CELLS IN THE DEEP LAYERS OF MOUSE BARREL CORTEX RECEIVE MONOSYNAPTIC THALAMIC INPUT. A.Agmon and B.W.Connors, Dept of Neurology, Stanford Univ., Stanford, CA 94305 and Brown Univ., Providence, RI 02912.

The deep layers of rodent neocortex contain two physiologically-distinct types of pyramidal cells (Connors, Gutnick and Prince, J. Neurophysiol. 48, 1302-1320 (1982); Agmon and Connors, Neurosc. Lett., in press). Whereas the majority of cells ("regular-spiking") respond to an intracellular suprathreshold current step by firing trains of individual action potentials, about one third of the cells in the same layers generate single or repetitive bursts of spikes. Using the thalamocortical slice preparation (Agmon, Ph.D. Dissertation, 1989) we characterized the thalamocortical synaptic responses of both types of cells and used their response latencies to determine their synaptic order. Half of the regular-spiking cells (7/14) were found to receive thalamus-evoked EPSP's at a monosynaptic latency. In contrast, only 1 of 10 bursters was activated monosynaptically, the rest being polysynaptic or non-responsive. We conclude that the intrinsic physiological properties of cortical cells are correlated with their thalamocortical inputs, and that bursting and regular-spiking cells occupy different positions in the synaptic circuit of the barrel cortex. Regular-spiking and bursting cells, though both pyramidal, belong to distinct morphological subtypes (Chagnac, Luhmann and Prince, submitted). It remains to be seen whether these two classes of cells also differ in their axonal targets. Supported by MH17047 and NS12151.

ORIGIN OF OPTICAL SIGNALS RECORDED WITH VOLTAGE SENSITIVE DYE IN THE RAT SOMATOSENSORY CORTEX. S.Ito*(SPON:S.Kawamura).Dept. Physiol., Kumamoto Univ. Med. Sch., Kumamoto, 860, Japan.

To estimate what aspects of neuronal activity are monitored by optical recording with voltage sensitive dye, fluorescence signals of the dye RH414 recorded with a single-element photodiode were compared with field potentials recorded with a metal microelectrode in the rat somatosensory cortex. Rats were anesthetized with sodium amobarbital, ventilated artificially, and mounted on a stereotaxic apparatus. Responses of the hindlimb area evoked with contralateral sciatic nerve stimulation were monitored. The optical signals had the very same latency and shape as those of the initial negative component of the field potential recorded at several hundred micrometers below the surface. On this component the stimulus intensity-response curve was identical. When double shocks were used, the relationship between the amplitude of the response to the second stimulus and the interstimulus interval was also identical. Thus, the optical signal was exactly alike the field potential recorded at a certain depth, suggesting that these two recordings represent the same process in the cortex, that is, the summated PSPs in layers I-IV. Supported in part by a grant of the NISSAN SCIENCE FOUNDATION.

123.13

COMPUTER SIMULATIONS OF INFORMATION PROCESSING IN A BARREL OF RAT SOMATOSENSORY CORTEX. H. T. Kyriazi* and D. J. Simons (SPON: N. Schor) Dept. of Physiology, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA 15261.

A computer model has been developed that incorporates known anatomical and physiological features of whisker-related barrels in cortical layer IV. The model consists of 98 interconnected stellate cells (84 excitatory, spiny and 14 inhibitory, smooth) each of which receives monosynaptic, excitatory inputs from up to 10 cells in the corresponding thalamic barreloid. These numbers correspond roughly to 5% of the estimated populations. Adjustable parameters include cell connectivity, synaptic strength, refractory period, synaptic delay, EPSP and IPSP decay rates, and shape of the function relating membrane potential to probability of spike discharge. Parameter values, set at the beginning of a simulation, are adjusted separately for spiny and smooth cells. Individual cell connectivities and synaptic strengths are assigned randomly according to a Gaussian distribution, with only the mean and range values being prespecified. The purpose of this randomization is to simulate natural variability. The network is activated by actual pre-recorded spike trains from barreloid cells. Circuit dynamics involve both temporal and spatial integration, and the activity of each cell is updated every msec.

Output consists of simulated spike trains that can be compared quantitatively to those of real barrel neurons. We have focused on the spontaneous and stimulus-evoked activities of spiny and smooth cells in response to single- and multi-whisker deflections. Specific response components include magnitudes of ON and OFF responses, temporal patterns of excitation/inhibition following single-whisker stimuli, and cross-whisker inhibition following sequential deflections of adjacent whiskers. Sets of parameter values have been identified that enable the model network to generate spike trains that reasonably simulate our neurophysiological data. Such computational studies may yield quantitative estimates of the relative importance of neuronal parameters which form the basis of cortical information processing. Supported by NS-19950.

SOMATOSENSORY CORTEX AND THALAMOCORTICAL RELATIONSHIPS II

124.1

DISSOCIATION OF THE EFFECTS OF INSULAR AND INFERIOR TEMPORAL (AREA TE) LESIONS ON TACTUAL AND VISUAL MEMORY IN MACAQUES. T.P. Pons, E.A. Murray and M. Mishkin. (SPON: M. Haenlein) Lab Neuropsychology, NIMH, Bethesda, MD 20892.

A severe deficit for both visual and tactual recognition memory in monkeys follows combined bilateral removal of the amygdala and hippocampus (Murray and Mishkin, 1984, J. Neurosci.). Bilateral removal of cortical area TE also produces a severe impairment in visual recognition memory (Mishkin, 1982, Phil. Trans. R. Soc. Lond. B.). In the present study we asked whether bilateral removal of the insula, which appears to be the somatosensory analogue of visual area TE by several connectional and physiological criteria, would produce a tactile memory deficit. To answer this question 6 cynomolgus monkeys were trained preoperatively on a delayed nonmatching-to-sample (DNMS) task in both the visual and tactual modalities. After achieving a criterion of 90% correct responses in 100 trials in both modalities, with 10 s delays between sample and test presentations, the animals' tactual performance was measured in blocks of 100 trials each with delays of 30, 60, and 120 s. Postoperatively animals were retrained on the tactual task to criterion or for 1500 trials with 10 s delays, and then given the tactual, followed by the visual, performance test. Four monkeys with insular lesions were severely impaired on tactual (59%) but not visual (>90%) DNMS. Conversely, 2 animals with TE lesions were impaired on visual (76%) but not tactual (>90%) DNMS. These findings provide evidence that the insula is a critical link in a cortico-limbic pathway for tactual memory, just as area TE is for visual memory.

NEURAL CODING OF TACTILE ROUGHNESS: CORRELATION BETWEEN HUMAN PSYCHOPHYSICAL ESTIMATES AND MONKEY PERIPHERAL AFFERENT RESPONSES. C.E. Connor*, S.S. Hsiao*, and K.O. Johnson (SPON: G.F. Poggio). Bard Laboratories, Dept. Neuroscience, The Johns Hopkins University Sch. Medicine, Baltimore, MD. 21205.

Previous results suggested that subjective roughness of embossed dot patterns is correlated with two measures of firing rate variation in macaque slowly-adapting (SA) Merkel's and rapidly-adapting (RA) Meissner's afferents (K.H. Fasman et al., Neurosci. Abstr., 11:906, 1985). One measure is based on temporal changes in firing rate within fibers due to intermittent stimulation as the dot pattern moves across the skin surface. The other is based on differences in firing rate between fibers due to the spatial distribution of dots across the skin surface. The present study was designed to distinguish between the temporal and spatial measures as neural codes for tactile roughness. The stimuli were 16 plastic surfaces with arrays of embossed 0.5 mm diameter dots. Dot spacing was separately varied in two directions, one parallel to the direction of scanning motion and one orthogonal, in an attempt to independently alter temporal and spatial stimulation. In psychophysical experiments, subjects were asked to scan the distal pad of their index finger sideways across the surfaces and report their estimates of roughness magnitude using a numerical scale. In neurophysiological experiments, the same surfaces were swept repeatedly across the receptive fields of macaque SA and RA afferents innervating the distal pads of the fingers.

Psychophysical results from 35 subjects showed that subjective roughness magnitude declines rapidly as dot spacing in the scanning direction decreases from 4.0 to 1.5 mm., and declines somewhat less rapidly as dot spacing decreases over the same range in the orthogonal direction. Temporal firing rate fluctuations in both SA's and RA's increase as orthogonal spacing decreases, and thus cannot explain the psychophysical results. Spatial (between-fiber) firing rate differences, however, provide a close match to the human roughness estimates. Supported by NIH grant NS18787.

FEATURE ANALYSIS OF SPATIAL PATTERNS IN THE MONKEY SOMATOSENSORY SYSTEM. S.S. Hsiao*, K.O. Johnson, J.R. Phillips. Bard Laboratories of Neurophysiology, Johns Hopkins University Sch. of Med. Baltimore, MD 21205.

Embossed letters of the alphabet were used as stimuli in an investigation of the representation and transformation of spatial patterns in the somatosensory system. Single unit recordings were made from peripheral afferents in the anesthetized monkey and from neurons in SI cortex in the awake monkey to generate a two-dimensional spatial event plot (SEP).

In order to quantify the responses, an analysis was developed to assess the degree of isomorphism and to see if neurons had any selective preference to particular features in the letters. The degree of isomorphism was assessed by investigating the distribution of distances of the neural impulses from a stick representation of the stimulus letters. Neurons with low distance distributions (i.e. most of the impulses near the letters) are more isomorphic than neurons in which the impulses are distant from the letters. Impulses from the SA afferents had mean rms distances from the stick letters of less than 1mm. The RA afferents had mean rms distances of slightly greater than 1mm. The PC afferents had much larger rms distances (>3.5mm), indicating their spatial structure was unrelated to the letters. The cortical responses had rms distances ranging from less than 1mm to very large values, with the SA neurons in area 3b having the lowest values.

The SEPs were also investigated for their sensitivity to letter features. The density of impulses were quantified relative to their spatial location around the letters. These distributions were then mapped into a feature map. Peripheral SA and QA neurons were isomorphic and showed leading edge enhancement with a loss of internal detail. The cortical responses were much more varied than the peripheral responses, ranging from being highly structured and isomorphic, to neurons with high feature sensitivity, to neurons with weakly structured responses. Supported By NIH grant NS18787.

124.4

ACTIVE VS PASSIVE TOUCH IN A LETTER RECOGNITION TASK: HUMAN PERFORMANCE AND VELOCITY EFFECTS. F. Vega-Bermudez*, K.O. Johnson, K.H. Fasman, S.S. Hsiao* (SPON:L. Haynes). Bard Laboratories of Neurophysiology Dept. of Neuroscience, Johns Hopkins Univ. Sch. of Med., Baltimore MD 21205.

The performance of human subjects in a letter recognition task was measured under two conditions: active touch where subjects scanned letters, 6 mm in height, with the tip of their right index finger and passive touch where the same letters were applied to the constrained fingertip by means of a rotating drum. Twenty five subjects were tested in the active task and 15 subjects in the passive task. Overall performance was nearly identical in the two tasks as measured by the distributions of individual percent correct identifications (Kolmogrov-Smirnov D=0.146, p 0.10), by the grand means (49.0% active, 50.7% passive) and by the correlation of confusion matrices from the two tasks (R=0.956, p 0.001). Finger scanning velocities in the active task varied from 10 to 60 mm/sec. For the purposes of comparison, the passive task was run at 20, 40 and 80 mm/sec. These observations suggest that self initiated movements do not contribute relevant information for fine form discrimination at the fingertips.

MODULATION OF CUTANEOUS INPUT FROM THE HAND TO SI CORTEX PRODUCED BY ICMS OF MOTOR CORTEX IN THE MONKEY. W. Jiang, Y. Lamarre and C.E. Chapman, Centre de recherche en sciences neurologiques, Université de Montréal, Canada H3C 3J7

We have previously shown that cutaneous inputs from the hairy skin of the arm to primary somatosensory cortex (SI) are decreased topographically by intracortical microstimulation (ICMS) of motor cortex. The present study tested the effects of ICMS on inputs from the glabrous and hairy skin of the hand.

ICMS (train of 11 pulses at 330 Hz, 0.2 ms pulse width) was applied to low threshold (<14 μA) sites in motor cortex and airpuff-evoked potentials (20 ms) were recorded in the adjacent SI areas. Data were pooled from 141 pairs of SI recording/ICMS (1-1.5 x threshold) sites in 3 monkeys. Evoked potentials elicited from the glabrous skin of the hand were not modulated (n=15 pairs). Hairy input from the hand was less often modulated (8/21) than input from the arm,' e.g. the forearm (43/72). Activation of hand and/or digit muscles (including intrinsic muscles of the hand) was less likely to modulate hairy input from the hand (3/13) than was the activation of elbow muscles (5/8). The results suggest that motor cortex modulates hairy, but not glabrous, inputs from the hand. This is consistent with the importance of glabrous inputs in active touch. Supported by the MRC of Canada and the FRSQ.

Gating of Cutaneous Inputs During an Active Tactile Discrimination Task versus Passive Receptive Field Testing in the Monkey. S.A. Ageranioti and C.E. Chapman, Université de Montréal, Montréal, CANADA

It is known that somatosensory transmission is reduced prior to, and during, voluntary movement, but this may vary as a function of the context in which the movement is made. The present study compared the discharge properties of neurones in the cutaneous hand area of SI cortex (n=150) in 2 monkeys during active movement and passive receptive field (RF) testing. The monkeys were trained to actively scan and to discriminate between a rough and a smooth surface.

Units were classified according to the location of their RF: those with a RF on the tip(s) of the digit(s) in contact with the surfaces (single digit, sd (n=18); multiple digit, md (n=95)); those with a RF elsewhere on the digit(s) (n=24); glabrous palm (n=9); or hairy dorsum (n=7). The majority of units with cutaneous RFs on the tips of the digits in contact with the surfaces showed as much (49-59%) or more (15-29%) modulation during the active task than during passive RF testing. The greatest modulation was seen in md units with large RFs including the glabrous palm. Only a small proportion (12- 36%) was more responsive to passive, than active, testing. In contrast, two-thirds of the remaining units with cutaneous RFs (other digits, palm or hairy dorsum) were more responsive to passive RF testing than to active movement. While the latter were also less frequently modulated in the task (43%), they showed no evidence for increased inhibitory influences during the active task (10% vs 13% for the units with RFs on the digit tips). These findings suggest that in a task in which the sensory inputs are behaviourally significant to the animal, the inhibitory controls over sensory transmission are suppressed. Supported by the MRC of Canada and the FRSQ.

NORMAL TACTILE FUNCTION PERSISTS DESPITE SENSORY DEPRIVATION IN INFANT MACACA M.Carlson & M. Pearce* Depts. Psychiatry, Anatomy & Neurobiology, Washington University School of Medicine, St. Louis, MO 63124

Infant macaques as young as 2 months of age, and infants with restricted tactile experience from birth to 4 months, can discriminate between textures as well as adults (Carlson,'84a). Although tactile function appears to be mature soon after birth, other features of the somatic system change with age. Infants with unilateral or bilateral removal of primary (SI) (Carlson,'84b,c) or secondary (SII) (Carlson and Burton,'88) somatic sensory cortex can recover normal tactile function whereas juveniles and adults have persistent deficits after the same damage. To explore the possible role of sensory input in tactile function early in life, we produced total sensory deprivation of the glabrous hand by crush of the medial and ulnar nerves (70mm from the digit tips) in two 5 week-old infants. When tested on texture discrimination tasks at 20 weeks, moderate retardation in tactile learning was seen. However, discrimination thresholds for sandpaper and nyloprint textured surfaces in both the normal and early-deprived hands were found equal (or superior) to that of adult macaques and humans. Currently we are testing an infant in which these nerves were crushed 120mm from the tips (extending the deprivation period to 17 weeks) and we will examine input to the SI and SII areas contralateral to the deprived hand in all animals. Given the mature level of function in normal infants and the failure to induce deficits by sensory deprivation, we suspect that tactile input is not needed for normal development of this system or that the critical period may occur in the late prenatal rather than the early postnatal period.

124.8

INTEGRATION OF INPUTS FROM MULTIPLE SKIN SITES BY CORTICAL TOPOGRAPHIC UNITS. M. E. Diamond and O. V. Favorov, Dept. of Physiology, Univ. of North Carolina, Chapel Hill, NC 27599.

The minimal RF ("minRF") method, which maps the dominant skin input to small neural populations, reveals that the somatic cortex of cat is a mosaic of discrete, columnar topographic units (Proc. Natl. Acad. Sci.(1988) 84, 6606-10). All recording sites within a topographic unit yield the same minRF; each unit is 250-400 um in diameter and is surrounded by six others. Single neuron maximal RFs (maxRFs) are larger and more variable than minRFs, but the site of overlap of all the maxRFs in a topographic unit matches the minRF of the unit. Experiments were carried out to determine whether the skin site of maxRF overlap, in comparison to sites in the RF periphery, is relayed to a topographic unit along a physiologically distinguishable pathway. Tactile stimuli were delivered to site 1 (corresponding to the minRF; the point of maxRF overlap) and to sites 2-4 (5, 10, and 15 mm from site 1) and single neuron response was recorded. On average, stimulation of site 1 led to shortest response latency and highest response probability; site 4 led to the opposite. When sites 1-3 were stimulated, middle layer neurons responded earliest; when site 4 was stimulated superficial neurons respond earliest.

A model is proposed whereby the site of maxRF overlap (the minRF) of a given cortical topographic unit is relayed to that unit directly through thalamus and site 4 is relayed primarily through neighboring cortical units; the model is compared to proposed pathways to the barrel field cortex in rodent. The role of intracortical inhibition is discussed. (Supported by NIH Grant DE07509)

VIBRISSAL ROUGHNESS DISCRIMINATION IS BARREL CORTEX DEPENDENT. E. Guic-Robles*, H. Bravo*, and W.M. Jenkins. Dpto. Fisiologia y Biofisica, U. Chile, Santiago 7, Chile.

Recently we have developed a behavioral discrimination procedure to study the rat's vibrissal sensory capacities. This procedure has been used to demonstrate that rats can learn a roughness discrimination using only their vibrissal system (Guic-Robles et al, Arch. Biol. Med. Exp., 20(2) R209, 1987; Behav. Br. Res., 39, 285-289, 1989).

In the present experiment we have investigated the contribution of the neocortical barrel field devoted to vibrissal representation (PMBSF) to the high performance levels obtained by rats in this complex tactile discrimination. Eight binocularly occluded rats were trained to make vibrissal system based roughness discriminations. All trained rats obtained the 85% correct discrimination criterion. The behavioral procedures, apparatus and test stimuli were identical to those previously reported. The PMBSF was subsequently bilaterally ablated after localization of this cortical area by electrophysiological recordings. The locus and extent of the cortical lesions were confirmed by histological analysis. There was no evidence of task retention after cortical lesions and barreless rats were not able to obtain prelesion discriminative performance levels when restricted to using vibrissal cues. After extensive post lesion training and testing, four of these rats were allowed to palpate the discriminanda with their forepaws. These rats rapidly reached the 85% correct criterion once again.

The present results indicate that the PMBSF cortex is essential for complex tactile discriminations when sensory information is obtained through the vibrissae. In contrast, the PMBSF is not essential for complex tactile discriminations when the source of the somatosensory information is provided by other non-vibrissal sensory receptors. Supported by NSF -INT8713322 and FONDECYT 5057 and 0133.

124.10

FUNCTIONAL DIFFERENCES OF HUMAN SOMATOSENSORY SI AND SII CORTICES: NEUROMAGNETIC RECORDINGS. H.Hämäläinen, R.Hari*, J.Kekoni*, and J.Tiihonen*. Dept. Psychol., Univ. Helsinki, and low Temp. Lab., Univ. Technol., Espoo, Finland.

Magnetic fields were measured with a 7-channel 1st-order SQUID-array to trains (ITI=10s; ISI=1s) of electrical stimuli applied to the left middle finger, or to stimuli presented to either the 1st or 3rd finger in an oddball paradigm (standards, p=0.9; deviants, p=0.1).

The responses showed clear deflections at 45-50 ms and 100-110 ms. According to field maps the earlier deflection (corresponding to P50 wave in electric scalp recordings) can be explained by an equivalent dipole located in the SI hand area, whereas the later one (corresponding to P100 wave in electric measurements) fits the anatomical location of SII area.

Both deflections decreased during the train of stimuli, and the decrement was largest between the 1st and 2nd stimuli. thereafter the responses tended to increase again suggesting that this phenomenon is based on active inhibitory processes.

The 100-ms magnetic deflection was significantly larger for infrequent deviants than for standards, suggesting that SII area codes even small changes in stimulus location.

CONTRALATERAL PARESTHESIA CAN UNUSUALLY BE ELICITED BY MAGNETIC COIL STIMULATION NEAR HUMAN CENTRAL SULCUS.
M. Somasundaram*, V.E. Amassian, R.Q. Cracco and P.J. Maccabee*. (SPON: Dr. Sloane Wolfson)
Depts. of Neurology and Physiology, SUNY Health Sci. Ctr. at Brooklyn, New York 11203.

Paresthesias are elicited by tetanic, but not by individual electrical stimuli to exposed, human postcentral gyrus (Libet et al. J. Neurophysiol. (1964) 27, 546-578). Although individual transcranial magnetic coil (MC) stimuli to motor cortex could elicit a sense of movement in a paralyzed limb (Amassian et al. Brain Research (1989) 479, 355-360), we also failed usually to elicit paresthesias by cortical stimulation. However, exceptional individuals describe reproducible, localized paresthesias following individual MC stimuli. For focal stimulation, we used a Cadwell MC composed of two coils, each 5.0 by 4.8 cm, optimal stimulation occurring under their junction. The 'best' subject is a physician, 56 years old and in good health. Using near threshold MC stimuli near central sulcus, the paresthesias (tingling) were projected to the palmar surface of fingers IV and V; no movements were elicited in the relaxed hand. To determine whether the paresthesias resulted from stimulation of pre- or postcentral cortex, the MC pulse was delivered during hand muscle contraction. Optimal sites for paresthesias correspond to those for muscle activation, implying a precentral origin. Stronger MC stimuli added other digits to the projected experience.

The paresthesias might result from an increased tendency to repetitive discharge by precentral neurons or an increased response by neurons more immediately related to perception. The latter is more likely because muscle responses elicited by the MC were unremarkable.

124.12

RESPONSE SUSCEPTIBILITY OF HUMAN BRAIN STRUCTURES TO EXTERNAL RHYTHMIC SENSORY STIMULATION.
L. Narici°, G. Iori°*, V. Pizzella*, G.L. Romani&, P.M. Rossini#*, G. Torrioli*, R. Traversa#*Istituto di Elettronica dello Stato Solido, CNR Roma, Italy.

We show results of a study on the relationship between brain spontaneous activities and inputs from visual and somatosensory systems as measured with neuromagnetic techniques.

It is often assumed that the response susceptibility of brain structures upon external rhythmic sensory stimulation features peaks in the same frequency channels where spontaneous activity can be detected. Using sensory inputs, a suitable stimulation paradigm, and the powerful localizing capability proper of the neuromagnetic method we are able to identify the source location and frequency characteristic of three underlying oscillating circuitry. Upon visual rhythmic stimulation we studied a 10 Hz rhythm, linked to the alpha rhythm generators. Using somatosensory stimulation we identified an oscillating 12 Hz activity linked to the mu-rhythm, and possibly to the generators of the short latency evoked fields, and another rhytmic activity, at 6 Hz, probably genarated by two widely separated sources (parietal and frontal) driven by the same, deep clock (possibly thalamic).

The method proposed is able to investigate non-invasively rise and time evolution of synchronization processes in the human brain and, therefore, can be of interest in the study of all those pathologies describing disruption or enhancement of the brain rhythms.

REGENERATION: GENERAL

125.1

ESTABLISHMENT OF SCHWANN CELL CULTURES FROM ADULT PERIPHERAL NERVE.
G. Ferrari*, M. Fabris*, L. Maffei* and M.G. Fiori. Fidia Research Laboratories, Abano Terme (PD) and Ist. Neurofisiol. CNR, Pisa - Italy.

Schwann cells are known to play a crucial role in promoting adult peripheral nerve regeneration following damage. Elucidation of underlying molecular event will be important to understand Schwann cell functions. For this purpose, availability of large numbers of relatively pure and well-characterized Schwann cells, in particular of primate origin, would be an important asset. While many studies have derived from neonatal tissue, the yield of Schwann cells from adult nerves is currently scarce due to the presence of abundant myelin and connective tissue. In this study we present a method for obtaining Schwann cells from adult sciatic nerve that circumvents these problems. To evaluate the percentage of Schwann cells in culture a time-course analysis of Schwann cell-associated markers was performed employing immunofluorescence and immunoperoxidase. At 1 day in culture 90% of the cells were bipolar and S100, NGF-R, 217C-immunopositive. Two weeks later 70-80% of the cells still expressed the above markers. Thus, this method provides proliferating Schwann cells from adult nerves in large numbers and in a reasonable time both for morphological and biochemical analysis, and for studying the effects of mitogenic agents.

125.2

EXPRESSION OF CYTOTACTIN IN SCHWANN CELLS DURING DEVELOPMENT AND REGENERATION OF NERVES.
J.K. Daniloff, K. Crossin*[1], N. Satterlee*, A. Smith*, and G.M.Edelman[1]. Dept. of Anatomy, LA. St. Univ., Sch. of Vet. Med., Baton Rouge, LA 70803 and [1]Lab. of Dev. & Mol. Biol., Rockefeller Univ. N.Y.,N.Y.10021

Cytotactin is an extracellular glycoprotein involved in neuron-glia adhesion in the CNS. We have described its action in the normal and regenerating neuromuscular system and at nodes of Ranvier (J. Cell Biol. 103:379, 1986 and 108:625, 1989). To extend these studies, we examined the localization and synthesis of cytotactin by embryonic, reactive, and transformed Schwann cells of the PNS of rats.

Embryonic sciatic nerves (E18) were double-labeled with antibodies to cytotactin and S100 protein. All Schwann cells were labeled at the light and electron microscopic level. Cultured sciatic Schwann cells treated briefly with antimitotics to remove fibroblasts synthesized high levels of cytotactin, as did transformed cells from the C-6 Schwannoma cell line.

Cytotactin is present only in small amounts in normal Schwann cells of adult sciatic nerves. When the nerve was transected, reactive Schwann cells were intensely labeled by antibodies to cytotactin. Synthesis returned to normal low levels upon reinnervation.

These data support our hypothesis that cytotactin is involved in development and regeneration of the PNS. Cytotactin expression by Schwann cells may mediate certain identified effects of Schwann cells in these processes.

125.3

REACTIVE ASTROCYTES AND NEONATAL ASTROCYTES DIFFER IN THEIR ABILITIES TO SUPPORT NEURITE EXTENSION IN VITRO.
A.M. Stewart* and E.E. Geisert, Jr. (SPON: J.W. Brown). Department of Cell Biology and Anatomy, Neurobiology Research Center, University of Alabama at Birmingham Medical Center, Birmingham, AL 35294.

To test the hypothesis that reactive astrocytes are involved in the lack of axonal regeneration following CNS injury, we compared the growth of rat E18 cortical neurons on reactive astrocytes, cultured from injured corpus callosum, to the growth of neurons on neonatal astrocytes. Following two days in culture, cells were fixed and neurons were stained selectively with a monoclonal antibody directed against class III ß-tubulin. Neurons contacting cultured astrocytes were digitized for a quantitative analysis of neurite growth. Neurons contacting neonatal astrocytes had a mean of 163 µm of neurite/neuron; while, neurons contacting reactive astrocytes had on average 84 µm of neurite/neuron. This difference was more pronounced when neurons were contacting process-bearing astrocytes (neonatal astrocytes 221 µm of neurite/neuron, and reactive astrocytes 81 µm of neurite/neuron). In control experiments neurons were grown on PLL coated coverslips suspended over the cultured astrocytes. No significant difference in neurite length between reactive astrocytes (88 µm of neurite/neurons) and neonatal astrocytes (81 µm of neurite/neuron) was seen, demonstrating that differences in soluble factors produced by the two populations of astrocytes cannot account for the ability of the cells to support neurite extension. These data demonstrate that neonatal astrocytes actively facilitate neurite growth; while, reactive astrocytes at best are a neutral substrate. These effects appear to be due to physical contact between the cultured astrocytes and the growing neurites. Supported by Whitehall Foundation, Inc. and PHS grant NS23613.

125.4

THE FATE OF THE SCHWANN CELL BASEMENT MEMBRANE IN PERMANENT NERVE TRANSECTION.
C. Giannini,* P. J. Dyck. Peripheral Nerve Center, Mayo Foundation, Rochester, MN 55905

Following nerve degeneration, Schwann cell basement membranes (SCBM) maintain Schwann cells in linear rows and serve as conduits for fiber regeneration to target tissue. Quantitative data on SCBM number, size, and integrity after denervation without reinnervation is lacking. SCBM (continuous or discontinous) were evaluated in transverse electronmicrographs of groups of permanently transected peroneal nerves of C57BL6J mice at various times after transection. A definite trend was already established by 1 month.

Groups	No.	No.SCBM/ nerve mean±SD	Continous profiles (%)mean±SD	Mean of mean length(um)	Σ SCBM length/ nerve(um)
Control	6	1234±109	100	14.5±.8	17,905±1138
1 wk	8	1538±220	93±3	13.5±1.9	19,934±3371
4 wk	7	2179±444	51±8	6.7±.9	14,137±3178
Cont. vs 1 wk		p>.05	p<.001	p>.05	p>.05
Cont. vs 4 wk		p<.001	p<.001	p<.001	p=.02

These results indicate that even within 1 month of permanent transection many SCBM tubes become discontinous in the transverse plane.The average length of continuous and discontinous SCBM becomes shorter. In addition, summated length of all SCBM becomes less, possibly suggesting degradation of nerve SCBM. Discontinuity and decrease in amount of SCBM may have implications for nerve regeneration.

125.5

ASTROCYTES AND THEIR RESPONSE TO SPINAL CORD LESIONS IN THE DEVELOPING OPOSSUM. Ganesh Ghooray, R.H. Ho, and G.F. Martin. Department of Anatomy and Neuroscience Program, The Ohio State University, Columbus, OH 43210.

The aim of this study was to observe the normal development of astrocytes in the spinal cord of the opossum and to see if the development of a glial scar correlates temporally with the loss of rubrospinal plasticity. We examined astrocyte development by immunostaining for vimentin and glial fibrillary acidic protein (GFAP) using the ABC technique. The results indicate that vimentin-like immunoreactivity is well developed at birth (12 days after conception) whereas very little GFAP-like immuno-reactivity is present. The subsequent development of GFAP follows ventral to dorsal and rostral to caudal gradients. GFAP and vimentin are first expressed in radial glia. In the lesion experiments, pouch-young animals were subjected to spinal hemisections at low to mid-thoracic levels and allowed to survive for two weeks. The tissue was then immunostained for GFAP. The earliest indication of a glial scar was seen when the lesion was made at estimated postnatal day (EPD) 26 (50 mm snout-rump length (SRL)); scar density increased gradually to reach adult levels by EPD 73 (125 mm SRL). Since rubrospinal axons can still grow around a lesion of their pathway at EPD 26 (Xu and Martin), the development of an astrocytic scar may not be the only factor which impedes developmental plasticity. (Supported by NS-25095).

125.6

CULTURED SCHWANN CELLS, BUT NOT ASTROCYTES, SUPPORT AXONAL GROWTH IN THE CENTRAL NERVOUS SYSTEM OF ADULT RATS. C.T. Montgomery* and J.A. Robson. Dept. of Anatomy and Cell Biology, SUNY Health Science Center, Syracuse, NY 13210.

Growing axons require an appropriate substrate to elongate. In the peripheral nervous system this substrate is provided by Schwann cells and in the developing central nervous system (CNS) astrocytes appear to be involved. We are comparing the abilities of Schwann cells and astrocytes to support axonal growth in the adult CNS by transplanting purified glial cells into the brain. Schwann cells are collected from sciatic nerves of newborn rat pups and astrocytes are taken from embryonic rat forebrain. Purified cultures are made according to standard techniques. For transplantation, cells are transferred into polycarbonate tubes. One end of each tube is inserted into the thalamus of an adult rat and the other end is secured subcutaneously. Five to eight weeks later, horseradish peroxidase (HRP) is placed on the external end of the tube. The next day the animal is perfused and the brain is sectioned and processed for HRP histochemistry.

Results show that implanted Schwann cells support axon growth. The tubes become vascularized and contain bundles of axons, many of which appear myelinated. Following HRP application, many retrogradely labeled cells are found in the CNS. Most are in the diencephalon although some are in the telencephalon. Tubes containing astrocytes do not appear to support axonal growth. They are sparsely filled with tissue and are not well vascularized. No retrogradely labeled cells have been found in the CNS. These results indicate that transplanted Schwann cells are able to support axonal growth in the adult brain in the absence of a preformed basal lamina. In comparison, cultured embryonic astrocytes, transplanted in the same fashion, do not support such growth. (Supported by NIH Grant EY03940 and NATO Grant 0235/87)

125.7

AXON GROWTH IN THREE DIMENSIONAL ASTROCYTE CULTURES. J.W. Fawcett*, L. Housden*, L. Smith-Thomas and R.L. Meyer. Physiological Laboratory, Downing St., Cambridge CB2 3EG, England, and Developmental Biology Center, U.C. Irvine, CA 92717.

A tissue culture model of axon regeneration in the CNS should contain neurons, astrocytes and oligodendrocytes. When we examine the growth of axons on astrocyte-oligodendrocyte combinations in flat cultures, we find that axons grow readily, between the astrocytes and oligodendrocytes. We have therefore been unable to reproduce the inhibition of axon growth by the mammalian CNS in two dimensional cultures.

We have designed a technique in which three dimensional tissues of selected cell types can be created and cultured in 0.5mm diameter cellulose ester tubes. Rat glia are cultured in flasks, then trypsinized off, pelleted, resuspended and packed into tubes attached to pipette tips, using a combination of air pressure and centrifugation. A source of axons is then inserted into one end of the tube. Later the tube is sectioned, and immuostained for neurofilament and GFAP.

Axons from newborn rat dorsal root ganglia (DRG's) will not penetrate astrocytes which have been cultured 3 weeks or more, but will grow sparsely in cultures less than 10 days old. However, axons from E15 embryonic DRG's will penetrate aged astrocyte cultures, even when they contain oligodendrocytes. Similarly, axons from adult retina do not grow into older astrocyte cultures, while axons from embryonic retina grow profusely, even when oligodendrocytes are present. Axons from all these types of neuron will grow for considerable distances on flat astrocyte cultures. Supported by MRC, ISRT and grant #EY06746

125.8

NEURITE OUTGROWTH ON CNS TISSUE SECTIONS: DIFFERENCE IN AGE, ANIMAL SPECIES AND EFFECT OF BRAIN LESION. E.Watanabe* and F.Murakami. Dept. of Biophysical Eng.,Fac.of Eng.Sci., Osaka Univ., Toyonaka 560, Japan (SPON: T. Bando)

Neurite-elongation inhibiting proteins in mammalian CNS myelin (Caroni and Schwab'88) might be responsible for infrequent occurrence of regeneration in CNS. Cell culture on cryostat tissue sections provides useful information on the role of such proteins in vivo (Watanabe and Murakami'89). We cultured E6 chick neocortical and E9-11 chick DRG neurons on cryostat tissue sections of nerve tissues. While cell attachment and neurite outgrowth were inhibited on the white matter of adult rat CNS, no inhibition was observed on frog and neonatal rat spinal cord, and adult rat sciatic nerve, where regeneration takes place in vivo. Inhibition of cell attachment was abolished in rat near the lesion site after transection of superior-cerebellar-peduncle decussation, in consistent with reported success of regeneration (Kawaguchi et al.'86). Correspondence of the presently obtained results to the phenomena occurring in vivo provides further evidence suggesting possible involvement of the inhibitory proteins in regulation of axonal regeneration.

PATTERN OF LECTIN BINDING TO NORMAL PERIPHERAL NERVE AND PERIPHERAL NEUROMAS. S. Kumar*, P.L. Wade*, G.P. Cole*, and A.K. Gulati* (SPON: S.D. Stoney,Jr.). Department of Anatomy, Medical College of Georgia, Augusta, GA. 30912.

In the present study we report binding of 10 different lectins to normal rabbit nerve and neuromas. These neuromas resulted from epineurial sutures used to repair gaps. Neuromas were obtained at 2 and 12 weeks after transplantation. The following lectins, Maclura pomifera agglutinin (MPA), Triticum vulgaris (WGA), Canavalia ensiformis (Con A), Griffonia simplicifolia-I (GS-I) and GS-II, Glycine max (SBA), Ulex europaeus (UEA), Dolichos biflorus (DBA), Arachis hypogaea (PNA), Bachinia purpurea (BPA) bound to the perineurium, with intense binding for MPA, WGA, GS-I and Con A. Endoneurium and blood vessels also bound by MPA and WGA. Morphological analysis of peripheral neuromas revealed an increase in connective tissue with increased duration after transplantation, along with axon regeneration. Lectin binding increased with the increase of connective tissue in neuroma. Some lectins (MPA, WGA, Con A) presented a uniform increase in binding, whereas others (GS-I) exhibited a network like binding. These observations describe selective changes in glycoconjugates in experimentally induced peripheral neuromas. Supported by NIH grant NS24834.

THE EFFECT OF HeNe LASER IRRADIATION ON THE REGENERATION OF THE RAT FACIAL NERVE. J.J. Anders, R.Borke,S.Woolery* and W.P.Vandemerwe*. Dept. of Anatomy and Laser Biophysics Center, USUHS, Bethesda, MD 20814

The use of laser radiation as a photobiological stimulator of nerve regeneration was examined. The facial nerve was exposed unilaterally in anesthetized rats and crushed for 90 secs. The wound was sutured and transcutaneously irradiated daily with a HeNe continuous wave laser (632nm, 8.5mW, for 60min) for 7, 8, or 9 days. Rats were injected subcutaneously, on the side of the face supplied by the injured nerve, with 20 μl of HRP (20%) in 5 areas, 24 to 30 hrs before aldehyde perfusion. The number of labeled neurons in the facial nucleus was counted as an assay of the degree of regeneration. Control, uninjured rats injected with HRP, had 1600 to 2000 facial motor neurons labeled. Rats in which the facial nerve was crushed but not irradiated had an average of 8 neurons labeled on day 7 post crush, 18 on day 8, 89 on day 9 and 1140 on day ten. After laser irradiation, 15 neurons were labeled on day 7, 1055 on day 8, 1365 on day 9. These results show that laser irradiation caused an increase in the rate of facial nerve regeneration.

125.11

CORTICO-SPINAL TRACT REGENERATION OCCURS IN X-IRRADIATED, MYELIN-FREE RAT SPINAL CORD, OR BY APPLICATION OF AN ANTIBODY AGAINST MYELIN-ASSOCIATED NEURITE GROWTH INHIBITORS. T. Savio, L. Schnell and M.E. Schwab. Brain Research Institute, University of Zurich, August-Forel-Str. 1, CH-8029 Zurich/Switzerland

Regeneration of nerve fibers in the adult CNS does not occur, although many central neurons have the capability to regenerate their lesioned axons inside PNS tissue transplants. Recently, inhibitory substrate components which could be involved in lacking CNS regeneration have been discovered in central myelin and oligodendrocytes (Schwab and Caroni, J. Neurosci. 8: 2381-2993, 1988). They consist of two main proteins of 35 kD and 250 kD which are responsible for the inhibition of the neurite extension observed in vitro on CNS myelin or on white matter as a substrate. Their effects can be neutralized by a specific monoclonal antibody (IN-1) produced against these proteins (Caroni and Schwab, Neuron 1: 85-96, 1988). In order to study regeneration in the spinal cord of lesioned rats, we have eliminated the inhibitory substrate components either by neutralizing them with IN-1 mAB through implantation of hybridoma cells, or by preventing myelin formation through X-irradiation of the thoracic and lumbar spinal cord of newborn rats. At 15 days of age, a time when regeneration of the cortico-spinal tract (CST) in normal rats is known to be totally absent, the dorsal spinal cord was cut, and 2-3 weeks later, the lesioned CST was traced by injection of WGA-HRP into the frontal cortex. Results showed clear fiber regeneration, which could be followed for up to 11 mm caudal to the lesion area. In non-irradiated controls or in rats implanted with hybridoma cells producing anti-HRP mAB no fibers were detected at > 1 mm caudal to the lesion. Therefore, our results show that lesioned central fibers can regenerate in the spinal cord after a treatment which either eliminates oligodendrocytes and myelin or neutralizes some of their specific proteins, confirming the hypothesis that inhibitory CNS myelin components are crucially involved in the lack of CNS regeneration.

125.12

RELATION OF MACROPHAGE ACTIVITY TO AXONAL REGENERATION IN THE INJURED SPINAL CORD. C.P. Barrett*, L. Guth* and R.P.Rees*, (SPON. T.H. OH) Dept. of Anat., U. MD. Sch. Med., Balto, MD 21201

The macrophages that accumulate at sites of tissue injuries secrete superoxides and other cytotoxic agents. In spinal cord trauma, they promote a progressive necrosis resulting in an environment hostile to axonal ingrowth. Conversely, other macrophage secretions promote mitogenesis, angiogenesis and neuritogenesis, which are favorable to the repair of injured neural tissues. Thus selective regulation of macrophage activity might enhance axonal regeneration. After crushing the spinal cord of adult rats, we treated them with intravenous E.coli lipopolysaccharide (LPS) , 0.4 mg/kg b.i.d., a dose known to prime monocytes and macrophages for secretion of growth factors. After 2, 4, or 8 weeks, the spinal cords were examined by LM histology and immunocytochemistry. In comparison with saline-treated controls, the lesion site of the LPS-treated rats exhibited (a) reduced tissue necrosis; (b) enhanced ingrowth of glial and ependymal cells which formed cellular bridges across the lesion; (c) accumulation of macrophages whose unusually basophilic cytoplasm was indicative of protein synthetic activity; (d) considerable ingrowth of regenerated axons; and (e) reduced density of the glial scar at the severed ends of the spinal cord. These observations corroborate the early findings of Windle who used Piromen, a bacterial LPS, to stimulate axonal regeneration in the cat spinal cord. We suggest that the favorable effect of LPS results from altered macrophage activity. Supported by NIH grant NS-21460.

EFFECT OF VARIOUS STRENGTH ELECTRIC FIELDS ON PERIPHERAL NERVE REGENERATION. M. F. Zanakis and M. J. Politis. American BioInterface Corp., New York, NY 10276 and University of Saskatchewan, Saskatoon, Canada S7N 0W0

Cathodally directed DC electric fields enhance the regenerative capabilities of the damaged mammalian nervous system. Several studies have demonstrated this effect, but few have focused on the critical parameters required. In this experiment, adult rat sciatic nerves were transected at mid-thigh and the distal stump was frozen with dry ice. DC stimulating devices (Traxon®) incorporated into a nerve cuff were applied over the lesion site, with the cathode located 10mm distal to the transection. The current delivered to the nerve was 0, 0.6, 1.4, 6.0, 19.0, or 38.0μA. After 14 days the distal stump was removed and processed with toluidine blue, and with a fluorescent probe for neurofilament protein. Results indicate a clear dose response to the treatment, with 1.4μA of current resulting in a greater number of axons distally as shown using both histological techniques. This enhanced regenerative effect is currently being investigated using other parameters of efficacy.

125.14

THE LACK OF AN EFFECT OF APPLIED DC ELECTRIC FIELDS ON THE RATE OR QUALITY OF PERIPHERAL NERVE REGENERATION IN ADULT GUINEA PIGS. M. E. McGinnis* (SPON: S. Ostroy). Ctr. for Paralysis Research, Sch. of Veterinary Medicine, Purdue Univ., W. Lafayette, IN 47907.

This study was undertaken to provide evidence of enhanced regeneration of mammalian peripheral nerves in response to applied electric fields. The peroneal nerves of adult guinea pigs were either transected or crushed under appropriate anesthetic and surgical conditions. Constant current DC stimulators (20 μA) were implanted subdermally in the flank and Pt electrodes routed to each ankle. One electrode served as a cathode or as an anode (the return electrode was at the stimulator implant site), and the other as a sham electrode delivering no current. All surgery and analyses were done without knowledge of electrode identities. Animals with crush lesions were tested for toe spreading ability from the 14th to the 23rd day. Animals with transection lesions were allowed to recover for 40 days before the sciatic nerve was exposed for supramaximal square pulse stimulation. The foot was clamped by two isometric force transducers to measure toe abduction and foot flexion. After evaluation, all animals were euthanized and the nerves removed for histology. Counts of myelinated fibers were made from toluidine blue stained thick sections and counts of unmyelinated fibers from electron micrographs.

There was no difference between legs with an anode, a cathode, or a sham electrode as evaluated by: the time to return of the toe spreading reflex, the isometric force of either twitches or tonic contractions, the latency between stimulation and contraction, or the number or density of either myelinated or unmyelinated fibers. These negative results are at variance with our previous work showing effects on the CNS of guinea pigs (Borgens et al, Science, 238:366-369, 1987) and those of others showing positive effects on the PNS of rats (Politis et al, J of Trauma, 28:1375-1381, 1988).

EFFECT OF GUIDANCE CHANNEL SURFACE MICROGEOMETRY ON PERIPHERAL NERVE REGENERATION. V. Guénard, P. Aebischer. Artificial Organ Laboratory, Brown University, Providence, RI 02912.

Various parameters such as permeability, electrical activity or ability to release growth or trophic molecules influence the outcome of peripheral nerve regeneration through synthetic guidance channels. In the present study, we focused on the surface microgeometry of the entubulating membrane. Non-porous and expanded polytetrafluoroethylene (PTFE) tubes with internodal distances of 1, 5, and 10 μm were used to bridge a 4 mm nerve gap in a transected mouse sciatic nerve model. Increase in surface roughness correlated with increased internodal distance. Asymmetric semipermeable acrylic copolymer (AC) tubes with smooth inner skins and rough microfibrillar outer surfaces were also compared to AC channels featuring rough microfibrillar inner surfaces and smooth outer skins. Cohorts of 5 animals were implanted for 4 and 12 weeks for each channel type. In all animals, regenerated neural tissue bridged the nerve ends. Non-porous PTFE and AC channels with smooth inner skins contained a well-defined centrally located nerve cable surrounded by an acellular gel whereas porous PTFE and AC channels with a rough inner skin contained nerve fascicles scattered in a loose connective tissue entirely filling the tubes' lumen. The greater the porosity of the PTFE tubes, the more randomly spread were the fascicles. Sleeving the 10 μm PTFE channels with silicone tubes so as to render them impermeable resulted in the same scattering pattern of nerve fascicles. These results suggest that the surface microgeometry of guidance channels, not their permeability characteristics, influences the spatial arrangement of the regenerated nerve elements within synthetic nerve guidance channels. Supported by NIH grant NS 26159.

125.16

CNS AXONAL REGENERATION IS INFLUENCED BY TRANSPLANTS OF MATRIX FILLED POLYMER TUBES. F. Massoudi*, J. J. Collins* and L. F. Kromer, Dept. of Anatomy & Cell Biology, Georgetown University, Washington, DC 20007

Since extracellular matrix (ECM) molecules can directly promote neurite outgrowth in vitro, the present study was undertaken to evaluate whether ECM substrates also could exert a direct effect on CNS axonal regeneration in vivo. For these experiments adult female Sprague-Dawley rats received bilateral aspiration lesions of the fornix-fimbria to transect the septal cholinergic projections to the dorsal hippocampus (HPC). Each animal then received bilateral transplants of tumor-derived ECM or pure collagen matrix cables located within selectively permeable whole or hemi-polymer tubes which bridged the lesion gap between the septum and HPC. The following observations were noted at 1, 2, and 4 weeks after transplantation. 1) Directed axonal growth from the septum to HPC only occured through a matrix cable contained within a whole polymer tube. 2) ECM regeneration substrates were no more effective in promoting axonal regeneration than simple collagen matrices. 3) Migration of immature astrocytes and fibroblasts into the collagen or ECM cables always preceded the initial wave of axonal growth onto the cables. These observations suggest that host-derived astrocytes and possibly fibroblasts play an important role in fostering post-trauma axonal regeneration in the adult CNS under the experimental conditions employed in this study. Our data also indicate that laminin containing ECM does not appear to be advantageous over a pure collagen matrix in enhancing axonal growth from injured CNS pathways.

125.17

COLLAGEN NERVE GUIDE TUBES SUPPORT AXONAL ELONGATION IN THE RAT CENTRAL NERVOUS SYSTEM. SM Weil[1*], R Madison[2], K A Crutcher[1] (Spon: J Tew, Jr.). [1]Dept. of Neurosurgery, Univ. of Cincinnati, Cincinnati, OH 45267 and Div. of Neurosurgery, [2]Duke Univ., Durham, NC 27710

Collagen nerve guide tubes support peripheral nerve regeneration (Madison, Soc. Neurosci. Abst. 13:1042, 1987; Archibald and Madison, 14:499, 1988). In the present study, 26 female rats (180-210 gm) received bilateral (n=20) or unilateral (n=6) suction lesions of the fimbria. Collagen nerve guides (1.0mm inner diameter, 3.0mm in length) were then oriented longitudinally to bridge the septum and hippocampal formation. Animals were killed at 2 weeks (n=12), 4 weeks (n=11), 5 weeks (n=2) and 8 weeks (n=1). The tube was consisently present at 4 weeks, but at longer periods only remnants of the tube remained. There was no evidence of inflammatory reaction. Consecutive coronal sections (16 μ thick) were obtained for histological evaluation using Nissl, acetylcholinesterase (AChE), catecholamine histofluorescence, collagen and silver staining methods. Monoclonal antibody to 68kd polypeptide neurofilament (Boehringer Mannheim Biochemica) was used to detect intraluminal axons. All 12 animals killed at 2 weeks exhibited a cellular tissue core in the proximal lumen of the tubes. Eleven of the animals also showed evidence of AChE staining that decreased toward the hippocampal end of the tube. All 11 animals killed at four weeks also contained a cellular core that spanned the length of the tube. Catecholamine fluorescent positive fibers were present in 2 week animals (17/22 tubes) and 4 week animals (17/21 tubes). Neurofilament-positive fibers were present in 2 week animals (6/10 tubes) and 4 week animals (10/16 tubes). In preliminary experiments, 8 tubes were pretreated with nerve growth factor (.2ug/ml). Animals killed at 2 weeks (n=2) and at 4 weeks (n=2) exhibited a marked increase in intraluminal cellular density and AChE staining. Moreover, the cellular response formed a concentric ring intimately related to the inner wall of the tube. These results suggest that synthetic collagen tubes persist for at least 4 weeks in the CNS, during which time they are colonized by various cellular elements including axons. Further studies, including ultrastructural analysis, are needed to unequivocally identify the contents of the tube and the origin of the axons. Tubes supplied by Colla-tec, Inc., Plainsboro, NJ.

125.18

SEMI-PERMEABLE COLLAGEN-BASED NERVE GUIDE TUBES ARE AS EFFECTIVE AS STANDARD NERVE GRAFTS TO REPAIR TRANSECTED PERIPHERAL NERVES: AN ELECTROPHYSIOLOGICAL STUDY IN THE NON-HUMAN PRIMATE. S.J. Archibald[1], C. Krarup*[2], J. Shefner*[2], B. Bonsack[3], and R. Madison[1] (SPON: E. Gregory). [1]Division of Neurosurgery, Duke University, N.C. 27710, [2]Laboratory of Neurophysiology, Harvard Medical School, Brigham and Womens Hospital, Boston, 11 MA., and [3]Division of Neuroscience Research, Childrens Hospital, Boston, MA.

Collagen nerve guide tubes permeable to macro-molecules up to 68kd have been shown to support sciatic nerve regeneration in rats that is equal to that achieved with a nerve autograft (Arichibald and Madison, Soc. Neurosci. Abst., 14:499, 1988). In the present study, five adult male Macaca Fasicularis monkeys received bilateral median nerve transection at the wrist, removal of a 4mm segment of nerve, and the deficit repaired with either a collagen nerve guide tube or a nerve autograft. Serial evoked EMGs of the APB muscle and sensory nerve conduction studies (SAP) were performed approximately biweekly up to 250 days following initial surgery. EMG activity was first detected between 48-61 days, and SAPs evoked by stimulating the index finger, after 54-77 days. EMG amplitudes recovered to 6.5-52% (conduction vel. 68% normal) and 45-101% (conduction vel. 74% normal) of baseline values for the autograft and tube repair groups respectively. SAPs recovered to 3.5-18% (velocity 73% normal) and 3.5-19% (velocity 64% normal) of baseline values for the autograft and tube repair respectively. Supported by Colla-Tec, Inc.

ELECTRICALLY CHARGED POLYMER GUIDANCE CHANNELS ENHANCE PERIPHERAL NERVE REGENERATION. R.F. Valentini, A. Sabatini *, P. Dario *, P. Aebischer. Artificial Organ Laboratory, Brown University, Providence, RI 02912 and Scuola Sup., Pisa, Italy.

Electrically charged guidance channels may provide a means of studying the effects of electrical phenomena on nerve regeneration. Polymer electrets are a unique class of dielectric materials which develop either transient (ie piezoelectric materials such as polyvinylidene fluoride [PVDF]) or static (ie true electrets such as polytetrafluroethylene [PTFE]) surface charges due to their molecular structure and mode of preparation. Thus, they do not require an external power source. In the present study, we compared the ability of various tubular electrets to support PNS regeneration using a transected mouse sciatic nerve model with a 4 mm gap. PVDF and PTFE tubes with an 0.9 mm ID were submitted to a high intensity corona poling procedure in order to render them electrically active. Positive or negative surface poling was achieved by connecting a custom-designed electrode array to a high voltage DC power supply. PVDF tubes were poled at 20°C for 12 hr at 21 kV and PTFE tubes were poled at 150°C for 20 min at 14 kV. Cohorts of 5 animals received (+), (-), or unpoled PVDF and PTFE 6 mm long tubes for 4 and 12 wks. At explantation all animals contained regenerated nerve cables bridging the nerve gap and the tissue reaction to the polymer was minimal. At 4 and 12 weeks the number of myelinated axons (MA) was significantly greater in the (+) and (-) PVDF and PTFE tubes than in the unpoled tubes. (+) poled tubes showed greater numbers of MA than (-) poled tubes although the difference was not statistically significant. These results suggest that the nerve regeneration process is affected by electrically active tubes.

DELAYED NERVE REPAIR STIMULATES NERVE REGENERATION IN A SILICONE CHAMBER MODEL. N. Danielsen*, L. B. Dahlin* and L. R. Williams (SPON: H. Müller). Dept. of Anatomy, Univ. of Gothenburg, Gothenburg, Sweden and CNS Diseases Research, The Upjohn Co., Kalamazoo, MI 49001.

Several studies have demonstrated that a previous injury to a nerve (preconditioning) increases the regeneration rate. In this study we used the silicone chamber model to analyze the effects of delayed nerve repair on nerve regeneration (a combination of preconditioning of the proximal nerve stump and predegeneration of the distal stump). The rat sciatic nerves on both sides were transected and repaired after a delay of 3-14 days with a silicone chamber, leaving a 10 mm gap between the two nerve stumps. Light microscopy demonstrated that chambers implanted after a delay of 3-7 days had a significant more advanced axonal migration into the chamber matrix than that of control chambers implanted immediately. The effect was most pronounced in chambers implanted after a delay of 7 days. Chambers implanted after 10-14 days did not differ from controls. Chambers implanted after a delay also showed an increased vascularization as compared to controls. We conclude that delayed nerve repair stimulates nerve regeneration in the silicone chamber model.

REGENERATION: GAP-43

DIFFERENTIAL POST-LESION EXPRESSION OF B-50/GAP43 AND OLFACTORY MARKER PROTEIN IN THE OLFACTORY SYSTEM. J. Verhaagen*, A.B. Oestreicher*, M. Grillo*, Y.-S. Khew-Goodall*, W.H. Gispen* and F.L. Margolis

Roche Inst. Molec. Biol., Nutley, N.J. 07110, U.S.A. and Rudolf Magnus Institute for Pharmacology, Utrecht, The Netherlands

The olfactory neuroepithelium contains a population of stem cells that gives rise to new neurons throughout the life of the animal. Following lesioning the degenerated olfactory epithelium is able to reconstitute itself by an activation of stem cell division resulting in the formation of new neurons. The regeneration of the olfactory neuroepithelium was studied with mRNA probes and antibodies for B-50/GAP43 and olfactory marker protein (OMP). The well-documented growth related expression of B-50/GAP43 makes this protein a reliable marker for immature neurons. In contrast, OMP is specifically expressed in olfactory neurons that have achieved a relatively advanced state of maturation. Thus, using these two proteins as markers, we were able to discern two stages in the regeneration of the lesioned olfactory pathway. The first stage occurs following either peripheral lesioning with Triton X-100 (TX) or after olfactory bulbectomy (BX) and is characterized by the formation of a large number of new olfactory receptor neurons. These newly formed neurons can be identified by virtue of their expression of B-50/GAP43. The second stage of the regeneration process differs between TX and BX animals. Thus, the formation of a full complement of OMP-expressing neurons is dependent on the presence of the olfactory bulb since this occurs only following TX-lesioning and not after BX. Apparently the stem cells in the olfactory epithelium are autonomous in their ability to undergo mitosis and initial maturation. However, in the absence of the olfactory bulb the complete post-lesion recovery of the olfactory nerve is clearly disturbed. This indicates that the olfactory bulb provides the primary olfactory neurons with as yet unidentified signals (e.g. trophic factors, electrical activity) that are necessary for their maturation and maintenance.

126.2

CHANGES IN THE SYNTHESIS OF CHROMATIN PROTEINS DURING GOLDFISH OPTIC NERVE REGENERATION. J.M. Gossels, S.E. Lewis*, N.I. Perrone-Bizzozero, and L.I. Benowitz. Harvard Medical School; McLean Hospital, Belmont, MA 02178.

Regeneration of the goldfish optic nerve is associated with the expression of specific proteins including β-tubulin, GAP-43, the ON complex and others. Similar changes have also been observed in mammalian peripheral nerve regeneration and during neuronal development, suggesting the existence of a common mechanism for nerve growth and regeneration involving a specific program of gene expression. To begin to elucidate this mechanism, we explored changes in levels of synthesis and phosphorylation of goldfish retinal chromatin proteins in response to optic nerve crush since non-histone DNA-binding proteins are major regulators of gene expression. Control retinas or those undergoing axonal regeneration for 5 or 14 days were dissected, incubated in the presence of radioactive amino acids or phosphate, and chromatin was isolated. The two-dimensional gel pattern of non-histone (acidic) chromatin proteins was entirely distinct from those of the nonnuclear particulate and soluble and the nuclear soluble fractions. In addition to an overall increase in synthesis of chromatin proteins during regeneration, specific increases were observed in the synthesis of 3 proteins, two at 58 kD and one at 51 kD. The specific changes were particularly evident at 14 days of regeneration. The 3 proteins were all phosphoproteins and had pI's at approximately 5.5. Further characterization of these proteins may lead to the identification of DNA-binding proteins which act as trans-acting elements to regulate gene expression during nerve regeneration. Supported by NEI EY 05690 and EY 06152.

126.3

REGULATION AND SEQUENCE OF THE GOLDFISH GAP-43 PROTEIN N.I.Perrone-Bizzozero, R.L.Neve, E.Franck*, J.Gossels, and L.I.Benowitz. Harvard Medical School; McLean Hospital, Belmont, MA, 02178, and Children's Hospital, Boston, MA, 02135.

GAP-43 is a protein that is involved in the development and plasticity of synaptic connections . It is expressed at high levels in all developing and regenerating systems, and is particularly evident in the goldfish optic pathway during axonal regeneration. To gain insight into the mechanisms that regulate the expression of this protein, we have studied the regulation of GAP-43 mRNA levels during regeneration of the goldfish optic nerve. A goldfish GAP-43 cDNA clone was isolated from a cDNA library prepared from regenerating goldfish retinal mRNA. Sequencing revealed that the size of the goldfish protein is similar to its mammalian counterparts, with an extensive conservation of the first 58 amino acids. Beyond this region the goldfish protein differs considerably, with a higher content of acidic residues. The N-terminal conserved region includes the PKC phosphorylation site and the putative calmodulin-binding domain . By Northern blot analysis, levels of GAP-43 mRNA were found to increase within 2-3 days after axotomy, peak at 5-14 days to 20 times the baseline value, and return to control values within 4-8 weeks. Nuclear run-off studies showed that the accumulation of GAP-43 mRNA can not simply be accounted for by an increase in transcription, since transcriptional levels increased only 1.5-fold during regeneration. By immunocytochemistry, GAP-43 could be detected in regenerating optic nerve terminals 17 days post-crush, but was not seen in the contralateral (intact) optic tectum. These results are consistent with the idea that GAP-43 is a specific marker of axonal growth .

126.4

GAP-43 IS A MARKER FOR GROWING FIBERS IN THE STRIATUM OF MPTP-TREATED MONKEYS S.K. DOSTER, K. BANKIEWICZ, I.J. KOPIN and M.A. PALMATIER. Clinical Neuroscience Branch, NINDS, NIH, Bethesda, MD 20892

GAP-43 is a neuronal protein found in developing or regenerating neurons which is enriched in growth cones. MPTP-parkinsonian monkeys which receive cavities in the caudate nucleus show some reversal of motor abnormalities. The behavioral improvements are accompanied by evidence of growth into the denervated striatum of dopaminergic nerve fibers from the ventral tegmental area. Striatal sections from MPTP-hemiparkinsonian monkeys, with or without cavities, were examined for GAP-43 immunoreactivity. GAP-43 immunoreactive fibers are present around the cavities and in areas of the striatum that coincide with the immunoreactive dopaminergic fibers. GAP-43 immunoreactivity is present in the striatum several months after cavitation. No GAP-43 immunoreactivity is seen in the striatum of a non-cavitated monkey 2 months after MPTP treatment. GAP-43 can be used as a marker for growing nerve fibers in the central nervous system of non-human primates. All monkeys were treated according to NIH Animal Care guidelines.

126.5

INCREASED EXPRESSION OF THE GROWTH-ASSOCIATED PROTEIN B-50 (GAP-43) IN UNILATERAL FIMBRIA-FORNIX LESIONED RATS. L.H. Schrama, B.J.C. Eggen*, H.B. Nielander*, P. Schotman*, A.B. Oestreicher*, B.M. Spruijt* and W.H. Gispen*. Div. Mol. Neurobiol., Rudolf Magnus Inst., Lab. Physiol. Chem., and Inst. Mol. Biol. & Med. Biotechnol., Univ. of Utrecht, Padualaan 8, 3584 CH Utrecht, NL.

The neuron-specific phosphoprotein B-50 (GAP-43) has been shown to be associated with neurite extension in the nervous system. The expression of B-50 increases after crush lesioning of the sciatic nerve (Van der Zee et al., J. Neurosci., 1989, in press). It has also been reported that lesioning of central nerves is accompanied by an increase in expression of B-50. This study investigates if the expression of B-50 is also affected by transection of the fimbria-fornix. Male Wistar rats (220-240 g b.w.) were subjected to left unilateral fimbria-fornix transection or sham operation. B-50 expression was studied by means of *in situ* hybridization with random-priming labeled [^{35}S]-B-50 cDNA at 4, 24, 48 and 96 h after transection. Control hybridizations were performed with a random-primed [^{35}S]-labeled linearized pBR328. Quantification of the autoradiogram by digital video-imaging showed that there were no major changes in any of the regions studied 4 h after transection. There was, however, a 5-fold increase in the expression of B-50 in the CA3/CA4 region of the hippocampus 24 h after transection in the ipsilateral as compared to the contralateral side. This increase persisted but was reduced to 2-fold at 48 and 96 h after transection. In the medial and lateral septum a bilateral increase was observed at 24, 48 and 96 h after transection. In the cingulate cortex, an ipsilateral increase was seen at the earlier time points, whereas a contralateral effect was only observed at 96 h. The enhanced expression of B-50 mRNA illustrates the cellular regenerative response following mechanical brain damage.

126.6

A CORRELATION BETWEEN THE RATE OF AXONAL REGENERATION AND THE AMOUNT OF GAP-43 AND ACTIN mRNA IN CULTURED RAT SYMPATHETIC NEURONS. M.I. Johnson[1] and M. Willard. Dept. Anat. & Neurobiology ([1]also Pediatrics, Neurology) Washington Univ. Sch. Med., St. Louis, MO.

Embryonic rat superior cervical ganglion neurons elongate axons approximately three times more rapidly when they are cultured on a laminin substrate than when they are cultured on collagen. We have performed in situ hybridization experiments to determine whether the amount of messenger RNA for GAP-43 (a protein associated with axonal growth) and for actin is correlated with the rate of axonal extension. Superior cervical ganglion neurons from embryonic day 21 rat embryos were dissociated and cultured on either laminin or collagen. After one to five days in culture, the cells were fixed and hybridized with ^{35}S-labeled cRNA probes for either GAP-43 or actin. Following in situ hybridization with GAP-43 cRNA, the average number of silver grains over neurons grown on laminin was approximately 2.5 times higher than the average number over neurons extending neurites more slowly on collagen. When the actin cRNA was used for in situ hybridization, we observed five times as many grains over neurons extending axons rapidly on a laminin substrate as compared to those extending axons on a collagen substrate. A control sense cRNA for GAP-43 hybridized equally to the neurons in the two types of cultures. We conclude that the nature of the substrate, which can influence the rate of axonal extension, also influences the accumulation of both GAP-43 and actin mRNA in superior cervical ganglion neurons. PLASTICITY OF A SPINAL MOTONEURON NUCLEUS AFTER PERIPHERAL NERVE GRAFT REPAIR D.M. Weinert*, H. Jaksche*, H. Ludt*, A.C. Nacimiento, Neurosurgical Research Laboratory, Saarland University Medical School, 6650 Homburg/Saar, F.R.G.

In adult Sprague-Dawley male rats under pentobarbital anesthesia, the left peroneal nerve was transected and the gap bridged by microsurgical autologous transplantation of a 1 cm long radial nerve segment. After 2,4,8 and 10 weeks, HRP was injected bilaterally into the anterior tibialis (AT) muscle, followed by perfusion 46 - 59 h later. Serial 40 m cross-sections of spinal cord L2-L6 segments were reacted with tetra-methyl-benzidine. Measurements included number, diameter, cell density and 3-D reconstruction of AT motor column. Position of labeled motoneurones in lamina IX was dorsolateral. Their number, relative to the intact side, increased over time from 10% (2 weeks) to 65% (8 weeks). Diameter range bilaterally was 18-66 m, unimodally distributed. Reconstruction revealed on the grafted side caudal shifts a) of peak cell density, which returned to its normal level in the rostral part of the column 8 weeks p.o. and b) of motor column as a whole.

CHANGES IN SOMA SIZE OF TROCHLEAR MOTOR NEURONS FOLLOWING AXOTOMY. P. G.Iannuzzelli*, J.Brown*, E. H. Murphy and R. Baker. (SPON: H. Warren Goldman). Depts. Anatomy (EHM,JB) and Pharmacology (PI), Medical College of PA, Philadelphia, PA 19129, and Dept. Physiol. & Biophys. New York Med Ctr., New York, NY 10016 (RB).

When the trochlear nerve is cut unilaterally, on average 50% of the cells eventually die and the remainder regenerate to innervate the superior oblique (SO) muscle. We measured the mean soma size of TMNs in Nissl material during the early postoperative period and in TMNs retrogradely labelled with HRP after the regenerating axons had reached the SO muscle. Soma sizes of neurons in the control and axotomised nucleus were compared within each animal (n = 15).Soma size changes were not observed until 7 days postaxotomy. At 2 and 3 weeks, axotomised cells were significantly smaller than controls. At 4 weeks, when axons first reach the SO muscle, soma size returned to normal. At 8 - 25 weeks mean soma size of axotomised TMNs was significantly larger than controls. However the average percent soma size increase was correlated with the extent of cell death. The data indicate that when the population of neurons innervating a target is reduced, the soma undergoes hypertrophy, and the extent of the hypertrophy varies with the extent of cell death and the change in the cell/target ratio. The time course of the changes indicate that this hypertrophy is not related to the process of regeneration (weeks 2-4) but must involve trophic signals transported retrogradely from the target during the restorative process of functional reinnervation.

TESTOSTERONE-INDUCED ACCELERATION OF RECOVERY FROM FACIAL PARALYSIS IN MALE HAMSTERS: TEMPORAL REQUIREMENTS OF HORMONE EXPOSURE. K.A. Kujawa * and K.J. Jones. The Chicago Medical School, North Chicago, IL 60064.

We have previously demonstrated that exposure to subcutaneous implants of testosterone propionate (TP) following crush axotomy of the facial nerve in adult male hamsters results in acceleration of recovery from facial paralysis (Kujawa et al., Exp Neurol., 1989). Recovery was defined behaviorally in the form of return of semi blink, blink reflex, full vibrissae movement, and complete recovery (=normal orientation of vibrissae). In this study, we examined the temporal requirements of TP exposure necessary for acceleration of recovery from facial paralysis to occur following facial nerve crush. For each of 2 experiments, castrated male hamsters were anesthetized via intraperitoneal injection of Nembutal, subjected to right facial nerve crush, and divided into 2 groups. In experiment #1, one group received TP implants on day 6 postoperatively (PO), and the other group was sham-implanted. In experiment #2, one group of animals with facial nerve crushes received TP implants on day 0 PO, with implant removal on day 7 PO. A control group of crush-axotomized animals was sham-implanted under the same time schedule. Signs of facial nerve recovery were monitored daily for 4-5 weeks PO in both experiments. The results of the first experiment indicated that, without exposure to TP during the first week PO, the accelerative effects of the hormone were essentially abolished. The results of the second experiment indicated that, while an initial acceleration of semi blink return was noted before capsule removal, no acceleration of return of the blink reflex and full vibrissae movement was observed after capsule removal. Also, an effect of TP, at 3 weeks PO, on acceleration of complete recovery was found. Thus, it appears that there is a priming effect of TP that 1) is exerted at the level of the neuron, 2) temporally precedes behavioral recovery by a week or more and 3) is critical to subsequent acceleration of recovery from facial paralysis. Supported by a grant from the Spinal Cord Research Foundation (KJJ).

PROGRESSIVE MORPHOLOGICAL CHANGES IN RAT SPINAL MOTOR NEURONS WITH LONG-TERM REGENERATED AXONS AFTER SCIATIC NERVE CRUSH INJURY. C.M.Bowe, V.Vlache*, N.H.Evans*. Section of Neurobiology, Brown University, Providence, RI 02912

Perikaryal enlargement and dendritic abnormalities are observed in spinal motor neurons (SMNs) with long-term regenerated axons after peripheral nerve crush (Bowe et al. Brain Res.(1988) 463:69-77). Since cord examinations in that study were performed only after the first year post-crush, progressive vs. chronic morphological changes could not be distinguished. The present study examined SMNs and dorsal root ganglion (DRG) cells with regenerated axons (REG) at 5 and 10 months following sciatic crush in adult rats. REG neurons were identified by retrograde labelling with HRP applied to the sciatic nerve distal to the point of the earlier crush. Control data were derived from labelled SMNs and DRG cells contralateral (CL) to the side of crush and from sham-operated (SO) rats in which HRP was applied to the sciatic nerve at a site comparable to that used for application on the crushed side.

Statistically significant differences in cell area were not observed between the REG and either control group of SMNs or DRG cells examined at 5 or at 10 months following nerve injury. However, morphological changes could be appreciated in REG SMNs examined at both post-crush intervals. HRP labelling was consistently more dense in REG SMNs compared to CL SMNs or to labelled cells in the SO rats. REG SMNs were more densely clustered than were CL or SO control SMNs. Many, but not all, of the REG SMNs had multiple, thickened dendritic processes. Abnormal morphology was noted in labelled SMNs with both large and small cell areas and was observed with increased frequency in cord sections at 10 months following crush injury compared to those at 5 months after the lesion. Morphological changes were not appreciated in REG DRG cells examined at either post-crush interval. These findings indicate that SMNs with long-term regenerated axons exhibit progressive morphological changes.

REGENERATIVE AXONAL SPROUTS IN THE TROCHLEAR NERVE FOLLOWING AXOTOMY. E. H. Murphy,J. Brown*, P. G. Iannuzzelli* and R. Baker. Depts. Anatomy (EHM, JB) and Pharmacology (PI), Medical College of PA, Philadelphia, PA 19129, and Dept. Physiol. & Biophys., New York Med. Ctr., New York, NY 10016 (RB).

In the previous study we showed that soma size of trochlear motor neurons (TMNs) which have regenerated is significantly correlated with cell death. In this study we investigated the mechanisms underlying this hypertrophy of the soma. The trochlear nerve was cut unilaterally in cats. Following a survival of 3-9 months, we studied soma size, dendritic arborization, axon diameter and the number of axonal sprouts in those cells which survived the nerve cut and regenerated to reinnervate the superior oblique muscle. Results show that (i) dendritic diameter and extent of arborization do not increase with increased soma size; (ii) axonal diameter increases between the third and sixth postoperative month and then reaches a plateau; (iii) axonal diameter does not increase with increased soma size; (iv) the number of axonal sprouts in the regenerated nerve is approximately 1000, the same as the number of axons in the normal nerve, regardless of the number of surviving cells; (v) the average number of axonal sprouts per surviving cell correlates with soma size. Thus, the results suggest that when the neuronal population is decreased, the surviving cells produce a sufficient number of axonal sprouts to maintain the original number. Hypertrophy of the soma of these surviving cells appears to be associated with the production and maintenance of additional axonal sprouts to compensate for altered cell\target ratio.

INTRAMEDULLARY REGENERATION BY "DENDRAXONS" IN CAT SPINAL MOTONEURONS AFTER VENTRAL RHIZOTOMY.
L. Havton* and J.-O. Kellerth* (SPON: H. Aldskogius). Dep. of Anatomy, Univ. of Umeå, S-901 87 Umeå, Sweden.

Peripheral nerve injury may lead to a series of retrograde effects including the formation of supernumerary axons (Havton and Kellerth, Nature 325:711, 1987), which originate from the cell body area and have variable but anomalous trajectories within the ipsilateral spinal cord. The aim of the present study was to investigate the regeneration in cat spinal motoneurons after ventral rhizotomy.

Three months after the injury, single axotomized motoneurons were labeled with horseradish peroxidase (HRP) through micropipettes. Fixation and histochemical processing of the spinal cord allowed morphological analyses.

In addition to the original stem motor axon, axon-like structures originating from the dendritic trees of the axotomized neurons were frequently encountered. The "dendraxons" (Lindå et al., Brain Res., 358:329, 1985) had variable projections and termination fields. In two cats the unilateral ventral rhizotomy was combined with bilateral implantation of peripheral nerve grafts into the dorsal region of the spinal cord. Three months later, a large number of myelinated axons originating from the axotomized motoneurons had regenerated into the ipsilateral peripheral nerve graft, whereas the contralateral control graft was almost devoid of axonal profiles.

127.7

CHANGES IN SYNAPTIC BOUTONS AFTER INJURY OF THE HYPOGLOSSAL NERVE IN THE ADULT HAMSTER. T.E. Durica and S.K. Jacob. Rush Medical College, Anatomy Department, Chicago, IL 60612.

This study examined changes in axosomatic synaptic bouton contacts on injured hypoglossal neurons. The right hypoglossal nerve was either cut or crushed and at 5 or 15 days postoperative (dpo) the brainstems were processed for EM examination. The Bioquant System IV was used for measurement and data analysis. A quantitative study assayed the percent coverage of somal profiles by synaptic boutons on normal and injured neurons. At 5dpo both types of injuries resulted in a decrease in the percent coverage: normal = 28%; cut = 17%; crush = 14%. At 15 dpo cut injury resulted in a continued decrease in percent coverage (9.3%) while crush injured neurons began to show some recovery (19%). Synaptic numbers also showed the same trend. There was a continued decrease after cut injury; crush injured neurons showed an initial decrease followed by a return to normal values at 15dpo. These results may reflect the fact that by 15dpo crush injured neurons have begun to reinnervate the tongue musculature while cut injury has prevented any reinnervation from occurring.

127.8

SYNAPTIC BOUTON CHANGES FOLLOWING INJURY TO THE FACIAL NERVE. S.K. Jacob and T.E. Durica. Rush Medical College, Anatomy Department, Chicago, IL 60612.

This study examined axosomatic synaptic bouton contacts on facial motoneurons following different injuries to the facial nerve. Two groups of adult hamsters underwent either 1) a crush of the right facial nerve or 2) a resection (cut and removal of a segment) of the right facial nerve. Brains were processed for routine ultrastructural examination at 5 or 15 days postoperative (dpo). A quantitative study assayed the percent coverage of somal profiles by synaptic boutons in normal and injured neurons. Both injuries result in significant decreases in bouton contacts at 5dpo (normal = 30%; crush = 16%; resection = 8%) and these values remain low at 15dpo (crush = 15%; resection = 12%). The mean number of synaptic boutons per neuronal profile was compared and the same trend was noted; decreased numbers at 5 and 15 dpo for both injuries. The initial response of the resected series is more severe but by 15 dpo the values are similar to the crush group.

REFLEX DEPRESSION RESULTS FROM ANAESTHESIA RATHER THAN SPINAL SHOCK FOLLOWING SPINAL TRANSECTION IN THE LAMPREY L. Margolin* and J. Ayers. Dept. of Biology and Marine Science Center, Northeastern University, East Point, Nahant, MA 01908

Lamprey exhibit a variable period of reflex depression following spinal transection. The present experiments were designed to determine whether this depression resulted from spinal shock or anaesthesia.

Tricaine anaesthesia elicited the following sequence of events: cessation of respiration, followed by the cessation of spontaneous movement, and finally the concurrent disappearance of the tail pinch and Mauthner reflexes. Recovery from anaesthesia was also stereotyped with respiration recovering first, followed by the recovery of the response to tactile stimulation, resumption of spontaneous movement and the return of the Mauthner reflex (J. Exp. Biol. **133**: 121-135) in response to electrical stimulation of the tail. These latencies are dose-dependent.

The effect of acute high spinal transection upon recovery from anaesthesia was determined in larvae and compared with that seen in normal ammocoetes and acutely transected adult specimens. Spinal transection had a profound effect upon latency to reflex recovery but the evoked behaviors remained the same even in chronic transectees. Recovery latencies in transected specimens ranged from two times normal (respiration) to a six-fold increase (Mauthner reflex). Recovery latencies of similar duration were seen in transected adult specimens, although the latency for recovery of the Mauthner reflex was significantly shorter in lesioned adults than in lesioned larvae. To control for the effects of anaesthesia 5 specimens were tested acute to unanaesthetized decapitation. All specimens exhibited caudal reflex responses within seconds of decapitation, eliminating the possiblity of spinal shock.

We conclude that the sea lamprey does not exhibit spinal shock, that reflex depression results from delayed effects of the anaesthetic and that spinal transection greatly increases the duration of anaesthetic-induced reflex depression.

127.10

RECOVERY OF FICTIVE LOCOMOTOR ACTIVITY FOLLOWING COMPLETE SPINAL CORD TRANSECTION IN BULLFROG LARVAE. J.K. Baek* and P.B. Farel (SPON: J. Capowski). Dept. of Physiol., Univ. N. Car., Chapel Hill, NC 27599.

Although anatomical continuity is restored across a complete thoracic spinal cord transection within 30 days, the pattern of neural connectivity across the site of injury is perturbed. Long ascending and descending projections between lumbar spinal cord and brainstem are replaced by axons that synapse within 1-2 mm of the injury site. We were interested in whether locomotor recovery could be mediated by this abnormal pattern of connections.

The isolated CNS of bullfrog larvae expresses ventral root activity that, in the intact animal, represents swimming. We found that spontaneous episodes of activity begun above the injury site elicited activity below the injury. Caudal activity was frequency-locked to rostral bursts. Phase relations between rostral and caudal bursts were fairly constant within an episode, although somewhat longer than normal.

These experiments show that aberrant connectivity, similar to that found following embryonic grafts into mammalian spinal cord, can mediate approximately normal locomotor activity.

127.11

EFFECTS OF SPINAL LESIONS ON EMBRYONIC MICE. R. Tompkins, M. Lail*, G. Romeo*, J. Gogola*. Biology Department, Tulane University, New Orleans, LA 70118

The ability of embryonic mice to recover from spinal transection was assessed behaviorally and histologically. At 14 days after mating, pregnant females were prepared for surgery. Full transects of the spinal cords, midway between the limbs, were made with scissors (n=6), forceps (n=4) or fine (10/0) sutures (n=10). Zero time controls showed complete section in nearly all cases. After lesion, exo utero development proceeded to term. Operated animals and their controls were stimulated by stroking and squeezing the face and anterior limbs to evoke posterior limb movement and stroking and squeezing the tail and hindlimbs to evoke head and forelimb movement. No such behaviors were seen in experimental animals cut with forceps or scissors. Such behavior was seen in all controls and those experimental animals cut with a suture. Histological analysis showed that few experimental spinal cords, regardless of how the cord was cut, showed any significant abnormalities. Silver stained sections clearly showed fibers traversing the level of the cut. Thus, embryonic spinal cords are capable of considerable restoration of structure and even function in some circumstances. The embryonic spinal cord of the mouse may provide a permissive environment for assessing the regeneration potential of appropriately marked transplanted cells from older animals.

127.12

ADULT DORSAL ROOT AXONS REGENERATE INTO INTRASPINAL TRANSPLANTS OF FETAL SPINAL CORD (FSC) MORE READILY THAN INTO FETAL BRAIN TRANSPLANTS. Y. Itoh, C. Rogahn*, A. Tessler. VA Medical Center and The Medical College of Pennsylvania, Philadelphia, PA 19129.

We have shown that the cut adult dorsal roots regenerate and form synapses within transplants of FSC. It is unknown whether the growth is specific to FSC, a normal target of DRG axons, or whether dorsal root axons will also grow into fetal brain transplants. In this study we used Nissl-Myelin staining to evaluate the growth and differentiation of spinal cord and brain transplants, calcitonin gene-related peptide (CGRP)-immunocytochemistry to label regenerated DRG axons in transplants, and video image analysis to measure the area occupied in transplants by regenerated CGRP-labeled axons.

Transplants of embryonic day (E)14 spinal cord, E14 or E18 cerebral cortex, E15 cerebellum, or E18 hippocampus were placed into a cavity in the L4 segment of adult rat spinal cord, dorsal roots L3 and L5 were transected, and the severed L4 dorsal root was juxtaposed to the graft. One month later sagittal cryostat sections were processed for Nissl-Myelin stain and CGRP immunocytochemistry. Fetal transplants of brain as well as spinal cord grew and differentiated in the damaged adult spinal cord. CGRP-labeled axons regenerated into transplants from all regions, but growth into FSC was the most robust. These results indicate that fetal CNS tissue whether an appropriate target or not provides an environment that supports or enhances dorsal root regeneration, but that the environment provided by FSC is the most favorable. REGROWTH OF CORTICOSPINAL AXONS AFTER SPINAL INJURY IN THE NEONATAL RAT. C.A. Bates and D.J. Stelzner, Dept. Anatomy, SUNY-HSC at Syracuse, Syracuse, NY 13214.

In the rat, corticospinal (CS) axons grow around a neonatal spinal lesion which includes both CS tracts and the right hemicord. These axons are late growing, unlesioned axons or severed axons which regrow after the injury. Here, we distinguish between these possibilities by double labeling the CS axons before and after spinal injury.

Rat pups were anesthetized with cold on postnatal day (PND) 2,4 or 10. Fast blue (FB 4%) was injected into the CS tract at C4. Two days later, the FB was aspirated. This removes the FB and lesions the CS tract. Two months post-op, diamidino yellow (DY) was injected caudal to the lesion. Three days later the animals were sacrificed and the CNS was fixed, frozen sectioned and viewed under epifluorescence.

FB labeled cells are located in layer V of the dorsal cortex in each age group. These cells projected at least to C4 before the lesion. In the PND 2 and PND 4 groups, some of the FB cells are also labeled with DY, with more at PND 2 than PND 4. These cells have regrown an axon around the lesion in the intervening two months. About an equal number of cells in the PND 2 or PND 4 groups are seen with only DY labeling. These cells represent a small group of late growing axons which reach the C4 level after the lesion. No double or DY labeled cells are seen in the PND 10 group. Supported by NS 14096.

127.14

RESPONSES OF LIZARD EPENDYMA CELLS TO DENERVATION AND RENERVATION BY PERIPHERAL AXONS. D. R. Liebich*, V. M. Grant and S. B. Simpson, Jr. Dept. Biol. Sci./Comm. Neurosci., Univ. of Ill. at Chicago, Chicago, IL 60680.

As part of a continuing study of ependymal epithelium in spinal cord regenerates of Anolis c. we ask the following: 1) How do the ependyma cells respond to removal of the CNS axons that they fasciculate; 2) What is the fate of the scattered cerebrospinal fluid contacting neurons (CSFN) in the ependymal epithelium when CNS axons are absent; and 3) How do ependyma cells respond to peripheral nerves? Autografts of the regenerated cartilage tube and ependyma were made to the backs and hind limbs of the same lizard. In the latter the graft was aligned with the cut sciatic nerve. The grafts were fixed at various times and examined using light and transmission electron microscopy. We have observed that CSFN are absent in back grafts that are sparsely innervated by peripheral axons. Grafts to the limb which fasciculates larger numbers of peripheral axons exhibit larger than normal numbers of CSFN. These experiments also demonstrate that the ependymal epithelium can fasciculate peripheral axons, some of which become myelinated.

127.15

NEUROGENESIS IN NATURALLY OCCURRING SPINAL CORD REGENERATION. B.M. Davis, J. L. Carlson*, L.D. Goldstein*, M.C. Anderson* and S.B. Simpson, Jr. Dept. of Biological Science, Univ. of Illinois at Chicago, Chicago IL 60680.

It has been proposed that regeneration of CNS axons naturally occurs only in those systems with ongoing neurogenesis (Holder and Clarke, TINS, **11**:99, 1988). To test whether neurogenesis plays a role in regeneration in salamander CNS, unlesioned and spinally transected adult salamanders (*Notophthalmus viridescens*) were injected (for a 2wk period) with ^{3}H-thymidine. Few if any supraspinal neurons were thymidine labeled in unlesioned salamanders, indicating no ongoing neurogenesis in spinally projecting nuclei. However, a significant number of labeled brainstem cells (neurons and glia) resulted from injections given during the first month, but not the second month, post-transection.

To examine whether axotomized CNS neurons regrow their axons, thoracic spinal cords were transected (abolishing normal walking and swimming behaviors), and HRP was applied to the lesion site. Following behavioral recovery (60-90d post-transection), Fast Blue was applied to a second transection 1.0 cm caudal to the first. In these salamanders (n=4) 18-27% of the supraspinal neurons which contained Fast Blue also contained HRP, indicating that a significant number of the supraspinal axons had undergone frank regeneration.

Thus, although damaged axons can regrow, a burst of neurogenesis is observed during regeneration, suggesting that the environment present during neurogenesis may be important for successful frank regeneration of CNS axons. (Supported by NIH NS25617 to BMD).

127.16

IS NEUROGENESIS NECESSARY FOR CNS REGENERATION? M. T. Duffy*, B. M. Davis and S. B. Simpson, Jr. (SPON: E. Pollack). Dept. of Biological Science, University of Illinois at Chicago, Chicago, Il. 60680.

We have previously shown that regeneration in the lizard tail spinal cord is accompanied by supernormal descending projections from local intraspinal and supraspinal nuclei. We have proposed that this results from a combination of frank regeneration and sprouting of axons. However, it has recently been proposed (Holder & Clarke, TINS, 11:99, 1988) that natural regeneration occurs only in animals exhibiting ongoing neurogenesis.

To test this hypothesis, normal lizards were injected every other day for 30 days with ^{3}H-Thymidine. This resulted in labeling of the telencephalon (as seen by Lopez-Garcia et al., 1987), but not in neurons of supraspinal nuclei. In a separate experiment, lizards had their tails autotomized and were injected with ^{3}H-Thymidine until their tails had regenerated. This resulted in an increase in labeling throughout the CNS due to angiogenesis and gliogenesis. No labeled cells were identifiable as neurons. Further, the number and spatial pattern of the thymidine labeled cells was inconsistent with the previously identified origins of "regenerated" and "sprouted" fibers (as demonstrated with HRP pathway tracing). We conclude that the portions of normal lizard CNS involved in locomotion, somatosensory and proprioceptive functions exhibits no ongoing neurogenesis and that regeneration causes no measurable neurogenesis. (Supported by NS24162 to SBS).

TRANSFORMATION OF ESCAPE REFLEX FUNCTION FOLLOWING ASEXUAL REPRODUCTION IN AN AQUATIC OLIGOCHAETE. C.D. Drewes* and C.R. Fourtner. Dept. Zool., Iowa State Univ. Ames, IA 50011, Dept. Biol. SUNY Buffalo, NY 14260.

Lumbriculus variegatus reproduces asexually by fragmentation (formation of complete worm from body fragments). Since fragments from either anterior or posterior body regions always regenerate short heads (7-8 segments) and much longer tails, segments originating in posterior regions become transformed, acquiring a more anterior axial identity in the regenerating worm. In the giant axon mediated withdrawal reflex, there is a constant ratio of sensory field partitioning along the body axis regardless of body length (Medial Giant Fiber [MGF] = anterior 40% and Lateral Giant Fiber [LGF] = posterior 70% of body length). Using electrophysiological and anatomical correlates, we described the day-by-day transformation in the proportional partitioning of the sensory field to the giant fibers mediating escape. Our results reveal that: 1) posterior fragments, originally subserved solely by the LGF sensory field, gradually become subserved by the MGF sensory field, conforming to their new anterior position; 2) appropriate increases in the ratio of MGF:LGF caliber and conduction velocity accompany the LGF to MGF sensory field transformation; 3) sensory field transformation can be repeatedly reversed by additional amputations. These results demonstrate that neural organization of the reflex is highly plastic and that transformation may result from the counterbalance of morphogenic influences localized within the anterior and posterior ends of regeneration body fragments.

SYMPOSIUM. HORMONES, NEURAL CIRCUITS, AND COMMUNICATION. A. Arnold, UCLA (Co-chairperson); E. Brenowitz, Univ. of Washington (Co-chairperson); A. Bass, Cornell Univ.; D. Kelley, Columbia Univ.; J. Wingfield*, Univ. of Washington; H. Zakon, Univ. of Texas.

Steroid hormones have a great influence on the structural organization and function of sexually dimorphic neural circuits that underlie the production and detection of communicatory signals in diverse animal species. The speakers will identify common principles that emerge from comparative studies of this topic and propose directions for future research. Wingfield will consider the interactions of ontogenetic hormone cycles, social behavior, and environmental variables in the regulation of communication. Brenowitz will discuss hormone accumulation by song control brain nuclei in bird species that vary in the degree of sexual dimorphism in song behavior. Bass will discuss the influence of hormones upon acoustic communication in fish. Zakon will consider steroid effects upon the production and reception of electrocommunication signals in fish. Finally Kelley will discuss how gonadal steroids direct sexual differentiation of neuroeffectors for vocal communication in frogs, and will provide concluding remarks.

131

SYMPOSIUM. THE INITIAL EVENTS IN TASTE: CHEMOSENSORY TRANSDUCTION IN THE VERTEBRATE TASTE BUD. Stephen D. Roper, (*Chairperson*), Colorado State Univ; John H. Teeter, Monell Chemical Senses Cntr; Myles Akabas, Columbia Univ; Patrick Avenet*, Univ. Saarlandes; Sue C.Kinnamon, Colorado State Univ.

Until recently, little was understood about how taste cells function. Taste receptor cells were considered to be passive transducers of the external chemical milieu, converting sapid stimulation of the apical chemosensitive region into graded receptor potentials that controlled transmitter release from synapses in the basolateral region. In 1983, two laboratories independently reported that taste cells generate action potentials in response to stimulation, thereby establishing that cells in taste buds possess voltage-gated ion channels (Kashiwayanagi, et al., *Am. J. Physiol.* **244:** C82; Roper, *Science* **220:** 1311). Since then, there has been a rapid accumulation of data concerning ion channels on taste cells and their role in chemosensory transduction. Key findings have been made in the last few years utilizing intracellular and patch recording methods and Ca-sensitive dye techniques.To date, the data suggest that amiloride-sensitive Na^+ channels mediate NaCl taste; apical voltage-dependent K^+ channels mediate sour taste; a ligand-gated non-selective cation channel mediates amino acid responses; and a receptor-stimulated second messenger system mediates bitter taste.

The intent of this symposium is to synthesize findings from a number of laboratories and to arrive at a working hypothesis for how the different types of cells present in taste buds and how the various ion channels and second messengers present in taste cells are orchestrated to produce intracellular signals that indicate the presence of salty, sweet, sour or bitter compounds on the tongue.

132.1

TEMPORAL RESPONSE OF MACAQUE V1 NEURONS TO CHROMATIC FLICKER D. D. DePriest* and P. Lennie, Center for Visual Science, University of Rochester, Rochester, NY 14647.

We recently characterized the responses of parvocellular (P) lateral geniculate (LGN) neurons in Macaque to temporal modulation of chromatic and achromatic stimuli, and compared these results to human psychophysical profiles obtained under identical conditions (ARVO, 1988). When stimuli are modulated along a line of preferred chromaticity (either constant B cone excitation, or constant R,G cone excitation) P cells behave as low-pass filters, with a corner frequency of 20Hz in most cases. The temporal characteristics of P cells are quite uniform and do not account for the limitations of performance seen psychophysically. These limits must arise centrally.

We have extended our analysis to striate cortex (V1). We measured chromatic flicker sensitivity in 47 chromatically responsive V1 neurons using either a spatially uniform field or a moving sinusoidal grating. Thirty (61%) of these units had non-oriented receptive fields; twenty-three (50%) demonstrated frequency doubling to chromatic stimuli. Twenty (42%) of all chromatically responsive neurons yielded temporal sensitivity profiles like those seen in P cells: low-pass with a corner frequency near 20Hz. The remaining cells formed a heterogeneous group with band-pass temporal characteristics.

Envelopes of V1 response profiles show relatively much higher sensitivities to high temporal frequencies than is found in psychophysical measurements. Neurons in striate cortex are therefore unlikely to set the limits to chromatic flicker sensitivity.

A NEW TWO-DIMENSIONAL PSEUDORANDOM STIMULUS FOR THE STUDY OF RECEPTIVE FIELDS IN THE LGN AND STRIATE CORTEX R. Clay Reid*[123], Robert M. Shapley[13], and Jonathan D. Victor[23], New York University[1], Cornell University Medical College[2], and The Rockefeller University[3].

We have adapted a new method of visual stimulation to the study of receptive fields in the LGN and striate cortex of both cat and macaque. The method employs pseudo-random binary stimuli, known as m-sequences (first used in VEP's by Sutter, 1988), which modulate the luminance or chrominance of each region in an 8x8 or larger array of squares. M-sequences hold several advantages over other random stimuli: specifically the auto- and cross-correlations among the regions are perfectly flat, allowing for an efficient estimation of first and second-order responses of receptive fields. Further, several mathematical relations make the extraction of all first as well as second-order responses, normally a lengthy calculation, very rapid.

This approach has proven useful in a variety of experiments. First, we have used it to study the the 2-dimensional chromatic structure of neurons in the macaque, using isoluminant, red or green cone isolating, and luminance-modulating stimuli. Second, we have studied the first and second-order components of the spatio-temporal interactions leading to directional selectivity in the cortex. Finally, we have used it in multielectrode experiments along with the BrainWave Systems data acquisition software. Since the stimulus elevates the firing rate of cortical neurons in an 'unbiased' way— being spatially distributed, unoriented, and non-repetitive— it has helped in the study of cross-correlations among cortical and LGN neurons while simultaneously mapping their receptive fields. *Supported by EY1472 and EY7977.*

132.3

SPATIOTEMPORAL CONDITIONS FOR MOTION DETECTION IN CAT STRIATE CORTEX NEURONS. C.L. Baker (Jr.) Dept. of Psychology, McGill Univ., Montreal, PQ, Can., H3A 1B1

Responses of single neurons in striate cortex of the cat were measured in response to sinewave grating stimuli. Firstly, a neuron's spatial frequency tuning was determined, and subsequent stimuli were set at the optimal spatial frequency for that neuron. Then a "jumping grating" stimulus was used: a sinewave grating subjected to a series of abrupt spatial displacements, while remaining stationary for a fixed exposure time between displacements. The amount of direction selectivity elicited by this stimulus was measured as a function of the amount of spatial displacement. Striate cortex neurons generally showed an optimal spatial displacement, corresponding to somewhat less than one quarter of a spatial period of the neuron's optimum spatial frequency (close to "quadrature phase").

This optimum displacement was not affected by increasing the exposure time between displacements, indicating that the measurement is not a simple consequence of temporal frequency tuning.

These results closely parallel recent human psychophysical data (Baker, Baydala, and Zeitouni, 1989), obtained from measurements of the motion aftereffect elicited by jumping grating stimuli.

DIRECTIONAL NEURONS IN AWAKE RHESUS MONKEYS: IMPLICATIONS FOR MOTION TRANSPARENCY. R.G.Erickson, R.J. Snowden, R.A. Andersen, and S. Treue MIT, Cambridge, MA.

The observation that motion cues alone are sufficient for perception of two transparent surfaces indicates that the brain can simultaneously resolve different motion vectors from an array of moving elements, a fact not well accounted for by current visual-motion algorithms. To examine how different cortical cells respond to one versus two transparent surfaces we compared the responses of 77 striate and prestriate neurons (32 directional) to the oppositely directed motion of two dot fields moved separately or simultaneously over their receptive field. Three results were obtained. 1) All nondirectional cells responded equally well to single and double surfaces. 2) There were two groups of directional cells within both V1 and V2. One had similar responses to a single surface moved in the preferred direction regardless of the presence or absence of a second moving surface. Thus, subgroups with different preferred directions can independently encode coherent motion occurring on separate transparent surfaces. Responses of the other group of V1 and V2 cells showed interactions (usually suppressive) between the two surfaces. 3) Development of suppressive interactions appeared to be hierarchical. Only weak interactions were observed in V1 while stronger suppression was found in V2. Complete suppression of excitatory responses by addition of a second surface moved in the null direction was observed only in V2 and other prestriate areas.

These results imply that subpopulations of V1 cells can encode the motions of individual, transparent surfaces.

ORIENTATION SELECTIVE RESPONSES TO MOTION CONTRAST BOUNDARIES IN MACAQUE V1. T.D. Albright and A. Chaudhuri*, The Salk Institute, La Jolla, CA 92037.

There are a variety of figural cues that our visual system can use to segregate objects (e.g., luminance, texture, relative motion, depth). We previously reported that many neurons in extrastriate visual area MT exhibit similar direction selectivity for stimuli defined by different figural cues (Albright, Soc. Neurosci. Abs., 13:1626, 1987). These neurons thus exhibit the same "form-cue invariance" that is manifest perceptually. We have now examined the possibility that such invariance may be present as early as V1. Single V1 neurons were isolated in alert fixating rhesus monkeys. Visual stimuli included drifting bars defined solely by either luminance contrast or motion contrast. The latter stimuli, possessing no coherent luminance boundary, have also been referred to as kinetic edges and non-fourier motion (Chubb and Sperling, JOSA, A5, 1988). Three-quarters of our sampled V1 neurons responded to the motion contrast stimuli. More specifically, of those V1 neurons exhibiting significant orientation selectivity for the luminance contrast stimuli, 50% responded selectively to the orientation of the motion contrast stimuli. In most cases the preferred orientation was similar for the two stimulus types but motion contrast stimuli typically elicited broader tuning and weaker responses. These results suggest that form-cue invariance seen in MT results from convergence of cue information as early as V1. (Supported by NIH EY07605)

SINGLE-UNIT RESPONSES TO TEXTURE PATTERNS IN AREA V1 OF THE ALERT MONKEY. J.J. Knierim and D.C. Van Essen. Div. of Biology 216-76, Caltech, Pasadena, CA 91125.

Human observers can effortlessly detect a target element in a field of distractors if the target and distractors differ in orientation. We recorded from single units in V1 of an alert macaque monkey and found possible neural correlates of this "pop-out" phenomenon.

Visual stimuli consisted of 1) a single line element, either at the cell's preferred orientation or orthogonal to it, and/or 2) concentric rings of elements, either of the same orientation as the central element (uniform orientation) or orthogonal to the central element (orientation contrast). The central element was within the classical receptive field, whereas the surrounding rings were entirely outside it. The response to the central element was significantly modulated by at least one type of surround pattern in 46/60 cells tested (77%). In about half of these cells (22/46, 48%), the response was significantly greater to the orientation contrast pattern than to the uniform texture field. Other cells were suppressed by all surround patterns (13/46, 28%). Cells responding better to the uniform texture field than to the orientation contrast pattern were rare. Taken together, these results show that, in many cells, static texture patterns placed outside the classical receptive field elicit strong orientation specific effects that correlate with the perceptual salience of a central target.

EVIDENCE FOR TEMPORAL FACILITATION ALONG THE LONG-AXIS OF VISUAL CORTICAL RECEPTIVE FIELDS. F.Wörgötter*† & U.T.Eysel (SPON: H. Orbach) Inst. f. Neurophysiologie Universität Bochum 4630 Bochum FRG.; †Present address: Div. of Biol., CALTECH, Pasadena, CA 91125.

Temporal mechanisms in visual cortical cells have been described mostly in terms of interactions between subfields. This study focusses on interactions along the long axis of the central excitatory zone. In Area 17 of anesthetized cats 81 cells were studied with moving light spots of 0.1-0.3° diameter. For most cells *the strongest response to a spot is elicited when the spot moves along the long axis of the receptive field.* Thus, this response component has a preferred direction (PD) which is orthogonal to PD for the response component elicited with a long bar. Applying short bar stimuli, a superposition of the two response components was also observed. This results in cortical tuning curves with four symmetrically arranged response peaks. We have reported that the first order fourier coefficients of cortical tuning curves can be regarded as directional component whereas the second order coefficients correspond to the orientation tuning (Wörgötter & Eysel Biol.Cybern. 57:349,1987). Consequentially the fourth order fourier coefficients can be used to quantify four-symmetrical tuning curves and it is statistically shown that pure axial response components predominate for spot stimuli, whereas they cannot be detected with long bars. Superposition between both components most often occurs at intermediate bar length. The importance of higher order symmetries in cortical tuning curves is further supported by tuning curves recorded in higher areas in monkey's visual cortex that already are four-symmetrical when stimulated with long stimuli (DeValois et al Vis. Res. 22:531,1982; Felleman & VanEssen J.Neurophysiol. 57:889, 1987).

Since the response to flashing spots is mostly much weaker than to moving spots, it is concluded that temporal facilitation can be elicited by motion along the receptive field long axis and that this response component is independent from response components that can be elicited with oriented long bars.

Bicuculline induced changes in excitability and orientation selectivity of striate cortical neurones. K.Albus and U.Baumfalk*. Dept. Neurob., MPI Biophys. Chem., 3400 Göttingen, FRG.

The effect of microiontophoretic application of bicuculline methiodide(BMI) on the orientation selectivity of single neurones was investigated in cats. BMI increased orientation tuning width (OTW) in 60% of the cells, decreased OTW, i.e. improved orientation selectivity(OS) in 10% and did not alter OTW in the remaining 30%. An increase in OTW was combined with either an enhancement(80%) or a suppression(20%) of the mean response to an optimally oriented light bar (ROPO). In most cells with an increase in OTW both ROPO and the response to a light bar oriented orthogonal to the optimal(RNOPO) were enhanced and the enhancement was stronger for ROPO. In a minority of cells with increases in OTW(20%) a strong enhancement of RNOPO was combined with either an increase or a decrease in ROPO. A substantial decrease in OS was usually present in neurones with increases in OTW of more than 20°; however, the general excitability of most of these neurones seemed to be altered as indicated by the appearance of spontaneously occuring and/or evoked bursting activity. Interestingly the glutamate or aspartate induced changes in OS were qualitatively and often also quantitatively similar to the BMI induced changes in OS in about 80% of the cells tested so far. We conclude that BMI causes only moderate changes in OS, in most cells; an actual loss of OS under BMI might be due to unspecific increases in excitability of cell(s) close to the application pipette.

ORIENTATION TUNING IN CAT STRIATE CORTEX INVOLVES INTRACORTICAL SUPPRESSION OF CROSS-ORIENTATION EXCITATION. U.Th. Eysel, J.M. Crook* and H.F. Machemer*. Dept. of Neurophysiology, Ruhr-Universität Bochum, D-4630 Bochum, F.R.G.

Orientation specificity in striate cortex of the lightly anesthetized cat was tested with flash presented and moving light bars. Based on the previous finding that orientation specificity in area 17 of the cat can be broadened most easily by local inactivation of cortical tissue in a distance of about 500µm (Wörgötter and Eysel, Soc.Neurosci.Abstr., 14:898,1988) we have constructed a circular array of four micropipettes glued externally to a guide tube with a radius of 500µm. The micropipettes were placed at a depth of 500-800µm and a tungsten in glass electrode was lowered through the guide tube so that single cells were recorded from the visual cortex in a lateral distance of 500µm from the surrounding pipettes. GABA (0.5M, pH=3.0) was ejected microiontophoretically from the micropipettes during continuous recording from single cells with the center electrode. During remote inactivation induced by GABA application, the responses to non-optimal orientations increased and orientation selectivity was reduced in 70% of the investigated S- and C-cells. In a number of cells the inactivation of surrounding tissue resulted in a broadening of orientation tuning at and close to the orientation perpendicular to the optimal orientation. A concomitant broadening of the excitatory receptive field and loss of directionality were often observed. The effects on orientation tuning were not dependent on stimulus motion; the orientation selectivity in response to flash presented bars was reduced in the same way. The results clearly demonstrate intracortical suppression of responses to orientations oblique and perpendicular to the optimal orientation. Cross-orientation inhibition seems the most probable underlying mechanism.

132.10

THE INFLUENCE OF CONTEXTUAL PATTERNS ON ORIENTATION SELECTIVITY IN V1 OF THE CAT. *C. D. Gilbert and T. N. Wiesel.* Laboratory of Neurobiology, The Rockefeller University, New York, NY 10021.

The extent of long range horizontal connections within the primary visual cortex suggests that a single cell can integrate information over a much larger part of the visual field than that covered by the cell's receptive field. In a similar vein, psychophysics has shown that perception of local features can be influenced by the visual context in which such features are presented. In the domain of orientation, psychophysical studies show that perception of an oriented line is influenced by nearby lines of a different orientation, the "tilt effect." To explore the neural mechanism underlying this illusion, we investigated contextual sensitivity in the domain of orientation at the level of single cells in the superficial layers of cat primary visual cortex. In these experiments we placed sets of lines outside the receptive field (the "surround lines"), in positions either along the orientation axis or orthogonal to it. The surround lines by themselves did not activate the cell, but when presented in conjunction with a line placed within the receptive field usually suppressed and on occasion facilitated its response, confirming earlier studies. An observation relevant to the tilt effect was a small shift in the optimal orientation of some cells (approx. 1/3, N=36) which was produced by the surround lines: when the surround lines differed in orientation from the preferred orientation of the cell by 20° to 30°, the peak in the orientation tuning curve shifted by 10°. For some cells the orientation shift showed hysteresis, such that when the surround lines were removed, the orientation tuning curve did not return to its original position and bandwidth, but had broadened. Presenting the cell with a succession of surround lines of different orientations caused the cell to "reset" its orientation tuning to its original width and position. These results suggest that neural processes allowing lateral interactions in the domain of orientation are seen even at an early level in the visual pathway, and that the tuning properties of cells are more dynamic than previously thought. ORIENTATION TUNING CHARACTERISTICS OF V1 NEURONS MEASURED IN THE DISCRIMINATING MONKEY. G.A. ORBAN and R. VOGELS. Lab. Neuro- en Psychofysiologie, K.U.Leuven, Campus Gasthuisberg, B-3000 Leuven, Belgium.

In our search for neuronal mechanisms underlying simple discrimination tasks, single striate cell responses were measured while the monkey performed an orientation discrimination task. Task of the monkey was to fixate a LED and to maintain fixation when two square wave gratings (duration 350 msec, diameter 8°, 2 cycles/deg, 80% contrast and luminance 7 cd/m^2) presented in succession over the receptive field had an identical orientation, and to make a saccade to the grating when they differed in orientation. Data were obtained from 285 neurons recorded in two monkeys. Striate neurons displayed a wide range of responses to the homogeneous screen during fixation and to the grating pattern. The orientation tuning characteristics of the striate neurons were derived from the responses to the first grating. The median response latency was 70 msec (first and third quartiles : 40, 100 msec respectively), the median orientation tuning width at half-height was 41° (first and third quartiles 25° and 75°). The variance correlated strongly with the response strength and equalled on average 1.9 times the response strength. Neurons were orientation tuned from the start of the responses. While a number of neurons had orientation tunings which remained stable over 350 msec, many neurons showed a decrease in gain and a few a change in tuning width over time. These results show that tuning characteristics vary over a wide range in striate cortex of the monkey.

132.12

ORIENTATION DISCRIMINATION THRESHOLDS OF SINGLE STRIATE CELLS IN THE DISCRIMINATING MONKEY. R. VOGELS and G.A. ORBAN. Lab. Neuro- en Psychofysiologie, K.U.Leuven, Campus Gasthuisberg, B-3000 Leuven, Belgium.

In our search for neuronal mechanisms underlying single discrimination tasks, we measured just noticeable differences in orientation of the monkey with the same task as used to investigate the orientation tuning characteristics of striate neurons (Orban and Vogels, Soc. Neurosci. Abstr., 1989). Monkeys are able to discriminate orientation difference as small as 1.5°, a capacity similar to that of humans. We then estimated how well single striate neurons can discriminate these small orientation differences. Nonparametric ROC analysis was performed on the responses to the first grating used to probe orientation tuning. Since the monkey responded behaviorally with an average latency of 250 msec we compared estimates for two time intervals : 175 msec and 500 msec. While 15 out of 45 neurons discriminate differences smaller than 3.5 deg for 500 msec interval, only 6 out of 45 did so for 175 msec. In order to isolate the contribution of short term variability we performed a ROC analysis on the difference between the responses to the pair of orientations presented in a single trial. Three out of 21 striate neurons could discriminate differences as small as 2.5 degrees. These results show that single striate neurons can discriminate orientation differences nearly as small as the behaving animal, but only on a restricted part of their tuning curve.

132.13

RELATING DISCRIMINATION KINETICS TO THE RELIABILITY OF SINGLE NEURONS.

E. Zohary, P. Hillman and S. Hochstein
Department of Neurobiology, Hebrew University, Jerusalem 91904, Israel.

The reliability of identification of visual targets in pop-out tasks increases with time available for stimulus inspection (i.e. the interval between stimulus and mask onsets, SOA). We have determined the experimental time course of this improvement and constructed a model to account for its kinetics. The model is based on the assumption that the reliability of the observer's response is limited by the variability of the responses of individual neurons. We assume that sensory information is coded in the neuron spike response integrated over the available time. The reliability of the discrimination at the neuronal level is then directly related to the ratio of the mean response to its standard deviation. This reliability increases with inspection time. Psychometric functions are derived from the firing rates of monkey V1 cortical neurons. Comparison with human psychometric functions suggests that very few cells may be needed to supply the psychophysical discriminating power.

132.14

COMPLEX CELLS ARE IDEAL BINOCULAR DISPARITY DETECTORS. I. Ohzawa*, G. DeAngelis* and R.D. Freeman. Neurobiology Group, School of Optometry, University of California, Berkeley, California 94720.

An ideal detector or sensor for any parameter **X** should have a high sensitivity to variations of **X**, but should be *insensitive* to all other parameters. Although both simple and complex cells of the visual cortex are sensitive to binocular disparity, it is not known if they differ with respect to sensitivity to other parameters of binocular stimuli. We have studied the sensitivities of striate neurons in anesthetized and paralyzed cats with respect to disparity, position, and contrast polarity.

After isolation of single cells, drifting sinusoidal gratings are used to determine the optimal orientation and spatial frequency for each eye. Sensitivity to binocular (phase) disparity is also evaluated by presenting optimal gratings dichoptically at a variety of relative phases. Then, using a binocular version of a receptive field mapping technique based on reverse correlation (Jones & Palmer, 1987), disparity selectivity is determined by brief (53msec) dichoptic flashes of bar stimuli at optimal orientations. For each eye, a stimulus is presented randomly with respect to position and polarity.

Results are as follows. For complex cells, disparity selectivity is much finer than the size of either monocular receptive field at all positions within the fields. In addition, both bright-bright and dark-dark pairs show identical disparity selectivity profiles. The optimal disparity for bright-dark pairs differs from that for the same polarity pair by 1/2 period of the cell's optimal spatial frequency. In contrast, simple cell responses depend critically on position of the bars. Bright-bright and dark-dark pairs with optimal disparity cause responses at mutually exclusive positions within the receptive fields.

In conclusion, complex cells are sensitive to disparity, but they are relatively insensitive to changes in stimulus position and contrast polarity. They are thus ideally suited as disparity detectors. Simple cells, however, do not exhibit these properties. (EY01175)

EXCITATORY AMINO ACIDS: RECEPTORS III

133.1

SIMILARITY BETWEEN QUISQUALATE RECEPTORS AND THE GLYCINE SITE ON NMDA RECEPTORS: EVIDENCE FROM ANTAGONIST PHARMACOLOGY. **N. W. Kleckner and R. Dingledine, Department of Pharmacology, University of North Carolina, Chapel Hill, NC 27599.**

Agonist-induced inward currents in Xenopus oocytes injected with rat brain mRNA were used to identify and characterize compounds that antagonize both the glycine site on NMDA receptors, and quisqualate/kainate receptors. Schild analysis of 7-chlorokynurenic acid (7-Cl-kyn) or 6,7-dichloro-3-hydroxy-2-quinoxaline carboxylic acid (6,7-diCl-HQC) vs glycine indicated competitive antagonism for both compounds with K_Bs of 350 and 300 nM, respectively. Both compounds also blocked the receptor mediating kainate-induced currents. Schild analysis of 6,7-diCl-HQC (K_B=3.0 μM) indicated competitive antagonism of kainate currents, but with a potency 10-fold lower than at the glycine site. 7-Cl-kyn antagonized kainate-evoked currents (K_B=14.1 μM), but the slope of the Schild regression was less than one. Thus 7-Cl-kyn was approximately 40-fold more potent at the glycine site than at the quisqualate/kainate receptor, but is probably not entirely competitive at the latter receptor. Omission of the Cl groups from 7-Cl-kyn or 6,7-diCl-HQC drastically reduced activity at both glycine and kainate sites. DNQX and CNQX were both more potent antagonists of kainate than glycine, but substitution of a Cl at the 6-position and especially the 6- and 7- positions increased potency at the glycine site. These results suggest that the glycine allosteric site of the NMDA receptor and the agonist binding site of the quisqualate/kainate receptor have some structural similarity. Halogenated derivatives of quinoxalines and kynurenines should be useful in evaluating the function of the glycine modulatory site in synaptic transmission mediated by NMDA receptors. In this regard we found that 7-Cl-kyn (5 and 15 μM) selectively attenuated NMDA receptor mediated epileptiform bursts in the CA1 region of hippocampal slices perfused with zero-Mg medium, without reducing the amplitude of the primary population spike. This block could be overcome by 300 μM D-serine. These results together indicate that the glycine site is functional on pyramidal neurons of the adult rat hippocampus.

133.2

GLYCINE REGULATES DESENSITIZATION OF ADULT RAT BRAIN NMDA RECEPTORS EXPRESSED IN XENOPUS OOCYTES. J. Lerma*, C. Samathanam*, S.G. Fan*, R.S. Zukin and M.V.L. Bennett, Dept. of Neuroscience, Albert Einstein Coll. of Med., Bronx, NY. (SPON: E.B. Masurovsky)

The N-methyl-D-aspartate (NMDA)-type glutamate receptor is a ligand-gated cation channel with several distinct regulatory sites. These include a positive allosteric site for glycine, an inhibitory site for Zn^{2+}, and a site or sites within the channel for phencyclidine (PCP) and Mg^{2+}. In Xenopus oocytes injected with adult rat brain mRNA, glycine potentiated NMDA-evoked inward current with no significant effect on NMDA affinity or Hill coefficient. The relationship between NMDA response and glycine concentration indicated a single component response with apparent affinities (K_D's) for glycine of 500 and 634 nM for the peak and steady state responses, respectively and Hill coefficients $n \approx 1$. In the absence of added glycine, a small transient was often observed at the onset of NMDA application. This response could be reduced by pre-washing with fresh Ringer solution and probably was due to glycine contamination. This response could be suppressed completely by pre-washing with the glycine antagonist 7-chloro-kynurenic acid. As glycine concentration was increased (30 nM-1μM), the NMDA response became bigger and desensitized less. The time course of desensitization at 100μM NMDA was fit by a single exponential with a time constant of 480 msec (n=15); this value was not affected significantly by altering glycine concentration. At higher NMDA concentration (300- 500μM), a second time constant of 1-2 sec became apparent. This component was enhanced by increasing extracellular Ca^{2+} and may have been due to Ca^{2+} influx. These results indicate that glycine has two actions on the NMDA channel; it enables channel opening and decreases one component of desensitization.

133.3

DESENSITIZATION OF NMDA RESPONSES IN OUTSIDE-OUT PATCHES PERSISTS IN LOW CALCIUM HIGH GLYCINE SOLUTIONS. W. Sather*, J.W. Johnson*, G. Henderson* and P. Ascher, Laboratoire de Neurobiologie, Ecole Normale Supérieure, 46, rue d'Ulm, 75230 Paris Cedex 05, France.

We have analyzed the influence of glycine and calcium on the desensitization of NMDA induced currents recorded in cultured mouse cortical neurons.

In outside-out patches, the response to NMDA (100 µM) always desensitized rapidly and profoundly. The decay of the response was well described by an exponential with a time constant of 100-400 ms. The amplitude of the steady-state response was always less than 20% of the peak response. Increasing the glycine concentration from 0 to 10 µM increased the absolute values of both the peak current and the steady-state current, but did neither alter the desensitization speed nor its amplitude. Similarly, reducing the extracellular Ca concentration from 1 to 0.01 mM did not alter markedly the desensitization.

The desensitization observed in the whole-cell recording mode differed from that observed in outside-out patches by its greater complexity (it often showed two components), by its smaller amplitude, by its variability from cell to cell and by its sensitivity to glycine and Ca. Increasing the glycine concentration and/or reducing the external Ca concentration often reduced the amount of desensitization, so that in certain cells desensitization was nearly absent in low Ca (0.1 mM) high glycine (10 µM) solutions. In other cells, however, desensitization was still observed in such conditions.

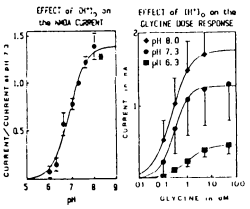
Our observations in the whole-cell mode do not contradict those recently reported by Mayer, Vyklicky and Clements (Nature, 1989, 338, 425) and by Clark, Clifford and Zorumski (Soc. Neurosci. Abstr., 1988, 14, 790). However the observations made in outside-out patches rule out the interpretation according to which the potentiation of NMDA by glycine results from a reduction of desensitization, since potentiation and desensitization are both present in outside-out patches.

133.4

USE- AND VOLTAGE-DEPENDENCE OF PCP BLOCK OF NMDA RECEPTORS EXPRESSED IN XENOPUS OOCYTES. M.V.L. Bennett, J. Lerma*, L. Kushner*, and R.S. Zukin, Dept. of Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461.

NMDA activated channels have several modulatory sites. In addition to the site of agonist action there is the glycine site which must also be occuped for the channel to open, a Zn^{2+} site which is inhibitory and a site or sites within the channel where PCP and Mg^{2+} block permeation. In oocytes injected with rat brain mRNA block of NMDA response by PCP is use dependent and very slow in the absence of NMDA. NMDA I_{max} is reduced without change in affinity or Hill coefficient. Rate of onset of block is increased at higher NMDA concentrations because of higher channel open probability, but the degree of block depends on PCP and not NMDA concentration. Also, recovery is very slow in the absence of NMDA and the rate increases with NMDA concentration. These data indicate that PCP enters and leaves the channels primarily when they are open, and that PCP can be trapped in the closed channel. Mg^{2+} decreases PCP's apparent affinity for the channel site; moreover Mg^{2+} slightly speeds recovery from PCP in the presence of NMDA, presumably by preventing PCP's rebinding. In contrast, Zn^{2+} slows both onset of and recovery from PCP block. In the absence of agonist, PCP produces a slowly developing block. PCP open channel block is greatly reduced by depolarization. The slow rate of recovery in the absence of NMDA is much less dependent on voltage than is the degree of open channel block. Although spontaneous openings of the channel cannot be ruled out, these findings suggest that PCP can enter and exit the NMDA channel via a lipophilic pathway. [Supported by NIH Grants NS20752 and NS07512 and Fogarty Fellowship TW 04040].

133.5



ZINC MODULATES NMDA CHANNELS AT VOLTAGE SENSITIVE AND VOLTAGE INSENSITIVE SITES. C.W. Christine and D.W. Choi. Dept. of Neurology, Stanford Univ. Med. Sch., Stanford CA 94305.

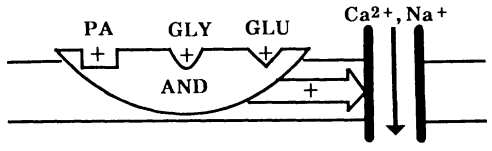
Recent data show that Zn^{++} can selectively block central neuronal excitation mediated by NMDA receptors. In outside-out patches removed from cultured murine cortical neurons, 3 μM glutamate in the presence of 5 μM glycine activated 50 pS channels that were blocked in a voltage-dependent manner by Mg^{++}. Zn^{++} appeared to have two effects on these NMDA channels. First, 1-10 μM Zn^{++} produced a concentration-dependent reduction in channel open probability, insensitive to membrane voltage between -60 and 40 mV; ED_{50} was about 3 μM. This reduction was mostly due to a decrease in opening frequency, and only weakly mimicked by Mg^{++}. Second, at higher concentrations (10-100 μM) and negative membrane voltages, Zn^{++} produced an apparent reduction in single channel amplitude associated with an increase in channel noise, suggestive of a channel block faster than that of Mg^{++} and hence only partially resolved with 2 kHz filtering. The amplitude reduction was voltage-dependent with a δ of 0.51 and K_d (0 mV) of 0.9 mM; amplitude distribution analysis suggested that this voltage-dependence may be primarily mediated by the "on" blocking rate. Zn^{++} may act at two sites: one outside the channel and affecting f_o, the other inside the channel and interfering with the passage of cations.

133.6

MECHANISM OF NMDA CHANNEL MODULATION BY H^+ AT NEAR PHYSIOLOGICAL pH. C.M. Tang*, M. Dichter, and M. Morad*. (SPON: E. Kicliter). Depts. of Physiology and Neurology. Univ. of Pa. and Graduate Hospital, Phila., PA 19104.

The NMDA-activated current is strongly modulated by $[H^+]_o$ at near physiological pH (Tang et al., S.N. Abst. p. 791, 1988). The lack of voltage sensitivity and the lack of sensitivity to changes in $[H^+]_i$ suggest that the protonation site is external to the voltage-sensing portion of the channel pore. Protonation at near physiological pH's primarily effects the probability of channel opening and not its unitary conductances. The major component of NMDA current modulation by H^+ cannot be explained by simple competition for glycine binding, since the glycine dose responses show prominent non-competitive behavior. However, a part of this modulation of NMDA channel gating by H^+ is due to shifts in the K_d of the glycine potentiation. (NMDA was constant at 100 uM.) K_d's are 900 nM at 6.3, 290 nM at pH 7.3, and 200 nM at 8.0. The sensitivity of the NMDA current to H^+ may play a protective role in hypoxic-ischemic conditions, and may, in part, contribute to the sensitivity of seizure threshold to pH.

133.7



POLYAMINE ACTIVATION OF NMDA EFFECTOR REQUIRES OCCUPATION BY AGONISTS OF BOTH GLYCINE AND NMDA SITES. **H. Canton*, F. Colpaert and J. Lehmann, FONDAX-Groupe de Recherche SERVIER, 92800 Puteaux France**

Agonists activate the NMDA-receptor effector complex, by acting at the glutamate (glu), glycine (gly), or polyamine (PA) site, stimulating the binding of [3H]MK-801 to the open state of the NMDA-linked cation channel.

In well-washed membranes, the NMDA site antagonist 2-amino-5-phosphonopentanoate (AP5; 100 uM) or the gly site antagonist 7-chlorokynurenate (7ClKyn; 100 uM) inhibited [3H]MK-801 binding, presumably due to residual neurotransmitter. Glu, gly, or spermidine (spmdn; each at 10 uM) alone stimulated [3H]MK-801 binding.

NMDA receptor blockade by AP5 prevented gly and/or spmdn from stimulating [3H]MK-801 binding. Likewise, gly receptor blockade by 7ClKyn prevented glu and/or spmdn from stimulating [3H]MK-801 binding.

Therefore the action of spmdn requires both glu and gly site activation. It remains to be determined if all three sites must be occupied for effector activation.

133.8

IFENPRODIL AND SL 82.0715 ARE ANTAGONISTS AT THE POLYAMINE MODULATORY SITE OF THE NMDA RECEPTOR COMPLEX. C. Carter*, J. P. Rivy*, F. Thuret*, K. Lloyd and B. Scatton. Synthélabo Recherche (LERS), Biology Dept., 31 Ave P.V. Couturier, 92220 Bagneux, France.

In an attempt to characterise the mechanism of action of the non-competitive NMDA antagonists ifenprodil and SL 82.0715, we have examined their interactions with the polyamine modulatory site of the NMDA receptor (Ransom and Stec, J. Neurochem., 51:830, 1988). Spermine and spermidine (0.1-100 μM) increased the binding of the competitive NMDA receptor antagonist ^{3}H-CPP and of the NMDA channel blocker ^{3}H-TCP to rat brain membranes. These increases in binding were blocked by ifenprodil and SL 82.0715 (0.1-10 μM). The polyamine-induced increase in ^{3}H-CPP binding was insensitive to MK-801 or 7-chlorokynurenate. Spermine or spermidine did not increase ^{3}H-glycine binding (NMDA modulatory site) nor did ifenprodil or SL 82.0715 (100 μM) affect ^{3}H-glycine binding. Spermine or spermidine (10-1000 μM) had no effect per se on cGMP production in immature rat cerebellar slices, but both increased the maximal effects of NMDA (80 μM) on this parameter (by 400 and 160% respectively). Spermine (100 and 1000 μM) reversed the inhibitory effects of ifenprodil (but not those of MK-801 or kynurenate) on the NMDA-induced increase in cGMP levels. The data show that spermine and spermidine increase the effects of NMDA receptor stimulation via a distinct modulatory site and suggest that ifenprodil and SL 82.0715 are antagonists at this site.

GLUTAMATE-MEDIATED GENE EXPRESSION IN PRIMARY CULTURES OF CEREBELLAR NEURONS. A.M.Szekely*, D.Grayson* and E.Costa (SPON: M.Santi). FIDIA-Georgetown Inst. for Neurosciences, Georgetown University, Washington D.C.,20007

The activation of glutamate receptors sensitive to N-methyl-D-aspartate (NMDA) is critical in the development of transsynaptically induced neuronal plasticity. We reported that in neurons the stimulation of this glutamate receptor subclass induces the expression of c-fos proto-oncogene mRNA . C-fos protein together with jun protein participate in a DNA-binding protein complex (AP-1) and may control the expression of target genes involved in neuron-specific responses, effectively functioning as a nuclear third messenger. In primary cultures of cerebellar granule cells we show that NMDA-receptor activation increases the mRNA content of both c-jun and jun-B genes, and these changes are reflected in an increased formation of AP-1 complex as shown by gel-retardation assay. To identify potential target genes we constructed a cDNA library from mRNA isolated from glutamate-stimulated cerebellar granule cells. By differential screening a number of clones have been isolated and characterized in respect to their cross-reactivity, hybridization to known clones, Northern blot and sequence analysis. This study may provide insights how a neurotransmitter receptor activation may alter the transcriptional program of the neuron.

SIGMA RECEPTOR LIGANDS MODULATE THE EXCITATORY EFFECT OF NMDA: AN ELECTROPHYSIOLOGICAL STUDY IN THE RAT DORSAL HIPPOCAMPUS. F.P. Monnet*, G. Debonnel and C. de Montigny. McGill University, Montréal, Québec, Canada

The functional role of sigma (σ) receptors is unknown. We have shown that haloperidol, a high affinity ligand for σ receptors, potentiates the antagonism by MK-801 of NMDA-induced activation of hippocampal pyramidal neurons. In the present experiments, we studied the effects of the σ ligands haloperidol and 1,3-di(2-tolyl)guanidine (DTG) on the neuronal responsiveness to excitatory amino acids.

Male Sprague-Dawley rats were anesthetized with urethane (1.25 g/kg, i.p.). Five-barelled glass micropipettes were used for extracellular recording of CA_3 dorsal hippocampus pyramidal neurons. One side barrel was used for automatic current balancing and the others were filled with three of the following solutions: NMDA (10 mM in 200 mM NaCl, pH: 8), quisqualate (QUIS; 1.5 mM in 400 mM NaCl, pH: 8), kainate (KA; 1 mM in 400 mM NaCl, pH: 8), DTG (0.2 mM in 200 mM NaCl, pH: 4) and haloperidol (0.2 mM in 200 mM NaCl, pH: 4).

DTG (0.25 - 3 μg/kg, i.v.) increased in a dose-dependent manner, the excitatory effect of NMDA but not those of QUIS and KA; at the dose of 1 μg/kg, DTG increased by seven fold the excitatory effect of NMDA. Haloperidol (10 μg/kg, i.v.) had no effect on NMDA-induced activation but completely suppressed the effect of DTG. In contrast, spiperone (10 μg/kg, i.v.), a butyrophenone with low affinity for σ receptors, did not block the effect of DTG. Microiontophoretic application of DTG also potentiated the excitatory effect of NMDA; this effect of DTG was abolished by the concurrent application of haloperidol.

The marked and selective potentiation of NMDA-induced activation by DTG, and the blockade of this effect by haloperidol, but not by spiperone, suggest that DTG is an agonist and haloperidol an antagonist of σ receptors. The present data suggest that a function of σ receptors might be to modulate the sensitivity of NMDA receptors.

DEVELOPMENTAL CHANGE IN THE MAGNESIUM SENSITIVITY OF THE NMDA RESPONSE IN HIPPOCAMPAL CA3 PYRAMIDAL CELLS. R.J. Brady and J.W. Swann, Wadsworth Ctr. for Labs. & Res., NYS Dept. of Health, Albany, NY 12201.

In the presence of 2mM magnesium the NMDA-induced depolarization of a CA3 pyramidal cell in a TTX-treated, mature hippocampal slice is strongly voltage-dependent. The size of the response decreases as the neuron is hyperpolarized relative to its resting membrane potential. Intracellular recordings were obtained of the responses to iontophoretic application of the agonist into the proximal portion of the basilar dendrites. As expected, changing to a perfusate with no added magnesium potentiated the NMDA response and dramatically decreased its voltage-dependence. These results stand in contrast to those obtained from CA3 pyramidal cells in slices taken from rats 10-15 days of age. Under control conditions the NMDA response of these immature neurons was also strongly voltage-dependent. However, a change to nominally magnesium free perfusate, although potentiating the response, did not remove its voltage dependence. This further supports the conclusion of our previous work that there is a developmental change in the divalent cation sensitivity of the NMDA receptor-channel complex. In immature CA3 neurons an isomeric form is expressed that is more sensitive to calcium than to magnesium. Supported by grants NS-23071 to RJB and NS-18309 to JWS from DCDND-NIH.

133.12

NMDA-ANTAGONISTIC PROPERTIES OF THE ENANTIOMERS OF 3-(2-CARBOXYPIPERAZIN-4-YL)-PROPYL-1-PHOSPHONIC ACID (CPP) AND OF ITS UNSATURATED ANALOGUE 3-(2-CARBOXYPIPERAZIN-4-YL)-1-PROPENYL-1-PHOSPHONIC ACID (CPP-ENE). P.L.Herrling+, B.Aebischer*+, P.Frey*+, H.J.Olverman*# and J.C. Watkins*##. +Sandoz Res. Inst., CH-3001 Berne, Switzerland;# Dept. Pharm. Univ. Edinburgh, U.K.;## Dept. Pharm. Med. Sch. Bristol BS8 1TD U.K.

A [3H]-CPP binding assay in rat cortical membrane preparations yielded Ki values in nM of: 138 for D-CPP, 2332 for L-CPP, 44 for D-CPP-ene and 597 for L-CPP-ene. There is no comparable binding to other neurotransmitter binding sites:NE α1+2, 5HT 1+2, DA 1+2, opiate, benzodiazepine, ACh, QUIS or KA. In frog hemisected spinal cord inhibition of NMDA induced depolarizations yielded following pA2 values: 6.6 for D-CPP, 5.4 for L-CPP, 6.8 for D-CPP-ene and 5.7 for L-CPP-ene. Testing several antagonist concentrations suggested competitive antagonism. D-CPP-ene was active after p.o. application in the rat electroshock test: around 80% protection at 10mg/kg (6h value). These results indicate that the enantiomerically pure D-CPP-ene is a potent and systemically active competitive NMDA antagonist.

DIFFERENTIATION, MORPHOGENESIS AND DEVELOPMENT: CELLULAR AND MOLECULAR STUDIES I

134.1

EXPRESSION OF THE MATURE ARRAY OF NEUROFILAMENT PROTEIN ISOFORMS BY A CLONAL CELL LINE DERIVED FROM THE CNS. H.J. Lee, G.J. Elliot, D.N. Hammond, Y.M.-Y. Lee§, and B.H. Wainer. Committee on Neurobiology, The University of Chicago, Chicago, IL 60637 and §Department of Pathology, University of Pennsylvania, Philadelphia, PA.19104.

The intermediate filaments of mammalian neurons are composed of neurofilament triplet proteins. Each protein is expressed in a developmentally regulated manner, differentially phosphorylated, and preferentially distributed within a neuron. However, the functional significance of these properties is poorly understood. SN 48.B12.2.C6 is the first reported cell line that expresses the mature array of neurofilament (NF) proteins in a normal fashion. The cell line was derived by somatic cell fusion of postnatal day 21 murine septal cells to N18TG2 neuroblastoma cells. Using immunofluorescence, the low molecular weight NF protein (NF-L) and differentially phosphorylated isoforms of the middle (NF-L) and high molecular weight (NF-H) NF proteins were detected. Growth cones contained the highest concentration of each NF protein. Within the perikarya and processes, NF-L was observed mainly in the cell body; NF-M was equally distributed to the cell body and processes; and NF-H was observed slightly more in the processes than in the cell body. Weak staining for vimentin was also noted. N18TG2 cells exhibited no immunoreactivity for neurofilament proteins. Neither SN 48.B12.2.C6 or the N18TG2 neuroblastoma expressed glial fibrillary acidic protein or cytokeratins 8, 18, and 19. Intermediate filament protein expression by both lines was confirmed by Western blot analysis.

SN 48.B12.2.C6 is unique in that it i) expresses the highly phosphorylated isoform of NF-H, ii) expresses all three NF proteins, iii) does not express other intermediate filament proteins, and iv) does not contain perinuclear aggregations of NF proteins. SN 48.B12.2.C6 cells provide an *in vitro* model which may be usedful in the examination of neurofilament phosphorylation events and the elucidation of the role of differentially phosphorylated neurofilaments in neural function. Supported by NIH grants T32HD070009, NS 01244, and NS 25787; grants from the Alzheimer Disease and Related Disorders Association; and the Illinois Department of Public Health.

EXPRESSION OF CA^{2+} CHANNELS IN CULTURED NEURONAL PRECURSOR CELLS FROM THE RAT TECTUM PARALLELS THE EXPRESSION OF N-CAM AND TETANUS TOXIN RECEPTORS. R.Grantyn, L.Hofer* and M.Perouansky*. Max Planck Inst. Martinsried. F.R.G.

Neuronal precursor cells were dissociated from the tectal plate of rat embryos at day E12, seeded on collagen-coated glass coverslips and maintained in MEM with 10% horseserum and 10^{-5}M AraC. The latter suppressed further mitosis. Only 5% of the freshly plated cell population stained with antibodies to N-CAM or Tetanus toxin. These cells generated voltage activated Na^+ currents ($I_{Na(v)}$) as well as high voltage activated Ca^{2+} currents ($I_{Ca(HV)}$) and bound [^{125}I]Ω-conotoxin (Ω-CT), a blocker of $I_{Ca(HV)}$. However, within the following 10 hours all cells acquired not only $I_{Na(v)}$ and $I_{Ca(HV)}$ but also N-CAM- and Tetanus toxin immuno-reactivity. Initially, only the protruding parts of growing cells were labeled with Ω-CT. Later on the label was distributed over the whole cell surface, including the neurite. After 10 hours in vitro all cells were Ω-CT-positive. Three different markers indicate thus the rapid, probably substrate-stimulated acquisition of neuronal properties by undifferentiated cells from the mammalian brain.

The expression of calbindin D-28k or substance P by sensory neurons in dorsal root ganglion cell cultures is regulated by soluble factors present in peripheral or central target tissues. I. Barakat* and B. Droz. Institute of Histology and Embryology, Univ. of Lausanne, CH-1005 Lausanne, Switzerland.

Primary sensory neurons display various neuronal phenotypes which may be influenced by factors present in central or peripheral targets. Dorsal root ganglion (DRG) cells were cultured from chick embryos at E6 or E10 (before or after functional connections with targets). Calbindin D-28k (CaBP) or substance P (SP) were detected in culture either by immunocytochemical reaction or by in situ hybridization. At E6, DRG cells were all devoid of CaBP immunoreaction at any time of culture; in contrast at E10, 22% or 11% of neurons were CaBP immunoreactive in neuron-enriched or mixed DRG cell cultures. The addition of muscle or skin extracts to cultures at E6 induced the expression of CaBP by 7.5% or 2.5% of the neurons respectively. In muscle extract, the factor, which induced CaBP in responsive cells according to a dose-dependent manner, was a protein with a M_r greater than 30kD.

SP was expressed by 98% of the neurons grown at E6 but only by 60% at E10. The addition of muscle, skin or brain extract at E6 reduced the percentage of SP+ neurons.

In conclusion, the expression of CaBP and repression of SP by DRG cells in culture is controlled by factors present in peripheral or central target tissues.(SNF N°3.097-86)

HEPARIN-BINDING FACTORS IN CNS NEURONAL CELL LINE CONDITIONED MEDIUM STIMULATE PROLIFERATION OF O-2A GLIAL PROGENITORS. W. Thangnipon*, G. H. Frost* and J. E. Bottenstein. Marine Biomedical Institute and Dept. of Human Biological Chemistry and Genetics, Univ. of Texas Medical Branch, Galveston, Texas 77550.

Our previous studies have identified mitogenic activity in conditioned medium (CM) derived from the B104 CNS neuronal cell line on A2B5$^+$ O-2A glial progenitors in dissociated neonatal rat brain cultures (Bottenstein et al., J. Neurosci. Res. 20:291-303, 1988). The CM is generated by growing B104 cells on microcarrier beads in serum-free N4 medium. Its growth-promoting activity is evaluated by a serum-free bioassay using either A2B5 immunostaining of neonatal rat brain cells or a colorimetric proliferation assay on C62B rat glioma cells. Both O-2A progenitors and C62B cells exhibit a dose-dependent increase in cell number when treated with B104 CM. Maximal responses are obtained at 8-16 μg protein/ml for O-2A progenitors and 2-4 μg protein/ml for C62B cells. Concentrated and dialyzed CM was applied to a heparin-Sepharose column, and all activity appeared in the bound fractions. Gel filtration chromatography on a Sephacryl S-200 column generated the most active fractions with apparent molecular weights of 38-44K and 98-110K. Various criteria suggest that this trypsin- and heat-labile activity is not identical to that of PDGF, FGF, IGF 1, interleukin 2, GMF, EGF, GPF, GGF, or TGFα. Supported by NIH grant NS20375.

INSULIN GROWTH FACTORS REGULATE MITOSIS AND SURVIVAL IN CULTURED CEREBELLAR GRANULE CELLS AND PRECURSORS E. DiCicco-Bloom, R.C. Cohen *&I.B. Black Div. Developmental Neurology, Cornell Univ. Med. Coll., New York, NY 10021

Although neurogenesis has been characterized descriptively, regulatory mechanisms remain undefined. Based on our previous work, we have developed a new cell culture system to study central neuronal precursor or neuroblast mitosis.

A highly enriched population of dissociated granule cells and precursors was obtained from 7 day rat cerebella (Hatten,M.E.,J.Cell Biol., 100:384, 1985) and was cultured in fully-defined medium. Immunocytochemical analysis indicated that <2% of cells were stained by markers for glia, fibroblasts and Purkinje cells. Time-lapse phase photomicrography revealed ongoing division and neuritic outgrowth. Further, >50% of cells exhibited nuclear incorporation of [3H]thymidine, a marker for DNA synthesis.

To define effects of insulin on central precursors, cells were cultured in various hormone concentrations and assayed for survival and incorporation of [3H]thymidine (Inc.). Increasing concentrations of insulin produced a marked 10-20 fold rise in Inc. at 48hrs, with peak effect at 5-10ug/ml, indicating that the hormone stimulated neuroblast DNA synthesis. In contrast, maximal survival was achieved at low hormone concentrations (3-10ng/ml), suggesting that insulin mitogenic stimulation was not due to increased cell survival.

Insulin is but one of a family of factors, including insulin-like growth factor-I (IGF-I), that bind to homologous and heterologous receptors. To define IGF-I effects, cells were cultured in control medium or in the presence of insulin (10ng/ml), IGF-I (25ng/ml) or both factors. IGF-I treatment reproduced the marked 10-20 fold stimulation of Inc., while eliciting no further increase in survival over that produced by insulin. These observations suggest that during granule cell development, insulin plays a trophic role whereas IGF-I serves as a neuroblast mitogen. (Support:NIH grants HD23315, NS10259)

134.6

REGIONAL SPECIFICITY OF NEURONAL REGULATION OF ASTROGLIAL DIFFERENTIATION M.E. Hatten and U.E. Gasser. Dept. Pathology, College of Physicians and Surgeons of Columbia University, New York NY 10032

The control of astroglial cell growth is critical to brain development, tumorigenesis and repair of brain injury. Recently we have shown that neuron-glia cell contacts arrest astroglial DNA synthesis (Hatten, ME, J. Cell Biol. 104: 1353, 1987). In the present experiments, we analyzed whether neurons isolated from one brain region would regulate the proliferation of glia from a heterotypic region. Early postnatal cerebellar granule neurons rapidly arrested the growth of late embryonic or early postnatal hippocampal glial cells and induced astroglial differentiation into forms resembling those seen *in vivo*. Quantitation of glial process number and length in homotypic and heterotypic neuron-glial co-cultures revealed that glial form is intrinsic to the region of origin of the glial cell and is not specified by the region of origin of the neuron. The mechanism of granule cell regulation of hippocampal glial growth appeared to be membrane-mediated, since membrane material purified from cerebellar granule neurons arrested hippocampal glial growth in a dose-dependent manner. These results are consistent with previous results showing that granule cell membranes inhibit the growth of astrocytoma cells derived from different brain regions (Hatten, M.E. and M.L. Shelanski, J. Neurosci. 8:1447, 1988) and suggest that neuron-glia cell contacts provide a general mechanism for regulating glial proliferation in the brain.

134.7

REGION- AND GENDER-SPECIFIC MATURATION OF RAT ASTROGLIA IN VITRO. I. REISERT*, Co. BEYER* and Ch. PILGRIM. Abteilung Anatomie und Zellbiologie, Universität Ulm, D-7900 Ulm, FRG.

Previous studies using dissociated cell cultures of fetal rat brain have revealed considerable regional diversity as well as sex differences in developmental schedules of dopaminergic neurons. Because these phenomena might be related to glial heterogeneity, cultures of male and female diencephalon, mesencephalon, and rhombencephalon of gestational day 14 rats were investigated with respect to the development of astrocytic markers. Cultures were incubated for 3-8 days in serum-supplemented or serum-free medium. Vimentin and GFAP were quantified by counting of immunolabeled cells and immunoblotting. Vimentin content was highest in mesencephalon and lowest in rhombencephalon and was more or less stable over the period investigated. GFAP content was initially low and increased with time. It reached high levels in rhombencephalon but remained low in mesencephalon. Sex differences were observed in diencephalic cultures only. Transiently, female cultures contained more GFAP-immunoreactive cells than male cultures.

The results thus demonstrate considerable regional heterogeneity of astrocytic maturation. However, neither the regional nor the sex differences show a clear-cut correlation with previous data on regional development of monoaminergic neurons. It may be concluded that the dependence of neurons on glial environment for realization of an inherent developmental program may vary among neuronal cell types.

134.8

ASTROGLIAL TRANSFORMATIONS IN THE DEVELOPING MURINE CEREBRAL WALL. V.S. Caviness Jr., J-P. Misson*,T.Takahashi*, J. Crandall, Dept. Neurology, Mass Gen Hosp,Boston MA 02114,and Shriver Center,Waltham, MA 02254

Bipolar radial glia are present in the developing murine cerebral wall during the period of active neuronal migration. They disappear during the first postnatal week after migrations are terminated. Until P0 the classical bipolar form is the dominant RGC in the cerebral wall. However, during the final week in utero and during the first postnatal week the bipolar is succeeded by monopolar and multipolar astroglial forms. We describe here four stages of cellular change involved in the glial population change. The analysis is based upon immunohistochemical staining with RC2(Misson et Al., Dev. Br. Res ,1988,44,95). The bipolar cells, dominant before P0, are grouped in fascicles. Through E17, Stage 1, the nuclei of these cells are confined to the VZ and SVZ. Between E17 and P0, Stage 2, the nucleus appears to be translocated to the upper IZ in many of the classical bipolar cells. At the same time monopolar cells with somata in the upper IZ and SP become prominent. These glial cells have multiple processes ascending radially from the soma and have no descending process. In the interval P0-P3, Stage 3, there is an explosive emergence of multipolar astrocytes which stain strongly with RC2 and which progressively predominate over declining populations of bipolar and monopolar RG. Beyond P4, Stage 4, cells of the astroglial lineage cease to stain with RC2; concurrently these cells begin to stain well with AB to GFAP. The set of observations suggest that nuclear translocation, previously considered to be a mechanism involved in neuronal migration.occurs in the course of radial glia to astrocyte transformation. The antigens recognized by RC2 are developmentally regulated in the course of transformations occurring within the astroglial lineage.

GAP-43 mRNA IS DEVELOPMENTALLY REGULATED IN CULTURED RAT CORTICAL ASTROCYTES L. Vitković, A. daCunha, and V. J. Aloyo Lab of Immunoregulation, NIAID, NIH, Bethesda, MD 20892; Deptartment of Pharmacology, Medical College of Pennsylvania, Philadelphia, PA 19129

Growth-associated protein 43 (GAP-43 also termed B-50, F1, P57, or pp46) is an intensely investigated membrane-associated phosphoprotein whose expression is characteristically altered during normal CNS development and reinduced during successful nerve regeneration. It is currently believed that GAP-43 is exclusively a neuronal protein and thus, its function(s), still unknown, are explored in that context. However, we have recently demonstrated the presence of this protein in cultured rat cortical astrocytes (Vitkovic, L., et al. Proc. Natl. Acad. Sci. USA, 85: 8296, 1988). We show here that the mRNA to GAP-43 is also present in astrocytes. This suggests that the presence of GAP-43 in astrocytes is due to expression of its gene rather than uptake of a neuronally-synthesized protein. Astrocytes in culture develop with the same schedule as in cortex. We found that the developmental pattern of GAP-43 mRNA expression in astrocytes was similar to that in vivo as shown by others (Basi, G.S. et al. Cell, 49: 785, 1987). This suggests that (1) molecular mechanism(s) controlling the developmental regulation of GAP-43 operates in astrocytes; (2) astrocytes contribute significantly to the overall experession of GAP-43 in cortex.

134.10

NEURAL BC1 RNA: TOWARDS AN UNDERSTANDING OF ITS FUNCTIONAL SIGNIFICANCE. Henri Tiedge*, Robert T. Fremeau, Jr., Peter Weinstock*, James L. Roberts, and Jürgen Brosius. Fishberg Research Center for Neurobiology, Mount Sinai School of Medicine, New York, NY 10029

BC1 RNA is a 152 nucleotide long ribonucleic acid which is prevalent in rat nervous tissue. *In vivo*, this non-messenger type RNA is most likely complexed with proteins in a ribonucleic acid protein particle (RNP). In order to try to understand the functional significance of the RNP in the nervous system, we have used *in situ* hybridisation histochemistry to analyse the spatial and temporal expression pattern of BC1 RNA, both at a cellular and a subcellular level. BC1 RNA is expressed by most, but not all neurons, and high amounts of the RNA are found in neuronal cell bodies. Furthermore, in stratified regions such as the retina, the olfactory bulb, the hippocampus, and cerebral and cerebellar cortices, high levels of BC1 RNA are detectable in layers that contain little or no cell bodies but are rich in dendrites, axons, and synapses. The expression pattern in some of these layers seems to coincide with dendritic fields. We are currently trying to localise BC1 RNA in processes of cultured neurons. A dendritic and/or axonal location would seem to indicate an unorthodox functional role of this RNA.

135.1

IMMUNOCYTOCHEMICAL EVIDENCE FOR DISRUPTED THALAMIC PROCESSING IN ALZHEIMER'S DISEASE. W.G. Tourtellotte, G.W. Van Hoesen, B.T. Hyman, and A.R. Damasio. Depts. of Anatomy and Neurology, Univ.of Iowa College of Medicine, Iowa City, IA 52242.

The thalamic reticular nucleus (Rt) forms a narrow band of neurons interposed among external medullary axons of the lateral and rostral convexities of the thalamus. It receives collateral projections from virtually all thalamocortical and corticothalamic pathways *en route* to their respective targets. In turn, the inhibitory neurons within Rt send projections to the thalamus. The neuronal loss and neurofibrillary tangle (NFT) formation that occur in the basal forebrain in Alzheimer's disease (AD) are thought to contribute to dementia due to loss of cholinergic projections to the amygdala, hippocampal formation, and to the entirety of the cerebral cortex. However, recent evidence demonstrating a powerful basal forebrain projection to Rt suggests that an additional consequence of basal forebrain pathology would be partial deafferentation of Rt. Thus, destruction of basal forebrain afferents to Rt could lead to altered thalamic processing. These predictions are particularly relevant to AD considering experimental evidence that Rt gates thalamic transmission and plays a role in attention mechanisms. Rt was studied in 10 cases of AD and 4 non-demented controls using Alz-50 immunocytochemistry to recognize an AD-related protein, and thioflavin S to demonstrate neurofibrillary tangles (NFTs) and neuritic plaques (NPs). Alz-50 demonstrated a terminal-like pattern in Rt in all 10 AD cases but none of the 4 controls. However, neither NFTs, NPs nor immunoreactive neurons were present in Rt, and Nissl stain revealed a normal appearing cytoarchitecture in both AD and control cases. Projections from the basal forebrain were the likely source of the Alz-50 immunoreactivity in AD since other known afferents of Rt such as layer VI of cortex, principal thalamic nuclei, and the mesencephalic reticular formation lacked immunoreactive neurons. By contrast, the basal forebrain was invested with NFTs and immunoreactive neurons in AD but not in control brains. We interpret our results to suggest disruption of the basal forebrain-Rt pathway in AD and propose that such changes may lead to altered thalamic and cortical processing. (Support: NS 14944, PO 19632, 5T32 GM0733. We thank P. Davies for Alz-50.)

135.2

Neurofilaments and MAPs in Human Olfactory Epithelium in Alzheimer's Disease. B.R. Talamo, R. Rudel, V. Lee, K. Kosik and J.S. Kauer. Tufts U. Medical School, Boston, MA 02111.

Nasal epithelia obtained at autopsy from Alzheimer's (AD) patients contains pathological accumulations of neurites (Talamo et al, Nature **337**:736, 1989). This tissue and that obtained from non-demented patients have been further characterized immunocytochemically. In normal and AD tissue, olfactory neurons were immunoreactive (ir) with antibody to microtubule associated protein MAP1b(5), but not to MAP2 using 4 different antibodies. In AD, MAP1b(5)-ir was also present in diffuse material near the basal lamina. Olfactory neurons were not ir for *tau*, using 3 different monoclonal antibodies. *Tau*-ir was normally seen only in nerves in the vicinity of blood vessels, glands, and in occasional varicose fibers in non-sensory epithelium. However, abnormal neurites in AD tissue showed *tau*-ir with all 3 antibodies and also stained with ALZ50, as previously noted. Most neurofilament (NF) antibodies do not stain olfactory neurons, but the olfactory axons in control tissue were stained with antibodies to dephosphorylated NF medium and heavy subunits. AD epithelium was stained for both dephosphorylated and phosphorylated NF. It appears that normal olfactory neurons have a cytoskeletal profile similar to developing neurons in the CNS. The pathological neurites of AD tissue showed staining for proteins more characteristic of mature neurons and contained epitopes reported to be present in neurofibrillary tangles and dystrophic neurites in AD brain.

135.3

LAMINAR AND REGIONAL DISTRIBUTIONS OF PLAQUES AND TANGLES IN THE VISUAL CORTEX OF ALZHEIMER PATIENTS. M-C de Lacoste, L.W. McCallister, K.S. Pollan*, N.Hirstein*, G.A. Mihailoff, C.L. White III*. *Depts. Cell. Bio. and Pathol., U.T. Southwestern Medical Center, Dallas, TX 75235.*

This study was undertaken to determine if there is a relationship between patterns of intracortical connectivity and the laminar and regional distributions of neuritic plaques (NP) and neurofibrillary tangles (NFT) in striate (ST), parastriate (PARA) and peristriate (PERI) cortical areas. Formalin-fixed blocks of tissue from neuropathologically confirmed Alzheimer (AD) brains obtained at autopsy were coronally sectioned at 50μm using a large-stage freezing microtome. NFT and NP were labelled on mounted sections by the avidin-biotin immunoperoxidase method using a polyclonal antiserum to AD paired helical filament. A basic Nissl and the Gallyas silver stain were used for cyto- and myeloarchitectural differentiations. CARP software (Biographics, Inc.) was utilized for semiautomated counts of NP and NFT by lamina and region and to obtain precise three-dimensional reconstructions of the distribution of AD neuropathology.

Preliminary results (n=2) suggest that although there are some minor regional variations, NP are located predominantly in supragranular layers in the visual areas studied. The overall density of NP is also similar for ST, PARA and PERI cortex. In contrast, there are regional differences in the distribution of NFT: 1) Few NFT are located in ST cortex; and 2) PARA and PERI cortical areas exhibit differences in the relative proportion of supra- and infragranular NFT. Regional and laminar differences in the distribution of NFT point to a possible relationship between the spatial course of AD and patterns of intracortical connectivity. *Supported by NIH-AG-08013-01, HD21711 and the Biological Humanics Foundation.*

135.4

THY-1 DISTRIBUTION AND DENDRITIC GROWTH IN ALZHEIMER'S DISEASE HIPPOCAMPUS. D. Leifer, S. A. Lipton, and N.W. Kowall. (Sponsor: R. H. Ackerman). Department of Neurology and Neurobiology, Harvard Medical School.

The membrane glycoprotein Thy-1 belongs to the immunoglobulin superfamily and is present in high concentrations in the brain. Growing dendrites in rat Purkinje cells are intensely Thy-1 immunoreactive and antibodies against Thy-1 enhance neuritic regeneration in cell culture. We examined the distribution of Thy-1 immunoreactivity in normal elderly and Alzheimer's disease (AD) hippocampus using a well characterized monoclonal antibody and immunoperoxidase methods. In normal elderly hippocampus,Thy-1 was primarily located in irregular patches on the perikarya and dendrites of pyramidal neurons and their axons. Dentate granule cells were lightly stained. A blush of granular immunoreactivity often surrounded small blood vessels in grey and white matter. In AD brain, the pattern of immunoreactivity was often polarized on the base of the apical dendrite of pyramidal neurons and within the cytoplasm of neurofibrillary tangle bearing neurons. Dendritic spines and filopodial outgrowths were occasionally labelled with Thy-1 but dystrophic neuropil neurites were not identified. Occasional reactive neurites were seen in senile plaques and a blush of Thy-1 immunoreactivity often surrounded senile plaques cores. The persistent labelling of neuronal perikarya and blood vessels in the human hippocampus is similar to the transient labelling of developing Purkinje cells and blood vessels in the newborn rat. The enhanced pattern of Thy-1 staining in AD suggests that active dendritic remodelling is a feature of this disease.

MOLECULAR AND CELLULAR CHARACTERIZATION OF CYTOKINES IN ALZHEIMER'S DISEASE. S.A. Allen, S.D. Styren, and J. Rogers. Institute for Biogerontology Research, Sun City, AZ 85351.

As part of an ongoing study of immune system involvement in the pathogenesis of Alzheimer's disease (AD), we are characterizing cytokines present in brain using Western blot analysis, in situ hybridization, and immunohistochemistry at the light and electron microscopic levels. Cytokines examined include interleukin-1 (IL-1), IL-2, IL-2R, IL-3, IL-6, tumor necrosis factor (TNF), and interferon-gamma. Several of these intercellular mediators of immune function show differential CNS expression in AD compared to nondemented elderly patients. For example, IL-1 (which activates peripheral T and B cells) exhibits sparse immunoreactivity in nondemented elderly cortex. In AD cortex, however, there is clear IL-1 immunoreactivity on Western blots, with many immunopositive glia evident in light and EM sections. Gray matter staining of AD cortex frequently shows dense clusters of IL-1 immunoreactive glial profiles, which in our other studies of immune markers in AD have been found to correspond to senile plaques. TNF is a cytokine that is expressed by activated monocytes and, among numerous cellular actions relevant to immune function, activates or induces T helper cells. In brain, TNF immunoreactivity is sparse in control cortex, but strongly expressed in AD cortex. Astrocytes are the predominant brain cell type immunopositive for TNF, with labelled cells evident in both white and gray matter. The presence and, especially, the differential expression of cytokines in AD brain begins to suggest a functional role of immune mechanisms in the pathogenesis of AD. Supported by NIA AGO 7367-01A1 (JR).

NEURONAL MRNA LEVELS ARE MAINTAINED IN DOWN'S BRAINS WITH ALZHEIMER PATHOLOGY. K.L.Goodison*, A.W.Clark, I.M.Parhad Pathology Dept., U. of Calgary, Alta, T2N-1N4, Canada.

Down's syndrome (DS) subjects almost invariably develop Alzheimer type (AT) pathology in the 4th decade. We have previously shown marked decrements of specific neuronal mRNAs in the neocortex of individuals with senile dementia of Alzheimer's type (SDAT). More recently we have shown that in SDAT the neuronal mRNA levels correlate inversely with the number of neurofibrillary tanlges (NfT). In this study we asked whether the AT changes seen in adult DS are associated with similar decrements. We used frontal cortex from 6 adult DS (25-57 yrs) and 2 controls (29, 53 yrs); 2 fetal DS and 1 control. There were amyloid plaques (AP) and NfT in neocortex of DS cases > 30 yrs. The least severe had 2 NfT and 31 AP/mm^2, and the most severe had 73 NfT and 68 AP/mm^2. Total RNA was isolated and Northern analysis performed using cDNAs for amyloid precursor protein (APP) and neurofilament light subunit (Nf-L). APP mRNA levels in DS remained 1.5X the control value, and Nf-L levels were the same as in controls. No decrement was detected even in the presence of the most extensive AT degeneration. We conclude that cortical neurons in DS, unlike those in SDAT, maintain their mRNA levels as NfT appear in the cortex. These findings indicate a difference between AT degeneration in DS and in SDAT at the level of gene transcription or RNA processing.

135.7

TAU MODIFICATION AND ALZ 50 REACTIVITY

K.S. Kosik, S.K. Bakalis*, H. Scoble*. Harvard Medical School, Boston, MA 02115 and Massachusetts Institute of Technology, Cambridge, MA 02139

Convergent data has demonstrated that tau is the antigen for Alz 50. The utility of this antibody is its robust reactivity on Alzheimer brain tissue sections where it can detect not only those neurons with neurofibrillary lesions, but also populations of neurons vulnerable to the lesions. This observation has led to the idea that Alz 50 may recognize a modification of tau that occurs early in the process of neurofibrillary degeneration. Human tau cDNAs which expressed a carboxy terminal tau fusion protein were reactive with Alz 50 on immunoblots after SDS-PAGE. However, when the bacterial plaque isolates were lifted onto nitrocellulose filters and reacted with Alz 50, no reaction was observed. The carboxy terminal location of the epitope was confirmed by direct sequencing of an Alz 50 reactive proteolytic fragment from bovine tau. Fast atom bombardment mass spectroscopy of the fragment contained an ion peak consistent with the presence of a phosphate in the sample with the reactive peptide. This in vivo phosphate bears an unknown relationship to the epitope. We conclude that the Alz 50 epitope is revealed by an unfolding of the carboxy terminus of tau and can be induced in vitro by denaturation with SDS, a process that might be analogous to the early transformation of tau into paired helical filaments.

TAU IMMUNOREACTIVITY IN ALZHEIMER'S DISEASE, NEURAL EXPLANTS UNDER ADVERSE CONDITIONS, AND IN HEAT-SHOCKED RATS. S.Ch. Papasozomenos, Dept. of Path., Univ. of Texas Med. Sch., Houston, TX 77225.

We have previously shown that localization of excessive tau immunoreactivity (TI) with ribosomes might be the primary event and its localization with the Alzheimer's abnormal filaments might be an epiphenomenon (Papasozomenos, S.Ch., Lab. Invest. 60:123 and 375, 1989). To test the hypothesis that excessive TI in Alzheimer's and other neurodegenerative diseases might be caused by stressful stimuli, we have examined by immunohistochemistry and immunoblotting rat fetal brains, rat fetal cerebral and dorsal root ganglia (DRG) explants following treatment with 1 μM monensin for 24 hr or 0.005% SDS for 18 hr or heat shock at 45^{o}C for 15 min. In cerebral explants, monensin, SDS and heat shock treatment produced marked increase in TI. In DRG explants, monensin, which interrupts the vesicular traffic in the Golgi region, produced accentuation of staining in a juxtanuclear region. Increased TI was also present in heat-shocked rats. Immunoblot analysis showed that: a)reduced amounts of the fetal form at tau, a 52 kd polypeptide, were always present in adult tissue, b)peripheral axons contained only one$\sim$130-140 kd tau polypeptides, which was always present in the DRG explants together with a 62 kd polypeptide, and in the CNS only in regions containing peripheral axons, c)in cerebral explants, 4 tau polypeptides of 52,54, 59, and 60 kd were progressively revealed with longer duration in vitro following dephosphorylation, and d) in all regions of CNS, 3 tau polypeptides of 52, 60, and 66 kd and another of 68 kd revealed only after dephosphorylation were present. These findings suggest that tau may play a role in the stressful response and its precise molecular changes can be studied by correlative analysis of in vitro and in situ models.

135.9

A DEVELOPMENTALLY-REGULATED CHYMOTRYPSIN-LIKE SERINE PROTEASE IN RAT BRAIN. R.B. Nelson and R. Siman, Medical Products Dept., The DuPont Co., Wilmington, DE. 19880.

Using substrate-containing polyacrylamide gels, we have identified a M_r 25 kD protease in rat brain which is active at neutral pH. This activity was classified as a serine protease on the basis of its inhibition by DFP and PMSF. The protease, termed SP-25, was more specifically characterized as a chymotrypsin-like enzyme (C-terminal cleavage of aromatic amino acids) using peptide boronic acid synthetic inhibitors. SP-25 was distinct from plasminogen activator as its activity was not modified by plasminogen. SP-25 was first detected in neonatal forebrain, but was below detection level in adult forebrain. It was exclusively associated with particulate vs. soluble fractions. SP-25 was not extractable from particulate fractions by Zwitterionic and nonionic detergents, nor by subsequent low-salt or high-salt treatment of the detergent-insoluble pellets. These characteristics suggest a tight association of the protease with cytoskeletal elements. SP-25 activity was partially inhibited by several divalent cations, including Ca^{++}. Although the functional significance of this brain protease is unclear at present, recent immunohistochemical studies indicate the presence of an inhibitor of chymotrypsin-like enzymes (α-1-antichymotrypsin) in both normal CNS and as a core component of neuritic plaques in Alzheimer's disease. The present evidence is the first to describe a chymotrypsin-like enzyme in brain which might interact with α-1-antichymotrypsin, and raises the possibility that SP-25 or similar proteases still to be found in brain may directly participate in certain CNS pathologies.

135.10

ELECTRON MICROSCOPIC LOCALIZATION OF CHOLINESTERASES IN ALZHEIMER BRAIN TISSUE. K.A. Carson, C. Geula and M-M. Mesulam. Harvard Medical School, Boston, MA; Old Dominion University and Eastern Virginia Medical School, Norfolk, VA.

Light microscopic examination demonstrated that neurofibrillary tangles (NFTs) in Alzheimer's Disease (AD) appeared to have acetylcholinesterase (AChE) and butyrylcholinesterase (BChE) activity (Mesulam and Moran, Annals of Neurol., 1987). The studies reported here were undertaken to reveal the subcellular site of this enzymatic activity. Frozen sections from fixed AD brains were used to demonstrate AChE and BChE activity with appropriate specific inhibitors. Following light microscopic examination the tissue was osmicated, embedded in epoxy resin and thin sectioned. In areas that contained AChE- or BChE-positive NFTs by light microscopic examination, the electron microscope showed that the reaction product was specifically associated with dense bundles of tangle-like intraneuronal filaments. Extraneuronal (ghost) tangles were often unstained. In contrast to tangle-bearing neurons, normal AChE-positive neurons contained reaction product in the nuclear envelope and rough endoplasmic reticulum, but not associated with neurofilaments. These observations confirm our earlier reports that NFTs have cholinesterase (AChE and BChE) activity and that this represents a major deviation from the subcellular distribution of cholinesterases in normal neurons.

135.11

CASEIN KINASE II IS ASSOCIATED WITH NEUROFIBRILLARY TANGLES IN ALZHEIMER'S DISEASE. D. Iimoto, E. Masliah*, and T. Saitoh, University of California, San Diego, School of Medicine, Neuroscience Dept., M-024, La Jolla, 92093, U.S.A.

Alzheimer's disease (AD) is characterized by the formation of structures known as neurofibrillary tangles (NFT) and neuritic plaques (NP). The composition of these structures is just now being elucidated. Because there are several aberrantly phosphorylated proteins, tau and neurofilaments, that are associated with NFT and the neuritic component of NP, it is likely that there is a kinase and/or phosphatase responsible for this abnormal post-translational modification. Yet none of the kinases that have been shown to phosphorylate tau have been proven to be responsible for tau phosphorylation in AD.

Casein kinase II (CK-II) was shown to be aberrant in AD in that its amount as measured by its immunoreactivity on a Western blot was 60% lower in AD than in control samples. We have evidence that the localization of CK-II is also altered in AD. Rabbit anti-CK-II serum reacts with NFT and the neurite component of plaques in AD. Furthermore, the anti-CK-II antibodies recognize NFT from a variety of other dementias including Picks' bodies, progressive supranuclear palsy, and Kuf's disease. Using Proteinase K treatment, the antibody staining pattern differed from the antibody staining of the other major components of NFT. These include anti-tau, anti-ubiquitin, and Alz-50. The colocalization of tau and CK-II on NFT suggests that CK-II may be responsible for phosphorylating tau and/or neurofilaments in AD.

HUMAN ANTIBODIES PREFERENTIALLY REACTIVE WITH BRAIN OR WITH TEMPORAL CORTEX IN ALZHEIMER'S DISEASE. F. Gaskin, M.R. Farlow*+ and S.M. Fu*, Univ. of Virginia Sch. of Med., Charlottesville, VA 22901 and +Indiana Univ. Sch. of Med., Indianapolis, IN 46223.

Monoclonal or oligoclonal Epstein Barr Virus transformed cell lines from patients with Alzheimer's disease (AD), Gerstmann-Straussler-Schreinker Syndrome-AD (GSS-AD), post stroke and age-matched controls were established. In our initial study, antineurofibrillary tangle (NFT) and antineural antibodies (Abs) were present in cell lines from AD and control groups. We have extended our studies. To date, 2489 cell lines have been screened for their reactivity on the temporal cortex of three AD brains and four age-matched control brains, HeLa cells and human fibroblast and neuroblastoma cell lines. We found 13 Abs that react only with AD brain and an additional eight Abs that react only with brain. These cell lines were derived from one patient with a neuropathological confirmation of AD, one patient with GSS-AD, one control aged individual and two patients with a history of stroke. Reactive structures included NFT, plaque neurites, neuritic processes, astrocytes, filaments and nuclei. These Abs constitute an unique resource to explore NFT, plaques and astrocytes in AD and other neurodegenerative diseases. Supported by AG-06348 and the Eleanor Naylor Dana Trust (New York).

136.1

ISOLATION OF A PEANUT AGGLUTININ-BINDING GLYCOPROTEIN FRACTION WHICH INHIBITS AXON GROWTH IN THE CHICK EMBRYO. J.A. Davies*, S.A. Wajed*, G.M.W. Cook*, C.D. Stern* and R.J. Keynes. Department of Anatomy, University of Cambridge, Cambridge CB2 3DY, U.K., and Department of Human Anatomy, South Parks Road, Oxford OX1 3QX, U.K.

The segmented pattern of peripheral spinal nerves in higher vertebrates is generated by interactions between growing nerve cells and somites. Neural crest cells, motor axons and sensory axons grow preferentially through the anterior half of each successive somite-derived sclerotome, and are excluded from posterior (P) half-sclerotome. In chick embryos, P cells bind the lectins peanut agglutinin and jacalin. By affinity chromatography with immobilised lectins we have isolated a glycoprotein fraction from chick somites with inhibitory activity for axon growth. Using a method devised by Dr J.A. Raper (University of Pennsylvania), in which liposomes containing the fraction are applied to cultures of chick sensory neurons, growth cones are found to undergo abrupt collapse, recovering within 8 hours of liposome removal. By SDS-PAGE the active fraction has two major components of apparent M_r 48,000 and 55,000. Rabbit polyclonal antibodies directed against these components recognise P cells only, consistent with a role for this material in excluding axons from P-sclerotome in vivo. Collapsing activity is attenuated following treatment with various endo-glycosidases, suggesting that N-linked glycan(s) may participate in the inhibitory mechanism.

136.2

TIME-LAPSE OBSERVATIONS OF NEURITE GROWTH BY SYMPATHETIC PREGANGLIONIC NEURONS *IN VITRO*. S.J. Moorman* and R.I. Hume (SPON: J. Walker) Dept. of Biology, University of Michigan, Ann Arbor, MI

Time-lapse microscopy studies have shown that neurons from chick embryos can respond in several different ways to the same extracellular matrix molecules, and to molecules on the cell surfaces of other neurons. This suggests that neurons respond in a cell-type specific manner to environmental signals. We previously developed methods, using the fluorescent dye di-I, that allow us to unambiguously identify particular classes of CNS cells in culture. Here, we examine the growth and interactions *in vitro* of neurites from an identified type of CNS cell, sympathetic preganglionic neurons.

Spinal cord cells from stage 30-32 chick embryos were plated onto laminin coated glass cover slips, and the growth of neurites from preganglionic neurons was observed beginning 24 hours after plating. The growth cones of all neurites of each cell were tracked for 2 to 6 hours using a digital image acquisition/analysis program. Our initial analysis included only cells whose growth cones did not encounter other cells or cell processes during the entire observation period. The growth rate of preganglionic neurites averaged 42.7 um/hr at 37° C, but when the growth of all of the neurites of a single cell was examined it became clear that the dynamics of growth are very complex. A variety of behaviors were observed, including; all neurites extending at the same time but at different rates, some neurites extending and some retracting at the same time, and one neurite growing while the others neither grow nor retract. We conclude from these observations that the growth of the different neurites of a single cell is relatively autonomous.

We also determined the effect of cell-cell contact on the rate of neurite extension. We found that when preganglionic neurites encountered the cell bodies and processes of their normal target cells, sympathetic ganglion neurons, they typically crossed them, although the rate of growth often transiently slowed. This behavior is very different from the growth cone collapse that has been reported by others to be the most common interaction *in vitro* between central and peripheral neurons that do not normally contact each other.

136.3

INTERACTION OF GOLDFISH RETINAL AXONS WITH FISH OLIGODENDROCYTES *IN VITRO* M. Beckmann* M.Bastmeyer and C.A.O.Stuermer, Friedrich-Miescher-Lab. der Max-Planck-Ges., Tübingen, FRG.

Mammalian oligodendrocytes impair the growth and regeneration of mammalian neurites *in vivo* and *in vitro*. These cells also affect goldfish retinal axons: Upon contact with mammalian oligodendrocytes, 60% of the fish growth cones collapsed, 40% avoided the cells, but never grew over the cells (Bastmeyer et al., 1988). To test whether the properties of fish oligodendrocytes differ from mammalian oligodendrocytes, we monitored the encounter of goldfish retinal axons with fish oligodendrocytes using time lapse videomicroscopy. Fish glial cells were cultured either from regenerating goldfish optic nerves or from brains of juvenile zebrafish. Oligodendrocytes were identified by the antibody O1.

1) Oligodendrocytes from optic nerves: Cells were bi- or multipolar and proliferated over several weeks. From 10d *in vitro* onwards most cells were $O1^+$, and, unexpectedly, coexpressed GFAP. Goldfish retinal axons grew readily over or even on these cells.

2) Oligodendrocytes from zebrafish brains: $O1^+$ cells were either of stellate or (like mature mammalian oligodendrocytes) of flat morphology and rarely $GFAP^+$. When confronted with fish oligodendrocytes of stellate morphology roughly 80% of the axons grew over the $O1^+$ cells. However, more than 20% of the growth cones retracted and 55% grew around the $O1^+$ cells of flat morphology, suggesting that these cells are not growth permissive.

Whether fish oligodendrocytes with flat morphology possess inhibitory proteins typical for mammalian oligodendrocytes remains to be investigated.

136.4

IN VITRO REGENERATION OF ADULT RAT RETINAL GANGLION CELL AXONS ON ASTROCYTES: GROWTH CHARACTERISTICS AND MOLECULAR MECHANISMS. M. Baehr[1], M. Schachner[2] and R.P. Bunge[3]. [1]Max-Planck Institut fur Entwicklungsbiologie, Tuebingen, FRG; [2]Univ. Heidelberg, FRG; [3]Dept. of Anatomy & Neurobiology, Washington Univ. Sch. Med., St. Louis, MO.

The adult rat optic nerve, which contains astrocytes and oligodendrocytes, is non-permissive for regenerating axons in vivo and in vitro. In order to investigate the influences of characterized populations of astrocytes on injured retinal ganglion cells (RGC) of the adult rat, we have studied RGC survival and axon regrowth in vitro. Retinal explants were obtained from adult rats 5 days after optic nerve crush and cultured with preparations of Type I cortical astrocytes prepared from newborn rats. Astrocyte cultures were used 7-10 days after purification (immature astrocytes expressing a flat morphology) or after subculturing for more than 3 weeks and shifting to defined medium (mature astrocytes expressing a stellate morphology). Neither flat (immature) or stellate (mature) astroglia, enhanced RGC survival in vitro. Both astroglia preparations, however, were permissive for the growth of regenerating RGC axons. The growth rate of axons on flat astrocytes was significantly higher than on stellate astrocytes. Polyclonal antibodies against murine sarcoma laminin, which decorated the surface of flat astrocytes, reduced the growth of RGC axons by more than 60% compared to controls. Growth of adult RGC axons on astrocytes was not significantly affected by antibodies against the cell adhesion molecules L1 or N-CAM, or the surface antigen Thy-1. From these studies of adult mammalian retinal tissue we conclude that the extracellular matrix component laminin, when expressed by astrocytes, is involved in mediating the regeneration of RGC neurites obtained from adult rats. 136.5

ANTIBODIES AGAINST THE CELL ADHESION MOLECULE L1 DO NOT BLOCK GROWTH OF ADULT RAT RETINAL GANGLION CELL AXONS ON SCHWANN CELLS. J.M. Hopkins, M. Schachner[1] and R.P. Bunge, Dept. Anat. & Neurobiol., Washington Univ., St. Louis, MO, USA; [1]Dept. Neurobiol., Univ. Heidelberg, Heidelberg, FRG.

Previous in vitro studies have demonstrated that isolated Schwann cells (SC) as well as Schwann cells with their basal lamina (SC+BL) support regeneration of axons from adult rat retinal ganglion cells (RGC). As part of a search for cell surface molecules responsible for the support of adult RGC axon regeneration, we have cultured explants of adult rat retina (5 days after optic nerve crush) on SC and SC+BL in the presence of antibodies against laminin or L1. Two measures of neurite growth were examined; the number of neurites which emerged from the explant to grow on the substratum (neurite access) and the rate of neurite elongation on the substratum (rate of growth). Antibodies against L1 did not reduce neurite access to either SC or SC+BL. The rate of growth on SC or on SC+BL was not significantly reduced by anti-L1. Antibodies against laminin did not reduce neurite access to SC, but did reduce access of neurites to SC+BL by 90%. Anti-laminin reduced the apparent rate of growth on SC+BL, but not on SC. These results suggest that the isolated SC surface supports growth of adult RGC axons via mechanisms that do not rely primarily on L1 or laminin alone, and that laminin may be involved in growth on SC+BL. The reduction of neurite access to SC+BL substrata by anti-laminin suggests that regenerating adult RGC neurites interact with laminin in the BL before gaining access to the underlying SC surface. Since it has recently been shown that the growth of embryonic rat retinal neurites on SC is dependent on L1, our current results reveal a fundamental difference between neurite growth mechanisms during development and regeneration in the mammalian visual pathway. [NS09923 (RPB), EY06073 (JMH), BMFT 0701771/4 (MS)]

136.6

AXOTOMY INDUCES NEURITES FROM RAT SEPTAL-BASAL FOREBRAIN EXPLANTS TO PREFERENTIALLY ELONGATE ON LAMININ. M. Schinstine & C.J. Cornbrooks, Dept. of Anatomy & Neurobiology., Univ. of Vermont, Burlington, Vt. 05405.

We have previously reported that Schwann cell-derived basal lamina acts as a preferred substratum for the elongation of neurites from embryonic day (E)18, but not E15, CNS neurons (Dev. Brain Res.,(1988) 43:23-37). These observations led to the hypothesis that regenerating (E18) and newly differentiated (E15) axons differentially respond to a laminin substratum. The present study was conducted to determine if rat, embryonic septal-basal forebrain neurons would preferentially elongate on a laminin substratum after axotomy. The length of neurites in E15 primary explant cultures was similar on laminin and collagen. In contrast, neurites from E18 SBF neurons grew significantly longer on laminin as compared to a collagen substratum. E15 explants could be induced to extend longer processes on laminin if they were axotomized after 5 days in primary culture and replated onto a laminin substratum in secondary culture. Under these conditions, neurites from axotomized E15 explants grew 27% longer on laminin as compared to growth on collagen. Control E15 explants, maintained in primary, suspension culture to avoid axotomy, demonstrated similar growth rates on laminin and collagen in secondary culture. These results suggest that embryonic, SBF neurons become more responsive to a laminin substratum subsequent to axotomy. Supported by NS 21811.

EVIDENCE FOR INHIBITION OF AXON OUTGROWTH BY KERATAN SULFATE/CHONDROITIN SULFATE PROTEOGLYCAN IN VIVO AND IN VITRO. D. M. Snow, V. Lemmon and J. Silver. Center for Neurosciences, Case Western Reserve University, Cleveland, Ohio 44106.

It has been suggested that inhibition of axonal growth cones may be as important a mechanism in the guidance of axons during development as is attraction. In a previous abstract (Snow et al., Soc. Neurosci. Abst., 1987), we presented in vivo data which suggested that keratan sulfate is present in the roof plate of the developing spinal cord at a time period when the dorsal column axons and the ventral commissural axons are elongating near the roof plate but do not cross the dorsal midline. We noted that other structures or regions which contain keratan sulfate are also not innervated, such as cartilage, epidermis and the dorsal midline of hamster tectum.

We report here that in an in vitro bioassay using intersecting stripes of various substrates bound to nitrocellulose-coated tissue culture dishes (Lagenaur and Lemmon, 1987), embryonic chick retinal neurites were inhibited from proceeding along the permissive substrate, laminin, when presented with a crossing stripe of keratan sulfate/chondroitin sulfate proteoglycan (KS/CS-PG). Retinal neurites grew robustly up to the edge of the KS/CS-PG then consistantly stopped abruptly or turned away and grew along the permissive substrate.

These data suggest that KS/CS-PG may function, in part, to inhibit axonal growth cones in vivo during development.

136.8

REMOTE TARGET CONTROL OF INDUCTION AND DIRECTIONAL GROWTH OF AXON COLLATERALS IN THE MAMMALIAN BRAIN. C.D. Heffner, A.G.S. Lumsden & D.D.M. O'Leary (SPON: L. Harris) Dept. of Neurosurgery, Washington Univ Sch of Med, St. Louis, MO 63110

Individual neurons in the brain send axons over considerable distances to multiple targets. An amenable system for studying axon growth and target selection is the mammalian corticopontine projection. This major connection develops from parent corticospinal axons that days before have grown past the pons, by a delayed interstitial budding of collaterals which then grow directly into their target, the basilar pons (O'Leary & Terashima, 88, Neuron 1:901). Thus, in this system, unlike others characterized to date, the target is not recognized by the growth cones of the primary axons, but the budding of collaterals at stereotypic positions suggests that cues do identify the basilar pons as a cortical target. Here we present evidence that the maturing basilar pons produces a diffusible signal that acts on the overlying cortical axons and induces the budding and directed ingrowth of collaterals. Basilar pons, co-cultured with appropriately aged explants of cortex in 3-D collagen matrices (which enable the detection of diffusible activities - see Lumsden & Davies, 86, Nature 323:538), attracts growing cortical axons by growth cone turning from a distance of 200-300 um, and also elicits the formation of collaterals within the cortical explant and their directional growth across the intervening matrix, as revealed by retrograde DiI filling. Control explants (olfactory bulb, mammillary bodies, hypothalamus, neocortex) do not elicit these effects. Thus, this influence appears to be target specific. Our in vitro evidence that a signal derived from the pontine target can operate over a distance and affect the elaboration of a major projection suggests an important role for diffusible molecules in the establishment of connections in mammalian brain. J1/TENASCIN IS AN INHIBITORY SUBSTRATE FOR CEREBELLAR NEURONS. A. Faissner* (SPON : D. Ganten). Dept. of Neurobiology, University of Heidelberg, Im Neuenheimer Feld 364 6900 Heidelberg, Germany (FRG).

The functional properties of J1/tenascin were investigated in vitro. J1/tenascin is an extracellular matrix (ECM) constituent consisting of two glycoproteins of 200 kD and 220 kD apparent molecular weight. It is transiently expressed by astrocytes during CNS development and mediates neuron-astrocyte interactions. We have prepared monoclonal antibodies against J1/tenascin and used J1/-tenascin immunoaffinity purified from early postnatal mouse brains to analyze its effects on the behaviour of defined neural cell types. Patterned substrates were constructed by absorbing J1/tenascin or other ECM components to poly-ornithine (PORN) treated glass coverslips and removing the glycoproteins from selected areas. Cerebellar granule cell neurons plated onto these substrates avoided J1/tenascin containing regions, whereas they grew well on PORN alone or PORN covered by laminin or fibronectin. The inhibitory activity of J1/tenascin was inactivated by heat or UV irradiation. In contrast to neurons, mouse cerebral astrocytes, the major source of J1/tenascin in the CNS, behaved normally on J1/tenascin carrying PORN surfaces. In view of these results and the pattern of expression of J1/tenascin during cortical barrel field formation (Steindler et al., Dev. Biol. 131, 243-260 (1989)), we propose that J1/tenascin is involved in CNS pattern formation.

136.10

LOCALIZATION OF A DEVELOPMENTALLY REGULATED MOLECULE DEFINED BY OZ42 ON ISOLATED CEREBELLAR GRANULE CELLS FROM EARLY POSTNATAL MICE. L.B. Pickford,[1]* P.E. Sheehy,[2]* D.A. Brown[2]* & R.V. Rouse[1]. Dept. of Pathology, Stanford Univ. School of Medicine, Stanford[1] & Veterans Admin. Hospital, Palo Alto[2], CA. (SPON: L.F. Eng)

Cerebellar granule cells (GC) complete their development postnatally undergoing proliferation, migration, axon and dendrite growth and synaptogenesis. OZ42 is a monoclonal antibody which specifically recognizes the deep region of the transitory external granular layer which contains postmitotic, premigratory GC (Pickford et al., (1989) J. Neurocytol., 18, in press). The temporal and spatial pattern of reactivity to OZ42 suggest an association with early axon extension by GC or with initiation of migration across the cerebellar molecular layer. We have examined the immunoreactivity of isolated GC cultured for different time periods and in cytospin preparations of freshly isolated GC. GC suspensions were prepared by mechanical disruption, incubated on poly-D-lysine coated glass microwell slides or coverslips, then acetone fixed and stained with antibodies. The reactivity of the GC was determined by immunoperoxidase, fluoresence and immunoelectron microscopy (IEM), using both single and double labelling methods to identify reactive cell types. In cytospin preparations small round cells with large nuclei (GC) had extranuclear reactivity with OZ42 in partial or complete rings. The proportion of reactive to unreactive small cells at different postnatal ages from P0-P20 correlated with the relative amount of reactivity in tissue sections at the same ages. Antibodies reactive with other cell types, including Thy1, glial, macrophage and endothelial cells showed distinct patterns of reactivity. Primary cultures developed networks of processes from both glial and neural cells. The presumptive GC neurites were very fine in cross section but were readily detectable with transmission and scanning IEM 24 hours after plating. A time course for this reactivity from 0-72 hours after plating of GC suspensions from mice of ages P0-P20 will be presented. This study indicates that the molecule recognized by OZ42 is expressed during GC axon development.

136.11

APLYSIA PROTEIN AP-100 IS A NEURON-SPECIFIC MEMBRANE PROTEIN ENRICHED IN SYNAPTOSOMES. F. Keller and S. Schacher, Ctr. for Neurobiol. & Behav., CPS, Columbia University and NYS Psych. Inst., New York, NY 10032.

We have generated a panel of monoclonal antibodies (Mabs) directed against membrane proteins in the CNS of juvenile *Aplysia californica*, with the aim of identifying and isolating membrane molecules involved in neuritic outgrowth and synapse formation. Several Mabs recognize antigens which are enriched in the neuropil (tissue sections), and in synaptosomes (sucrose-gradient fractionation). One antibody, Mab 4E8, appears to recognize a 100 kDa integral membrane protein, which is only present in the nervous system, is localized in a subset of neurons, and is enriched in synaptosomes. The protein was immunoprecipitated and is presently being sequenced with the method described by Kennedy et. al. (PNAS 85:7008, 1988). Interestingly, other protein bands are co-precipitated with the 100 kDa protein but do not crossreact with the antibody. Their identity and association with the 100 kDa protein is currently being investigated. Mab 4E8 appears to specifically perturb the pattern of neuritic growth in culture (S. Schacher and F. Keller, Abstract presented at this meeting). Furthermore, we are investigating how these membrane proteins might be associated with the cytoskeleton and with intracellular second messenger systems which are thought to shape developing axons and synapses.

136.12

MONOCLONAL ANTIBODY (MAB) THAT RECOGNIZES APLYSIA PROTEIN AP-100 ALTERS PATTERN OF NEURITE OUTGROWTH BY IDENTIFIED APLYSIA NEURONS IN CULTURE. S. Schacher and F. Keller. Ctr. for Neurobiol. & Behav., Columbia CPS & NYS Psych. Inst., New York, NY 10032.

Mab 4E8 recognizes a neuron-specific membrane protein that is localized to axons and terminal regions in the intact CNS of Aplysia (F. Keller and S. Schacher, Abstract in this volume). A similar pattern is observed for abdominal ganglion cells in culture. All identified cells examined thus far by light microscopic immunofluorescence, with the exception of the right upper quadrant cells (R3-R13), are stained positively with 4E8. Positive reaction is restricted to axons and regenerated neurites and appears to be enriched at growth cones. To explore the role of the antigen recognized by 4E8, we compared the pattern of neurite outgrowth for a number of identified cells maintained continuously in the presence of 4E8 to that obtained for cells maintained either without antibodies or with various control antibodies. Compared to the other treatments, 4E8 appeared to defasciculate extending neurites into a large number of finer diameter processes. The antibody had no significant effect, however, on the time required to initiate neurite outgrowth or on the rate of neurite extension. The consequences of 4E8 application on the structure and motility of growth cones, and on the cell-cell interactions associated with synapse formation are being investigated.

137.1

CHOLINERGIC NEURON ATROPHY AND SEVERE SPATIAL MEMORY IMPAIRMENTS IN AGED RATS ARE PARTIALLY AMELIORATED BY CHRONIC INFUSION OF NGF. (SPON: G. Doucet)
W. Fischer*, K. S. Chen§, F. H. Gage§ and A. Björklund, Dept. Med. Cell. Res., University of Lund, Sweden and §Dept. Neurosci. UCSD, 92093, USA.

In a previous experiment, we showed that continuous intracerebral infusion of NGF improved retention of a spatial memory test in aged (23-25 month) female Sprague Dawley rats and partially ameliorated cholinergic neuron atrophy, as visualized by AChE histochemistry. In the present study we have pursued this NGF-effect further using a combination of ChAT and NGF receceptor immunocytochemistry in behaviorally severely impaired 28-30 month old rats. NGF was administered during 4 weeks into the lateral ventricle using osmotic minipumps (0.25 ug/day). As previously, the NGF treated rats showed improved retention of place navigation in the Morris' watermaze. Using a double labelling procedure, neurons which were stained for ChAT, NGF-receptor or both, could be detected and analyzed. The mean number of measured ChAT positive neurons was about 560 in the aged group and 940 in the young group. Proportionally, about 15% of all the ChAT positive neurons in the NBM in the aged group and about 20% in the young group only stained for ChAT. Cell size: In the vehicle-treated group, size of double labelled neurons was reduced by about 15% compared to the young animals. The single labelled neurons showed a further reduction to about 25% compared to the young group. This was also observed on the contralateral side of the infusion in the NGF-treated animals. On the NGF-infused side, an increase in cell size compared to the contralateral (nonimfused) side of about 25% of double labelled and single labelled neurons was observed. Cell numbers: An approximate 30% loss of double labelled neurons, compared to the young group was observed in both aged groups. A reduction in the number of single labelled ChAT-positive neurons of about 60% was detected in the NGF- as well as the vehicle treated rats. Taken together with previous results, these findings further support the notion that the cholinergic neurons in the NBM are affected by the ageing process and that NGF exerts an important trophic effect on these atrophic neurons.

137.2

RESTITUTION OF STRUCTURE IN HEMISECTIONED RAT SPINAL CORD BY X-IRRADIATION.
N. Kalderon#, J. Palmer,# A. Alfieri*, J.H. Kim* and Z. Fuks*. Rockefeller Univ.# and Radiation Oncology Dept., Memorial Sloan-Kettering Cancer Cnt., NY, NY 10021.

The potential use of x-irradiation in the management of CNS injury is being studied. It was established in our studies that irradiation of severed olfactory bulbs (OBs) resulted in reduction/elimination of reactive astrocytes at the site of incision, structural healing with partial anatomical regeneration, rescue of axotomized primary neuronal (mitral) cells and salvage of the tissue from degeneration (Kalderon et al., Proc. Natl. Acad. Sci., 1989 submitted). These results suggest that irradiation eliminates cells which obstruct and impair the cascade of recovery processes in injured CNS. We report here effects of irradiation on transected spinal cord. Experiments were performed on adult rat spinal cords which were hemisectioned at thoracic level T11-T12. Radiation was delivered at 16-18 days postinjury (total dose 10 Gy), and animals were analysed 60 days after injury. Segments of the lesioned cords (15-20mm) were cryostat-sectioned and analysed by histological and immunocytochemical techniques. Results so far show that as in the OB, x-irradiation is effective in averting some of the deleterious consequences of transection injury to the adult rat spinal cord. Irradiadion of the hemisectioned cords led to partial restitution of structural integrity along the site of incision, preservation of neurons and extensive neurite growth (neurofilament staining) around the cut.

137.3

PREFERENTIAL MOTOR REINNERVATION:PATHWAY REGULATION.
T.M.Brushart.Dept. of Neurology, Johns Hopkins Univ., and the Curtis Hand Center, Baltimore Md. 21218.

When regenerating motor axons are given equal access to sensory and motor branches of the rat femoral nerve, they preferentially reinnervate the motor branch (J. Neurosci. 8:1026-31). Pruning axon collaterals from inappropriate distal pathways may contribute to generation of this specificity (Neurosci. Abst. 14:166). The present experiments evaluate the role of the pathway in this process. Both femoral nerves of 30 3 week old female Sprague Dawley rats were severed proximally and the stumps separated by 1/2mm within silicon tubing to eliminate mechanical axon alignment as a source of specific regeneration. The distal sensory and motor branches of these nerves were severed at the level of quadriceps innervation,ligated, and enclosed within silicon caps to deny regenerating axons end organ contact. Groups of 10 animals were evaluated at 2,3,and 8 weeks by application of HRP to one femoral branch and Fluoro Gold to the other. The mean number of motoneurons projecting axons into the motor and sensory branches was not significantly different at 2 wks (M-106,S-96), but at 3 wks (M-142,S-82) and 8wks (M-175,S-70) a significant difference was found (p=.01). The mean number of double-labeled neurons decreased significantly (p=.01) from 62 at 2wks to 43 at 3 wks and 26 at 8 wks. Regenerating motor axons demonstrated no preference for motor or sensory Schwann cell tubes at 2 wks. Neurotropic guidance of axons to "correct" Schwann cell tubes is thus unlikely. Previous work has shown the pruning of axon collaterals to accompany the generation of specificity. In the present experiments this occurred even when end organ contact was denied. There is thus a specific interaction between regenerating motor axons and old motor pathways which is probably trophic in nature.

REGENERATION OF THE GOLDFISH MAUTHNER CELL DOES NOT UNDERLIE BEHAVIORAL RECOVERY OF THE STARTLE RESPONSE.
S.I. Zottoli, S.C. Northen*, and T.L. Scalise*. Dept. of Biology, Williams College, Williamstown, MA 01267.

The goldfish central nervous system is capable of functional regeneration after spinal cord injury. Although many behaviors including swimming return by 3 months, a startle response (C-start) does not return until about 6 months postoperatively. To test whether functional regeneration of the Mauthner cell (M-cell) could underlie the return of a C-start, we have studied the EMG responses elicited by intracellular M-axon stimulation in goldfish. Ten control and 7 experimental fish were pretested for startle responses with a sound pulse. The animals responded with C-starts in approximately 80% of the trials. The spinal cords of the experimental fish were crushed at the spinomedullary level. After injury, these animals all regained swimming, and equilibrium in 2-3 months. They all displayed C-starts beginning at about 6 months. 421-468d postoperatively these fish were restrained and EMG electrodes were placed bilaterally in the trunk and tail musculature. The M-axon was activated by intracellular stimulation, EMG responses were recorded, and visual observations of trunk and tail muscle movements were made. The EMG responses and movement of trunk musculature of the experimental fish were significantly smaller than those of controls. Although the M-cell is capable of regeneration caudal to a wound site, we suggest this regrowth does not underlie the return of a C-start. Therefore, we hypothesize that the C-start recovery results from functional regeneration of another neuronal system. Supported by NSF grant BNS 8809445.

137.5

ADULT SYMPATHETIC AXONS REGENERATE INDEPENDENTLY OF NGF.
Andrew Gloster and Jack Diamond. Dept. of Biomedical Sciences, McMaster University, Hamilton, Ontario CANADA L8N 3Z5.

In the adult rat the functional regeneration of crushed sensory nerves, but not the collateral sprouting of undamaged ones, occurs independently of endogenous NGF (PNAS 1987; 84, 6596). We have now studied sympathetic neurons, which retain their need for NGF throughout life (Gorin and Johnson, 1980; Brain Res. 198, 27). Sympathetic axons were revealed by amine fluorescence, and their cutaneous fields by evoked pilomotor responses. As expected, daily anti-NGF treatment appeared to prevent sympathetic collateral sprouting into surrounding denervated skin; it also reduced the fluorescence of the dermal axons to undetectable levels, although fluorescent axons were visible within the nerve trunk. In normal animals, sympathetic nerves regenerating after a crush restored pilomotor function to denervated skin at about the same rate as regenerating C fibers restored heat-nociception. We tested how daily anti-NGF treatment would affect this. Not only did regeneration of sympathetic axons occur along the nerve trunk, as evidenced by their fluorescence, but in a significant number of instances pilomotor responses were restored to the skin. It seems that, like sensory axons, sympathetic fibers regenerate independently of NGF. However, prolonged anti-NGF treatment reduces amine levels, and may compromise pilomotor function. We are now examining whether enhancement of amine content will improve the incidence of functional recovery by regenerating axons.

137.6

MUSCLE REINNERVATION BY CNS AXONS REGENERATING VIA VENTRAL ROOTS IMPLANTED INTO THE SPINAL CORD.
K.J. Smith[1] & R.T. Kodama[2]* (SPON: C. Morgan). Depts. Anatomy & Cell Biology[1], Urology[2], Eastern Virginia Medical School, Norfolk, VA, 23501, & Neurology[1], U.M.D.S., Guy's Campus, London SE19RT

Central axons can regenerate into a peripheral nerve implanted into the spinal cord, but the ability of these axons then to innervate denervated muscle has been little investigated. To examine this, 17 rats had their T8 ventral root (VR) divided, and a cord stab. In 11 rats, the distal VR stump was implanted into the stab. After 12-15 months, the implant was isolated by severing the ipsilateral T_{7-9} VRs (redividing the T_8 proximal stump) and intercostal nerves (ICN) 4-7 & 9-12. Pharmacological and electrical stimulation (ES) of the spinal cord were used to activate individual motor units in the 8^{th} intercostal muscle. Our criteria for considering a motor unit as reinnervated by central axons included the presence of: a) "giant" potentials, b) with ES, the latency jitter expected from a variable central synaptic delay, and c) the presence of the initiating nerve impulse in the 8^{th} ICN. These criteria were met in implanted animals only. We conclude that central regenerating axons can establish effective synapses on denervated skeletal muscle. Supported by NIH grant NS25118.

IDENTIFICATION OF CELL TYPES EXPRESSING MHC ANTIGENS IN THE RAT CNS AFTER SUBLETHAL AND LETHAL NEURONAL INJURY. W.J. Streit, M.B. Graeber and G.W. Kreutzberg. Dept. of Neuromorphology, Max Planck Institute for Psychiatry, D-8033 Martinsried, F.R.G.

Recent studies from different laboratories have shown that not astrocytes, but microglial cells function as antigen presenting cells in the brain. In the present study we show that few perivascular and microglial cells carry Ia antigen in normal brain, but that Ia expression is greatly enhanced on these cell types after local neuronal injury. One week after transection of the facial nerve or intraneural ricin injection a striking increase in the number of Ia-positive perivascular cells was observed in the facial nucleus. This increase was more pronounced after ricin treatment than after axotomy. From week 2 to 6 Ia-immunoreactivity was found increasingly on microglial cells while at the same time the number of Ia-positive perivascular cells was decreasing. The changing morphology of Ia-positive cells occured much faster during ricin-induced neuronal degeneration than during regeneration. Ia-positive cells had disappeared completely from the degenerated facial nucleus by week 15, but persisted in the regenerating nucleus in the form of ramified microglia. Based on our observations we suggest that microglia are heterogeneous with regard to their ability to express MHC antigens, and that Ia-positive microglia arise through direct transformation of Ia-positive perivascular cells.

INDUCTION OF MAJOR HISTOCOMPATIBILITY CLASS I ANTIGENS ON ADULT PRIMATE RETINAL CELLS IN VITRO. *M.R. Burrous and P.R. MacLeish*, Laboratory of Neurobiology, Rockefeller University, New York, New York 10021

The expression of the major histocompatibility (MHC) class I molecules has been reported to be inducible on neonatal CNS neurons by interferon both *in vivo* and *in vitro* (Wong *et al.*, Nature 310: 688 (1984)). We have investigated the expression of MHC class I antigens on cells isolated from the adult monkey retina and maintained with or without human gamma interferon (IFN) in the growth medium. The presence of class I MHC antigen was detected by immunofluorescence labelling with the monoclonal antibody W6/32 (kindly donated by Ralph Steinman) and by observing adhesion and process outgrowth of retinal cells cultured on a monolayer of this class I MHC antibody. When grown in the absence of IFN on W6/32 antibody, retinal cells showed weak labelling by 5-7 days in culture, but a striking enhancement in process outgrowth over cells grown on other substrates (including antibodies to the class II MHC molecules). In cultures treated with IFN (1-100 units antiviral activity/mL), there was a clear dose-dependent increase in the labelling of nearly all cells growing directly on the W6/32 substrate. IFN also effected even more complex elaboration of neuronal processes, especially at the lowest doses. In addition, IFN treatment evoked a striking increase in the number of identifiable Müller cells at all doses. These results suggest that class I MHC molecules are induced on regenerating adult retinal cells, and this expression may be sensitive to physiological doses of IFN. TARGETED NERVE LESION INDUCED BY PHOTOSENSITIZING DYES: A NOVEL MEDEL FOR STUDYING NERVE DEGENERATION-REGENERATION. LT Wang-Bennett and DJ Liebl* Dept. of Otolaryngology, Baylor College of Medicine, Houston, TX 77030.

Photosensitizing dyes are excited to an elevated electron state by a specific wavelength of light. In the presence of a reductant the excited dye converts oxygen in the cells into reactive oxygen radicals and causes various cellular damage. Free dyes (Azure-C or mesoporphyrin) or the dye conjugated to a protein carrier (horseradish peroxidase, HRP) are injected into rabbit whisker pad muscles. By retrograde transport these dyes or the dye-HRP conjugates are uptaken into the facial nerve buccal branch and localized centrally in the facial motor nucleus by HRP histochemistry. The absorbance peak of the conjugate or the free dye was at the same wavelength and were activated by a helium-neon laser (λmax=632.8 nm).

EM ultrastructural analysis revealed debris of axon cytoskelton, demyelination, disruption of perineural cells and basal laminal segregation following the irradiation of mesoporphrin injected facial nerve. At longer survival times, the regeneration and sprouting are observed.

In vitro experiment with nerve homogenate incubated with Azure-C or Azure-C-HRP conjugate showed cleavage of a high molecular weight protein (approximate 200 KDa) by laser irradiation.

REGENERATION OF SINGLE LASER-ABLATED MOTOR AXONS AND THE REOCCUPATION OF POSTSYNAPTIC SITES FOLLOWED IN LIVING MICE. P. van Mier and J.W. Lichtman. Department of Anatomy and Neurobiology, Washington University School of Medicine, St.Louis, MO 63110.

In order to simplify the study of axonal regeneration, we have used a laser in conjunction with a microscope to selectively damage single motor axons and observe over time regeneration and reinnervation in the sternomastoid muscle of living mice. After microscopic visualization of vitally stained motor axons and their synapses, one axon having a superficial preterminal branch was selected for laser damage. The laser beam focussed to a spot the size of an axon diameter, was positioned over the axon at least 100 μm proximal to the terminal site to avoid direct damage to the junction or the postsynaptic muscle fiber. The axon was then irradiated for 1-5 seconds with 1-100 pulses (pulse length 3 nsec) of blue laser light (λmax. 503 nm). Usually the neuromuscular junction distal to the axonal damage became spontaneously active within seconds causing the postsynaptic muscle fiber to twitch. Vital re-staining of the distal axon and terminal was no longer possible after several hours, and one day after the lesion the distal axon was no longer evident in the Schwann-cell sheath. Within 5 days after laser treatment the axons rapidly regenerated and accurately reoccupied the original synaptic sites. Typically, the regenerating axons are far thinner than normal, even after they have reoccupied the synaptic site. We are presently following the regeneration of single axons and monitoring the behavior of surrounding neuromuscular junctions in response to the denervation of single muscle fibers.

137.11

FUSION OF REGENERATING LEECH AXONS CUT INDIVIDUALLY BY FLUORESCENCE PHOTOINACTIVATION. J.M. Camhi and E. Macagno. Dept. Biol., Columbia Univ., New York, NY 10027.

After cutting or crushing the leech nerve cord, the severed proximal and distal axonal segments are known to be capable of fusion (De Riemer et al. (1983) Brain Res. 272:157-161). This occurs, though, in only 3-9% of the axons, depending on the type of lesion. We have tested whether cutting instead just a single axon, in an otherwise undisturbed nerve cord, increases this rate of fusion.

To cut selectively a Retzius axon, its soma was filled with Lucifer Yellow (LY) and an 80 μm length of axon was then illuminated. Upon refilling 1-2 days later with LY, HRP or DiI, such axons were seen to be cut. Several sprouts had usually developed from the cut end.

When refilled with LY instead after 3-4 days, in 80% of the cells the dye traveled in a single axon, through the cut region and at least 500 μm beyond, finally fading gradually into background. Often there was a constriction and/or sprouting in the region of the cut. Refilling instead with HRP after 3-4 days showed the same features in over 70% of the axons, though the HRP often was visible all the way to the next ganglion. Regenerative growth of sprouts is far to slow to account for these axonal lengths. Since HRP does not pass through known gap junctions, we conclude that axonal fusion has occured.

We are currently studying whether the proximal segment of a cut Retzius axon fuses selectively with its own distal segment when presented with a choice. We are also examining other systems, both invertebrate and vertebrate, for similar instances of fusion.

137.12

MORPHOLOGICALLY DIFFERENT RETINAL GANGLION CELL TYPES FROM ADULT RATS AND CHICKENS REGROW THEIR AXONS IN VITRO. J. Vanselow* and S. Thanos. Max-Planck-Institut für Entwicklungsbiologie, Abt. I, Spemannstr. 35, D-7400 Tübingen, FRG

Retinal explants from adult rats and chickens were cultured to investigate the regenerative ability of distinct retinal ganglion cells in higher vertebrates. Precrushed retinae of 8 rats and 5 chickens were explanted on a poly-lysine/laminin substratum. After 2 days to 2 weeks, the explants were fixed and the cells, whose neurites had grown out, were stained retrogradely with the fluorescent dye Di I by applying crystals of the dye to processes emerging from the explant. In explants from rats, all ganglion cell types (type I, type II and type III) were found having regenerated axons. Some of these cells also showed sprouting of their dendritic processes, which were typically tipped with growth cones. In explants from chickens, 8 different ganglion cell types had regrown their axons. These results indicate that different retinal ganglion cell types of adult rats and chickens have the ability to regrow injured axons in vitro and to maintain their cell type specific morphology for several days.

CERVICAL SYMPATHETIC NERVE RESPONSES TO BAROCEPTOR LOADING OR UNLOADING IN NEONATAL SWINE. P.M. Gootman, H.L. Cohen, B. W. Hundley*, G. Condemi*, L. Eberle*, M. Brust*, Dept. Physiol. SUNY-Hlth. Sci. Ctr. Bklyn, Brooklyn, NY 11203

We decided to investigate the usefulness of power spectral analyses in the examination of changes in sympathetic activity elicited by changes in baroceptor inputs. In neonatal swine (<1 - 6 weeks of age), lightly anesthetized with Saffan, paralyzed with C-10 and artificially ventilated on 100% O_2, monophasic recordings of phrenic (PHR) and cervical sympathetic (CS) activity were obtained simultaneously with aortic pressure (AoP), EKG, end-tidal CO_2 and intratracheal pressure. Baroceptors were stimulated by increasing AoP with phenylephrine (PE; 20 ug/kg, iv) or inhibited by decreasing AoP with Na nitroprusside (NP; 30 ug/kg, iv). PHR activity was frequently inhibited with baroceptor stimulation. Nerve activity was computer analyzed utilizing the FFT and measures of averaged power. Equi-AoP changes of 30 mm Hg elicited changes in the averaged power of CS activity. Increased AoP resulted in decreased averaged power while falls in AoP had the opposite effect. The magnitudes of the changes in averaged power were equivalent (@ ±30%). Thus equi-AoP changes elicited equi-sympathetic activity changes in neonatal swine. Furthermore, power spectral analyses can be useful in the quantitation of changes in sympathetic activity. (Supported by NIH grant HL-20864.)

138.2

RELATIONSHIPS BETWEEN BASAL DISCHARGES OF SYMPATHETIC NERVES. B. Kocsis, G.L. Gebber and S.M. Barman. Dept. Pharmacol., Mich. St. Univ., E. Lansing, MI 48824.

The coherence function and phase spectrum were used to study the relationships (in the frequency domain) between the discharges of sympathetic nerves (e.g., inferior cardiac and renal) in baroreceptor-denervated cats. The coherence values in the 2- to 6-Hz band were significantly different from zero. The phase spectrum was linear in the coherent frequency band and showed random fluctuations elsewhere. The difference in conduction times from the brain stem to the two nerves was reflected by the slope of the linear portion of the phase spectrum. Taking this into account, two patterns of relationship were discernable. One pattern was characterized by the absence of a time delay between activity in the central circuits controlling both nerves while the other was characterized by the dependency of the time delay on frequency in the 2- to 6-Hz band. In the latter case, the activity of one nerve could lead that of the second at some frequencies and lag at others. The results point to two modes of operation of the central network responsible for 2- to 6-Hz sympathetic nerve activity. In one mode, the components of the network are activated in unison (i.e., without a time delay). Although strong coupling also characterizes the second mode of operation, the phase relations between activity of the components of the central network are variable. (Supported by NIH grant HL13187.)

138.3

COHERENT FREQUENCIES IN SYMPATHETIC NERVE DISCHARGE (SND) AND FRONTAL CORTICAL ACTIVITY (EEG). G.L. Gebber, M.J. Kenney, B. Kocsis and S.M. Barman. Dept. Pharmacol., Mich. St. Univ., E. Lansing, MI 48824.

The coherence function was used to study the relationships (in the frequency domain) between inferior cardiac SND and EEG of chloralose-anesthetized cats. The coherence function contained one or two sharp peaks in the delta and/or theta frequency bands. These peaks were larger in baroreceptor-denervated than in baroreceptor-innervated cats. The coherence of delta-theta frequencies in SND and EEG was reversibly blocked by iv brevital (1-2 mg/kg). The sharp peaks in the coherence function could be attributed to a forebrain influence on sympathetic circuits since midcollicular decerebration eliminated the delta-theta peaks in SND autospectra that cohered to EEG. In contrast, these frequencies persisted in the autospectrum of EEG after decerebration. We also noted that coherence of delta-theta frequencies in SND and EEG was strongest during frontal cortical spindling. Spontaneous spindles were 1-3 s in duration and occurred regularly once every 5 to 10 s. Such spindles could be triggered and entrained by single electrical shocks applied to intralaminar thalamic nuclei. These results support the view that both a forebrain delta-theta rhythm generator and the thalamic spindle generator contribute to SND in chloralose-anesthetized cats. (Supported by NIH Grants HL13187 and HL33266.)

NONLINEAR DYNAMIC ANALYSIS OF CARDIAC R-R INTERVAL VARIATION FOLLOWING COCAINE ADMINISTRATION. R.K. Harper*, R.C. Frysinger, R.R. Terreberry, A. Garfinkel*, C.A. Richard and R.M. Harper (SPON: R. Strandburg). Brain Research Institute and Depts. of Anatomy & Cell Biology and Kinesiology, UCLA, Los Angeles, CA 90024.

We examined sequencing of cardiac R-R intervals following acute intravenous and intraventricular administration of 3 dose levels of cocaine (5, 7.5, and 10 mg/kg intravenously; .625, 1.25, and 2.5 µg intraventricularly) in intact, freely moving cats. Five cats were instrumented with EEG, ECG, and diaphragmatic EMG electrodes. Following recovery, each cat was allowed to sleep undisturbed in a quiet chamber and then administered cocaine either intravenously or intraventricularly. Cardiac R-R intervals were stored on digital disks. Each cardiac interval was plotted against the successive interval for 10 minutes (a) prior to and (b) following cocaine administration, and the distribution of dependencies was noted. A linear regression was also calculated for each condition. Both intravenous and intraventricular cocaine administration caused an extreme organization of cardiac intervals such that interinterval sequences of correlations of near zero were followed postinfusion by a correlation near 0.8. On one occasion the extreme organization erupted into ventricular tachycardia. We suggest that cocaine predisposes an extreme organization of cardiac rhythm that can deteriorate into chaotic rhythms. Supported by DA04913.

CHANGES IN HEXOKINASE ACTIVITY IN THE BRAINSTEM AND FOREBRAIN DURING AFFERENT RENAL NERVE (ARN) STIMULATION. J. Schoeneman* and J. Ciriello (SPON: M. Robinson). Dept. of Physiology, Univ. of Western Ontario, London, Canada, N6A 5C1.

Changes in metabolic activity of brainstem and forebrain structures during ARN stimulation were studied using the hexokinase (HK) histochemical method in the rat. ARN stimulation (st-ARN) significantly elevated arterial pressure (AP; 120±6mmHg) compared to the sham stimulated animals (sh-ARN; 97±2 mmHg). In the contralateral brainstem of st-ARN animals increases in HK reaction product were observed in the region of the C1 adrenergic cell group, the commissural and rostral medial subnuclei of the solitary tract, and Kolliker-Fusé nucleus. In the diencephalon increased HK reaction product was observed in the contralateral arcute nucleus, median preoptic nucleus, medial parvo- and magno-cellular components of paraventricular nucleus of the hypothalamus, posterior hypothalamus, supraoptic nucleus, and subfornical organ. Similar results were obtained in st-ARN rats with total autonomic blockade and in which AP was maintained at a level not different from sh-ARN rats. These results have demonstrated that ARN stimulation alters the activity of central structures previously implicated in the regulation of body fluid balance and cardiovascular function. (Supported by HSFO).

138.6

RESPONSES OF MAGNOCELLULAR NEURONS OF THE PARAVENTRICULAR NUCLEUS OF THE HYPOTHALAMUS (PVH) TO ACTIVATION OF RENAL RECEPTORS. J.K. Simon* and J. Ciriello. Dept. of Physiology, Univ. of Western Ontario, London, Canada, N6A 5C1.

Single-unit recording experiments were done in pentobarbital anesthetized rats to investigate the responses of vasopressin (AVP) and oxytocin (OXY) containing cells in the PVH to selective activation of renal receptors. Following the transpharyngeal exposure of the hypothalamus and the neurohypophysis (NH), neurosecretory PVH neurons were identified by antidromic activation from the NH and classified as putative AVP cells if they were phasically firing and/or inhibited by baroreceptor activation or putative OXY cells if they were continuously firing and unresponsive to baroreceptor activation. Renal ischemia excited 3 of 6 AVP cells while renal venous occlusion excited 2 of 6 AVP neurons tested. Intrarenal infusions of bradykinin (2/6), sodium cyanide (2/5), capsiacin (4/6), and adenosine (1/3) excited AVP cells. Renal ischemia did not affect putative OXY cells while renal venous occlusion was found to excite 1/5 OXY cells. Intrarenal infusions of bradykinin (3/4), of sodium cyanide (2/3), and of adenosine (1/2) excited OXY cells. On the other hand, capsiacin was without effect. These data demonstrate that AVP and OXY neurons in the PVH are responsive to activation of different renal receptor populations and suggest that these receptors contribute to the control of AVP and OXY release into the circulation. (Supported by HSFO).

EFFECTS OF IBOTENIC ACID (IBO)-INDUCED LESIONS IN MEDIAN PREOPTIC NUCLEUS (MnPO) ON CARDIOVASCULAR FUNCTION IN RATS. H. Ohta, J.T. Cunningham, T.G. Beltz,* A.K. Johnson and M.J. Brody, Univ. of Iowa, CV Ctr., Iowa City, IA 52242

The anteroventral third ventricle region contains key structures which participate in drinking behavior and cardiovascular responses induced by angiotensin II (AII) and other centrally acting agents. A previous study showed that drinking behavior induced by systemic administration of AII was abolished in rats with IBO lesions of MnPO. The aim of the present study was to determine whether cardiovascular responses elicited by central and systemic administration of pressor agents are altered in rats twelve weeks after lesions of MnPO produced by microinjection of IBO (5 µg in 1 µl). A guide cannula was implanted into the lateral cerebroventricular (icv) and both femoral artery and vein were catheterized. The pressor response induced by icv injection of AII (100 ng) in MnPO lesioned rats was greater than that in vehicle treated rats (28 ± 3 vs. 19 ± 1 mmHg), whereas the responses induced by intravenous (iv) administration of AII were not altered. Pressor responses induced by icv administration of carbachol (50 ng) and hypertonic NaCl (1M) in both groups were identical. These results indicate that whereas cell bodies in MnPO are required for AII-induced drinking, they are not involved in the pressor response induced by either icv or iv administration of AII.

BRAIN AND PITUITARY ANP IN EURYHALINE FISH: ITS ROLE IN ADAPTION TO DIFFERENT SALINITIES. Sara M. Galli*, Keping Qian*, Maria Trolliet*, Birgitta Kimura* and M. Ian Phillips. (SPON: P.S. Kalra), Dept. of Physiology, University of Florida, Gainesville, FL 32610

Atrial natriuretic peptide has been reported in brain and neural tissue of most groups of vertebrates and invertebrates, but its physiological function is not known. To study the physiological role of ANP in fish, four species of euryhaline fish were studied; toadfish, mullet, killifish and tilapia. The fish were captured in sea water and given 4 weeks to adapt in sea water tanks. Groups of the fish were then transferred to 50% SW or FW for different periods of time. Blood samples were taken and brains and pituitaries removed after exposure to lower salinity. ANP was analyzed by HPLC and measured by RIA. The the distribution in the brain located by immunocytochemistry. Highest levels of ANP in all species studied was in the diencephalon 180 ng/g tissue with lesser concentrations in telencephalon, metencephalon, myelencephalon, and pituitary. When placed in 50% SW (killifish) ANP brain levels rose >100% within 12 hours and stayed elevated (compared to levels at sea water) for up to 7 days. Pituitary ANP levels also rose (5-25 ng/g tissue). Plasma levels, by contrast, decreased in 50% SW and FW. The decrease was reversed when fish were returned to SW. These results suggest that plasma and brain ANP play a physiological role in the osmoregulation of fish as they move into SW from the lower salinity in estuaries. The opposite changes in brain and pituitary, versus plasma, indicate a reciprocal role in the maintenance and control of Na^+, Cl^-, and volume. (Supported by American Heart Association).

REDUCED CARDIOPULMONARY REFLEX ACTIVITY IN CONSCIOUS SHR. M.J. Brody, S.J. Lewis* and H. Ohta. Dept. of Pharmacolology and Cardiovascular Center, University of Iowa, Iowa City, IA 52242 USA

The intravenous (iv) injection of 5-HT produces cardiopulmonary afferent-mediated hypotension and bradycardia in rats. The hypotension is produced by vagally-mediated bradycardia and a reduction in sympathetic outflow to the vasculature. This study compared cardiopulmonary reflex (CPR) function in spontaneously hypertensive (SHR) and age-matched (8 week) Wistar-Kyoto (WKY) rats. IV injections of 5-HT in the WKY (1-9µg/kg) produced dose-dependent falls in diastolic arterial blood pressure (DABP) and heart rate (HR) (see table). The SHR were markedly less sensitive to 5-HT (5-40µg/kg). Pretreatment with methylatropine (MA, 0.2 mg/kg, iv) markedly reduced the hypotension and bradycardia in the WKY and abolished these responses in the SHR.

Slopes (Δ parameter/$\log_{10}$dose 5-HT) pre and post MA

	WKY		SHR	
	pre	post	pre	post
HR	-181±11	-12±2*	-57±5†	-1±1*
DABP	-74±5	-23±3*	-28±4†	-4±2*

*p < 0.05 pre vs post, †p < 0.05 WKY pre vs SHR pre

These results demonstrate that CPR function is markedly impaired in the SHR and this impairmment involves both vagal and sympathetic efferent functions.

138.10

ADAPTATION OF BARORECEPTORS WITH ELEVATED STATIC ARTERIAL PRESSURE IS ABSENT OR ATTENUATED WITH PULSATILE PRESSURE. M.W. Chapleau*, G. Hajduczok and F.M. Abboud*. CV Ctr. and Depts. of Internal Med. and Physiol., U. of Iowa Coll. of Med., and VA Med. Ctr., Iowa City, IA 52242.

Most receptors adapt to sustained stimuli. The purpose of this study was to contrast the magnitude of adaptation of baroreceptors (BR) during elevations in static pressure (SP) vs. pulsatile pressure (PP) in the isolated carotid sinus (CS) of dogs anesthetized with chloralose. At an elevated mean pressure of 100 mmHg, whole CS nerve activity (n=9) decreased over a period of 5 minutes by 39±9% during SP and by 12±4% during PP ($P<0.05$ for difference between SP and PP). Single-fiber activity also decreased more ($P<0.05$) during SP (-20±6%) than during PP (-2±6%) (n=6). Relaxation or "creep" of the vessel wall has been proposed as the mechanism of BR adaptation. CS diameter (sonomicrometers, n=6) increased over the 5-minute period of constant elevated pressure (100 mmHg) to the same extent during SP (+37±16 µm) and PP (+37±9 µm). Therefore, other mechanisms besides "creep" of the vessel wall must explain the difference in adaptation. We conclude that adaptation of BR is absent or markedly attenuated during elevated PP in contrast to SP. This may explain the sustained baroreflex inhibition of sympathetic activity seen with PP in contrast to the escape from inhibition reported with SP.

EFFECTS OF ANGIOTENSIN II (ANG II) INFUSION ON ANG II BINDING SITES IN THE NODOSE GANGLION. Debra I. Diz, Susan M. Bosch*, and Carlos M. Ferrario. Dept. of Brain and Vascular Research, Cleveland Clinic Fdn, Cleveland, OH 44195.

To determine whether the novel high affinity (K_D=0.8 nM) Ang II binding sites present in the nodose ganglion (NG) exhibit ligand-mediated receptor-regulation, male Sprague-Dawley rats (292±3g) were given an ip infusion of Ang II (100 ng/min for 7 days via osmotic minipump). Others have documented that plasma Ang II increases about three-fold using this protocol (Aguilera et al, 1980). In awake rats given Ang II, mean arterial pressure rose by the 6th day of infusion to 142±8 mm Hg (n=5) versus 116±6 mm Hg in control rats (n=3; $p<0.07$). The NG were removed on the 7th day of the Ang II infusion and Ang II binding was assessed over a range of 0.1-1.5 nM using *in vitro* receptor autoradiography (Diz et al; Brain Research Bulletin, 1986). Analyses (EBDA and LIGAND) revealed that neither the binding affinity nor the density were altered in the NG by the Ang II infusion. In the control rats (n=3), a K_D of 1.2±0.3 nM and a Bmax of 25±4 fmol/mg protein was observed. In the Ang II infused rats (n=6), the values were 1.1±0.3 nM and 28±7 fmol/mg protein, respectively. Hill coefficients (control=0.99; infused=0.97) indicate a single population of binding sites. Non-specific binding averaged 44±5% in the NG from infused rats and 38±2% in control rats. These data suggest that low-dose Ang II infusion does not down-regulate receptors in the NG. Thus, in contrast with the regulatory action of Ang II on vascular and adrenal cortex Ang II receptors, neuronal NG receptors may not share the same regulatory mechanisms. Further studies are required to characterize the regulation of Ang II binding in this neural structure. (Supported in part by HL-6835, HL-38535, and the Reinberger Fdn.)

ROLE FOR NEUROKININS IN THE PERIPHERAL REGULATION OF THE CARDIOVASCULAR SYSTEM. R. Couture, H. Hasséssian and C. Guimond*. Dept. of Physiology, Faculty of Medicine, University of Montréal, Montréal, Qué., Canada.

This study characterized the neurokinin (NK) receptor subtype and mechanism mediating the cardiovascular responses evoked by the i.v. administration of NKs. In urethane anesthetized Wistar rats, substance P (SP), neurokinin A (NKA), neurokinin B (NKB), and seven NK receptor subtype selective agonists: [Sar^9, $Met(O_2)^{11}$]SP, (A); [Pro^9, $Met(O_2)^{11}$]SP, (B); [β-Ala^4, Sar^9, $Met(O_2)^{11}$]SP (4-11), (C); NKA(4-10), (D); [succinyl-Asp^6, $MePhe^8$]SP (6-11), (E); [β-Asp^4, $MePhe^7$]NKB (4-10), (F); [$MePhe^7$]NKB, (G) were studied on blood pressure and heart rate (HR). Vasodepressor responses were obtained using 0.65 to 65 nmol/kg doses, with the following rank order of potency: A = B > C = E = F = G > SP > NKB = NKA >> D. NKA and the NK-2 selective agonist (D) stimulated HR, while NKB and NK-3 selective agonists (E, F, G) inhibited HR. SP and NK-1 selective agonists (A, B, C) produced a rise in HR, which was followed by a modest bradycardia. These results and our additional pharmacological investigation lead us to conclude: a) NKs act on NK-1 receptors of blood vessels to reduce blood pressure, b) activation of NK-2 receptors on cardiac sympathetic fibers and/or adrenal medulla causes HR acceleration, c) activation of the vagus via NK-3 receptors produces a bradycardia, d) some NK-1 agonists can also affect cardiac function by releasing prostaglandins. (Supported by the MRC of Canada).

TOXIN I, A MAMBA SNAKE DENDROTOXIN, INDUCES LONG-LIVED SUB-CONDUCTANCE EVENTS WHEN APPLIED TO THE INTRACELLULAR SIDE OF MAXI K(Ca) CHANNELS. K.J. Lucchesi* and E.G. Moczydlowski, Dept. Pharmacology, Yale Univ. Sch. Med., New Haven, CT 06510. Dendrotoxins have previously been shown to block a variety of voltage-dependent K-channels at peripheral nerve terminals, frog node of Ranvier and brain neurons. We examined the effect of Toxin I from Dendroaspis polylepis on maxi K(Ca) channels from rat muscle incorporated into planar lipid bilayers. 40 nM Toxin I produces novel subconductance blocking events when applied to the internal side of the channel. In contrast, 5 uM Toxin I has no effect on the external side. The induced subconductance behavior is highly complex, involving transitions between at least four discrete current levels. A primary effect is the appearance of long-lived 2.8 pA states in single channel records that normally fluctuate between 0 and 4.1 pA under control conditions (50 mM symmetrical K+, +20 mV holding potential). The toxin dose-dependence indicates that the long-lived subconductance events correspond to the dwell time of bound toxin. A kinetic analysis based on a one-site model gives a Kd_5 of 93 nM for Toxin I with koff = 0.042 s^{-1} and kon = 4.5 x 10^{5} s^{-1} M^{-1} at 50 mM symmetrical K+. Kon varies inversely with internal ionic strength and the duration of the substate induced by bound Toxin I is lengthened by depolarization. These results add to growing evidence for homology among classes of K-channels and provide a unique perspective on K-channel structure and function. We thank Alan Harvey for Toxin I. Supported by NIH HL38156.

SOLUBILIZATION AND PURIFICATION OF RAT BRAIN DENDROTOXIN RECEPTORS ASSOCIATED WITH VOLTAGE-GATED POTASSIUM CHANNELS. R.G. Sorensen. Dept. Med., Div. Environ. Med. and Toxicol., Jefferson Medical College, Philadelphia, PA 19107.

The venom of the green mamba, Dendroaspis angusticeps, contains four polypeptides (dendrotoxins, DaTX), that block brain voltage-gated K channels. The receptors for two of the dendrotoxins, α-DaTX and β-DaTX, which preferentially block inactivating and non-inactivating K channels, respectively, have been solubilized and partially purified from rat brain.

The dendrotoxin receptors were extracted from brain membranes in the presence of 150 mM KCl, 2 mM $MgCl_2$, 10 mM HEPES, pH 7.0, containing 0.8% zwittergent 3-12 and 0.25% lecithin. Toxin binding to the soluble receptors was then measured by a spun column method. The addition of lecithin increased the recovery of soluble toxin binding activity by 2-fold. Potassium ion optimally preserved soluble toxin binding, which was reduced as K was replaced in the order: K > Rb > Cs > Li > Na.

The affinity of [^{125}I]α-DaTX decreased 10-fold (K_D = 7 nM), and of [^{125}I]β-DaTX decreased 3.5-fold (K_D = 124 nM), after receptor solubilization. The molecular weight of the solubilized receptors was estimated to be 270,000 by sucrose density gradient centrifugation.

Partial purification of the dendrotoxin receptors has been achieved by DaTX-affinity chromatography. The purification of the receptors will be discussed. (Supported by NIH grant NS 27533).

IMMUNOLOGICAL EVIDENCE FOR A RELATIONSHIP BETWEEN THE DENDROTOXIN BINDING PROTEIN AND THE MOUSE BRAIN POTASSIUM CHANNEL GENE, MBK1. R. A. Newitt*, H. Rehm* and B. L. Tempel. GRECC, VA Medical Center, Seattle, WA 98108 and Dept. of Pharmacology, Univ. of WA, Seattle, WA 98195

We have asked whether the cloned potassium channel gene, MBK1 (Tempel et al, 1988) is related to the putative potassium channel protein purified from rat and bovine brain using dendrotoxin as an affinity ligand (Rehm and Lazdunski, 1988). Polyclonal antibodies were raised against synthetic peptides from different parts of the predicted amino acid sequence of the mouse potassium channel gene and used to probe purified putative potassium channel proteins (DMB proteins) from rat and bovine brain membranes on Western blots following SDS-PAGE. DMB proteins of both species consisted of a toxin binding subunit of mol. wt. of 90 Kd (rat) and 83 Kd (bovine) and a smaller 38 Kd subunit. Antibodies recognized specifically the dendrotoxin binding subunit. The difference in molecular weight of this toxin binding protein subunit between the species was at least partially due to differential glycosylation. The 38 Kd subunit did not bind antibody nor did it appear to be appreciably glycosylated. Presently, the sequence of both of these subunits is being determined to elucidate their function and compare with those of other ion channel proteins.

TISSUE SPECIFIC EXPRESSION OF MBK1, A POTASSIUM CHANNEL GENE. B. L. Tempel, M. A. Miller*, J. H. Urban and D. M. Dorsa (SPON: R. Malenka). GRECC, VA Med. Ctr., Seattle, WA, and Depts. of Pharmacology and Medicine, Univ. of WA, Seattle, 98108

The molecular mechanisms underlying K+ channel diversity are not known. Questions remain regarding the number of genes involved or the distribution of expression of members of this gene family. We are studying the tissue specific expression of a mouse brain K+ channel gene, MBK1, which induces the appearance of a non-inactivating K+ conductance when expressed in frog oocytes (see Houamed, et al, these abstracts).

Sequences derived from both coding and non-coding regions of MBK1 were used at high strengency to probe poly A+ RNA blots from various tissues of rat and mouse. A single 8 Kb transcript was seen in brain stem, cortex, hippocampus, cerebellum and, at a much lower level, in heart and skeletal muscle. Oligonucleotide probes were used for in situ hybridization studies to determine the cellular distribution of MBK1 in the CNS. Specific hybridization was widely distributed but varied in intensity from region to region. For example, we found heavily labeled cells in the area of the cranial motorneurons in the brain stem and a much higher level of expression in the CA3 pyramidal cells than in other hippocampal areas.

SITE-DIRECTED MUTAGENESIS OF THE S4 SEQUENCE OF THE SHAKER K^+ CHANNEL. D.M. Papazian*, L.C. Timpe, Y.N. Jan, and L.Y. Jan. HHMI and Dept. of Physiology, UCSF, San Francisco, CA 94143.

The A-type K^+ channel encoded by the Shaker gene of Drosophila contains an S4 sequence similar to those in Na^+ and Ca^{2+} channels. S4 sequences, which consist of repeated triplets of one basic (arginine or lysine) and two hydrophobic amino acids, have been proposed to function as transmembrane voltage sensors. This proposal has been tested by site-directed mutagenesis of the S4 arginine and lysine residues in the Shaker cDNA clone, ShB1. Three types of single amino acid mutations have been made. Basic residues have been switched to 1) glutamine, 2) glutamate and 3) arginines have been changed to lysines, and vice versa. Mutant A channels have been expressed in Xenopus oocytes and analyzed by the two electrode voltage clamp technique.

Mutations of basic amino acids in the middle positions of the S4 to glutamine or glutamate eliminated channel activity, whereas all other mutations gave A currents. Although some of these mutant channels conducted normal currents, the others affected a subset of the functional properties of the channel. 1) The conductance-voltage and steady state inactivation-voltage relationships were shifted along the voltage axis in the depolarized direction. The slopes of these curves were affected in at least one mutant. 2) The rate of macroscopic inactivation was slowed. None of the mutations had dramatic effects on the K^+ selectivity of the channel, or on its rate of recovery from inactivation. These results indicate that the S4 sequence is important for the voltage-dependence and kinetics of the K^+ current.

Shaker Potassium Channels: a Leucine Zipper Motif may Indicate a Site for Subunit Interaction and Gating. K. McCormack*§, M. Ramaswami *§, M.K. Mathew*§, M. A. Tanouye§, L. Iverson*‡,T. McCormack*† & B. Rudy † (SPON B. Trevarrow) § Division of Biology, California Institute of Technology, Pasadena,CA; ‡ Division of Neurosciences, City of Hope,Duarte,CA; † Department of Physiology, New York University, New York, NY.

Recent work on a class of DNA-binding proteins, including *fos* and *jun* , has shown that dimerization is mediated by a "leucine zipper" motif. We report the presence of this motif in a family of potassium channels, including *Shaker* (*Sh*), which are thought to form functional multimers. The *Sh* motif is a heptad repeat containing 5 leucine residues. This region indicates a likely site for subunit interactions which, in turn, could be a major determinant in channel structure.

Interestingly, the leucine zipper motif is immediately adjacent to the S4 domain: this proximity suggests that S4 translocation may affect the association and/or dissociation of subunits. We propose that subunit association/disassociation through the leucine zipper motif acts as the transduction mechanism for the voltage-sensing S4 domain in determining open and/or closed states of the channel. A similar motif is present in sodium and calcium channels suggesting that this may be a common mechanism for gating in all voltage-gated channels. Mutations of amino acid residues within the *Sh* zipper motif have been constructed to test this model in the *Xenopus* oocyte expression system.

139.7

MUTATIONS IN THE AMINO TERMINAL VARIABLE DOMAIN ALTER INACTIVATION OF *SHAKER B* POTASSIUM CHANNELS IN *XENOPUS* OOCYTES T. Hoshi*, W. N. Zagotta* and R. W. Aldrich, Dept of Neurobiology, Stanford University, Stanford, CA 94305.

We have compared the properties of single channels in *Xenopus* oocytes injected with mRNA from the *Shaker B* variant and from variants generated by *in vitro* mutagenesis. We have found that all of the molecular transitions after first opening, including the inactivation transition, are voltage independent and therefore not associated with charge movement through the membrane. A partially coupled model accurately reproduces all of the single-channel and macroscopic data. Comparison of microscopic inactivation rates of channels that vary in amino-acid sequence in a putative cytoplasmic domain near the amino terminus suggests an involvement of this region in the inactivation process. We have further examined this by constructing and analyzing the gating of mutant channels, generated *in vitro*, that delete different portions of the sequence in this region. The inactivation rate is profoundly slowed in mutants that delete amino acids beginning at the 6th position. The gating and conductance properties of these mutant channels closely resemble those of delayed rectifier channels in *Drosophila* muscle, suggesting that only small structural differences may exist between A-type and delayed potassium channels. Deletion of amino acids in a region closer to the splice junction leave inactivation intact, and in some cases increases the microscopic inactivation rate. Treatment of channels in inside-out patches with internal trypsin mimics the mutations that slow inactivation, suggesting that the amino terminal is cytoplasmic. External trypsin has no effect. The lack of voltage dependence of inactivation rates, the ability of internal proteolytic agents to modify inactivation, and the effects of mutations that slow or speed inactivation suggest a mechanism of inactivation similar to the ball and chain model originally proposed by Armstrong and Bezanilla for voltage-gated Na channels. Supported by NS 23294, NS07158 and the American Heart Association.

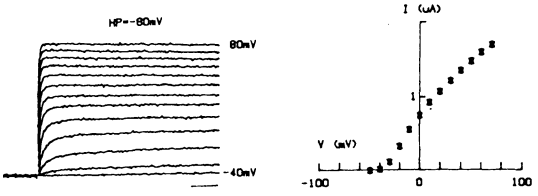
139.8

PROPERTIES OF ShB A-TYPE K^+ CHANNELS EXPRESSED IN *SHAKER* MUTANT *DROSOPHILA* BY GERMLINE TRANSFORMATION. W. N. Zagotta*, S. E. Germeraad*, S. S. Garber and R. W. Aldrich (SPON: D. A. Baylor). Dept. of Neurobiology, Stanford University, Stanford, CA 94305.

The *Shaker* gene codes for a large variety of alternatively spliced mRNAs, many of which have been shown individually to produce functional K^+ channels when injected into *Xenopus* oocytes. These channels differ in gating and pharmacology from the native channels normally expressed in *Drosophila* myotubes. To begin to investigate *Shaker* variants in their native environment we have used P-element mediated germline transformation to express ShB channels in *Drosophila* cells. ShB cDNA under the control of a heat shock promoter (*hsp70*) was transformed into a host strain of *Drosophila* mutant in the endogenous *Shaker* gene. Northern blots reveal that the transformed DNA is efficiently transcribed in response to heat shock. The transformant homozygotes, however, continue to shake as vigorously as the *Shaker* host strain. Primary cultures of myotubes were prepared from the transformant embryos and heat shocked for 30 to 60 min at 37°C. Whole-cell patch clamp of the cultured myotubes reveals large A-type potassium currents in the heat-shocked cultures, but only delayed potassium currents in the non-heat-shocked cultures and cultures made from the host strain. While qualitatively similar to the native *Shaker* A-currents expressed in wild type myotubes, the transformant A-current inactivates more rapidly and recovers from inactivation more rapidly, similar to the ShB channels expressed in *Xenopus* oocytes. Unlike the channels in oocytes, however, the transformant A-current was present in 50 nM charybdotoxin. The *Shaker* transformants will allow us to study the interactions of the ShB protein with other *Shaker* variants and other gene products in their native cells. Supported by NS23294, NS07158, and a National Cystic Fibrosis Foundation fellowship.

139.9

EXPRESSION OF VOLTAGE-GATED POTASSIUM CHANNELS USING RECOMBINANT VACCINIA VIRUS. R.J. Leonard[1], A. Karschin*[1], J. Aivar*[1], N. Davidson[1], M.A. Tanouye[1], L. Thomas*[2], G. Thomas*[2] & H.A. Lester[1]. Div. Biology, [1]Caltech, Pasadena, CA 91125 *and* [2]VIABR, Oregon Health Sciences Univ. Portland, OR 97201.



Vaccinia virus (VV) is a useful tool for the transient expression of foreign proteins, because it replicates in the cytoplasm and has a broad host range. We constructed a recombinant vaccinia virus containing the coding region of the *Shaker* H4 cDNA, a member of the Drosophila "A-current" channel family. The VV:H4 virus was used to infect four types of cells in culture: NIH-3T3 fibroblasts; rat basophilic leukocytes (RBL-1); undifferentiated PC-12 cells; and monkey kidney CV-1 cells. Whole-cell patch clamp records one day post-infection revealed robust (>2 nA peak) transient outward currents in all four cell types. The induced currents possessed the hallmarks of Drosophila *Shaker* A-currents: They were activated by depolarizations above -40 mV. The mid-point for inactivation by a depolarizing prepulse was -30 mV. Recovery from inactivation was rapid ($t_{1/2}$= 200ms). Both activation and inactivation rates increased with depolarization. Tail currents reversed at the potassium equilibrium potential. We estimate >4 functional channels/μ^2 in RBL-1 cells. Currents were blocked by 4-AP and (like H4 expressed in oocytes) charybdotoxin. No such currents were observed in recordings from uninfected cells. Endogenous voltage-activated currents in PC-12 cells were not suppressed by the infection. Vaccinia should be a useful tool for expressing cloned ion channels and neurotransmitter receptors, and may provide a vehicle for the study of cell-specific modulation of channel function. Support: GM-10991 & GM-29836 (NIH) and The Cystic Fibrosis Foundation.

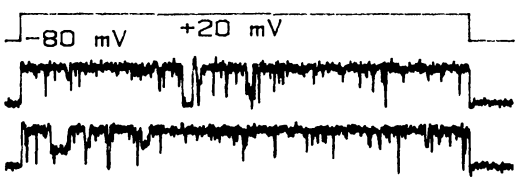
CLONING AND EXPRESSION OF DELAYED RECTIFIER K^+ CHANNELS FROM RAT BRAIN AND SOLEUS MUSCLE. G. Koren*, E.R. Liman*, D.E. Logothetis*, P. Hess*, B. Nadal-Ginard* (SPON: M. Plummer). Dept. of Cardiology, Childrens Hospital, Dept. of Physiology and Program in Neuroscience, Harvard Medical School, Boston, MA. 02115.

Using oligonucleotide probes from published rat brain potassium channels we have isolated a clone from a rat brain cDNA library that is identical in the coding region to RCK1 (Baumann et. al., EMBO 7:2457, 1988), but differs in the 5' untranslated region. The S4-S6 region of this clone was used to screen a rat soleus cDNA library. High stringency hybridization resulted in the isolation of 3 clones. Partial sequencing and restriction map analysis indicated that these clones are most likely to be identical to the brain clone. Injection of in vitro transcribed mRNA from one of the clones (RSK1) into xenopus oocytes resulted in the expression of a delayed rectifier K^+ current, which was never observed in uninjected oocytes. Low stringency hybrization of the same cDNA library resulted in the isolation of 2 different clones that are 80% homologous at the nucleotide level to the rat brain cDNA clone.



These results suggest that both brain and muscle express identical delayed rectifier K+ channels.

139.11

STABLE EXPRESSION IN A MAMMALIAN MUSCLE CELL LINE OF A CLONED DELAYED RECTIFIER K^+ CHANNEL FROM RAT BRAIN . E. Liman*, G. Koren*, B. Nadal-Ginard*, P. Hess* (SPON:M. Segal). Dept. of Physiology and Program in Neuroscience, Harvard Medical School, and Dept. of Cardiology, Childrens Hospital, Boston, MA. 02115.

Mouse SOL 8 cells were transfected with a plasmid containing a brain K^+ channel identical to RCK-1 (Baumann et. al., 1988) under the control of a mouse metallothionein-I promoter. The colonies were cloned by limited dilution. Out of seven colonies examined, one expressed large delayed rectifier type potassium currents (up to 178 pA/pF at 0 mv) that differed both in their magnitude and kinetics from currents seen in control cells (n = 20) The current was potassium selective, exhibited steady state inactivation at potentials greater than -50 mv, and was sensitive to Charybdotoxin. Single channels recorded in the cell attached configuration from this cell clone (5mM KCl in the pipette) had a slope conductance of 14 pS, activated steeply with the boltzman parameters of V1/2 = -50mV and k = 5 mV, and displayed multiple sub conductance levels. Periods of channel opening were punctuated by long intervals (upto several minutes) when the channel did not open.

139.12

K CHANNEL mRNA REGULATED BY ESTROGEN IN MYOMETRIUM MAY BE UNRELATED TO SHAKER FAMILY. M. Pragnell*, L.K. Kaczmarek, and M.B. Boyle. Dept. of Physiol. & Biophys., Univ. of Iowa, Iowa City, IA 52242 and Depts. of Pharmacol. & Physiol., Yale Univ., New Haven, CT 06510.

The enhancement of myometrial excitability by chronic exposure to estrogens may involve the regulation of K channel mRNA. A very slow voltage-dependent K current is expressed in Xenopus oocytes injected with myometrial RNA from estrogen-treated but not estrogen-deprived rats. Injection of size-fractionated RNA suggested that an mRNA species similar in size to the 18S ribosomal RNA, about 2 kb, was responsible for the expression of the slow K current. We now report the results of Northern blot analysis with probes showing sequence homology with the Shaker potassium channel clones. A rat brain cDNA clone (K41) detected mRNA species of about 3 and 6 kb from 12-day-old rat brain. Bands at 3 kb only were apparent in the lanes containing uterine RNA. This brain cDNA clone has previously been used to isolate a small uterine cDNA clone found to be identical in sequence with the 3' end of the brain clone. Although these results are consistent with the identification of homologous ion channel mRNA species in the brain and myometrium, the absence of the 6 kb band from uterus implies some difference in the regulation of expression. The intensity of the 3 kb bands did not differ substantially between uterine RNA from estrogen-treated and estrogen-deprived rats. Our results suggest that the mRNA species regulated by estrogen is unrelated to Shaker. We are now testing the hypothesis that the estrogen-regulated uterine mRNA species may be similar to a small kidney mRNA species (Takumi et al., Sci. 242:1042) which is capable of inducing a very slow K current in RNA-injected oocytes.

140.1

SYNCHRONIZATION OF INHIBITORY POTENTIALS IN THE NEOCORTEX IS RESISTANT TO EXCITATORY AMINO ACID BLOCKERS. J.A. Aram* & R.K.S. Wong. Dept. of Neurology, Columbia University, N.Y. N.Y. 10032.

Excitatory synaptic transmission can be blocked in neocortical slices by bath application of 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX; 5-20uM) and D-2-aminophosphonovaleric acid (AP5; 10-30uM). In these conditions 4-aminopyridine (4-AP; 30-100uM) elicited spontaneous membrane depolarizations which occurred at a frequency of 2-4 min^{-1}. These events represented synaptic potentials resistant to CNQX and AP5 as they were reversibly blocked in low Ca^{2+} perfusate (0.5mM Ca^{2+}/10mM Mg^{2+}). Application of bicuculline or picrotoxin (10-25uM) reversibly abolished the synaptic potentials. In contrast phaclofen (1mM), a $GABA_B$ antagonist, had little effect on the occurrence or time course of the event. Varying membrane potential revealed two components of the event with reversal potentials of -68mV and -75mV. These results suggest that the synaptic potentials resistant to excitatory amino acid blockers were elicited via the activation of GABAergic interneurons.

At RMP (mean =-73mV) the synaptic potentials were 6-15mV in amplitude and lasted 1-3 seconds. These values are significantly larger than those of unitary i.p.s.p.s. Two actions of 4-AP are possible. Firstly 4-AP causes bursting and enhanced release in individual inhibitory neurons to bring about these synaptic events. Or secondly 4-AP uncovers a synchronizing mechanism for GABAergic interneurons that is not dependent on glutamatergic synapses. Our data suggests that the events were synchronized as (i) coupling of potentials existed between two recording locations of up to 3mm apart, and (ii) stimulation of the white or grey matter evoked similar events in an all-or-none manner with variable latencies close to threshold. The results suggest that functional coupling may exist between inhibitory neurons that is resistant to excitatory amino acid blockers and that 4-AP enhanced such coupling to bring about spontaneous synchronized potentials.

140.2

ECTOPIC ACTION POTENTIAL GENERATION INCREASES WITH KINDLING -LIKE INDUCTION OF ELECTROGRAPHIC SEIZURES IN VITRO. S. F. Stasheff and W. A. Wilson. Depts. of Pharmacology and Medicine, Duke Univ. and V.A. Medical Centers, Durham, N.C.

We have previously described an in vitro model of kindling-like epileptogenesis in which electrographic seizures (EGSs) are induced in rat hippocampal slices. We now report that EGS induction is accompanied by a marked increase in the occurrence of a novel type of action potential which arises sharply from the baseline membrane potential, without preceding depolarizing potentials. We call such action potentials "baseline spikes."

EGSs were induced in rat hippocampal slices with repeated stimulus trains. Twenty-seven CA3 pyramidal cells were continuously recorded before, during and after the induction of EGSs. Baseline spikes were present in ten of these cells (37 %) prior to EGS induction, and in 23 cells (85 %) after induction. Furthermore, in 21 of these 23 cells displaying baseline spikes (91 %), the frequency of baseline spike firing after EGS induction was markedly greater than before induction.

In a number of cells, the soma was hyperpolarized by 10 to 20 mV, to reveal any underlying depolarizing potentials which might be difficult to detect near resting membrane potential. Baseline spikes continued to occur, without such prepotentials. This lack of preceding depolarizations, as well as the inability of soma hyperpolarization to block baseline spikes, suggest that baseline spikes are generated at an "ectopic" site remote from the soma.

MODULATION OF KAINIC ACID-INDUCED BEHAVIORAL SEIZURES IN RAT PREPIRIFORM CORTEX BY ADENOSINE RECEPTOR ACTIVATION AND ANTAGONISM. G. Zhang*, P. H. Franklin and T. F. Murray. College of Pharmacy, Oregon State University, Corvallis, OR 97331.

We have previously shown that adenosine receptors in rat prepiriform cortex (PC) play a fundamental role in suppression of seizures induced by bicuculline (Franklin, P. H. et al., Eur. J. Pharmacol., 150:207, 1988). Kainic acid is a neurotoxicant which stimulates glutamate and aspartate release via presynaptic receptors in CNS (Ferkany, J. W. et al., Nature, 298:757, 1982). The aim of the present study was to investigate the possibility of adenosine receptor involvement in the modulation of seizure activity elicited by kainic acid in the PC.

Kainic acid (100, 150 and 200 pmol/rat) microinjected unilaterally into the rat PC evoked bilateral motor seizures. Co-injection of the adenosine receptor agonist N-ethylcarboxamidoadenosine (NECA) afforded protection against kainic acid (200 pmol)-induced seizures in the rat PC. The ED_{50} value for the anticonvulsant effect of NECA was 25.6±2.1 pmol/rat. In addition, this seizure suppressant effect of NECA (81 pmol) was completely abolished by the adenosine receptor antagonist 8-p(sulfophenyl)theophylline (8pSPT) indicating adenosine receptor activation underlies the seizure suppressant action of NECA. Moreover, the severity of seizures induced by kainic acid (100 pmol/rat) was significantly enhanced by co-administration of 8pSPT (1.6 nmol) as compared to kainic acid alone. Taken together, the anticonvulsant effect of NECA and proconvulsant effect of 8pSPT on kainic acid-induced seizures support the involvement of adenosine receptor modulation of presynaptic excitatory amino acid release in the observed anticonvulsant actions of adenosine analogs in the prepiriform cortex. DENTATE GRANULE CELL NEUROPHYSIOLOGY IN HUMAN EPILEPTIC HIPPOCAMPUS *IN VITRO*. Masako Isokawa-Akesson[1], David M. Finch[1], Giuliano Avanzini[2], Michel F. Levesque[1], and Thomas L. Babb[1] [1]Brain Research Institute and Dept. of Neurology & Neurosurgery, UCLA, Los Angeles, CA 90024, USA and [2]Istituto Neurologico C. Besta, Milano 20133, Italy.

Neuronal excitability was studied in hippocampal slices prepared from human epileptic patients who underwent surgical treatment for intractable seizures. Intracellular recordings were obtained from dentate granule cells. Satisfactory penetration provided the average resting membrane potential of -51.8 mV ± 0.67 SD, the average spike amplitude of 62.7 ± 16.4 mV and the average membrane resistance of 43.9 ± 1.98 MΩ based on I-V curves. The recordings showed features such as spontaneous EPSPs and depolarizing afterpotentials that are characterisitic of these cells. Perforant path stimulation commonly produced EPSP-IPSP sequences, and the IPSPs lasted about 300 msec. In 2 additional neurons (ave.spike amp.: 30.8 mV, ave.rest.mem.pot.: -37.9 mV), giant EPSPs (>15 mV, >150 msec) were observed upon perforant path stimulation. Application of APV (100 μM) reduced the amplitude of the EPSP in 10 min and eliminated them in 20 min, indicating that NMDA receptors were involved in their generation. Histochemical analysis of the tissue showed that the giant EPSPs were always accompanied by mossy fiber sprouting. This suggests that sprouting may be a morphological substrate for temporal lobe epilepsy, and that it may play a role in inducing abnormal NMDA responsivity. Further studies of the correlates of dentate hyperexcitability are in progress. Supported by NIH Grant NS 02808.

LAMINAR INTERACTIONS IN RAT MOTOR CORTEX DURING CYCLICALLY OCCURRING SEIZURE BURSTS

DANIEL S. BARTH[1,2], CHRISTOPH BAUMGARTNER[1,4] and SHI DI[1,2,3] *Departments of [1]Neurology and [2]Psychology, University of California, Los Angeles, Los Angeles, CA 90024 (U.S.A), [3]Mental Health Institute, Beijing Medical University (China) and [4]Neurological University Clinic, Vienna (Austria)*

Laminar interactions between neurons in rat motor cortex during cyclical seizure episodes in the penicillin focus were studied using a combination of current source-density (CSD) and principal component analysis (PCA), combined with computer based physical modeling. These data suggest that polyspike bursts (PSB) during seizures are produced by interactions between two distinct populations of neurons, the same neuronal circuits previously reported to give rise to the direct cortical response (DCR) and electrically evoked interictal penicillin spikes (EIIS). The first population consists of small pyramidal cells in the supragranular layer, and the second population consists of larger pyramidal cells in the infragranular layers with apical dendrites extending to the cortical surface. The supragranular cells serve as a trigger zone for initiating PSB. Fast activity in the supragranular cells is typically followed by a hyperpolarizing slow wave that may be the result of Ca^{++} activated K^+ currents. This slow wave increases during seizures, possibly reflecting changes in Ca^{++} associated with seizure onset and termination. The response of infragranular cells is similar in polarity and morphology to the intracellularly recorded paroxysmal depolarization shift (PDS) and may indicate that these deeper neurons are mainly responsible for this phenomena in neocortex.

140.6

SEIZURE AND OSMOLALITY: OF SLICE AND MEN. R.D. Andrew. Dept. of Anatomy, Queen's University, Kingston, Ontario. K7L 3N6.

Over 60 years ago it was found that antidiuretic hormone (ADH) administration and water loading promoted grand mal seizure in patients and experimental animals. Rapid reduction of plasma osmolality (normally 287 mOsm/kg) can also induce seizure in several clinical situations. 1) Compulsive water drinking occurring in 8-17% of schizophrenics; ADH levels are elevated. 2) The syndrome of inappropriate (elevated) ADH secretion presenting with hyponatremia. 3) Dialysis disequilibrium syndrome, where rapid urea clearance shifts water from plasma to brain. 4) Rapid rehydration of dehydrated patients, again causing a shift in water from plasma to brain. In all cases, raising plasma osmolality inhibits seizure onset.

It is not clear how overhydration and seizure are related. We studied this question using hippocampal and neocortical brain slices from rat and found that hyposmolar saline (240-270 mOsm) promotes electrographic seizure in slices bathed in zero-Mg^{2+} saline by a) increasing excitatory postsynaptic potential (EPSP) amplitude as measured intracellularly, whether spontaneous or evoked and b) increasing population spike amplitudes and so presumably, field (ephaptic) effects. Both responses are inversely proportional to osmolality and are not the result of Na^+, Ca^{2+} or Mg^{2+} dilution in the hyposmotic media. Hyposmolality has no effect on intrinsic neuronal properties in rat cortex; rather it appears to strengthen excitatory interactions among neurons. Direct osmotic effects, rather than brain injury caused by swelling or edema, can help explain the clinical relationship between overhydration and seizure noted above.

PHENOTYPIC CHANGES OF HIPPOCAMPAL NEURONS AND DYNORPHIN IN HUMAN EPILEPSY. N.C. de Lanerolle, S. Sundaresan*, M.L. Brines* and D.D. Spencer. Sections of Neurosurgery and Neuroendocrinology, Yale Univ. Sch. Med., New Haven, CT 06510.

The imunocytochemical distribution of dynorphin-A (DYN) was examined in surgically removed hippocampi of patients with medically intractable tumor associated (TTLE) and cryptogenic or non-tumor related (CTLE) temporal lobe epilepsy. In TTLE, DYN immunoreactivity was in the somata of dentate granule cells and in their mossy fiber axons which terminate on CA4 and CA3 neurons. There was no immunoreactivity in the dentate molecular layer (ML). This pattern is similar to that reported in non-epileptic human tissue and animals. In the CTLE hippocampi DYN was localized within the somata of granule cells and mossy fiber axons/terminals as in TTLE. Additionally, DYN immunoreactivity was observed in two new locations. (1) There was a dense band of immunoreactivity confined to the inner part of the ML, perhaps reflecting axon collateral "sprouting" from granule cells into this region. Such collateral sprouting has been reported in animal models of epilepsy (Science 239:1147, 1988). (2) Immunoreactivity was present within the cell bodies of large hilar neurons. Such neurons were present in TTLE but did not manifest DYN. In situ hybridization using anti-sense [35S]-prodynorphin mRNA oligonucleotide probe has been employed to determine the potential of hilar neurons in TTLE to express DYN. These changes in CTLE may be associated with increased excitability of hippocampal neurons if DYN functions as an excitatory neurotransmitter (Life Sci. 31: 1785, 1982).

A HUMAN DIALYTRODE: IN VIVO MEASUREMENTS OF NEUROACTIVE SUBSTANCES IN THE HUMAN HIPPOCAMPUS WITH SIMULTANEOUS DEPTH EEG RECORDINGS. M.J. During, G.M. Anderson*, R.H. Roth, D.D. Spencer. Departments of Neurosurgery, Pharmacology, Psychiatry and Laboratory Medicine, Yale School of Medicine, New Haven, CT 06510.

A combination microdialysis probe and depth electrode for human use was developed and characterized in vitro. Probes were stereotactically implanted (using MRI-derived coordinates) into the left and right hippocampi of patients with intractable epilepsy. The dialytrode enabled simultaneous monitoring of the depth EEG with hippocampal neurotransmitter release and ECF composition. During four seizures, in which microdialysis perfusion was pooled at 3 min intervals, neuroactive amino acid concentrations were elevated. GLU increased by 77±25% (basal levels 0.59±0.05μM); ASP increased by 43±26% (basal levels 1.58±0.13μM); TAU increased by 61±17% (basal levels 0.16±0.03 μM); both SER and GLN levels were unchanged. In addition, interictal spike activity correlated with dialysate lactic acid concentration - a measure of local glucose metabolism. Hippocampal ECF levels of anticonvulsants were detectable and showed pharmacokinetics similar to the plasma compartment. This technique makes possible the quantification of the neurochemical concomitants of regional brain activity, and a means to determine basal, diurnal, ictal and stimulated neurotransmitter release, glucose metabolism, ionic concentrations and drug monitoring. Implantation of bilateral probes enables comparison of the in vivo neurochemistry of the lesion (epileptic focus) versus nonlesion side in selected patients.

LAMINAR AND CIRCUMFERENTIAL ALTERATIONS IN INHIBITORY AND EXCITATORY NEUROTRANSMITTER RECEPTOR DENSITY IN THE DEVELOPING EPILEPTIC FOCUS USING THE ALUMINA PRIMATE MODEL. RAE Bakay, MS Fiandaca, D Levy*, GP Brinkley* & CM Epstein*. Yerkes Regional Primate Research Center of Emory Univ. & Veterans Admin. Medical Center, Atlanta, GA 30322.

Fourteen juvenile monkeys (M. mulatta) received alumina injections into the left pre-central gyrus to produce a focal motor epilepsy. Electroencephalographic recordings were used to determine the stage of epileptogenisis of the subject prior to sacrifice. Four pre-epileptic animals with only slowing on EEG were sacrificed from 2 to 4 weeks following alumina injection. Two of the subjects demonstrated an increase in the number of muscimol (MUS) and flunitrazepam (FNZP) receptors in the area adjacent to the alumina. Four acutely epileptic subjects (seizures < 1 wk) demonstrated loss of multiple neurotransmitter receptors in the epileptic focus. Six mature epileptic animals (seizures > 1 mo) demonstrated further loss of receptors but only the MUS and FNZP receptors were reduced to background. Although the total number was decreased, the relative density of glutamate receptors was increased in the area of the epileptic focus. A relative increase in MUS receptors in the cortex adjacent to the epileptic focus was suggestive of an "inhibitory surround." Saturation binding studies indicate that the changes in the focus are due to loss of receptors without significant change in affinity. This work was supported by the Medical Research Service of the Veterans Admin. and the Yerkes NIH Core Grant (RR-00165).

SLOW DEPOLARIZATIONS FOLLOWING PENICILLIN-INDUCED PAROXYSMAL DEPOLARIZATIONS IN THE MOTOR CORTEX

O.W. Witte, S. Uhlig* and E. Valle*. Neurologische Universitätsklinik, Moorenstr. 5, D-4000 Düsseldorf, F.R. Germany

Depolarizing afterpotentials of penicillin-induced paroxysmal depolarizations (PDS) were further investigated in the present study. The experiments were performed on the motor cortex of the rat in vivo using standard intracellular recording techniques.

Neurones with high resting membrane potential (-84.9 mV, n=21) displayed slow afterdepolarizations with a duration of 1800 ±200 ms. Similarity of duration, time course and changes with epicortical stimulation to extracellular K^+ accumulation suggested that these afterpotentials were caused by K^+ accumulations in the extracellular space.

Reduction of neuronal K^+ conductance by intracellular injection of large amounts of Cs^+ revealed afterdepolarizations which peaked 700 ms following PDS onset and increased in amplitude with membrane depolarization. The potential dependence was caused by membrane rectification.

It is concluded that in the penicillin focus in vivo excitatory postsynaptic potentials as well as passive membrane depolarizations caused by extracellular K^+ accumulation can be demonstrated to follow the PDS.

$GABA_A$- AND $GABA_B$-DEPENDENT IPSPs FOLLOWING PENICILLIN-INDUCED PAROXYSMAL DEPOLARIZATIONS IN THE HIPPOCAMPAL SLICE

R. Domann*, T. Dorn* and O.W. Witte (SPON: ENA). Neurol. Klinik, Univ. Düsseldorf, Moorenstr. 5, D-4000 Düsseldorf, F.R.Germany

Penicillin-induced paroxysmal depolarizations are followed by pronounced afterhyperpolarizations caused by synaptically and intrinsically evoked inhibitory potentials. In this study the participation of inhibitory postsynaptical potentials (IPSPs) was further analyzed.

The study was performed on slices of rat hippocampus, using standard preparation techniques. Intracellular recordings were obtained from 47 CA1 pyramidal cells.

The afterhyperpolarization lasted 2100 ms (S.D.=300, n=21). An early component of about 400 ms duration was Cl^--dependent as revealed by intracellular injection of KCl. Bath application of the $GABA_A$-antagonist bicuculline blocked this component. A second component of the afterhyperpolarization which lasted for about one second was blocked by bath application of the $GABA_B$-antagonist phaclofen. The reversal potential of this component indicated K^+-dependence.

It is concluded that penicillin-induced paroxysmal depolarizations are followed by $GABA_A$- and $GABA_B$-mediated IPSPs. The $GABA_A$-mediated IPSP in the penicillin superfused slice is larger than that in normal tissue.

CONNEXIN mRNAs ARE ELEVATED IN EPILEPSY. C.C.G. Naus and J.F. Bechberger*. Dept. of Anatomy, University of Western Ontario, London, Canada, N6A 5C1.

To determine a possible role for gap junctions in epilepsy, the level of mRNA coding for the gap junction proteins, connexin32 and connexin43, was examined in RNA isolated from cerebral tissue samples obtained at the time of surgical resection for the treatment of intractable seizure disorder. Pathological examination revealed mild gliosis and cytoarchitectural changes such as ectopic neurons and focal neuronal loss. No neoplastic characteristics were found in these samples. Northern blot analysis of total cytoplasmic RNA isolated from these samples indicated a much higher level of the connexin43 mRNA in the seizure tissue than in similar peritumoural tissue obtained during surgical removal of cerebral tumours. In contrast, there was only a slight increase in the level of connexin32 mRNA in the epileptic tissue.

In order to examine the expression of gap junction mRNA at the cellular level, we are pursuing in situ hybridization and immunocytochemistry on sections of similar brain tissue.

AN ANIMAL MODEL OF GLOBAL ISCHEMIA IN THE MONKEY: NEUROPATHOLOGICAL AND BEHAVIORAL FINDINGS. S.Zola-Morgan, L.R. Squire, D.G. Amaral, J.E. Fleischer,* M.S. Scheller,* and M.H. Zornow.* V.A. Medical Center, San Diego, Dept. of Psychiatry, UCSD School of Medicine, La Jolla, CA 92093, Salk Institute, La Jolla, and Dept. of Anesthesiology, UCSD School of Medicine, La Jolla.

Patient R.B. exhibited marked anterograde amnesia following an ischemic episode. The principal histological finding was a bilateral lesion involving the entire CA1 field of the hippocampus. We have developed a model of global ischemia in the monkey using pharmacologically-induced hypotension in combination with abrupt inflation of a neck cuff. Six cynomolgus monkeys were subjected to ischemia lasting 14-17 min. Following a two-week survival, neurohistological examination revealed bilateral symmetrical neuronal loss within the CA1 field of the hippocampus. Cell loss was most extensive at caudal levels of the hippocampus. There was also substantial loss of somatostatin-staining cells in the dentate gyrus. In four additional monkeys the cognitive effects of a 15-min period of ischemia were evaluated. On delayed non-matching to sample, the ischemic monkeys performed normally at delays of 8s and 60s, but exhibited a marked impairment at a delay of 10 min. This model makes it possible to compare the severity of memory impairment associated with ischemia to the memory impairment associated with surgical lesions of the medial temporal region.

141.2

REDUCED SIZE OF HIPPOCAMPAL FORMATION IN AMNESIC PATIENTS: A MAGNETIC RESONANCE IMAGING STUDY. L.R. Squire, D.G. Amaral, G. Press. VA Med. Ctr. San Diego, CA, Dept. Psychiatry, UCSD, LaJolla, CA, Salk Institute, La Jolla, CA and Dept. Radiology, UCSD, La Jolla, CA.

Neuropathological study of a well-characterized amnesic patient (R.B.) demonstrated that damage limited to the hippocampus can cause a clinically significant memory impairment. This case, together with a few others, provides the only available information about the anatomy of amnesia in humans. In an effort to obtain improved anatomical information from living patients, we developed a new high-resolution protocol for imaging the human hippocampus. The images were obtained with a 1.5 T magnet using a T1-weighted sequence (TR=400, TE=20, 6 NEX, FOV=16, matrix = 256x256). Six interleaved, 5mm-thick slices were obtained in the coronal plane, with the patient's head tilted posteriorly so that the hippocampus was imaged precisely perpendicular to its longitudinal axis. In normal subjects, the hippocampal formation could be visualized in considerable cytoarchitectonic detail. Specifically, it was possible to identify the pyramidal cell layer of the hippocampus and the subiculum, the perforant path, the fimbria, the alveus, and the stratum lacunosum-moleculare. In three amnesic patients, one who had suffered a respiratory arrest, and two of unknown etiology, the area comprising the dentate gyrus, the hippocampus, and the subiculum was markedly reduced bilaterally. In the patients this area was 49% of the corresponding area in age-matched control subjects ($t[5]=5.3$, $p<.01$). The size of the temporal lobe was the same in the two groups. These findings provide the first magnetic resonance evidence from amnesic patients of bilateral medial temporal lobe damage. The method provides a means for classifying memory-impaired patients independently of their behavioral test scores and a way to understand quantitative differences among patients.

141.3

THE STRUCTURES DAMAGED IN AMNESIA CONTRIBUTE SIMILARLY TO RECALL AND RECOGNITION MEMORY. F. Haist, A.P. Shimamura, and L.R. Squire, VA Med. Ctr., and Dept. of Psychiatry, UCSD, La Jolla, CA 92093.

The rate of forgetting in recall and recognition memory was assessed in seven patients with Korsakoff's syndrome, six other amnesic patients, and two groups of control subjects. Subjects participated in 12 separate learning/test sessions, each of which involved a different study list of 20 words and a subsequent retention test. Six of the 12 sessions assessed free recall followed by cued recall from 3-letter stems, and 6 sessions assessed recognition memory using a two-alternative, forced-choice procedure. The retention interval between word-list learning and testing ranged from 15 s to 2 weeks for amnesic patients, and from 15 s to 8 weeks for control subjects. Patients with Korsakoff's syndrome and non-Korsakoff amnesic patients were impaired on all 3 tests: recognition, recall, and cued recall. In order to compare the severity of impairment in recall and recognition memory, recognition memory scores were equated between amnesic patients and control subjects by matching shorter retention intervals for amnesic patients to longer retention intervals for control subjects. When levels of recognition memory were equated in this way between amnesic patients and control groups, levels of recall were also virtually the same for amnesic patients and control subjects. The results support the conclusion that recall and recognition memory are linked deficits of declarative memory that reflect damage to the same functional system.

141.4

INTACT LEARNING OF SPECIFIC TEXT BY AMNESIC PATIENTS AS MEASURED BY READING SPEED G. Musen*, A. P. Shimamura and L. R. Squire, V.A. Med. Ctr., and Dept. of Psychiatry, UCSD, La Jolla, CA 92093

Amnesic patients exhibit preserved learning abilities in certain skill-based tasks such as the reading of mirror-reversed words. It has been unclear whether this learning ability reflects a general practice effect or a specific learning of the particular words read. Efforts to address this question have been complicated by differences in baseline reading speed between memory-impaired and normal groups. We measured reading speed for passages of text in 8 amnesic patients (four with Korsakoff's syndrome and four other amnesic patients) and 9 age-matched control subjects. Subjects read a text (20 lines) three consecutive times and then read a different text three times. The order of the two texts was counterbalanced across subjects. The amnesic patients exhibited the same initial reading speed as the control subjects (70s vs. 68s) and decreased their reading speed across the three trials at a similar rate. Importantly, on the first reading of the second passage, the reading speed of both groups returned to the same level that had been achieved on the first reading of the first passage. Finally, the amnesic patients were impaired in answering questions about the content of the passages. There was no difference in the reading speed performance between patients who performed well on the comprehension test and patients who performed poorly. These results show that improved reading speed in amnesic patients is specific to the words and to the associations between words that occur in particular texts. Thus, facilitatory effects of previous exposure to specific items can be demonstrated in skilled behavior independently of declarative memory and independently of the structures damaged in amnesia.

141.5

DIRECT CONNECTIONS FROM HIPPOCAMPUS TO PREFRONTAL CORTEX: A TOPOGRAPHIC STUDY IN CAT AND MACAQUE MONKEY. C. Cavada and F. Reinoso-Suárez. Dept. Morfología, Fac. Medicina, Univ. Autónoma de Madrid, Spain.

In the course of a broader study on the connectivity of the prefrontal cortex (PFC), we have uncovered the existence of heavy direct projections between two structures involved in memory function, the hippocampus and the orbitofrontal sector of PFC.

Injections of the retrograde tracers HRP, Fast Blue and Diamidino Yellow were placed in various sectors of PFC in cats and macaque monkeys. Large numbers of retrogradely labeled neurons were observed in the hippocampus ipsilateral to the injections only following orbitofrontal cortex deposits. The labeled neurons were located principally in field CA1. In cat, the rostral two-thirds of the hippocampus contain 75% of the labeled neurons. In macaque, however, over 70% of hippocampal cells projecting to orbitofrontal cortex are located in the rostral third.

A double labeling experiment carried out in both hemispheres of a macaque monkey revealed that Walker's cytoarchitectonic areas 14 and 10-11 are the targets of hippocampal projections. Interestingly, ~60% of the cells that project to caudomedial area 14 are located in the rostral third of the hippocampus, whereas the caudal third contains ~60% of the hippocampal neurons that project to rostal areas 10 and 11.

The prominent connectional links between the hippocampus and orbitofrontal cortex, and their remarkable topographic specificity open new questions regarding the neuronal circuitry involved in memory processing.

AUDITORY-VISUAL ASSOCIATIONS, HEMISPHERIC SPECIALIZATION, AND TEMPORAL-FRONTAL INTERACTION IN THE RHESUS MONKEY. D. Gaffan and S. Harrison*. Dept. Exptl. Psychology, Oxford University, OX1 3UD, England.

The left superior temporal gyrus (STG) is more important than the right STG for audition in the monkey. The prefrontal cortex (PFC) is important for cross-modal association. The left PFC is specialized for language in man. Therefore, we investigated the involvement of the left and right PFC in auditory-visual association in the monkey. Each of 6 noises was the instruction to choose one of 6 visual stimuli. Six normal animals achieved a performance level of 12.5 percent errors in 2-choice trials (chance = 50 percent) and were divided into 2 groups for surgery. Group 1: unilateral right PFC ablation left error rate nearly unchanged, at 13 percent. Addition of a left unilateral STG ablation to this group reduced their performance nearly to chance. Group 2: unilateral left PFC ablation doubled error rate, to 24 percent. Addition of right STG ablation produced no further impairment. Further addition of forebrain commissurotomy reduced their performance nearly to chance. Thus, auditory-visual association requires a temporal-frontal cortical interaction for which the left hemisphere is specialized, and the forebrain commissures are important in recovery from left prefrontal lesions.

141.7

EXPERIMENTAL MEMORY CHANGE AFTER FRONTAL AND TEMPORAL LOBE LESIONS. P.J Eslinger and L.M. Grattan,* Neurobehavioral Lab, Brown Univ. Rhode Island Hospital, Providence, R.I.

We probed the nature of visual memory processing after brain injury with an experimental technique that may influence organization and encoding of information. Nineteen adult patients with focal frontal and temporal lobe lesions were studied and compared to 7 patients with focal posterior (parietal-occipital) lesions. Each subject copied complex figures in standard format (self-directed copy of full figure) and experimental format (examiner-directed sequential presentation of elements comprising figure). Stimuli and formats were randomly chosen for 2 sessions separated by 48 hours. Twenty minute delayed visual recall (measured relative to initial copy scores and treated as "percentage recall from copy") indicated that memory was more accurate under experimental conditions for the following lesion groups: inferior, mesial frontal, right dorsolateral frontal, and temporal lobe. The experimental format led to dissociations between superior and inferior mesial frontal groups, and between left and right dorsolateral frontal groups.

Findings indicate that the system of cerebral structures subserving visual memory are selectively amenable to sequential stages for perceiving, encoding and retaining complex visual information. Results are discussed within a framework of how experimental formats of information processing may affect visual memory. Supported in part by NINDS Grant NS 26985 Memory Disorder Research Center.

MONKEYS DEMONSTRATE HIGH LEVEL OF RECOGNITION MEMORY IN DELAYED NON-MATCHING TO SAMPLE WITH RETENTION INTERVALS OF 6 WEEKS. R.C. Saunders, NIMH, Washington, D.C. 20032.

In humans, long term retention of visual 'habits' and 'memories' has been well documented even with delays of many weeks. In monkeys, while long term retention of 'habits' has been readily demonstrated, high level long term retention of 'memories' has not. The present study assessed long term recognition memory in monkeys using a modified delayed non-matching to sample task. Rhesus monkeys were presented two identical sample objects over two lateral wells and allowed to view them for 30 s. After a 10 s interval the sample object was presented together with a new object for a total of 20 s. Recognition memory was assessed by comparing the viewing time of the novel object with that of the more familiar sample object. Because monkeys are attracted to novel stimuli they tend to view the novel object longer than the previously presented sample object at the retention test. For long retention intervals of 1 to 6 wks, the object to be remembered was presented as a sample object in 6 trials during 2 consecutive testing sessions. For the retention test the sample was presented only in a retention trial together with a novel object. Retention was assessed for delays of 10 s, 24 hrs, 48 hrs, 1 wk, 2 wks, 3 wks and 6 wks. Monkeys were capable of discriminating novel from familiar objects on nearly 80% of the test trials even at a delay of 6 wks.

141.9

EFFECTS OF RHINAL CORTICAL LESIONS ON VISUAL RECOGNITION MEMORY IN RHESUS MONKEYS. E.A. Murray, J. Bachevalier, and M. Mishkin. Lab. Neuropsychology, NIMH, Bethesda, MD 20892.

Earlier work had provided indirect evidence that the rhinal cortex (Rh) is a third temporal-lobe component of a limbic memory system (Murray et al., 1985, Soc. Neurosci. Abstr., 11: 461). In order to directly assess the contribution of the Rh to recognition memory, we have now examined the behavioral effects of removal of this region. Naive rhesus monkeys were trained on the trial-unique version of delayed nonmatching-to-sample (DNMS) with 10s between sample presentation and choice test until they attained the criterion of 90 correct responses in 100 trials. They then received an Rh lesion that included the entorhinal cortex, which occupies the medial bank of the rhinal sulcus and the ventral surface cortex medial to it, and the perirhinal cortex, which occupies the lateral bank of the rhinal sulcus. Following a 10-14 day recovery period, the monkeys were retrained on DNMS. When they reattained criterion, they were given a performance test that taxed their recognition memory by requiring them to remember either single objects for increasingly longer periods of time or a list of objects. Monkeys with Rh ablations required about 400 trials to relearn DNMS and attained a mean of 68% correct responses on the performance test whereas the controls relearned immediately and attained 92% correct responses. These preliminary results indicate that the Rh itself makes a critical contribution to recognition memory, either directly, by virtue of its connections with the neocortex and diencephalon, or indirectly, by relaying sensory information from modality-specific neocortical areas to the other medial temporal lobe limbic structures known to be important for memory.

141.10

CORTICAL AFFERENTS TO THE POSTERIOR PARAHIPPOCAMPAL GYRUS OF THE RHESUS MONKEY. I. INPUT FROM LIMBIC, MULTIMODAL AND UNIMODAL AREAS IN TEMPORAL, INSULAR, PARIETAL AND OCCIPITAL CORTICES. G.J. Blatt, D.L. Rosene and D.N. Pandya. Boston University School of Medicine, Department of Anatomy, Boston, MA, 02118 and Edith Nourse Rogers Memorial Veterans Administration Hospital, Bedford, MA 01730.

The posterior parahippocampal gyrus (PPHG) receives input from limbic, auditory, visual and somatosensory association cortices as well as from multimodal cortices. The present study investigated the organization of this cortical input to areas TH, TLc, TF, THO, TLO and TFO using injections of fluorescent retrograde tracers in five rhesus monkeys. Injections into area TH or THO labeled cells in the lateral part of the rostral bank of the superior temporal gyrus (auditory association areas TS2 and TS3), multimodal area TPO of the superior temporal sulcus (STS), visual area PGm, areas 23, 29, 30 of the cingulate gyrus (CG) and the insula. In contrast, injections in area TF or TFO in the medial bank of the occipitotemporal sulcus labeled cells in multimodal areas PGA, IPa and TPO and visual areas TEA and TEM in the STS, visual areas in the parietal and occipital lobes (areas PGm, 7a, LIP, 19, V3A and V4d), areas 23 and 29 of CG and in the agranular insula (AgI). In between TH and TF lies another area that we have designated TL. While it receives inputs from some of the same areas as TH and TF, the relative absence of cortical inputs is striking. Thus, while the medial (TH, THO) and lateral (TF, TFO) parts of the PPHG receive some similar cortical inputs, most originate from different limbic, unimodal or multimodal association cortices, e.g., medial PPHG receives unimodal input from auditory association areas while the lateral PPHG receives unimodal input from visual areas. It is interesting that different longitudinal strips of projection neurons in CA1 of the hippocampal formation differentially project to area TH, TL or TF. Taken together these data suggest that specific areas in the PPHG receive differential cortical and hippocampal inputs that may contribute to memory processes in the rhesus monkey brain. PROJECTIONS FROM INFERIOR TEMPORAL CORTEX TO WIDESPREAD PERIRHINAL AREAS IN INFANT MONKEYS. M.J. Webster, L.G. Ungerleider, and J. Bachevalier. Lab. Neuropsychology, NIMH, Bethesda, MD 20892.

Visual recognition memory depends on interactions of inferior temporal cortex (IT) with both the amygdala, via direct connections, and the hippocampus, via indirect connections through entorhinal cortex. Last year we reported a transient projection from area TEO (posterior IT) to the amygdala in infant monkeys. We now have evidence in the same animals for an exuberant but transient projection from area TE (anterior IT) to the perirhinal cortex. To investigate the development of IT-limbic connections and their relationship to the ontogeny of memory, we injected tritiated amino acids into area TE and WGA-HRP into area TEO, or vice versa, in a total of 6 adult and 4 infant rhesus monkeys. Previous studies have shown that area TE has access to the hippocampus via a two-stage pathway involving both perirhinal areas 35 and 36 and entorhinal area 28. Our results for the adult are consistent with those studies and indicate that neither area TE nor TEO is connected directly to area 28. In addition, we found area TE to be reciprocally connected to areas 35 and 36, primarily along the anterior extent of the rhinal sulcus. In contrast, area TEO does not project directly to areas 35 and 36, although it does receive a projection back from these areas. This asymmetry parallels the one shown for TEO-amygdala connections (Iwai and Yukie, '87). Projections in the infant monkey resemble those in the adult, although the projection from area TE to areas 35 and 36 is much more extensive in the infant, terminating along the entire length of the rhinal sulcus. These transient projections may become stabilized in infants with brain injury, thus explaining recovery of memory function in such cases.

141.12

LIMBIC-DEPENDENT MEMORY: EARLY OR LATE DEVELOPING? Adele Diamond, Psychology Dept, U of P, 3815 Walnut, Phila, PA

Success on Delayed Non-Match to Sample (DNMS) does not appear until late in infancy (4 months in rhesus monkeys, over 12 months in human infants). This has been taken as evidence that the limbic-dependent memory system matures late, as DNMS is dependent on hippocampal function. However, success on Visual Paired Comparisons (VPC), which is similar to DNMS, appears very early (by 15 days in monkeys, 2 months in humans). In both DNMS & VPC, the subject is presented a sample, a delay is imposed, then the sample is paired with a novel stimulus. On both tasks, memory of the sample is inferred from subject's choice of the novel (non-matching) stimulus. Performance on VPC is disrupted by hippocampal-amygdala lesions even at 15 days. Thus, while DNMS results suggest late maturation of limbic memory system; VPC results suggest early maturation.

Might success on DNMS appear late because of requirements of the task other than memory? In VPC, the subject looks at whichever stimulus is interesting; reward = the stimulus. In DNMS, the subject displaces the stimulus to retrieve the food reward beneath; reward = the food, not the stimulus. Perhaps the indirect, means-end response required by DNMS is what accounts for the late appearance of success on the task.

120 human infants were tested; 60 on VPC & 60 on DNMS. On both tasks the same trial-unique objects were used and the stimulus served as its own reward. Each subject received 2 trials at delays of 0, 10, 60, 180, & 600 sec. Infants of 6 & 9 months succeeded on DNMS & withstood delays on DNMS fully as long as those on VPC (180 sec at 6 mo & 600 sec at 9 mo). Conclusion: success on DNMS appears very early when subjects reach, not in order to obtain something else, but to obtain the stimulus itself. This is consistent with an early maturational timetable for limbic-dependent memory. (Supported by NIMH R01 MH/HD41842 & NIH BRSG S07-RR-07083.)

141.13

DIFFERENTIAL FORGETTING OF PAIRED ASSOCIATES, PROSE, AND FIGURAL STIMULI IN DEMENTIA. A. Tröster*, D. Jacobs*, D. Salmon, and N. Butters (SPON: P. Langlais). Dept. of Psychiatry, Univ. of California, San Diego, La Jolla, CA 92093 and VA Medical Center, San Diego, CA 92161.

Studies of forgetting rates in Alzheimer's disease(AD) disagree whether or not AD patients forget more rapidly than do normals (NC).These conflicting results may be due to different methodologies employed (i.e., repeated vs. single learning trials). This study compared forgetting rates of AD, Huntington disease (HD), and NC subjects on the WMS-R Verbal and Visual Paired Associates (VerPA and VisPA) (repeated trials), and Logical Memory (LM) and Visual Reproduction (VR) (single trials) tests.

AD and HD patients forgot LM and VR materials more quickly than did age and education matched NCs.LM and VR, but not VerPA and VisPA forgetting rates, differentiated AD and HD patients in both the early and later stages of the diseases. A discriminant function based on LM and VR savings scores correctly classified 84% of the 176 subjects. The addition of VerPA and VisPA savings scores to the discriminant function failed to enhance classification accuracy. These results suggest that the use of repeated learning trials may lead to overlearning in some patient groups and thereby obscure important differences among patient groups' forgetting rates. 141.14

PICTORIAL PRIMING AND WEIGHT BIASING IN DEMENTIA. W. Heindel*, D. Salmon and N. Butters. Depts. of Psychiatry and Neurosciences, Univ. of Cal., San Diego, La Jolla, CA 92093 and VA Medical Center, San Diego, CA 92161.

Alzheimer's Disease (AD) and Huntington's Disease (HD) patients have been shown to display different patterns of performance on motor skill learning and verbal priming tasks. The present study compares AD and HD patients on two other tests of "implicit" memory: (1) A pictorial priming test in which patients were asked to "say the first thing you think of" when shown incompletely drawn pictures; and (2) A weight biasing task in which subjects first were exposed to either a relatively heavy or a relatively light series of weights, and later were asked to rate the heaviness of a standard set of weights. HD patients, but not AD patients, demonstrated a normal increase in their ability to identify fragmented versions of previously seen pictures relative to novel pictures. In contrast, AD patients', but not HD patients', ratings of the standard set of weights were significantly influenced by the relative heaviness of the first series of weights. These results suggest that pictorial priming, like verbal priming, is dependent upon the neocortical association areas involved in the storage of semantic memory, whereas the biasing of weight judgments, like motor skill learning, may be dependent upon the integrity of the neostriatum. Supported by the Medical Research Service of the VA and by NIA grants AG-05131 and AG-08204.

mRNA REGULATION I

142.1

PRODYNORPHIN mRNA LOCALIZATION AND REGULATION IN THE RAT PITUITARY. R. Day, M.K.-H. Schafer*, S.J. Watson and H. Akil. Mental Health Res. Inst., Univ. of Michigan, Ann Arbor , MI, 48109-0720.

The presence of prodynorphin (proDyn) related opioid peptides in the pituitary is well established. By immunohistochemical and radioimmunological techniques, proDyn peptides were co-localized in gonadotrophes with LH and FSH. ProDyn peptides are also known to exist in the neurosecretory terminals of the posterior pituitary which originate in is the magnocellular cells of the hypothalamus. Our study has re-examined the distribution of proDyn in the pituitary by detection and quantification of its mRNA. *In situ* hybridization and Northern blot analysis were used in this study. The distribution of ProDyn mRNA in the anterior lobe as observed by *in situ* hybridization correlates with the previous observation of localization within gonadotrophes. In addition, we provide evidence that all the melanotrophes of the intermediate lobe contain proDyn mRNA. These are the same cells which are well known for their high abundance in proopiomelanocortin (POMC) peptides and mRNA. This co-expression of opioid precursors is unique and the functional significance needs to be further explored. By Northern gel analysis intermediate lobe proDyn mRNA is more abundant than anterior lobe proDyn mRNA, but proDyn mRNA from both tissues are the same size as proDyn mRNA from other sources such as hippocampus and striatum (~ 2.4 k base pairs). Since melanotrophes are known to be under dopaminergic control (POMC mRNA has been shown to be modulated by dopaminergic compounds), this study has also examined the effects of dopaminergic agonists and antagonists on proDyn mRNA in the intermediate lobe. The results will be discussed in the context of co-regulatory aspects with POMC. Supported by the Theophile Raphael Fund and NIMH grant MH 422251. 142.2

NUCLEUS CAUDALIS PREPROENKEPHALIN mRNA: BIPHASIC ENHANCEMENT BY AFFERENTS. T. Nishimori*, G. Buzzi*, M. Moskowitz, and G.R. Uhl. NIDA/ARC and Depts. of Neurology & Neuroscience, JHUSM, Baltimore, MD 21224, and MGH & HMS, Boston, MA 02114.

Preproenkephalin mRNA in neurons of laminae I and II of the nucleus caudalis of the trigeminal may play an important role in modulating pain. Large- and small-caliber primary afferents may regulate the function of these segmental neurons. To investigate the impact of different inputs, we have used *in situ* hybridization to assess the influences of high- and low-intensity stimulation and capsaicin lesions of the trigeminal nerve on levels of preproenkephalin mRNA expression in nucleus caudalis neurons.

0.1 mA stimulation, activating large-caliber fibers, increases the number of neurons expressing preproenkephalin mRNA immediately after the end of 1 hour stimulation and at 6-24 hrs. Expression was less altered 2 hrs. following stimulation. 1.0 mA stimulation, activating both large and small caliber fibers, failed to increase the number of preproenkephalin expressing neurons until 6 hours following the stimulus in normal animals. Animals that were subjected to selective small-fiber capsaicin lesions displayed more hybridizing neurons both immediately and 6 hours after the end of 1.0 mA stimulation.

Primary afferent information can thus produce a time-dependent induction of preproenkephalin gene expression. A "rapid response" (0-1 hr) appears to be induced by large caliber inputs but suppressed by simultaneous stimulation of small caliber fibers. A "later response" (6 hr) is found when either large diameter or large- and small- caliber fibers are stimulated.

142.3

AGE-RELATED DECREASE IN PROOPIOMELANOCORTIN (POMC) GENE EXPRESSION IN THE ARCUATE NUCLEUS (ARC) OF THE MALE RAT. D. A. Gruenewald* and A. M. Matsumoto. VAMC, GRECC, and Univ. of Washington Sch. of Med., Seattle, WA 98108.

Hypothalamic β-endorphin (βE) activity has been hypothesized to increase with age, inhibiting gonadotropin releasing hormone (GnRH) and gonadotropin secretion. We determined the effects of aging on gene expression of the βE precursor POMC in male rats. Three 20μm coronal sections from the rostral ARC of 3-month (n=6) and 23-month old (n=4) F344 rats were anatomically matched, and POMC mRNA levels were quantitated by in situ hybridization, using a ^{35}S-labeled oligodeoxynucleotide probe complementary to a portion of rat POMC cDNA and a computerized image analysis system. The number of silver grains/cell and cells/ section were used as indices of cellular POMC mRNA content and number of neurons expressing the POMC gene, respectively. Results (mean ± SEM):

	Grains/Cell	Cells/Section
3-month old	73 ± 4	72 ± 6
23-month old	59 ± 3 (p<0.05)	57 ± 9 (p<0.20)

There was an age-related reduction in rostral ARC POMC mRNA content and a trend towards fewer neurons expressing the POMC gene. We conclude that in the male rat, aging is associated with reduced POMC gene expression in rostral ARC neurons, suggesting that age-related reduction in GnRH activity is not related to increased synthetic capacity of βE neurons.

142.4

TISSUE-SPECIFIC CHOLINERGIC MECHANISMS REGULATE PREPRO-ENKEPHALIN mRNA. J. DeCristofaro, G. Weisinger*, E. La Gamma Depts of Peds and Neurobio, Stony Brook, NY 11794-8111.

Adrenal enkephalin (ENK) peptide and prohormone levels increase 3-fold after combined cholinergic-nicotinic and muscarinic treatments (Neurosci, in press). To determine whether mRNA levels for prepro-ENK also increase and whether this effect is tissue-specific, groups of rats were treated for four days with nicotine (5 mg/kg sc q12h), oxotremorine (muscarinic agonist, 1 mg/kg sc q12h), both agents, or an equal volume of saline vehicle, or not treated (control). Twelve hours after the last injection, total RNA was extracted from the adrenal medulla and the brain striatum. Northern blots were performed using a 435 bp Pvu II fragment of pRPE2 (entire translated region of rat prepro-ENK). Northern blot analysis revealed that nicotine treatment increased adrenal prepro-ENK mRNA levels 20-fold over saline treated or control groups. Oxotremorine treatment resulted in a 50-fold rise and combined cholinergic treatment >100-fold rise. Striatal prepro-ENK mRNA increased only slightly (2-3 fold) with each of these treatments including saline. Saline treatment alone did not alter adrenal prepro-ENK mRNA levels. S1 analysis showed that these treatments alter transcription at the level of initiation (see Weisinger et. al. Neurosci abstr, 1989). These data suggest that cholinergic interactions regulate prepro-ENK mRNA in a tissue-specific manner and that transduction mechanisms may be cell type-specific. Supported by NSF #BNS8719872.

142.5

VASOPRESSIN mRNA IN THE NEUROHYPOPHYSIS. S.L.Lightman, D.Murphy*, A.Levy* & D.Carter*.Medical Unit, Charing Cross & Westminster Med.Sch.London, UK & Neuropeptide Laboratory, Inst.of Molecular & Cell Biology, Nat.Univ.of Singapore.

Vasopressin (VP) transcripts were detected by Northern blot analysis of RNA extracted from both rat and mouse pituitary neurointermediate lobes (NILs). These VP transcripts were shorter than those in the hypothalamus. Following digestion with RNAase H in the presence of Oligo(dT) the hypothalamic and neurointermediate lobe mRNAs co-migrated on Northern analysis. Adrenalectomy had no effect on NIL VP mRNA, but following osmotic stimulation with 2% saline drinking water there was an 8-fold increase in NIL VP transcript levels at 5 days and a 25-fold increase at 10 days. The anatomical distribution of the VP mRNA was investigated by *in situ* hybridization. In the basal state VP mRNA was only seen in the intermediate lobe. Saline loading, however, did not alter intermediate lobe VP mRNA - the marked increase detected by Northern blotting was found to be due to the dramatic appearance of abundant VP transcripts in the neural lobe. The origin of this mRNA is uncertain but is likely to be the neural lobe glial cells - the pituicytes, although the possibility of transport into the neurosecretory endings of hypothalamic supraoptic and paraventricular neurons cannot be discounted. The potential role of locally synthesized VP is also a matter for conjecture, but it may be involved in local paracrine control.

142.6

PROTRH GENE EXPRESSION IN THE RAT HYPOTHALAMIC PARAVENTRICULAR NUCLEUS (PVN) IS NOT REGULATED BY GLUCOCORTICOIDS. R.M.LECHAN, E.M. DYESS* AND S.L. LEE.* Div. of Endo., New England Med. Cntr. , Boston, MA 02111.

At pharmacologic doses, glucocorticoids reduce TSH secretion in both experimental animals and man (Wilber & Utiger, JCI 48:2096,1969). Since a glucocorticoid-receptor binding consensus sequence is present in the 5'-flanking region of the TRH gene (Lee et al., JBC 263:16604, 1988), we determined whether dexamethasone (dex) regulates proTRH mRNA levels in the hypophysiotropic neurons of the hypothalamic PVN. Adult male adrenalectomized (adx) Sprague-Dawley rats were treated with dex (100 ug/100 g B.W. i.p.) or vehicle. After two weeks, the brains were fixed by intracardiac perfusion with 4% paraformaldehyde and sectioned coronally on a cryostat through the PVN. Serial sections were hybridized with a 35S-labeled cRNA probe to proTRH or proCRH (gift of R.C. Thompson) and autoradiographed. PVN cell densities were analysed by computer imaging and compared to age matched normal controls. ProCRH mRNA content increased in adx animals compared to normal controls, whereas dex treatment resulted in suppression (Normalized Density Units (NDU) ± S.E.M.: Adx 3.5± .41; Cont. 1.99± .64; Dex 1.26 ± .29). In contrast, no significant alterations were observed in total proTRH mRNA content (NDU ± S.E.M.: Adx 1.31 ± .16; Cont 1.12± .20; Dex 1.34 ± .18). These studies indicate that glucocorticoids do not exert a significant effect on proTRH gene expression in the hypothalamic tuberoinfundibular system. The suprahypophysial effects of glucocorticoids on TRH secretion, therefore, may occur as a result of post-translational modification of proTRH gene products or are mediated by changes in other hypophysiotropic substances.

142.7

VASOPRESSIN AND OXYTOCIN SYNTHESIZING NEURONS RESPOND DIFFERENTIALLY TO INCREASE OF cAMP IN PRIMARY CULTURE .H. Schmale[1], K. Schilling*[2] and P. Oeding*[1] Inst.of Cellbiochem.[1],Univ.of Hamburg,2000 Hamburg 20 and Dept.of Anatomy and Cellbiol.[2],Univ.of Ulm, 7900 Ulm, Federal Republic of Germany.

Vasopressin(VP) and oxytocin(OT) genes are expressed in mutually exclusive sets of magnocellular neurons in the hypothalamus. Cell specificity and regulation have to be controlled by extra - and intracellular signals acting on one or the other gene. In order to identify such factors , we have used primary hypothalamic cultures prepared from 14 day old rat embryos to monitor specific gene expression by combined immunocytochemistry and in situ hybridization. Treatment of the cultures with either forskolin, the phospodiesterase inhibitor IBMX, or a combination of both, increased the number of VP expressing cells up to tenfold, whereas the number of cells expressing OT remained unaltered. Drug application had no mitogenic effect on VP-synthesizing neurons as determined by ^{3}H-thymidine labelling in combination with specific immunocytochemistry. The results show that increase of intracellular cAMP in hypothalamic primary cultures affects the expression of VP and OT genes in a differential fashion. The presence of putative response elements for the transcription factor AP2 in the 5'promoter regions of all VP genes sequenced so far but not in OT genes may provide the basis for the observed cAMP effect.

142.8

DETECTION OF VASOPRESSIN mRNA IN THE POSTERIOR PITUITARY BY SOLUTION HYBRIDIZATION AND NORTHERN BLOTTING. J.T.McCabe, E. Lehmann*#, J. Hänze*#, R. Lang*#, D. Ganten*# and D.W. Pfaff. Neurobiology and Behavior Laboratory, Rockefeller University, NY, NY 10021-6399 and #Department of Pharmacology, University of Heidelberg, Heidelberg, FRG.

Vasopressin messenger ribonucleic acid (VP mRNA) has been detected in several peripheral organs as well as in different areas of the brain. Results initially found by Lehmann indicate VP mRNA is present in the posterior pituitary as well (Lehmann, unpublished dissertation 1988, U. Heidelberg). We have employed solution hybridization and Northern blotting to analyze VP mRNA in hypothalamus, cortex, cerebellum, whole pituitary, and in separate anterior/intermediate lobe and posterior lobe samples (procedures: McCabe, et al., Neuroscience, 27:159, 1988). A low, but reliably detectable level of VP mRNA was present in the whole pituitary and posterior lobe tissue samples. In rats drinking 2% NaCl-water for 0, 2, 4, or 10 days, or 10 days and then 14 days of tap water, the levels of VP mRNA in the posterior pituitary were altered in a fashion that paralleled changes seen in the hypothalamus. The results from Northern blotting suggest VP mRNA in the pituitary is similar, but slightly shorter, than the message in the hypothalamus. To date, we have not determined, by in situ hybridization, whether VP mRNA is synthesized in pituicytes.

142.9

Sex steroids and fos expression in the rat brain and uterus. R.B. Gibbs, C. Mobbs, & D. Pfaff. Laboratory of Neurobiology and Behavior, Rockefeller University, N.Y., N.Y. 10021

Fos expression in the adult rat brain and uterus was examined following systemic treatment with estrogens and progesterone. Fifty female Sprague-Dawley rats were ovariectomized at least two weeks prior to steroid treatment. Animals received a subcutaneous injection of either estradiol (E: 5 µg E_2 in 10% ethanol/saline + 5 µg EB in oil), progesterone (P: 1 mg in oil), estradiol followed 24 hr. later with progesterone (E+P: same doses as above), or vehicle. Relative concentrations of fos mRNA in the uterus and ventromedial hypothalamus (VMH) were determined. Immunocytochemistry was also performed using an affinity purified rabbit IgG raised against fos amino acids 127-152 (provided by Dr. Tom Curran).

Fos mRNA within uterine tissue increased several fold relative to controls within 3 hr. after receiving E (consistent with Loose-Mitchell et al., Molec. Endocrin. v2, 1988 and Weisz et al., Molec. Endocrin. v2, 1988). Fos-like immunoreactivity (IR) was barely detectable in the uteri of untreated animals. However, IR within epithelial cells (but not myometrial or stromal cells) increased dramatically within 3 hr. after receiving E. This effect was dose-dependent and steroid-specific – IR did not increase in response to P, nor in response to a low concentration of E (0.13 µg E_2 + 0.13 µg EB) followed 24 hr. later with 1 mg P.

No induction of fos mRNA in the VMH was observed. Likewise, no effect of E, P, or E+P on fos-like IR was detected in the VMH, amygdala, hippocampal formation, or midbrain central gray. As a positive control, increases in fos-like IR in the PVN, SON or hippocampal formation following water deprivation or metrazol-induced seizures, were sucessfully detected as described by others (Morgan et al, Science v237, 1987 and Sagar et al., Science v240, 1988).

These data demonstrate that the regulation of fos by estrogens is both cell- and tissue-specific, and suggest that estrogenic effects in the adult brain are not mediated *via* an induction of fos mRNA or fos-related immunoreactive molecules.

142.10

TISSUE SPECIFIC EXPRESSION OF RAT ANDROGEN RECEPTOR mRNA. R. I. McLachlan*, B. L. Tempel, M. A. Miller*, D. B. Lubahn*, D. R. Joseph*, F. S. French*, E. M. Wilson*, W. J. Bremner*, D. M. Dorsa (SPON: D. Bredeson). Dept. Med. & GRECC, VAMC, Univ. Wash., Seattle, WA. 98108, & Lab. Reprod. Biol. Univ. N. Carolina, Durham, NC 27599.

We have used two probes from the rat androgen receptor (AR) cDNA (Tan et al, Mol. Endo., 1988:2, 1276) to assess tissue specific expression of AR mRNA. The probes were a 962 bp fragment [AR1] from the 5' untranslated region and a 532 bp fragment from the 5' end of the coding region (AR2). Poly A^+ selected RNA was isolated from adult male Wistar rats and was size-fractionated on a 0.75% agarose, 18% formaldehyde gel, partially hydrolyzed in 50 mM NaOH, transferred to a Nytran membrane and hybridized with ^{32}P-labeled cDNA probes. With the AR1 probe a single band of approx. 12Kb was detected in mRNA from the prostate and epididymis with lower levels apparent in the testis, kidney, skeletal muscle, and liver whilst transcript was just detectable in whole brain and spleen. With the AR2 probe a similar 12 kb band was apparent in the prostate, epididymis, kidney, and testis. In situ hybridization with ^{35}S-labeled AR1 riboprobe showed labelling of cells in the medial preoptic area and in the hippocampus. The latter two regions have been shown to specifically bind radiolabelled androgens. This AR probe should prove useful in further studies on the localization and physiological relevance of AR receptors in the brain.

142.11

THE DISTRIBUTION AND REGULATION OF ANDROGEN AND ESTROGEN RECEPTOR mRNA IN THE RAT BRAIN. R.B. Simerly and L.W. Swanson. The Howard Hughes Medical Institute and Salk Institute, La Jolla, CA 92138.

Recent studies suggest that steroid hormone receptors mediate the actions of their respective hormones by functioning as ligand-dependent nuclear transcription factors which alter the expression of specific genes or gene networks (see Evans, Science 240:889, 1988). A prerequisite to understanding the impact of these transcription factors on neural function is a clear understanding of the organization and regulatory profile of the neural systems in which steroid hormone receptors are expressed. We have begun to address these questions by applying *in situ* hybridization histochemistry and examing the distribution of neurons that express detectable levels of androgen (AR) and estrogen (ER) receptor mRNA-containing cells in the rat brain. ^{35}S-labeled RNA probes complementary to AR and ER mRNA were synthesized from cDNA inserts generously provided by Drs. C. Chang & S. Liao (Univ. Chicago) and Drs. M. Muramatsu & S. Koike (Univ. Tokyo), respectively. In both male and female animals, AR mRNA-containing neurons were found to be widely distributed in the forebrain, but the distribution of ER mRNA-containing cells was limited to a subset of the regions that contained AR mRNA-containing cells. Both ER and AR mRNA expression was particularly abundant in several sexually dimorphic nuclei including the anteroventral periventricular nucleus of the hypothalamus (AVPv), the medial preoptic nucleus, the encapsulated part of the bed nucleus of the stria terminalis (BSTe), and the posterodorsal part of the medial nucleus of the amygdala (MeAp). In addition, two other nuclei which share strong connections with these sexually dimorphic nuclei, namely the amygdalo-hippocampal area (AHZ) and the ventral premammillary nucleus, contained heavily labeled AR mRNA-containing neurons, but only the AHZ contained a high density of ER mRNA-containing cells. Nevertheless, the extensive overlap of the distributions of AR and ER mRNA-containing cells suggests that in many regions individual cells may express both receptors.

In order to evaluate the possible regulation of AR and ER mRNA levels within cells in sexually dimorphic nuclei we compared the density of AR and ER labeling over selected nuclei in intact and gonadectomized (28 days) male and female rats. In each sex, gonadectomy reduced levels of AR mRNA, but ER mRNA levels were significantly reduced only in ovariectomized female rats. These findings suggest that AR expression may respond to either testosterone or estrogen treatment, but that ER expression is selectively autoregulated.

142.12

IDENTIFICATION OF ESTROGEN-INDUCIBLE GENES IN RAT HIPPOCAMPUS VIA SUBTRACTIVE LIBRARIES. A. Maggi and E. Bettini*. MPL, U. of Milano, Piazza Durante 11, 20131 Milano, Italy.

We have recently demonstrated the presence of estrogen receptors in the rat hippocampus. The physiological significance of an action of this female sex hormone in this brain area is still unclear: the identification of genes induced by the hormone in this area might help in the understanding of the role played by estradiol in the control of this important area of the limbic system. To this aim, a cDNA library was constructed with mRNA isolated from the hippocampus of rats ovariectomized and injected with E_2. The library was probed with ^{32}P cDNA synthesized on templates of poly(A+) RNA extracted either from controls or E_2-treated rats. At the moment, a clone (13.4.3) of 600 bps has been isolated which hybridizes with a mRNA of ≈8000 bp present in hypothalamus, cerebellum, mid-brain, hippocampus. The induction of the 13.4.3 mRNA occours as soon as at 3 hours following the subcutaneous administration of the hormone. Preliminary analysis of the 13.4.3 sequence indicates a strong homology with the rat mitochondrial gene cytochrome oxidase subunit III

PEPTIDES: RECEPTORS I

143.1

EXPRESSION IN XENOPUS OOCYTES OF FUNCTIONAL BOMBESIN/GRP RECEPTORS TRANSCRIBED FROM A BACTERIOPHAGE cDNA LIBRARY. E.R. Spindel, T.P. Segerson*, P. Brehm, and R.H. Goodman*, Div of Neuroscience, Oregon Regional Primate Research Center, Beaverton OR 97006 and Div of Molecular Medicine, New England Med Center, Boston, MA 02111.

Bombesin and its mammalian homolog, gastrin-releasing peptide (GRP) are potent growth factors, neurotransmitters and paracrine regulators of GI function. To begin to characterize the diverse physiologic actions of bombesin-like peptides, we have examined the expression of mRNA encoding the bombesin receptor in *Xenopus laevis* oocytes. We have previously reported that oocytes injected with poly(A) RNA from murine Swiss 3T3 fibroblasts express functional bombesin receptors. Using this RNA, a size-selected cDNA library was prepared in the RNA expression vector lambda ZapII. Phage DNA was prepared from pools of 50,000 clones, linearized with the restriction enzyme *Not*I to produce sense-strand templates, and transcribed with T7 RNA polymerase. To each reaction, 1 ng of the serotonin Ic receptor cDNA was added as an internal control. Transcripts from 16 pools were screened by two-electrode voltage clamp analysis of microinjected oocytes treated with 2 μM bombesin. One pool of 50,000 transcripts produced a 20 nA peak inward current flow in response to bombesin. The pool of 50,000 bacteriophage clones was subdivided twice to enrich for the bombesin receptor cDNA, resulting in a pool of 7500 clones which gave a 50 nA peak response to 1 μM bombesin. It is likely that the bombesin receptor is encoded by a single cDNA within this pool.

143.2

EXPRESSION OF FUNCTIONAL PITUITARY SOMATOSTATIN RECEPTORS IN *XENOPUS* OOCYTES Michael M. White and Terry Reisine. Dept. of Pharmacology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

Functional somatostatin (SRIF) receptors were expressed in *Xenopus* oocytes following injection of RNA isolated from the anterior pituitary cell line AtT20. SRIF receptors were detected by measuring the ability of SRIF to inhibit cAMP formation stimulated by β2-adrenergic agonists in individual oocytes. β2-adrenergic receptors (β2AR) were expressed in oocytes by co-injecting RNA prepared by *in vitro* transcription of a β2AR cDNA clone with the AtT20 cell RNA. Uninjected oocytes do not express detectable levels of either β2ARs or SRIF receptors. In oocytes injected with both β2AR and AtT20 RNA, on the other hand, isoproterenol tretment led to a 2-3 fold increase in cAMP levels, while co-treatment with SRIF reduced this accumulation by 50-60%. The SRIF precursor somatostatin-28 and the cyclopeptide agonist MK678 also inhibited cAMP accumulation, whereas the biologically inactive *N*-terminal 14-amino acid fragment of somatostatin-28 was ineffective. The ability to detect changes in cAMP levels in individual oocytes provides a simple procedure for the expression cloning of SRIF receptor cDNAs and those for other receptors functionally coupled or stimulation or inhibition of adenylate cyclase. EXPRESSION OF ANGIOTENSIN II RECEPTORS FROM MURINE NEUROBLASTOMA N1E-115 RNA IN XENOPUS OOCYTES. S.J. Fluharty, J.S. Camardo, R. Mir and M.M. White. (Spon: P.J. Hand) Depts. of Animal Biology and Pharmacology, and Institute of Neurological Sciences, Univ. of Pennsylvania, Phila., PA 19104.

Angiotensin II receptors (AngII-R), which are coupled to the mobilization of intracellular Ca^{2+}, are found on murine neuroblastoma N1E-115 cells. In the present report we compare the properties of AngII-R on N1E-115 cells with those expressed in Xenopus oocytes after translation of N1E-115 RNA. Injection of N1E-115 RNA (50 ng) into oocytes resulted in the appearance of surface receptors for the Ang II antagonist [^{125}I]-SARILE. These expressed binding sites exhibited a similar specificity for Ang II related peptides as that observed in N1E-115 cells. Moreover, in vitro differentiation of N1E-115 cells, which resulted in a 12-fold increase in AngII-R density on intact cells, substantially increased the levels of expressed binding sites as well. Coincident with the expression of these AngII-R, Ang II produced a dose-dependent modulation of endogenous chloride currents characterisitic of Ca^{2+} mobilization in oocytes. These responses were not observed in uninjected oocytes. As was the case in N1E-115 cells, the magnitude of the Ca^{2+} mobilization response was similar after injection of RNA from undifferentiated or differentiated cells. These results suggest that the Xenopus oocyte expression system is well suited for cloning the cDNA which codes for the N1E-115 AngII-R. Supported by NS 23986, MH 43787, and Alfred P. Sloan Research Fellowship BR-2733.

SPECIFIC EXPRESSION OF THE NGF RECEPTOR GENE IN BASAL FOREBRAIN NEURONS OF TRANSGENIC MICE. Nila Patil*, Elizabeth Lacy*, and Moses Chao* (SPON: J. Adler). Cell Biology and Molecular Biology program, Cornell University Graduate School of Medical Sciences, Medical College division, 1300 York Avenue, New York, NY 10021

The receptor for nerve growth factor(NGF) is expressed on neuronal and nonneuronal derivatives of the neural crest in a highly regulated manner during development. The human NGF receptor gene contains 6 exons spanning over 23 kilobases(kb) with a promotor sequence characteristic of constitutively expressed genes. To study the regulation of the receptor gene, we have generated six independent lines of transgenic mice carrying a 35 kb cosmid clone encoding the human NGF receptor gene. The number of integrated copies ranged from 10 to over 100 per genome. Expression of human receptors in the transgenic mice was investigated by (1) using a monoclonal antibody(ME20.4) specific for the human receptor in immunocytochemistry experiments, (2) immunoprecipitation of affinity crosslinked receptor, and (3) detection of receptor mRNA by S1 nuclease protection. Our results indicate that the human gene is specifically expressed in cholinergic neurons from the basal forebrain and Purkinje cells of the cerebellum. This suggests that the cis-acting sequences necessary to direct specific expression of the NGF receptor gene lie within the 35 kb fragment used to generate the transgenic mice.

Characterization of a High Affinity Neuropeptide γ Binding Site in Rat Duodenum, Urinary Bladder and Vas Deferens.
Y. Takeda and J.E. Krause, Department of Anatomy & Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

Two N-terminally extended derivatives of Neurokinin A, called Neuropeptide γ [NPγ;γ-PPT-(72-92)-NH_2] and Neuropeptide K [NPK; β-PPT-(72-107)-NH_2] can be derived from the γ- and β-preprotachykinin (PPT) precursors, respectively. These peptides are differentially expressed in rat tissues and are potent in certain tachykinin-sensitive bioassays. In this study, we have characterized a high affinity NPγ binding site that has the characteristics of a tachykinin receptor.

^{125}I-NPγ was prepared by chloramine T iodination and was purified by HPLC. Radioligand binding in duodenal (D), urinary bladder (UB) and vas deferens (VD) membranes was performed using a rapid filtration assay. Specific ^{125}I-NPγ binding to membrane fractions was saturable, temperature dependent and reversible. Scatchard analysis indicated that binding was due to a single class high affinity binding component. K_d and B_{max} values ranged from 0.14 to 0.26 nM and from 16 to 60 fmol/mg membrane protein for the three preparations. The rank order of tachykinin peptide potency was NPγ=NPK> or =NKA>NKB>SP, suggesting that ^{125}I-NPγ binds predominantly to the NK-2 receptor subtype. The potency of NKA on the displacement of ^{125}I-NPγ binding was similar to NPγ and NPK in UB and VD membranes, however NKA was 8 to 10-fold less potent than NPγ and NPK in D membranes. In addition, NPγ had potent smooth muscle contractile activity in these tissues.

We conclude that NPγ and NPK specifically bind with a high affinity to the NK-2 type receptor in peripheral tissues, and that the properties of ligand binding in rat D appear to be somewhat different from those in rat UB and VD. Thus, differential posttranslational processing of β-and γ-PPT into NPK and NPγ, compared to NKA, can dramatically alter ligand binding and biological activity of these tachykinin peptides.

AXONAL TRANSPORT OF PEPTIDE YY BINDING SITES IN THE RAT VAGUS NERVE. E.S Corp*, and G.P. Smith (SPON:J. Sechzer). E.W. Bourne Laboratory, Dept. of Psychiatry, NYH-Cornell Medical Center, White Plains, NY 10605.

We used quantitative in vitro autoradiography with computerized (film) image analysis to characterize parameters of [^{125}I]-PYY (NEN-Dupont) equilibrium binding to slide-mounted sections of cervical vagus nerve which had been ligated 24 h. prior to extraction. Accumulations of saturable PYY binding sites were measured on the proximal side of ligatures (approx. 0.40 mm^2), with smaller accumulations detected on the distal side (approx 0.1 mm^2). Analysis (LIGAND) of preliminary binding data resolved [^{125}I]-PYY binding to a single class of vagal sites with a Kd of 1.71 $\pm$ 0.4 nM and a Bmax of 173 $\pm$ 43 fmol/mg tissue. Under these same binding conditions, [^{125}I]-PYY bound with similar affinity to sites in the area postrema (Kd=0.93 $\pm$ 0.06 nM, 41 $\pm$ 2 fmol/mg tissue).

These findings suggest that PYY receptors undergo anterograde and retrograde transport along fibers of the vagus nerve. The localization of these sites to visceromotor or sensory components of the vagus, their distal terminus, and their functional significance is not yet determined. [Supported by St. Lukes\Roosevelt Obesity Core Center (ESC) and NIH MH 40010 (GPS).]

SOLUBILIZATION AND CHARACTERIZATION OF SUBSTANCE P RECEPTORS FROM PORCINE STRIATAL MEMBRANES: POSSIBLE NATURE OF THE CARBOHYDRATE COMPOSITION OF THE RECEPTOR. Y.F. Liu* and R. Quirion, (Spon: M. Dalpé) Dept Pharm. McGill Univ. & Douglas Hosp. Res. Center, Montreal, Quebec, Canada H4H 1R3

Substance P receptors were solubilized from porcine striatal membranes using 10 mM (3-[(choramidopropyl)-dimethylammoniol]-1-propanesulfate, CHAPS) (yield of solubilization: 75-85%). In solubilized preparation, [^{3}H] substance P (SP) apparently bound to a single class of high affinity sites (K_D= 0.82 $\pm$ 0.13 nM), data which are comparable to values obtained in membrane homogenates. The ligand selectivity pattern observed in both membrane and solubilized receptor preparations indicated that [Sar^9, Met $(O_2)^{11}$]SP = SP >> [MePhe^7] neurokinin B = [Nle^{10}] neurokinin A (4-10). This suggests the selective labelling of the NK-1 receptor sub-type. Solubilized receptor preparations were then applied to various agarose affinity columns with different mobilized lectins. The solubilized receptors were retained by lectins that bind galactose (Recin I and Recin II; most potent ones), mannose (concanavalin A and lectil), N-acetylglycosamine (wheat germ) but not by lectins that bind fucose (lotus A) and N-acetylgalactosamine (dolichos biflorus A). After desorption, [^{3}H] SP binding was enriched between 20-50 folds. In summary, [^{3}H] SP binding sites can be solubilized with CHAPS and they appears to be enriched with carbohydrate moieties, galactose being presumably predominant. (MRC, Canada).

SUBSTANCE P RECEPTORS ON HUMAN ASTROCYTOMA CELLS : STUDIES ON INOSITOL PHOSPHOLIPID TURNOVER AND TAURINE RELEASE. C.M. Lee and W.L. Tung*. Department of Biochemistry, Chinese University of Hong Kong, Shatin, Hong Kong

We have recently demonstrated the presence of NK-1 tachykinin receptors on a human astrocytoma cell line U-373MG (Lee C.M. , Kum W., Cockram C.S., Teoh R. and Young J.D., Brain Res., in press, 1989). The binding of ^{125}I-Bolton Hunter conjugate of substance P to these receptors can be modulated by guanyl nucleotides which suggests that the NK-1 receptors may be coupled with a G-protein regulated biochemical process. In the present study we have examined the effects of substance P on inositol phosphates and cyclic AMP formation in these cells. While substance P (1 μM) did not alter the basal or isoproterenol-stimulated cyclic AMP levels, it did cause a concentration dependent accumulation of inositol monophosphate with an EC_{50} of 0.3 nM. This stimulatory effect of substance P on inositol phospholipid turnover can be inhibited by spantide (1 μM), a substance P receptor antagonist. The activation of NK-1 receptors on U-373MG cells stimulated the incorporation of uridine into nucleic acids as well as the release of taurine. The latter effect is distinct from that of a rat glial cell line LRM 55 where activation of substance P receptor was shown to inhibit cyclic AMP dependent beta-adrenergic stimulated taurine release (Perrone M.H., Lepore R.D. and Shain W., J.Pharmacol. Exp. Ther., 238: 389, 1986).

IDENTIFICATION AND CHARACTERIZATION OF THE ZETA (ζ) OPIOID RECEPTOR IN NEUROBLASTOMA CELLS IN CULTURE. I.S. Zagon, S.R. Goodman and P.J. McLaughlin. Dept. Anatomy, Penn. State Univ. Coll. Med., Hershey, PA 17033 and Dept. Structural and Cellular Biology, Univ. South Alabama, Mobile, AL 36688.

Endogenous opioid systems are involved in the growth of normal and neoplastic cells/tissues of human and animal origin. Utilizing murine S20Y neuroblastoma (NB), tumor transplantation and tissue culture studies have revealed that [Met^5]-enkephalin is the most potent opioid peptide associated with growth. Binding assays using NB tissue and [^{3}H]-[Met^5]-enkephalin have demonstrated the presence of a new opioid receptor - zeta - which is involved in growth. To elucidate the zeta receptor in NB cells in culture, binding assays with [^{3}H]-[Met^5]-enkephalin were performed. Specific and saturable binding was detected in cell homogenates, with a K_d of 1.6 nM and a B_{max} of 48.1 fmol/mg protein. Binding was dependent on protein concentration, time, temperature, and pH, and was sensitive to Na^+, Ca^{++}, and Mg^{++}, but not GppNHp. Displacement experiments indicated that [Met^5]-enkephalin was the most potent displacer of [^{3}H]-[Met^5]-enkephalin. The results of these studies conducted with cells in culture are consistent with earlier findings which have identified the zeta receptor in neuroblastoma tissue.

Quantitative In Vitro Autoradiography of Transferrin Receptors in the Striatum of MPTP Treated Mice. I. Pablo, M. Basile*, S. M. Efange*, I. Sanchez-Ramos*, W. J. Weiner, and D. C. Mash, Dept. of Neurology, University of Miami School of Medicine, Miami, FL. 33101 and the Dept. of Radiology, University of Minnesota, Minneapolis, MN. 55455.

We have recently demonstrated a loss of transferrin binding sites in the putamen in Parkinson's disease (Neurology *suppl.* 39: 424, 1989). The reduced number of transferrin receptors in Parkinson's disease may result from either primary and/or secondary degenerative changes occurring in the striatum. The apparent selective reduction in transferrin binding in the putamen may reflect the differential loss of striatal dopaminergic terminals. However, the cellular location of transferrin binding sites in the CNS is, at present, unknown. One possibility is that ferrotransferrin-receptor complexes are transported down the axon to the dopaminergic terminals fields. Iron bound to transferrin may be internalized via transferrin receptors which are located on nigral cell bodies and dendrites. We have addressed this possibility in animal studies by using high resolution in vitro autoradiography of transferrin receptors in brains of mice treated with the dopaminergic neurotoxin, MPTP. Our results suggest that [^{125}I]-transferrin binding sites are significantly reduced in the caudate-putamen at 7 and 10 days post lesion. At 28 days after an injection of MPTP, the density of transferrin receptors in the caudate-putamen were elevated as compared to control brains (~ 8 pmol/g tissue). This increase in [^{125}I]-transferrin binding appeared to correlate with the recovery of dopaminergic innervation in the striatum as assessed by differential [^{3}H]-mazindol autoradiography performed on adjacent slide-mounted sections. These results suggest that striatal transferrin receptors may be located, in part, on dopaminergic terminals.

IDENTIFICATION OF NEUROTENSIN AUTORECEPTORS IN THE VENTRAL MIDBRAIN TEGMENTUM OF THE RAT. J. Woulfe* and A. Beaudet (SPON: D. Baxter). Neuroanatomy Laboratory, Montreal Neurological Institute, Montreal, Quebec, H3A 2B4. Canada.

The presence of D2 autoreceptors confers upon midbrain dopaminergic neurons the capacity for autoinhibition in response to local, dendritically-released dopamine. Many of these neurons also contain and release neuroactive peptides. Whether these peptides are capable of similar autoregulation has not been established. In the present study, the possibility that neurotensin-containing neurons in the ventral midbrain bear autoreceptors was investigated in adjacent 5μm sections alternately processed for the immunohistochemical demonstration of endogenous neurotensin or for the autoradiographic localization of ^{125}I-neurotensin binding sites. Within the midbrain, neurotensin immunoreactive perikarya were consistently identified in the parabrachial pigmented and paranigral nuclei of the ventral tegmental area, the interfascicular nucleus, the caudal linear raphe nucleus, and occassionally in the rostral linear raphe nucleus, central grey and substantia nigra. A proportion of these neurons exhibited ^{125}I-neurotensin binding sites in the adjacent 5μm autoradiograph. Whether these binding sites represent functional autoreceptors at the level of the perikaryal and dendritic plasma membrane or intracellular receptors undergoing storage, synthesis, degradation, and/or transport to more remote sites remains to be elucidated. Supported by MRC.

NEUROETHOLOGY I

144.1

AUDITORY PROPERTIES OF SONG NUCLEI OF ESTRILDID FINCHES. A.J.Doupe and M.Konishi. Div. of Biol. 216-76, Calif. Inst. of Technology, Pasadena, CA 91125

The importance of auditory experience and feedback in song development suggests that there must be links between the auditory and vocal motor systems. To identify the location and physiological nature of such connections, we have studied estrildid finch song nuclei using single unit recordings and anatomical tract tracing. Both nuclei MAN and X of adult male finches have auditory responses. In area X, the auditory units have latencies of 20 msec or more, are broadly tuned to frequency, and prefer complex stimuli such as white noise and finch song. In MAN, some of the units show inhibition or no response to white noise and pure tone bursts, but fire briskly to presentation of the bird's own song and more weakly to finch songs from other individuals.

Tracing of inputs to the auditory neurons in MAN and X with horseradish peroxidase confirm a recently described circuit from X to the medial dorsolateral thalamic nucleus (DLM) and back to MAN. Preliminary results of direct recordings in DLM suggest that this nucleus also contains long latency auditory units. These data provide clear evidence for auditory responsiveness in the song nuclei MAN and X, support the neuronal circuit from X to DLM to MAN suggested on the basis of earlier connnectivity studies, and raise the possibility that this circuit carries auditory information.

NMDA RECEPTORS MEDIATE SYNAPTIC TRANSMISSION IN A ZEBRA FINCH SONG CONTROL NUCLEUS. R. Mooney* and M. Konishi. Div. of Biology 216-76 Caltech, Pasadena, CA 91125 (Sponsor: S. Volman).

We are interested in studying synaptic properties which may be correlated with song learning in passerine birds. The forebrain song nucleus RA is in a descending motor pathway implicated in vocal control during song. It is known to receive input from two other song control nuclei, HVc and MAN. HVc axons "wait" in an area dorsal to RA from day 15 to day 30 posthatch, after which they enter RA. MAN terminals, on the other hand, are present within RA from day 15 onward.

We have characterized afferent input to RA in acute brain slices prepared from 15-30d birds. Electrical stimulation in an area lateral to RA, known to contain MAN axons, elicits EPSPs in RA neurons. These EPSPs are antagonized by kynurenic acid and often display longer latency components which are blocked by AP5 or by hyperpolarization of the postsynaptic membrane. These results suggest that as early as day 15, MAN provides afferent input onto RA which is glutamatergic and has properties associated with NMDA receptor-mediated transmission.

After day 35, stimuli applied to the HVc and MAN axonal tracts entering RA generate EPSPs at the same postsynaptic RA neuron. These EPSPs summate when stimuli to HVc and MAN axons are paired. Therefore, HVc and MAN provide convergent excitatory synaptic input onto single neurons within RA.

144.3

LHRH-LIKE IMMUNOREACTIVITY IN THE BRAIN OF A SEX REVERSING FISH: MODULATION BY GONADAL STEROID HORMONES. M.S. Grober* and A.H. Bass (SPON: P. BRODFUEHRER). Section of Neurobiology and Behavior, Cornell University, Ithaca, N.Y. 14853.

The sex-reversing fish, *Thalassoma bifasciatum*, exhibits two color morphs (primary phase, PP, and terminal phase, TP). PP fish are born either male or female, while TP males result from the transformation of PP males or females. This analysis initiates immunocytochemical studies of hormone binding in the central nervous system (CNS) of these fish and describes the possible role of gonadal steroid hormones on the binding of gonadotropin releasing factors in the CNS.

LHRH immunoreactive (IR) fibers were found widespread throughout regions of the forebrain and brainstem, although there were no differences in binding between the different sexual phases. Areas of dense labeling included the olfactory tract and bulb, area ventralis of the telencephalon, midbrain tectum and tegmentum, posterior tuber region of the diencephalon, and ventral brain stem. LHRH-IR somata were located in the olfactory nerve and probably comprise a nervus terminalis system. More suprising however, was the presence of LHRH-IR in cranial and spinal motor nuclei. Intra-peritoneal implants of 11 Ketotestosterone into PP (male and female), transitional (sex undetermined), and TP fish produced a marked increase in LHRH-IR both in cranial and spinal motor nuclei, and in a group of small cells surrounding the nucleus glomerulus of the hypothalamus. Typically, a granular-like precipitate was found throughout the cytoplasm surrounding the nucleus. Lower levels of this characteristic binding are seen in field collected specimens or fish maintained in the laboratory for periods of up to 4 months, suggesting that LHRH-IR in motor nuclei is a naturally occuring event and thus may play an important role in the hormonal control of sex reversal and subsequent behavioral transformations. Supported by a NIH Postdoctoral Training Grant (MG) and NIH / NSF Grants (AHB).

VISUAL ACTIVATION OF THE OCTAVOLATERALIS EFFERENT SYSTEM DEMONSTRATED IN THE LATERAL LINE OF FREE-SWIMMING TOADFISH. T. C. Tricas and S. M. Highstein. Wash. Univ. Sch. Med., Dept. Oto., St. Louis, MO 63110.

The octavolateralis efferent system (OES) can be activated by multimodal sensory stimuli in the toadfish (Highstein and Baker, 1985, J. Neurophys. 54:370) and has a predominantly inhibitory action on the firing of lateral line (LL) primary afferent fibers in fishes. We studied the OES in a semi-natural setting to determine if visual stimuli of biological significance can activate it. Single LL afferents were recorded chronically with metal microelectrodes for periods up to 9 days in toadfish swimming freely in a small tank. Trains of bright photic stimuli (10 flashes/sec for 3 sec) resulted in a 20% increase in spontaneous spike rates of afferents for the stimulus duration with an onset delay of about 1 sec. In contrast, flashes were often followed by decreased mechanically evoked afferent firing rates. When small prey fish in a clear sealed chamber were presented to toadfish, some LL fibers decreased their spontaneous activity while others did not change. Mechanically evoked firing (by mild 25-90 Hz vibrations of the tank) decreased following prey presentation and persisted up to 120 sec. OES axons to the LL are spontaneously active and modulated by visual stimuli as confirmed by direct chronic recording from one putative efferent fiber. Thus, the OES modulates the sensitivity of the LL system via visual input pathways. This modulation may be behaviorally significant for the detection of water motion or capture of nearby prey.

144.5

SUPPRESSION OF 'COMMON-MODE' SIGNALS IN THE CENTRAL ELECTROSENSORY SYSTEM. G.J. Rose. Dept. of Biology, Univ. of Utah, Salt Lake City, UT 84112.

Gymnotiform fish generate electrical discharges via an organ located in the tail and sense these signals with electroreceptors distributed over their body surface. Since a variety of motor activities can result in modulations of the discharge properties of primary afferents (e.g. ventilation, courtship signaling), the problem arises as to how such 'reafferent' information is distinguished from 'exafferent' (environmental) sensory input. During ventilation, electroreceptors on corresponding regions of the left and right opercula should experience similar modulations of activity; in courtship behavior the entire body surface experiences modulations in the amplitude and/or frequency of electric organ discharges (EODs).

One potential mechanism for discriminating between such reafferent input and exafferent information is to suppress activity resulting when antipodal areas of the body surface experience similar modulations of the EOD amplitude. Evidence for this 'common-mode' suppression mechanism has been obtained for the little skate (New, J.G. and Bodznick, D., Neurosci. abst., 114.10, 1988). In the present study, evidence in support of such a mechanism was found in the electrosensory lateral line lobe of Eigermannia. 'E-' and 'I-type' units in this structure increase their discharge rates during rises or falls of signal amplitude, respectively. Units of these types were found that discharged strongly to stimuli in which particular antipodal areas of the body surface experienced opposite patterns of amplitude modulation, but responded poorly when the entire body surface experienced identical modulations.

144.6

FREQUENCY AND TEMPORAL SELECTIVITY OF SINGLE AUDITORY NERVE FIBERS IN THE TOKAY GECKO. F. Dodd and R. R. Capranica, Section of Neurobiology & Behavior, Cornell University, Ithaca NY 14853.

Auditory nerve fibers in the Tokay gecko have sharp V-shaped tuning curves with $Q_{(10dB)}$'s from 2-10. The best excitatory frequencies (BEF) range from 200 to 5000 Hz with thresholds from 4-35 dB SPL. All fibers exhibit pronounced two-tone suppression on the high frequency side, but not on the low frequency side.

We measured the spike rate contour for single fibers as a function of frequency with the intensity held fixed. These iso-intensity functions divided the population of nerve fibers into 3 groups. Units with BEF from 250-950 Hz had peaked iso-intensity contours, which did not change shape with increasing sound intensity and the responses were phase-locked from 100-700 Hz. For units with BEF 950-2250 Hz the peak of their spike-rate contour shifted to lower tonal frequencies with increasing sound intensity, reaching their maximum firing around 600 Hz. For this group the phase-locking was also observed from 100-700 Hz, but only at high intensities. Cells with BEF 2250-5000 Hz have peaked iso-intensity contours at intensities from 10-30 dB above threshold and do not show phase-locking. At higher intensities these contours flatten and become bell-shaped, centered around their BEF. The flattening occurs even though saturation has not yet been reached. All units with BEF 200-2250 Hz responded below 600 Hz to the waveform periodicity in a 1:1 manner, i.e. one spike per cycle, and the individual unit is thus constrained by the periodicity of the stimulus and can therefore not encode intensity changes in this frequency range.

The natural vocalizations of these geckos contain complex harmonic structure with a fundamental frequency around 375-450 Hz and these units can therefore reliably encode both the waveform periodicity and spectral patterns of these signals over a wide intensity range. This work was supported grants form NIH, the Danish Research Academy and the Carlsberg Foundation.

144.7

INTERACTION OF SOUND AND VISUAL CUES IN ORIENTATION BEHAVIOR OF CRICKETS. K.Schildberger and H. Böhm. MPI f. Verhaltensphysiologie Seewiesen FRG.

A female cricket can find a singing male by orienting toward the sound source without any other orientational cues. In nature crickets perform partner finding under more complex situations. The influence of visual signals on the phonotaxis was studied under open-loop condition.

Firstly, the turning tendency was determined for various sound directions in the dark and in the presence of a patterned environment. The precision and strength of the phonotaxis is increased with visual cues available. Secondly, the turning tendency was measured while moving a stripe drum. This optomotor response increases for contrast frequencies up to 2/s. Thirdly, sound and movement stimuli were combined. The visually and acoustically induced turning tendencies are additatively superimposed, i.e. the optomotor response curve is shifted by the contribution of the sound signal and vice versa.

It might be concluded that the optomotor system is used to enhance the precision of orientation to a conspecific calling song.

144.8

THE NEUROETHOLOGY OF SEX AND DEATH IN CRICKETS: A ONE-NEURON "SWITCH" THAT DEPENDS ON BEHAVIORAL CONTEXT. R.Hoy and F.Libersat, Section of Neurobiology & Behavior, Cornell University, Ithaca, NY 14853

Hearing in crickets mediates both sexual behavior and predator (bat) detection. Males sing courtship songs (CS) to facilitate copulation. In two species, T.oceanicus and G.bimaculatus the power spectrum of CS sound pulses show peaks at the fundamental frequency (4.5 kHz) and its harmonics (9,13.5, 18 kHz). Yet, the high frequencies can trigger an escape response, during flight. An identified neuron, int-1, mediates the escape response, and here we investigate its possible role in courtship behavior. For the CS of T.oceanicus the carrier frequency, 4.5 kHz (95dB) is always more energetic than higher harmonics (13.5 kHz (82dB). When males are muted by wing amputation, their courtship success decreases by 80%. Playback of tape-recorded courtship songs (natural CS or a 4.5 kHz model) during courtship restores a muted male's courtship success, but not playback of 13.5 kHz. Thus in ocean. where 5 kHz is the major component of CS and 13.5 the minor, the 13.5 kHz does not promote mating. For the CS of G.bimaculatus the dominant frequency is 13.5 kHz (104 dB) and always exceeds the carrier, 4.5 kHz (89dB). Murray & Hoy (Neurosci.abst 14:310) showed that in G.bimac.a 13.5 kHz model CS restores courtship success but a 4.5 kHz does not.

In both species, 13.5 and 30 kHz ultrasound elicits avoidance steering in tethered flight. When 30 kHz CS models were played during the courtship of mute males,females ignored them. While int-1 signals the presence of ultrasound to the brain in both courtship and escape contexts, the behavioral consequences of its activation depends on the activation of other parallel neural systems.

144.9

COLLISION AVOIDANCE BEHAVIOUR IN THE LOCUST. R.M. Robertson and D.N. Reye*. Department of Biology, Queen's University, Kingston, Ontario, K7L 3N6, Canada.

The visual properties of the locust DCMD neurons and their synaptic connections to flight motoneurons suggest that they are involved in directing flying locusts around objects with which they are about to collide.

We have characterized evasion manoeuvres of tethered locusts flying in a wind-tunnel by videotaping their responses to rapidly looming objects which were directed toward the head of the animal and on either side of the midline. Locusts respond to such stimuli with brief and rapid movements of the abdomen and the wings. The abdomen either bent always to the same side regardless of the target position or bent such that the animal would have turned away from the approaching target. At the same time the relative phasing of the wings, the amplitude of wing movement and angle of attack of the wings were altered. On the inside of the turn the wing pronated and the stroke amplitude increased. A reciprocal relationship existed so that changes in wing parameters depended on the side of the animal that the target approached.

The results show that the locust possesses a robust behaviour for avoiding collision with objects during flight. There is a good correlation of the motor output with the visual and synaptic properties of the DCMD neurons, supporting the hypothesis that these neurons play a major role in mediating this behaviour.

144.10

NEUROETHOLOGICAL ASPECTS OF ULTRASOUND AVOIDANCE IN KATYDIDS. F. Libersat and R. R. Hoy, Section of Neurobiology & Behavior, Seeley G Mudd Hall, Cornell University, Ithaca NY, 14853.

Several nocturnally flying insects including lacewings, moths, mantises, and crickets detect and avoid ultrasound such as that produced by echolocating insectivorous bats . Bats are likely to exert strong predation pressure on other insect groups as well. Katydids (Tettigoniidae) are nocturnally active insects not previously known to avoid ultrasound. In the present work we show that Katydids respond both physiologically and behaviorally to ultrasound.

Suspended freely flying animals were tested. One species of katydid (*Neoconocephalus ensiger*) responded to ultrasonic pulses (100ms, 90dB) by folding its wings as lacewings do. This results in a sudden drop in the flight path . We further characterized the behavioral response of *N. ensiger*, using a photocell to monitor wing movements in tethered flight. When single tones with frequencies ranging from 10 to 80 kHz (100ms, 90dB) were presented to the tethered flying katydid, escape responses were triggered only by frequencies ranging from 20 to 60 kHz. The threshold for the escape response at 30 kHz was 80 dB. This response latency was short and ranged between 30ms and 90ms, averaging 57±14 ms.

We also investigated the underlying neural correlates of ultrasound avoidance. An auditory interneuron was found, a T-neuron, whose physiology suggests that it is involved in the escape behavior. The response latency of this neuron to single tones (3ms, 30 kHz, 90dB) was 12.3±0.6ms Its lowest threshold was below 70 dB for frequencies ranging from 20 to 60kHz. Moreover, the number of spikes elicited in response to single tones (3ms, 90dB) for frequencies from 20 up to 60 kHz was at least twice that to frequencies of 5,10,70 and 80 kHz. Its average discharge frequency was 390±70 Hz. Therefore, the T-neuron is a good candidate for mediating the ultrasound avoidance in katydids. This neuron has its soma located in the prothoracic ganglion and sends two relatively large axons both rostrally and caudally. Its anatomy suggests that it may have a direct access to the thoracic flight circuitry. Work is now in progress to determine wether T-neuron mediates bat avoidance in Katydids.

MULTISENSORY CONTROL OF COCKROACH ESCAPE: SOME PREDATORS ARE DETECTED BY ANTENNAL AND OTHER NON-CERCAL SENSORY SYSTEMS. C.M. Comer, M.E. Getman*, M.C. Mungy* and J. Plishka*. Dept. Biol. Sciences & Committee on Neuroscience, Univ. of Illinois, Chicago, IL 60680

Some natural predators of cockroaches (P. americana) generate wind cues as they strike, and these cues are used by the cercal-to-GI system to control escape. We have described tactile sensory pathways associated with the antennae, and provided evidence that antennal stimulation may lead to escape (Brain Res. 445:370). To understand the significance of such non-cercal pathways we studied interactions of cockroaches with small predators that might generate less wind during attack: rodents (mice), arachnids (wolf spiders) and insects (mantids). Behavior was recorded by high-speed videography. Also, responses of cockroaches with either cerci or antennae removed were compared with intact animals.

Many features of these interactions suggested involvement of tactile cues rather than, or in addition to, wind cues. These included: 1) evasive turning often did not begin until contact was made with the antennae or body. 2) When predators struck from one side, but went over the cockroach and made contact on the opposite side, turns were directed away from the side of contact not the side from which the predator lunged. 3) Antennal removal significantly increased the probability of a cockroach being captured, while cercal ablation did not cause a comparable increase. We suggest that tactile sensory pathways may be as important as wind pathways for understanding the evolution and neural control of escape. (Supported by NSF grant #BNS-8617393 to C.M.C.)

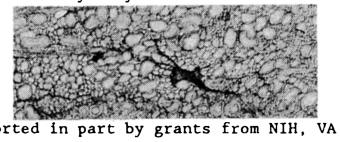
DEVELOPMENT OF SWIMMING BEHAVIOR IN THE MEDICINAL LEECH. S.A. Reynolds* and W.B. Kristan, Jr. (SPON: W.A. Harris) Dept. of Biology, UCSD, LaJolla, CA 92093



One prerequisite for studying how neurons make appropriate connections with one another to produce coordinated behavior is a detailed description of the normal course of behavioral development. Therefore, we have characterized the development of swimming behavior in the medicinal leech, *Hirudo medicinalis*. Videotapes of swimming leech embryos were analyzed frame-by-frame, and the changes in various components of the behavior were followed over embryonic time. The major increase in normalized swimming velocity (rate of forward progress/body length) occurred during the last 10 days of embryonic development. 20% of this increase was due to a rise in swim cycle frequency, and the remaining 80% was due to increased efficiency of swimming. Factors that were important for increased swimming efficiency included the flattening and widening of the animal prior to swimming, how far along the animal the body wave was propagated, and the amplitude of the tail stroke during swimming. Factors that could potentially have affected swimming, but did not, include the rate of wave progression through the body, coordination of different parts of the body, variability in swimming behavior, and the amplitude of the body wave at the head. These studies set the stage for determining how the pattern of synaptogenesis between members of the neuronal swim circuit gives rise to this observed pattern of behavioral development. (Supported by NIMH research grant MH43396.)

NEUROGLIA: MYELIN AND MYELIN-FORMING CELLS

145.1

IN SITU DEMONSTRATION OF OLIGODENDROCYTES IN THE ADULT CNS WITH A NEW MONOCLONCAL ANTIBODY, RIP. B. Friedman, J.A. Black, S. G. Waxman, Dept. Neurology, Yale Univ. Sch. med. and VAMC, West Haven, Ct. 06516

Monoclonal antibody Rip is a new marker for oligodendrocytes that appears to stain pre-ensheathing, ensheathing and myelin related oligodendrocytes. Double-labelling experiments with Rip and anti-GFAP antibodies indicate that Rip does not recognize astrocytes in the mature CNS. In adult rat spinal cord, Rip strongly stains oligodendrocytes and their cytoplasmic processes (see figure). Myelin is only lightly stained in nonpermeabilized adult tissue. The arborization patterns of mature oligodendrocytes vary but are distinct from branching patterns of immature pre-ensheathing oligodendrocytes. However, in adult rat neocortex, oligodendrocytes with both mature and immature arborization patterns were observed. Further studies of Rip staining in 1-2 year old rats will examine if immature cells persist and if they can be triggered to differentiate by demyelination.

S-100 IS PREFERENTIALLY DISTRIBUTED IN MYELIN FORMING SCHWANN CELLS. D.J.Fink, D.Alessi* and M.Mata. University of Michigan and VA Medical Center, Ann Arbor, MI, 48105

The S-100 proteins are a group of abundant low molecular weight proteins, members of the large family of calcium binding proteins of the EF hand structure, which are highly enriched in nervous tissue. In order to gain some insight into the role of S-100 in the peripheral nervous system *in vivo*, we used EM immunocytochemistry to study the localization of S-100 in the peripheral nervous system of the rat.

Male Sprague Dawley rats were used in all experiments. The animals were sacrificed by intracardiac perfusion with 0.5% glutaraldehyde and 4% paraformaldehyde in phosphate buffer, and the sciatic nerve and the cervical sympathetic trunk placed in the same fixative for an additional 2 hrs, then embedded in LR White. Ultrathin sections were exposed to anti S-100 antibody (Dako) in dilutions from 1:300 to 1:1000 for 2 hr, followed by goat anti-rabbit IgG bound to colloidal gold.

In normal nerve, S-100 immunoreactivity was found predominantly in Schwann cells, but was differentially distributed. Most of the S-100 immunoreactivity was found in the cytoplasm and over the nucleus of Schwann cells of large myelinated fibers, less S-100 immunoreactivity was found in the Schwann cells of smaller myelinated fibers, and very little was found in those Schwann cells surrounding unmyelinated axons. Within the Schwann cells the immunoreactivity was seen in the nucleus, the perikaryal cytoplasm, as well as in the Schmidt Lanterman clefts and in the paranodal loops at the node of Ranvier. Using these antibodies we did not see intra-axonal immunoreactivity in normal nerve. These results suggest that in Schwann cells S-100 expression may be related to axon diameter and degree of myelination.

Supported by grants from the JDF, the NINDS, and the VA.

145.3

EXPRESSION AND PURIFICATION OF MYELIN-ASSOCIATED GLYCOPROTEIN. J. Attia*, P. Johnson*, J. Roder, and R.J. Dunn. Dept. Medical Genetics, University of Toronto, Toronto, Ontario. M5S 1A8.

Myelin-associated glycoprotein (MAG) is expressed by glial cells of the PNS and CNS during development (in uncompacted myelin) and in the mature animal (inner and outer mesaxons, Schmidt-Lanterman incisures, and especially in the periaxonal space). By virtue of its location, its membership in the immunoglobulin gene superfamily, and the results of MAG liposome/DRG binding assays, MAG is believed to be an adhesion molecule involved in the initiation of myelin wrapping.

Since MAG constitutes less than 1% of myelin proteins, the baculovirus expression system has been used to overexpress a soluble form of MAG. Differing multiplicities of infection, with constructs varying in 5' non-coding region, are being tested for optimization of the expression level. A simple purification involving ammonium sulfate precipitation and lentil-lectin chromatography has been established. The purified protein has been used in a number of binding assays, e.g. binding to membrane preparations and to whole cells, ligand blotting, and emulsion autoradiography.

Future work on MAG will focus on physical and structural analyses, including crystallization.

145.4

MAPPING OF FUNCTIONAL DOMAINS OF THE MYELIN-ASSOCIATED GLYCOPROTEIN. A. Meyer, P. Fischer+*, K. Beyreuther+*, M. Tropak++, J. Roder++ and M. Schachner. Dept. Neurobiology and +ZMBH, University of Heidelberg, and ++Mount Sinai Hospital Research Institute, Toronto.

The myelin-associated glycoprotein (MAG) is a cell adhesion molecule belonging to the carbohydrate-based L2/HNK-1 family and the immunoglobulin superfamily. It has been implicated in axon-myelinating cell interactions and binds to different types of collagens and heparin. To map the molecular domains responsible for these functions, cyanogen bromide fragments of immunoaffinity-purified MAG from adult mouse brain were obtained and assigned to the primary protein structure by partial aminoacid sequencing and alignment with the cDNA-deduced primary aminoacid sequence. In addition, monoclonal antibodies recognizing distinct epitopes on the molecule were used. The binding to heparin and collagen types I and III was located by radio-ligand binding and interaction with heparin-agarose to the fragments containing the first two immunoglobulin domains. Binding of MAG-containing liposomes to cultures of spinal cord neurons could be prevented by antibodies recognizing epitopes localized to the immunoglobulin domains III, IV and V. These observations indicate that the heparin- and collagen-binding domains of MAG are different from those involved in cell binding.

145.5

EXPRESSION OF P_0 mRNA and P_0 GLYCOPROTEIN DURING RAT PERIPHERAL NERVE DEVELOPMENT. P.L. Baron*, M. Shy*, H. Honda*, J. Sladky*, M. Sessa*, G. Conti*, D. Pleasure and J. Kamholz, Neurology, Univ. of Pennsylvania, Phila. PA 19104

The integral membrane glycoprotein P_0 is the major protein in PNS myelin. We investigated transcription and translation of P_0 during development of rat sciatic nerve, using frozen sections prepared from day 1, 5, 10, and 42 postnatal rats and from E16 and E18 rat embryos. In situ hybridizations were performed with uniformly labelled sense and antisense single stranded RNA probes transcribed from a 1.9 kb P_0 cDNA. A rabbit antiserum against rat P_0 glycoprotein and an avidin-biotin system were used to detect P_0 glycoprotein in the sections. P_0 message was detected in nerves of all ages studied form E18 onward. Grain density within endoneurium was highest between postnatal days 5 and 10, consistent with Northern blot estimates of P_0 mRNA abundence in rat sciatic nerve. Silver grains were found in clusters around Schwann cell nuclei. The proportion of Schwann cells expressing detectable levels of P_0 mRNA decreased by 42 days postnatally, but some Schwann cells remained intensely positive. Immunohistologically demonstrable P_0 glycoprotein was present in occasional Schwann cells on day E18, and had become much more abundant by day 5 postnatally. The results of this study indicate that transcription and translation of P_0 glycoprotein in rat sciatic nerve commence prenatally, and that active transcription of P_0 continues within a subset of Schwann cells in mature nerves.

145.6

A FUNCTIONAL ROLE FOR MYELIN Po PROTEIN AS AN ADHESION MOLECULE. M.T. Filbin*, F.S. Walsh and G.I. Tennekoon* (SPON: R.T. Johnson). The Johns Hopkins Sch. of Med., Baltimore and Inst. of Neurol., London, England.

The major glycoprotein of peripheral myelin, Po, is postulated to be involved in the compaction of myelin through homophilic interaction of its extracellular domains. To assess the ability of Po to interact with itself we compared adhesion of Chinese hamster ovary (CHO) cells transfected with the rat Po-cDNA and control transfected cells (without Po-cDNA). Cells expressing an abundance of Po (both RNA and protein) were selected by the dhfr/MTX gene amplification strategy. Po expressed by these cells was glycosylated and reached the cell surface. Adhesion was assayed by allowing a single cell suspension to reaggregate at 37°C in a couette viscometer. By visual examination (light microscopy) within 70 min the Po-expressing CHO cells had formed large clumps, whereas control transfected cells had formed only doublets and triplets. In agreement with this observation, when assessed with a Coulter counter, the total particle number in the reaggregating Po-expressing cells decreased to 20% of the starting number while control transfected cells decreased to only 50%. Furthermore, reaggregation was independent of the calcium concentration. These results suggest that Po increases the aggregation of CHO cells, which in turn indicates that Po is behaving as an adhesion molecule. (Supported by grants NS 26242, NS 21700, and BNS 8720070.

145.7

COMPARATIVE STUDY OF MYELINATED NERVES USING TETRACYCLINE DERIVATIVES. by P.M. Pereyra * and B.I. Roots. Department of Zoology, University of Toronto, Toronto, Canada.

We have previously reported that tetracycline (TC) forms a fluorescent adduct with myelin membranes in vertebrates as well as with the myelin-like membranes in invertebrates (e.g. Lumbricus; Brain Res. 458:377-382 (1988)). Despite the fact that invertebrate "myelin" seems to have no molecular relationship with vertebrate myelin (Neurochem. Res. 13(9):893-901 (1988)), the fluorescent staining by tetracycline and the presence of an intrinsic blue-green fluorescence seem to be two factors associated with all myelinated nerves (ISN Abstracts 14:584 (1988), Trans. ASN 20:260(1989)) Under in vitro myelinated nerves will show a TC fluorescence associated with axonal mitochondria as well as with a series of discrete compartments associated with myelin or surrounding glial cells: In vertebrate PNS myelin, the fluorescence is exclusively associated with the paranodes, while in fish spinal cord, it is associated with unidentified cytoplasmic compartments under low extracellular Ca+2 and with the myelin sheath under high (>3mM) extracellular Ca+2. In vitro incubation of earthworm nerve cords shows TC fluorescence associated with two intracellular compartments, one related to the "myelinating" glial cells, and a second one related to one of the three components of the limiting sheath around the nerve cord. Inhibition of oxidative metabolism (e.g. addition of KCN) produces an immediate shift in the TC fluorescence to the compact myelin compartment. These results are taken to indicate that the relationship of Ca+2 with myelin is an active one, as already implied from previous X-ray studies (Blaurock et al. (1986) Neurochem Res. 11:1103-1129) and not only due to electrostatic interactions of Ca+2 and myelin phospholipids. In vitro experiments using a series of TC derivatives with different binding affinities for cations as well as a different membrane permeability has reinforced the idea that Ca+2 is actively extruded from myelin. The implications of our observations will be discuss with respect to axonal injury, axon-myelin stability and theinterpretation of X-ray studies.

145.8

PRESENCE OF Ca^{++}/CALMODULIN-DEPENDENT PROTEIN KINASE IN A PURIFIED MYELIN ISOLATED FROM ADULT RAT FOREBRAIN. Y. Huang*, M. Stanley, and K. Wu* (SPON: P. Siekevitz).Div. of Neuroscienc, New York State Psychiatric Inst., New York, N.Y. 10032, and Dept. of Neurology, Cornell Univ. Medical Center, New York, N.Y. 10021.

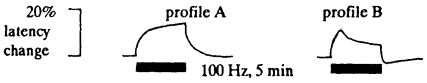
Our previous studies indicated that myelin fraction purified from forebrain of adult rat contains Ca^{++}/CaM-dependent protein kinase. Phosphorylation of 48/50 kDa and 56/58 kDa polypeptide doublet were observed in a Ca^{++}/CaM-dependent manner. The 50 kDa phosphprotein was not detectable in synaptic plasma membrane fraction and other subcellular fractions studied in parallel, suggesting that this phosphoprotein is specifically located in the purified myelin fraction. In the present study, we examined the proteins in the purified myelin fraction which bind CaM in the presence of Ca^{++}. To this end, the proteins in purified myelin fraction was separated by SDS-PAG electrophoresis, and ^{125}I-CaM binding to the proteins in the gel was carried out as described by Carlin et al.(1981). It was found that there are about 5 major CaM binding polypeptide bands in the myelin fraction. Polypeptide bands of 48 kDa and 58 kDa regions also bind CaM, although to a lesser extent. Our results suggest that the phosphoprotein bands of 48 kDa/58 kDa are either protein kinase themselves or are substrates of protein kinase. We are currently investigating these possibilities.

145.9

CHARACTERIZATION OF NEURAMINIDASE ACTIVITIES IN RAT OLIGODENDROGLIA. R.K. Yu, M. Saito*, and C. Sato*. Department of Biochemistry, Medical College of Virginia, VCU, Richmond, VA 23298.

Myelin has an intrinsic neuraminidase (myelin-associated neuraminidase), which is probably synthesized in oligodendroglial cell bodies (oligos) and is transported to the myelin membrane. In this study, neuraminidase activities in rat oligos were examined. The enzyme activity toward the ganglioside GM3 (GM3-Nase) in oligos increased continuously after the onset of myelination and reached to the adult level (636 pmol/mg prot/min), which was much higher than those in neurons and strocytes (40 and 4 pmol/mg prot/min). The GM3-Nase activity in myelin also increased in the active myelination period, but decreased thereafter to the adult level. In myelin subfractions, the enzyme activity was distributed evenly in all fractions at the younger age, but was enriched in "heavy" myelin fraction at the adult age. These results suggest that the GM3-neuraminidase in oligos may play an important role in the formation and maintenance of the myelin sheath. (supported by USPHS grants NS 23102 & NS 11853)

145.10



OLIGODENDROCYTE SUBPOPULATIONS ARE DIFFERENTIALLY AFFECTED IN THE MYELIN DEFICIENT RAT. A. Espinosa de los Monteros*, M. Zhang*, M.N. Gordon, S. Kumar*, S. Scully* and J. de Vellis. Mental Retardation Research Center, UCLA School of Medicine, Los Angeles, CA 90024-1759.

The myelin deficient (*md*) mutant rat is a model that offers the possibility for a better understanding of abnormalities in oligodendrocyte development and function. Recently, we proposed a model of oligodendrocyte development based on double immunocytochemistry for transferrin (Tf) and myelin basic protein (MBP) from studies done in vitro and in vivo (freshly dissociated cells). In the present study, we compared the distribution pattern of these oligodendrocyte markers, Tf and MBP, in freshly-dissociated cells from the *md* and wild-type rat brain. The *md* mutant rat possessed oligodendrocytes displaying the three different phenotypes previously described: Tf+/MBP-, Tf+/MBP+ and Tf-/MBP+. However, the distribution of cells among these three phenotypes was altered compared with control littermates. Tf expression was delayed in the *md* rat brain, and Tf+/MBP- oligodendrocytes were larger than Tf+/MBP+ cells from the same animal. Tf+/MBP+ cells were the expected size. Finally, cells with the Tf-/MBP+ phenotype were reduced in number, but of normal size. RNA hybridization (Northern) blots also demonstrated a developmental delay in the appearance of Tf mRNA, and decreased mRNA levels, in the *md* brain compared with unaffected littermates. In conclusion, these results suggest that a major abnormality in oligodendrocyte development in the *md* rat brain coincides with the Tf+ phenotype.

145.11

GENETIC DELETION OF MYELIN BASIC PROTEIN IS ASSOCIATED WITH ABNORMAL LATENCY SHIFTS DURING REPETITIVE IMPULSE DISCHARGE. S.C. Steffensen, S.A. Raymond, A.L. Ganser, and G.R. Strichartz. Anesthesia Research Laboratories, Brigham & Women's Hospital, & Neurology Research, Children's Hospital, Harvard Medical School, Boston MA 02115.

The latency of spike conduction in single myelinated fibers from excised mouse sciatic nerves was recorded during trains of 100Hz stimulation lasting 5-10 min. In normal controls, the latency increased throughout the stimulation for 12 of 13 fibers studied at 36 °C and for 9 of 10 fibers at 26 °C (profile A). In shiverer mice (age-matched and genetically-matched to controls except for a deletion in the gene for myelin basic protein "MBP"), the latency (N=17) showed a different profile (B), with a similar initial slowing but without progressive slowing during the maintained high-frequency discharge. Instead, conduction actually became more rapid. After the train, recovery in shiverer fibers was marked by a transient speed-up in conduction. Conduction velocities in normals at 36 °C (range 12-37 m/s, avg 29) overlapped extensively with that of the fiber population from shiverer (range 17-30 m/s, avg 25), leaving the absence of MBP to account for the difference in profiles. Normal axons showed the shiverer profile (B) after exposure to phorbol di-acetate at concentrations (14-28 μM) that are known to activate protein kinase C, and that did not change profiles of shiverer fibers. These results implicate myelin, and specifically phosphorylation events contingent on presence of MBP, in active processes that modulate impulse conduction during sustained impulse activity.

145.12

HYPOMYELINATION IN A NEW NEUROLOGICAL RAT MUTANT
I.D. Duncan, University of Wisconsin, Madison WI, B. Holmgren*, R. Urba-Holmgren*, and L. Riboni*, Universidad Autonoma de Puebla, Puebla, Mexico

A spontaneous mutation in a colony of Sprague-Dawley rats has been detected, which results in progressive neurological disturbances from 1 month of age onwards. Affected rats develop a fine tremor, ataxia (4 months), immobility episodes, and seizures and paralysis (after 10 months). Selective breeding suggests that it may be an autosomal recessive trait. There are no gross abnormalities of the CNS but weights of both the cerebrum and the cerebellum are significantly reduced in the mutant. Affected rats at 2, 3 and 6 months and normal littermates were perfused with Karnovsky's fixative and the tissue collected from the corpus callosum, cerebellum and spinal cord, for light microscopy, EM and immunocytochemistry. In the spinal cord there was marked hypomyelination in all funiculi, most notably at 6 months in the dorsal columns. This myelin abnormality was more marked at 6 months than at 2 months in the cord and cerebellum. Preliminary counts of glial cell number in the thoracic spinal cord show a marked increase in the mutant compared with controls at all ages. EM observations showed a widespread microtubular proliferation in oligodendrocytes. As microtubules are thought to play a role in vesicular transport of myelin constituents it is possible that this cytoplasmic abnormality plays a role in the myelination disorder. (Supported by NIH grant NS23124 and NMSS grant RG1791)

145.13

THE FACTOR(S) IN GLIAL CONDITIONED MEDIUM RESPONSIBLE FOR MYELIN EXPRESSION IN JIMPY CULTURES IS A PROTEIN. W.P. Bartlett. Dept. of Anatomy, M.S. Hershey Medical Center, Hershey, PA 17033.

Jimpy is a sex-linked mutation that results in severe hypomyelination in the CNS of affected male mice. In culture, jimpy oligodendrocytes express the mutation in a manner similar to that found in vivo. The number of oligodendrocytes and the expression of myelin-related features is significantly reduced in cultures of jimpy glial cells compared to controls. However, when cultures of jimpy glial cells are maintained in medium that has been "conditioned" by normal glial cells (GCM), there is a dramatic increase in the number of oligodendrocytes, synthesis of myelin-like membrane and expression of myelin basic protein. In order to determine whether the factor(s) in GCM responsible for myelin expression in jimpy cultures is a protein, GCM was subjected to trypsin and heat treatment. The trophic activity of GCM was abolished by both trypsin digestion (0.1% for 30' at 37°C, followed by 0.2% trypsin inhibitor) and heating (100°C for 4'). In these experiments, the normal cultures used to condition medium consisted principally of astrocytes (>95% GFAP+). These results suggest that the factor(s) responsible for myelin expression in jimpy cultures is a protein synthesized by astyrocytes. (Supported by National Multiple Sclerosis Society, Grant 1998.)

NEUROGLIA: ACTIVE MEMBRANE RESPONSES

146.1

STIMULATION OF α_2-ADRENERGIC RECEPTORS INCREASES $CA^{++}{}_i$ IN TYPE I ASTROGLIA. A. K. Salm and Ken D. McCarthy*. Dept. of Pharmacol. & Curriculum in Neurobiol., Univ. N. Carolina, Chapel Hill, NC, 27599.

Putative α adrenergic receptor (α AR) subtypes which influence $Ca^{++}{}_i$ in cultured rat type I astroglia were pharmacologically characterized using the fluorescent Ca^{++} probe fura-2. Spectrofluorometric and video imaging systems were used to monitor single cell and population $Ca^{++}{}_i$ responses in astroglia after exposure to α AR agonists and antagonists. Nearly 80% of astroglia (~200 cells) exhibited increased $Ca^{++}{}_i$ in response to norepinephrine. In experiments carried out in the presence of 1 uM propranolol to block β ARs, the majority of these responses appeared to be mediated via α_1ARs, e.g., they were more potently blocked by the α_1 AR selective antagonist prazosin than by the α_2 AR selective antagonist yohimbine. 10 μM of the α_1 AR selective agonist l-phenylephrine (l-phen) was also effective in eliciting increased $Ca^{++}{}_i$. These results were expected as α_1ARs are linked to 2nd messengers controlling the release of intracellular Ca^{++}. Surprisingly however, yohimbine was equally or more potent than prazosin in blocking the NE-evoked $Ca^{++}{}_i$ response in a number of cells. In some of these cases 10 uM of the α_2 AR selective agonist clonidine was also able to increase $Ca^{++}{}_i$. Testing of populations of cells in the presence of propranolol, 1 uM prasozin and 10 uM l-phen to block and then desensitize residual α_1ARs showed that a subpopulation of cells responded to the highly selective α_2 AR agonist UK 14,304. When the procedure was reversed, i.e., testing of l-phen following incubation with yohimbine and UK 14,304, it was seen that the populations of cells which expressed pharmacological characteristics of α_1ARs and α_2ARs only partially overlapped. Thus, it appears that subpopulations of type I astroglia exist: those that express α_2ARs and/or α_1ARs which regulate $Ca^{++}{}_i$. To our knowledge, this is the first indication that α_2ARs in brain may regulate Ca^{++}. (NS20212).

146.2

DISTINCT SUBSETS OF ASTROGLIA CAN BE IDENTIFIED BY THEIR CALCIUM RESPONSE TO DIFFERENT NEUROLIGANDS.
Ken D. McCarthy* and A.K. Salm (SPON: Barry Pallotta).
Dept. Pharmacology, Univ. North Carolina, Chapel Hill, NC 27599

The combined results from many different laboratories indicate that in culture, polygonal (type 1) astroglia exhibit in excess of twenty different neuroligand receptor systems. Most of these studies were completed using large numbers of purified astroglia and examining either second messenger responses or radioligand binding of the total population. Using these methods it has been difficult to establish whether pharmacologically-distinct subsets of astroglia are present in astroglial cultures. To address this question we have developed a video imaging system to simultaneously study the effect of neuroligands on multiple individual astroglia loaded with the indicator dye, fura-2. Images were stored within 2 sec of drug application and every 6 sec over the subsequent 1 to 2 min. Greater than 95% of cells in these cultures stain for GFAP. In several cases it was possible to immunocytochemically-identify studied cells as $GFAP^+$ polygonal astroglia. Distinct subsets of astroglia responded to different receptor agonists with an increase in calcium levels. Among six different ligands examined, stimulation of P_{2Y} purinergic receptors increased calcium in the largest percentage of astroglia. Histamine, carbachol, serotonin, glutamate, and phenylephrine each stimulated a subset of astroglia when added at their maximally effective concentration. While there was some overlap among cells responding to the different ligands, there were many examples of cells responding to a subset of the ligands. Cells also varied in the magnitude and time course of their calcium response to a given drug. The results of these studies indicate that, like neurons, astroglia consist of subpopulations of cells that respond uniquely to different receptor agonists. (Supported by NS 20212)

146.3

TYPE 2 ASTROGLIA EXHIBIT A NUMBER OF DIFFERENT NEUROLIGAND RECEPTORS THAT REGULATE INTRACELLULAR CALCIUM LEVELS.

Vijendra Dave* and Ken D. McCarthy* (SPON: P. Maness). Dept. Pharmacology, Univ. North Carolina, Chapel Hill, NC 27599

Type 2 astroglia appear to represent a distinct lineage of astrocytes which can be morphologically and immunocytochemically distinguished from type 1 astroglia. Problems in obtaining large numbers of purified type 2 astroglia have made it difficult to examine the expression of neuroligand receptors by these cells. In order to address the question of receptor expression by type 2 astroglia, we have developed a video imaging system to simultaneously study the effect of neuroligands on calcium levels in multiple individual astroglia loaded with the calcium indicator dye, fura-2. Type 2 astroglia were isolated from rat cerebral cortical tissue by the method of McCarthy and de Vellis and maintained in medium containing 10% FCS. Cells were loaded with 2.5 uM fura-2 AM for 30 min prior to analysis. Images were stored within 2 sec of drug application and every 6 sec over the subsequent 30 to 60 sec. Studied cells were marked and processed for GFAP immunostaining. Only results from GFAP+ process-bearing astroglia were analyzed. Agonists examined to date include norepinephrine, carbachol, histamine, 2-methyl-thio-ATP (a P2Y purinergic receptor agonist) and bradykinin. Treatment with any one of these agonists in uM concentrations led to a rapid rise in intracellular calcium. The magnitude and duration of the rise in calcium varied among cells. Type 2 astroglia also appeared to exhibit spontaneous oscillations in their calcium levels whose frequency could be influenced by certain neuroligands. Where it was possible to sequentially examine a series of neuroligands on a group of type 2 astroglia, it seemed that the ability of these cells to respond to the different drugs varied. These experiments indicate that like type 1 polygonal astroglia, type 2 astroglia exhibit a variety of neuroligand receptors that regulate their levels of calcium. (NS 20212).

146.4

ASTROGLIAL CALCIUM CONCENTRATION FALLS DURING SPREADING DEPRESSION. R.P. Kraig. Department of Neurology, Univ. of Chicago, Chicago, Il 60637

Astroglia are structurally and functionally robust. The molecular mechanisms by which this dynamism is accomplished are unknown, though fluctuations in cellular pH and Ca2+ are likely. Indeed, a significant pH rise occurs in these cells when they are depolarized &, i.e., can reach 7.6-7.8 pH during spreading depression (SD) (see refs below). To begin to assess any interrelation between pH & Ca2+ in astrocytes, Ca2+ measurements were made during SD. Rats (n=9) were anesthetized with halothane, & experiments done as previously described (Chesler & Kraig, Am J Physiol, '87: J Neurosci, '89). Ca2+ measurements were made with electrodes whose detection limit was 7-8 pCa2+ & showed the typical absence of change in astrocytic (& variable rise in neuronal) Ca2+ during stimulation (Morris et al., Neurosci, '85). Surprisingly, astrocytic Ca2+ fell during SD from about a uM to the detection limit of the electrodes (n=12). Since astrocytic pH rises during SD part of the fall in Ca2+ seen may be due to passive, physicochemical buffering of Ca2+ though active uptake into organelles is also likely. These results raise the possibility that astrocytic Ca2+ (like pH?) may be modulated from some resting level when cells are activated.

ATP-DEPENDENT CALCIUM INFLUX STIMULATES PROTEIN PHOSPHORYLATION/DEPHOSPHORYLATION IN ASTROCYTES. J.T. Neary, J. Blicharska*, L.O.B. Norenberg* and M.D. Norenberg, Lab. Neuropath., Vet. Admin. Med. Ctr. & Univ. of Miami/Jackson Mem. Hosp., Miami, FL 33101.

We have recently shown that ATP and other purines stimulate calcium uptake in astrocytes (Biochem Biophys Res Commun 157: 1410, 1988). Since some actions of calcium are mediated by protein phosphorylation, we have now investigated the effect of the ATP-stimulated increase in intracellular calcium on protein phosphorylation in astrocytes. Primary astrocyte cultures were prepared from newborn rat cortices. Following incubation of the cells in physiological salt solution containing 32-Pi for 1.5 hr, ATP (1 uM-1 mM) was added for 0.5-1.5 min. We found 4- and 2-fold increases in phosphorylation in 55 and 52 kDa proteins, respectively; the latter protein co-migrated with glial fibrillary acidic protein. We also noted 50% decreases in phosphate incorporation in 24 and 21 kDa proteins. These effects were time- and dose-dependent. The changes were completely blocked by $LaCl_3$ and partially reduced by EGTA, thereby suggesting that the ATP-induced changes in 32-P incorporation were dependent on increased levels of intracellular calcium. Cultures previously treated with dibutyryl cyclic AMP have increased calcium-stimulated phosphorylation and elevated levels of 32-P incorporation in 55 and 52 kDa proteins (Neary et al, Brain Res 410: 164, 1987); addition of ATP to these cells had little effect on the phosphorylation of these proteins but did decrease 32-P incorporation in the 24 and 21 kDa proteins. In summary, these results suggest that calcium-dependent protein kinases and phosphatases transduce the effects of the calcium signal brought about by activation of purinergic receptor-operated calcium channels in astrocytes.

EFFECTS OF BRAIN NATRIURETIC PEPTIDE (BNP) AND ATRIOPEPTINS ON RAT CEREBROCORTICAL ASTROCYTES. K. Beaumont and P.K. Tan. Dept. of Medicine, UCSD, La Jolla, CA 92093.

BNP is a peptide recently isolated from porcine brain that has high sequence homology to atrial natriuretic factor (ANF). The separate distribution of BNP and atriopeptin III immunoreactivity in rat CNS (Saper et al., Neurosci. Lett. 96:29, 1989) indicates that these structurally-related peptides have separate functions. Prior studies (Friedl et al., J. Neurochem 52:589, 1989; Fiscus et al., ibid, 48:522, 1987) have demonstrated that atriopeptins elevate cyclic GMP levels in glial cultures and C6 glioma cells. We determined the effects of porcine BNP (pBNP) and ANF-related peptides upon astrocytes from rat cerebral cortex, a region with high BNP and low atriopeptin levels, in order to identify possible distinct actions of these peptides.

In astrocyte cultures (21-26 days) prepared from 1-2 day rat pup cerebral cortices, 1 μM rat ANF (rANF) increased cyclic GMP levels over 100-fold to 31 pmol/mg. Lowest concentration of rANF producing stimulation was 1 nM. Atriopeptin III and auriculin B were somewhat less potent than rANF, while atriopeptin I was significantly less effective and ring-deleted C-ANF(4-23) had no effect. BNP was less potent than atriopeptin III at concentrations below 100 nM, but produced greater stimulation than rANF at 1 μM. In preliminary studies, rANF did not alter basal potassium transport in astrocytes. Astrocyte cultures contained relatively high densities of 125-I-rANF binding sites (10 fmol/mg at 150 pM). Competition curves with rANF and BNP were biphasic, indicating presence of multiple sites. Potent competition by C-ANF(4-23) indicates the presence of the C-ANF (clearance) receptor subtype in astrocytes in addition to guanylate-cyclase coupled (B-ANF) receptors.

IMMUNO-ULTRASTRUCTURAL LOCALIZATION OF SODIUM CHANNELS AT NODES OF RANVIER AND ASTROCYTES IN RAT OPTIC NERVE. J.A. Black, B. Friedman, S.G. Waxman, L.W. Elmer[1*], and K.J. Angelides[1*]. Dept. Neurology, Yale Univ. Sch. Med. and VAMC, West Haven, CT. 06516 and Dept. [1]Physiol. and Molec. Biophys., Baylor Col. Med., Houston, TX 77030.

Voltage-dependent sodium channels are concentrated within the axon membrane at nodes of Ranvier and are in much lower density within the axon membrane beneath the myelin sheath. The distribution of sodium channels within rat optic nerve was examined ultrastructurally with anti-sera 7493, which is directed against purified sodium channels from rat brain and which recognizes a single band of Mr 260 kDa in immunoblots.

Rat optic nerve sections incubated with anti-sera 7493, and then reacted with biotin-avidin-HRP, exhibited intense immunostaining of the axon membrane at nodes of Ranvier; notably, axon membrane beneath the myelin sheath did not display immunoreactivity. Perinodal astrocyte processes, as well as somata and major longitudinally-oriented processes of astrocytes, were immunostained by anti-sera 7493. Astrocyte processes forming the glia limitans and surrounding blood vessels generally exhibited limited immunostaining with anti-sera 7493.

These observations suggest a role for astrocyte in the aggregation/maintenance of sodium channels within the axon membrane at the node of Ranvier.

TUMOR NECROSIS FACTOR PRODUCES PROCESS RETRACTION AND POTASSIUM CURRENT INHIBITION IN OLIGODENDROCYTES. B. Soliven*, S. Szuchet*, and D.J. Nelson* (SPON: S. Bursztajn). University of Chicago, Department of Neurology, Chgo, Il. 60637.

Tumor necrosis factor (TNF-α), a cytokine secreted by activated macrophages, has been reported to induce a delayed-onset oligodendrocyte (OLG) necrosis and demyelination *in vitro* (Selmaj & Raine, Ann. Neurol. 23:339-346, 1988). We used the whole-cell patch-clamp technique to investigate whether dysfunction of ion channels in OLGs might contribute to these pathological changes. Adult ovine OLGs after 2-3 weeks in culture were incubated with recombinant human TNF (10^4 U/ml) for 48-72 hrs. These cells remained viable as determined by dye exclusion, but some of them had either partially or completely retracted processes. Resting membrane potential (RMP) was estimated as the zero current potential from current-voltage plots. Cells that had retracted processes (grp.A) were found to have a depolarized RMP: -37.3 ± 2.0 mV (n=18), as compared to -62.4 ± 2.3 mV (n=8) in cells that retained normal processes (grp.B). RMP in untreated cells (grp.C) was -68.6 ± 1.5 mV (n=16). Mean amplitude of inwardly rectifying K^+ current measured at -120 mV was -63 ± 12.5 pA in grp.A; -185.8 ± 35.8 pA in grp.B, and -507 ± 126 pA in grp.C. There was no significant difference in the cell membrane capacitance (grp.A = 16.6 ± 2.1 pF, n=8; grp.C = 20.1 ± 3.1 pF, n=7). Preliminary data from OLGs incubated with IL-2 showed no reduction in RMP or inward current amplitude. We conclude that TNF-treated OLGs exhibit reduced mean current amplitude. Resting membrane potential is reduced in cells with retracted processes. We postulate that dysfunction of ion channels may precede process retraction based on our finding that current amplitude was also reduced in TNF-treated cells that appeared morphologically normal. Supported by NIH grant PO1 NS24575. B.S. is a fellow of Natl. M.S. Soc.

146.9

INWARD RECTIFYING POTASSIUM CHANNELS IN RETINAL GLIAL (MÜLLER) CELLS. Eric A. Newman, Eye Research Inst. and Dept. Ophthalmol., Harvard Med. Sch., Boston, MA 02114.

Current-voltage (I-V) relations of dissociated salamander (*Ambystoma tigrinum*) Müller cells were determined with two-electrode, whole-cell voltage clamp. Patch electrodes contained 88 mM K^+; cells were bathed in a solution containing 88 mM K^+ and 2 mM Cd^{2+} (to block Ca^{2+} and Ca^{2+}-activated K^+ currents).

The I-V relation of cells whose endfeet had been shorn off during the dissociation process showed strong inward rectification. Cell reversal potential was near 0 mV, the K^+ equilibrium potential. For hyperpolarizing command pulses, the evoked current showed partial inactivation. The I-V relations of Müller cells with their endfeet intact were almost identical to those of cells lacking endfeet in the degree of rectification and in the time course of inactivation. They differed only in the magnitude of the current, which was 8.8 times larger for cells with endfeet.

In cell-attached patch clamp recordings from the soma region, multi-channel currents showed strong inward rectification. Much larger currents showing similar rectification were recorded from patches on the endfoot. Currents of single, inward rectifying channels were recorded from soma patches. However, single channel currents could not be resolved from endfoot patches due to the high density of channels in this cell region.

These results indicate that the principal conductance of amphibian Müller cells in all cell regions is mediated by K^+ inward rectifying channels. Greater channel density in the endfoot is responsible for the high conductance of this cell region. Supported by grant EY04077.

EXCITATORY AMINO ACID AGONIST-EVOKED TAURINE RELEASE FROM CULTURED ASTROCYTES. G.R. Dutton, R.A. Philibert, M.L. Simmons*, R. Miyazaki* and J. Eastburn*. Department of Pharmacology, College of Medicine, University of Iowa, Iowa City, IA 52242.

Cultured cerebellar astrocytes from 7-9 day rats and grown 17-19 days in vitro release taurine in response to elevated K^+ levels in a dose-dependent fashion requiring Ca^{2+} and Na^+. Since these cells are reported to possess excitatory amino acid receptors, we began studies to determine if elevated concentrations of glutamate, or its receptor agonists, produced similar increases in efflux.

Quisqualate (1-100 μM) and N-methyl aspartate (0.1-1000 μM) had no effect on the basal levels of taurine efflux. However, kainate (10-1000 μM) increased release approximately 3-500% at concentrations >200 μM. In addition, L-glutamate produced a dose-dependent, 4-fold increase in taurine efflux (EC_{50} = 100 μM) over the range 10-1000 μM. The kainate-evoked taurine efflux may not be receptor mediated since the antagonist 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX, 200 μM) did not attenuate release evoked by 500 μM kainate.

Thus, these and our previous results suggest, that in cultured astrocytes increased taurine efflux produced by elevated K^+, glutamate and kainate may be related to a recovery phase following cellular swelling during which taurine is expelled into the extracellular space.

This work was supported by NIH grant NS 20632.

THE EFFLUX OF PRELOADED GABA FROM CEREBRAL ASTROCYTES IS STIMULATED BY ELEVATED POTASSIUM BUT NOT BY VERATRIDINE AND OUABAIN. J. Albrecht* and M.D. Norenberg. Laboratory of Neuropathology, Veterans Adm. Med. Ctr. and Univ. Miami Sch Med/Jackson Mem. Hosp., Miami, FL 33101.

Studies on mixed glial preparations have indicated that glia release GABA upon treatment with depolarizing agents (c.f: Sarthy, J.Neurosci. 3, 2494, 1983). However, in cerebellar astrocytes potassium-stimulated GABA release was not detected (Pearce et al., Brain Res., 206, 485, 1981), casting doubt on its ubiquity in glia. In the present study, GABA release was investigated in cultured astrocytes derived from neonatal rat cerebral cortex. The cells (21-30 DIV) were preloaded with [^{3}H] GABA and subjected to superfusion in Krebs-Ringer medium followed by a change to stimulation media. GABA efflux was stimulated by K^+ in a dose-dependent manner from 7.5-120 mM. The effect of K^+ appeared Ca^{2+}- and Mg^{2+}-independent, suggesting a non-vesicular mechanism of GABA release. Veratridine (100 uM) and ouabain (1 mM), which in synaptosomes stimulate Ca^{2+}-independent GABA release by collapsing the Na^+ electrochemical potential, evoked in astrocytes a transient decrease of GABA efflux. The results indicate that astrocytes derived from neonatal rat cerebral cortex are capable of GABA release upon treatment with depolarizing concentrations of K^+. While the mechanism of K^+-induced, Ca^{2+}-independent GABA release from astrocytes remains to be elucidated, the results suggest that, unlike that in synaptosomes, it must occur by a process other than a reversal of the Na^+-driven GABA uptake.

HYPOOSMOTIC MEDIA-INDUCED RELEASE OF AMINO ACIDS FROM ASTROCYTES. H.K. Kimelberg, S. Goderie* and †R. Waniewski. Div. of Neurosurgery, Albany Medical College and †Wadsworth Center for Labs and Res., N.Y. State Dept. of Health, Albany, New York

During exposure of primary astrocyte cultures to hypo-osmotic media the cells rapidly swell and then return to normal values, a process termed regulatory volume decrease or RVD. We have found that under these conditions the cells lose label after loading them with [^{3}H] D-aspartate, [^{3}H] L-glutamate or [^{3}H] taurine, as previously reported for [^{3}H] taurine (Pasantes-Morales & Schousboe, J. Neurosci. Res. 20, 505, 1988). There is also comparable loss of endogenous L-glutamate, glutamine or taurine as measured by high pressure liquid chromatography. We have found that this release, measured by loss of label, can be inhibited by the anion exchange transport inhibitors SITS and furosemide, but not by bumetanide a specific inhibitor of $Na^+ + K^+ + 2Cl^-$ co-transport. A novel fluorenyl compound, L-644,711, an effective anion exchange inhibitor, also inhibits release of [^{3}H] L-glutamate and [^{3}H] taurine and this compound has been shown to improve recovery from a brain trauma/hypoxia injury in which astrocytic swelling occurs (Kimelberg et al. Central Nervous System Trauma, 4,3, 1987). It now seems possible that part of this beneficial effect may be due to inhibition of release of excitotoxins such as L-glutamate from swollen astrocytes.

IONIC DEPENDENCE OF [^{3}H]ADENOSINE UPTAKE INTO CULTURED ASTROCYTES. A.S. Bender, D.M. Woodbury, and H.S. White*. Dept. Pharmacol. & Toxicol., Univ. of Utah, Salt Lake City, UT 84112.

Astrocytes in primary culture possess a high-affinity uptake system for the inhibitory neurotransmitter adenosine that is equivalent to that of cultured neurons. Removal of either Na^+, Cl^- or Ca^{2+} significantly reduced [^{3}H]adenosine uptake into cultured mouse astrocytes by 42, 27 and 13%, respectively. Pretreatment with ouabain (1 mM), DIDS (1 mM) or the Ca^{2+} ionophore A23187 (1 μM) also reduced uptake by 50, 33 and 15%, respectively. In addition, uptake was blocked by the proton pump inhibitor omeprazole, the K^+ channel activators BRL 34915 and nicorandil and the Na^+/K^+-Cl^- exchange inhibitor furosemide (IC50's: .047, .075, .696 and 2.2 mM, respectively). The potent inhibition of uptake by BRL 34915 probably represents a direct effect on the adenosine carrier as opposed to the K^+ channel since its effect was not antagonized by glyburide and since the removal of K^+ or the addition of excess K^+ failed to affect [^{3}H]adenosine uptake. These results demonstrate that astrocytic adenosine uptake is under complex regulation and may represent a potential target for CNS-acting drugs such as vasodilators and anticonvulsants. Supported by NIH grant NS-22200 from the NINDS (HSW) and a fellowship from the Medical Research Council of Canada (ASB).

PH REGULATION IN GLIAL CELLS OF NECTURUS OPTIC NERVE. M.L. Astion*, A. Chvatal*, and R.K. Orkand. Inst. of Neurobiology, Univ. of Puerto Rico Medical Sciences Campus, San Juan, PR 00901.

Glial cells from intact Necturus optic nerve were impaled with double-barreled pH-sensitive microelectrodes. At a bath pH of 7.5, the mean intracellular pH (pH_i) was 7.32 (S.D.=0.03, n=6) in nominally HCO_3^--free solution and 7.39 (S.D.=0.1, n=6) in HCO_3^-/CO_2. Superfusion (4 min) followed by withdrawal of 15 mM NH_4^+ induced an acidification of less than 0.4 pH unit after which the pH_i recovered toward the original baseline. In the absence of HCO_3^-/CO_2, the recovery from acidification was Na^+-dependent, and blocked by 1 mM amiloride. The recovery was stimulated by HCO_3^-/CO_2 which also hyperpolarized the membrane. In HCO_3^-/CO_2, the recovery from acidification was Na^+-dependent, inhibited by 0.5 mM SITS, and associated with a hyperpolarization of the membrane. Removal of Na^+ or addition of SITS induced a depolarization which accompanied the inhibition of the pH_i recovery. The data strongly suggest that the relatively alkaline pH_i of glial cells is maintained by at least two mechanisms, Na^+/H^+ exchange and electrogenic Na^+/HCO_3^- cotransport. Supported by NIH grants NS07464, GM07170, and RII8705802 (NSF).

147.1

CAPSAICIN INHIBITS VOLTAGE-ACTIVATED CALCIUM CURRENTS IN A SUB-POPULATION OF ADULT RAT DORSAL ROOT GANGLION NEURONES. *B. Robertson*[T], *R.J. Docherty* and S. Bevan** (SPON: I. Forsythe) Sandoz Institute for Medical Research, 5 Gower Place, London WC1E 6BN, UK.

Capsaicin opens a cation (Ca^{2+}, Na^+, K^+) permeable channel in a sub-population of DRG neurones. In addition, capsaicin has been reported to increase the inactivation rate of voltage gated calcium currents in guinea pig DRG neurones, where it had no agonist action.

We have examined whole cell calcium currents in freshly plated rat DRG neurones, which show the agonist effect of capsaicin. In calcium (2.5-10mM) containing solutions, capsaicin (0.5-30μM) evoked an inward calcium current (V_H=-80mV) in some neurones. In such cells, voltage activated calcium currents were inhibited during exposure to the agonist. With brief exposures (<10secs) some recovery of the calcium current was noted whereas longer exposure always resulted in an irreversible inhibition or abolition. In cells where capsaicin failed to elicit an inward current the calcium currents were either unaltered or showed an apparent increase in inactivation rate, which was reversible. In solutions with either Ba^{2+} (10mM) or Na^+ (140mM + 1μM TTX) as the charge carrier, capsaicin no longer produced an irreversible depression of the voltage activated current even though a large agonist induced current was elicited.

We conclude that the irreversible effects of capsaicin on voltage activated calcium currents are secondary to increases in intracellular calcium and are unlikely to be due to a direct effect of capsaicin on calcium channels.

DEPOLARIZING ACTION OF DANTROLENE Na ON CA1 HIPPOCAMPAL NEURONS. K. Krnjević and Y. Z. Xu. Anaesthesia Research Department, McGill University, Montréal, Québec, Canada.

At a concentration of 10-20 μM dantrolene (DAN) consistently depolarized pyramidal cells in slices from Sprague-Dawley rats (by 5-30 mV). This effect which was rapidly reversible after washing-out DAN, was accompanied by no change or some apparent reduction in input resistance and a marked depression of slow after hyperpolarization (both measured at initial resting potential). Neither the depolarization nor the corresponding slow inward shift recorded by single electrode voltage clamp was blocked by tetrodotoxin: they were therefore unlikely to be mediated by Na currents. Similarly they were not affected by 4 mM Cs, which fully blocked anomalous rectification and the time-dependent Q-current. Being equally well defined when recording with KCl or K acetate-filled microelectrodes, the DAN-evoked depolarization also cannot be due to activation of a Cl^- current. We therefore conclude that the inward current that is either activated or uncovered by DAN is probably carried by Ca^{2+}. Such an effect could be produced by diminished Ca^{2+} release from internal binding sites. A direct action of DAN on surface membrane channels has not been excluded. Supported by Medical Research Council of Canada.

CALCIUM SPIKES ARE REDUCED BY SOMAN IN BULLFROG SYMPATHETIC GANGLION CELLS. T.J. Heppner* and J.F. Fiekers (SPON: B. Kapp). Dept. Anat. and Neurobiol., Univ. of Vt. Coll. Med., Burlington, VT 05405.

The action of soman on Ca^{++} spikes was examined in sympathetic ganglion cells located in the isolated 9th and 10th paravertebral ganglion of the bullfrog Rana catesbeiana. Intracellular recordings were obtained from ganglion cells superfused with high Ca^{++} saline (Ca^{++}, 9.0 mM; TTX, 1.5 uM; TEA, 20 mM). Prolonged action potentials (~70 mV; 23ms-43ms) were recorded in response to brief depolarizing current pulses. Soman (0.1 uM) decreased the duration of the Ca^{++} spike to 37% of pretreatment values. Similar results were obtained when Ca^{++} was replaced with 2 mM Ba^{++}. Although the spike duration was greatly prolonged in Ba^{++} (ranging from 57 ms to 12 sec), soman (0.1 uM) reduced the Ba^{++} spike duration to 23% of pretreatment values. Both Ca^{++} and Ba^{++} spikes fully recovered within 6 min of a wash period. The membrane input resistance measured with hyperpolarizing pulses was not significantly altered by soman (0.1 uM). Pretreatment with atropine (5 uM) or hexamethonium (10 uM) did not prevent the soman-induced reduction in spike duration, suggesting that this action of soman was not mediated through nicotinic or muscarinic receptors. These results suggest that soman alters Ca^{++} channel properties in bullfrog sympathetic neurons. This work supported in part by the USAMRDC, Contract No. DAMD17-86-C-6031.

147.4

A DEVELOPMENTAL PROFILE OF RECEPTORS FOR PHENYLALKYLAMINE CALCIUM CHANNEL LIGANDS IN *DROSOPHILA*. Robert M. Greenberg[1]*, H. Glossmann[2]*, and Linda M. Hall[1] (SPON: D.Gil). [1]Dept. of Mol. Genetics, Albert Einstein Coll. Med., Bronx, NY 10461 and [2] Institut für Biochemische Pharmakologie, Innsbruck, Austria.

We are interested in establishing a molecular genetic system for studying voltage-sensitive calcium channels in *Drosophila*. As a first step, we defined receptors for calcium channel blockers in *Drosophila* head membranes. Phenylalkylamine calcium channel ligands bind to high and low affinity receptors in membranes from *Drosophila* heads. These receptors are associated with 136 kDa (high affinity) and 27 kDa (low affinity) proteins. Receptors for other classes of calcium channel ligands (dihydropyridines, benzothiazepines) are barely detectable in this preparation. The phenylalkylamine binding activity has been solubilized in 1% digitonin and the digitonin/receptor complex runs on sucrose gradients with an apparent molecular weight of 260,000 (Greenberg, R.M. *et al.*, *Insect Biochem.*, in press). We have been examining the tissue specificity and developmental profile of each receptor. Both the stereoselective, high affinity receptor and the low affinity receptor are enriched in membranes from *Drosophila* heads compared with bodies. Thus, both receptors are likely to be components of the nervous system. The B_{max} of the high affinity receptor is very low during embryogenesis and then increases dramatically. The density of the receptor then remains relatively constant during later developmental stages. In contrast, the low affinity receptor is present at high levels in embryonic stages and remains at these levels throughout development. Thus, the two receptors for phenylalkylamine calcium channel blockers in *Drosophila* are not coordinately regulated during development.

IONIC BASIS OF THE CARDIAC ACTION POTENTIAL IN THE MOTH: EVIDENCE FOR A TTX-SENSITIVE CALCIUM CHANNEL. D.L. Brink and N.J. Tublitz. Inst. Neurosci., U. Oregon, Eugene, OR 97403.

We are investigating the mode of action of 2 cardioregulatory neuropeptides on the heart of the tobacco hawkmoth, M. sexta. As part of this study, the ionic mechanisms underlying the cardiac action potential were analysed using standard intracellular recording of spontaneously contracting heart cells. The moth heart action potential is characterized by a slow pre-potential leading to a fast, overshooting depolarization, followed by a pronounced, 100-200 ms long depolarizing plateau and terminated by a rapid repolarization. Ion substitution experiments, in which $[Na^+]_{out}$ was replaced by isotonic dextrose, had no detectible effect on action potential shape or duration. In contrast, the action potential was markedly affected by manipulation of $[Ca^{2+}]_{out}$. Elevated $[Ca^{2+}]_{out}$ increased pre-potential duration, while reduced extracellular Ca^{2+} diminished action potential amplitude and duration. Exposure to Ca^{2+}-free saline or saline containing 5 mM Co^{2+} reversibly eliminated all spontaneous electrical activity whereas replacement of $[Ca^{2+}]_{out}$ by equimolar Ba^{2+} substantially prolonged the depolarized plateau and prepotential. The organic Ca^{2+} channel blockers verapramil and w-omega conus toxin were totally ineffective. Surprisingly, the Na^+ channel blockers TTX (1 uM) and STX (1 uM) applied in a Na^+-free saline reversibly eliminated the action potential. These results suggest the hypothesis that the Manduca heart muscle contains a class of cation channels with the ionic selectivity of a calcium channel and the pharmacology of a voltage sensitive sodium channel. We are currently testing this hypothesis with patch-clamp techniques.

147.6

DIFFERENTIAL INHIBITION BY ω-CONOTOXIN OF cGMP PRODUCTION IN CULTURED CEREBELLAR NEURONS. P.G. Lysko* and G.Z. Feuerstein (SPON: K.M. Woodbury). Dept. of Neurology, USUHS, Bethesda, MD 20814.

Cultured cerebellar granule cells have previously been shown to have dihydropyridine binding sites which regulate Ca^{2+} influx through voltage-sensitive Ca^{2+} channels. Ca^{2+} influx has been shown to be inhibited by nifedipine and the inorganic ion Cd^{2+}, and stimulated by the Ca^{2+} channel agonist Bay K 8644. The excitatory amino acid glutamate, the analog kainate, and the alkaloid veratridine are all known to cause depolarization leading to Ca^{2+} influx and cGMP production. Here we measured cGMP production in granule cells exposed to these different depolarizing agents and examined their sensitivity to the Ca^{2+} channel blocker ω-conotoxin GVIA (ω-CT). Only glutamate-stimulated cGMP production was significantly inhibited (25-30%) by ω-CT. Inhibition by ω-CT occurred over a narrow dose-response range, with no inhibition at 2 μM and maximal inhibition at 20 μM. At these high concentrations, ω-CT displayed no agonist activity. Inhibition of glutamate-induced cGMP production by ω-CT was dependent on incubation conditions; the greatest inhibition occurred in buffer containing Mg^{2+} but not glucose, conditions which enable glutamate to become excitotoxic in these cells. The results suggest that glutamate mediates Ca^{2+} influx via different channels than other stimuli, which may be useful in understanding glutamate-induced excitotoxicity.

IFENPRODIL TARTRATE INHIBITS SLOW PHASE OF VOLTAGE-DEPENDENT $^{45}Ca^{2+}$ UPTAKE INTO SYNAPTOSOMES. H. Honda[1'2], T. Shibuya[1'2], B. Salafsky[1], and B. Curtis[1] 1: Department of Biomedical Sciences University of Illinois College of Medicine at Rockford, Rockford, IL 61107-1897. 2: Department of Pharmacology, Tokyo Medical College, Tokyo 160, Japan.

Ifenprodil tartrate (IFT), which has been used in the treatment of human cerebrovascular disease, has both α-adrenergic blocking [1] and vasorelaxing actions [2]. IFT also has the action of increasing cerebral blood flow [3]. We have previously suggested that the vascular myorelaxing action of IFT is due to the inhibition of Ca^{2+} mobilization in the cell [2,3]. We report here the effect of IFT on fast and slow phases of voltage-dependent $^{45}Ca^{2+}$ uptake into cerebrocortical synaptosomes of rats. IFT (10^{-8} to 10^{-4}M) induced dose-related inhibition of voltage-dependent $^{45}Ca^{2+}$ uptake during the slow phase. But IFT had little affect on the fast phase of $^{45}Ca^{2+}$ uptake. Results suggest that IFT specifically inhibits the slow phase of voltage-dependent $^{45}Ca^{2+}$ uptake into cerebrocortical synaptosomes of rat.

INHIBITION OF DEPOLARIZATION-INDUCED CALCIUM UPTAKE IN RAT BRAIN SYNAPTOSOMES BY TRICYCLIC ANTIDEPRESSANTS. G. Beauchamp*, P.-A. Lavoie and R. Elie*. Dept. Pharmacology, Univ. of Montreal, Montreal, Canada.

We have used a choline-based medium, so that the increased calcium uptake due to replacement of choline by K^+ was only a reflection of calcium channel activation by depolarization. Brain cortex synaptosomes were preincubated for 20 min at 30°C in medium rich in choline (145 mM), with or without imipramine, desipramine, chlorimipramine, amitriptyline, or diltiazem (classical calcium channel antagonist). A 100 µl aliquot of preincubated synaptosomes was then added to an equal volume of either choline-based or potassium-based medium containing ^{45}calcium, and incubated for 10 sec at 30°C. Calcium uptake was terminated by addition of 5 ml cold calcium-free choline buffer containing 1 mM ethyleneglycol-bis-(β-aminoethyl ether)-N,N'-tetraacetic acid, followed by rapid filtration on Whatman GF/C filters. The filters were rinsed, and then immersed in Aquasol for liquid scintillation counting. Basal uptake (5 mM K^+) was essentially unaffected by drug concentrations ranging from $2X10^{-6}$ M to $2X10^{-4}$ M. In contrast, stimulated uptake (60 mM K^+) was dose-dependently reduced, which may indicate an antagonist activity at the neuronal voltage-dependent calcium channels; all drugs tested appeared equipotent, and virtually complete inhibition was achieved at $2X10^{-4}$ M. (Supported by CAFIR fund of University of Montreal).

THE HIGH-AFFINITY RECEPTOR FOR ω-CONOTOXIN IN BRAIN DIFFERS FROM THE DIHYDROPYRIDINE RECEPTOR. T. Abe, N. Hayakawa*, T. Yamaguchi*, T. Morita*, H. Saisu* and H. Mitsui*[1]. Dept. of Neurochem, Brain Res. Inst. and [1]Dept. of Biol., Faculty of Sci., Niigata Univ., Niigata 951, Japan.

Multiple types of voltage-sensitive calcium channels exist in the nervous system. However, the molecular basis of the diversity is not known. We prepared monoclonal antibodies (mAbs) to the dihydropyridine (DHP) receptor purified from the rabbit skeletal muscle to identify calcium channel molecules in the brain. One mAb immunoprecipitated practically all the DHP binding activity in the digitonin extract of the skeletal muscle microsomes. It could also precipitate most (>80%) of the high-affinity DHP binding activity in the digitonin extracts of the bovine cardiac muscle and brain membranes However, it did not significantly precipitate the receptor for ω-conotoxin GVIA (GVIA) in the digitonin extract of the bovine brain membranes. These results indicate that most, if not all, of the GVIA receptor in the brain differs from the DHP receptor (L-type channels). Since GVIA probably does not affect T-type channels, the high-affinity GVIA binding site in the brain most likely represents N-type calcium channels.

CALCIUM CHANNEL BLOCKING ACTIONS OF OCTANOL. D.A. Twombly* and T. Narahashi (SPON: D.L. Colbern). Dept. Pharmacology, Northwestern Univ. Sch. Med., Chicago, IL 60611.

Octanol has been reported to produce specific block of low-threshold calcium conductances in inferior olivary neurons (Llinas and Yarom, Soc. Neurosci. Abstr., 1986) and reticular neurons (Leonard & Llinas, Soc. Neurosci. Abstr., 1987). The objective of our study was to determine whether the block of low-threshold channels could involve modification of inactivation mechanisms.

Whole-cell voltage clamp experiments were performed on N1E-115 neuroblastoma, cells which possess low-threshold "type I" calcium channels as well as high-threshold "type II" channels. At concentrations of 20 - 300 µM, octanol reversibly suppressed the amplitudes of both types of calcium channel currents, without altering the voltage dependence of activation. Type II currents were somewhat more sensitive to octanol than were type I currents. After exposure to 100 µM octanol, for example, peak type I and type II currents were reduced by 27% and 35%, respectively. Octanol also produced changes in type I channel inactivation, including accelerated inactivation kinetics and 5 - 8 mV hyperpolarizing shifts in the voltage dependence of steady-state inactivation. During repetitive stimulation at 0.5 - 8.0 Hz, the peak amplitudes of type I currents decreased less in the presence of octanol than in control. The differences in use-dependent behavior were partly due to more rapid recovery from inactivation.

These experiments have confirmed the ability of octanol to block voltage-dependent calcium channels. The potency of octanol was approximately 1000-fold greater than that of ethanol, which also blocks type I and type II currents (Twombly *et al.*, Alcohol. Clin. Exp. Res., 1988). Octanol did not prove to be selective for low-threshold channels in this preparation. However, it exerted specific effects on type I channel inactivation which could modulate the block as a function of holding potential and cell activity (supported by grant AA07836).

CHLORODIAZEPOXIDE BLOCKS TWO TYPES OF Ca^{2+} CHANNELS IN NEUROBLASTOMA CELLS. E. Reuveny and T. Narahashi. Dept. of Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611.

Benzodiazepines (BDZ) in µM concentrations inhibit voltage-dependent Ca^{2+} uptake in mammalian nerve terminal preparations and Ca^{2+} conductance in leech and sea snail neurons. In synaptosomes Ca^{2+} uptake is regulated by µM affinity BDZ binding site rather than the Cl^- conductance site. These two binding sites have been distinguished on the basis of kinetic and pharmacological studies and the inhibition of electric shock-induced seizures. We studied the effect of chlorodiazepoxide (CDZ), a BDZ with anticonvulsant properties on voltage-gated Ca^{2+} channels. CDZ was slightly more potent in producing resting block of type I (K_i=350 µM) than type II (K_i= 420 µM) Ca^{2+} channels in a dose-dependent and reversible manner. CDZ block of type II channels was also time- and voltage-dependent, increasing with larger depolarizations. In addition, CDZ produced use-dependent block of type I channels and shifted the steady-state inactivation curve by 7.4 mV in the hyper-polarizing direction. Closed and open channel block by CDZ of the two types of Ca^{2+} channels may be correlated with the inhibition of electric shock-induced seizures, by either inhibiting Ca^{2+}-dependent transmitter release or decreasing the peak and duration of the Ca^{2+} action potential. Supported by NIH grant NS14144.

147.12

PHYLOGENETIC AND SUBTYPE SPECIFICITY OF ω-CONOTOXINS FOR CALCIUM CHANNELS. L. J. Cruz, J. S. Imperial*, G. C. Zafaralla*, J. Rivier* and B. M. Olivera. Dept. of Biology, Univ. of Utah, Salt Lake City, UT 84112, Salk Institute, La Jolla, CA 92307 and Marine Sci. Inst. and Dept. of Biochem., Univ. Philippines, Metro Manila.

ω-Conotoxin GVIA was first demonstrated by McCleskey, et al. (*PNAS* 84:4327, 1987) to block both the N and L subtypes of calcium channels in chick dorsal root ganglia. So far, eleven ω-conotoxins have been isolated and sequenced from several fish-hunting *Conus* species. In addition, a number of ω-conotoxin-like peptides have been purified but these do not induce the same in vivo symptomatology in mammals. Recently, a number of investigators have used GVIA as a pharmacological tool for determining the calcium channel subtypes present in neuronal tissues of mammalian species. Results obtained in a number of laboratories however suggests that caution must be exercised in interpreting interaction with ω-conotoxins as proof for the presence or absence of N and L type channels. In the mammalian CNS, ω-conotoxin GVIA apparently binds only with a small subset of voltage sensitive Ca channels; less than 50 percent of ^{45}Ca uptake by synaptosomal preparation is inhibited by GVIA. In contrast, in avian systems the spectrum of targets is much wider and almost all ^{45}Ca uptake is inhibited. Comparison of in vivo effects in fish, frogs, chicks and mice and binding studies using radioiodinated derivatives of the toxins have indicated not only phylogenetic and channel subtype specificity but also the dependence of interaction on the particular ω-conotoxin used. Biochemical characterization of calcium channel subtypes is presently in progress using different ω-conotoxins. (Supported by Grant GM22737 to BMO and AM 26741 to JR).

147.13

THE INHIBITION OF 125I OMEGA CONOTOXIN GVIA BINDING BY NEOMYCIN TO NEURONAL MEMBRANES IS MODULATED BY GTP-γ-S. R.J. Stumpo*, L.M. Pullan, B.A. Meiners and A.I. Salama. Dept. of Pharmacology, ICI Pharmaceuticals Group, ICI Americas Inc., Wilmington, DE 19897.

Omega conotoxin GVIA (ωCT) blocks calcium currents at the L and N-type calcium channels. Omega conotoxin and neomycin, an aminoglycoside antibiotic, have been shown to inhibit 45Ca2+ uptake and to block neurotransmitter release, presumably acting at the N-type calcium channel. We have previously shown that neomycin inhibits dihydropyridine insensitive [125I] ωCT binding to neuronal membranes. We demonstrate here that the inhibition curve of neomycin against [125I] ωCT binding is shifted to the right by GTP-γ-S or GMP-PNP, increasing the IC_{50} of neomycin from 0.9 μM to 3.6 μM. The ωCT inhibition curve is unaffected by the GTP analogues. The effect is specific for GTP analogues; GDP, cGMP, ATP, ADP and cAMP did not modulate neomycin or ωCT potency at the [125I] ωCT binding site. Sodium fluoride, which stimulates G-protein activity, also reduced the potency of neomycin for the [125I] ωCT binding site. These results may indicate that the [125I] ωCT binding site of the N-channel may be coupled to a G-protein.

147.14

MPP^+ CAUSES A LONG-LASTING EFFLUX OF STRIATAL DOPAMINE IN VIVO VIA A NIMODIPINE SENSITIVE L-TYPE NEURONAL CALCIUM CHANNEL. C.C. Chiueh and H. Miyake*. NIMH, Bethesda, MD 20892.

Intracerebral administration of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPP^+) causes an accumulation of ^{45}Ca (Sun et al., 1988). MPP^+ produces also an increase in the release of dopamine (DA; Rollema et al., 1986; Ozaki et al., 1987) and serotonin (Miyake and Chiueh, 1989). Microdialysis perfusion of the rat striatum with MPP^+ caused a dose-dependent increase in the efflux of DA. The MPP^+-induced release pattern of striatal DA appears to be **'biphasic'**. In addition to a fast releasing peak of DA, a **slow releasing peak** of DA appeared at 20 min after the termination of MPP^+ perfusion (10^{-3}M, 5min). MPP^+ produced only the fast release peak of DA when the striatum was perfused with a Ca^{++}-free artificial CSF containing 10 mM EDTA or EGTA. Nimodipine (L-type Ca^{++} channel antagonist) inhibited the MPP^+-induced late DA releasing peak but not of the initial fast DA releasing peak. These results indicate that MPP^+ produces a biphasic increase in the DA efflux from the striatum via two different mechanisms of action. The fast DA releasing action of MPP^+ resembles that of d-amphetamine (Ca^{++} insensitive). The long-lasting late DA releasing action of MPP^+ is a Ca^{++} dependent process which involves a L-type neuronal Ca^{++} channel.

BLOCKADE OF HIGH-VOLTAGE-ACTIVATED CALCIUM CURRENTS BY PHENYTOIN IN ACUTELY DISSOCIATED GUINEA-PIG HIPPOCAMPAL NEURONS. J. Black, L.J. Larson-Prior and N.T. Slater. Department of Physiology, Northwestern University Medical School, Chicago, IL 60611 U.S.A.

Anticonvulsant agents currently employed in the treatment of partial complex seizures have been proposed to exert their therapeutic effects through actions on neuronal sodium and calcium currents. However, little biophysical evidence has been obtained to evaluate this hypothesis in neurons in the limbic or cerebral cortex, the sites of initiation of generalized seizures. We have studied the effects of phenytoin on high-voltage-activated calcium currents in enzymatically dissociated neurons from the CA1 and CA3 regions of adult guinea-pig hippocampus using whole-cell patch-clamp recording techniques. 3 mM external barium was employed as the charge-carrying cation; the internal solution included 5 mM CsBAPTA and MgATP. The kinetic properties of the macroscopic calcium currents were studied using 10 to 2000 ms command steps to potentials of -80 to +60 mV from holding potentials (V_h) of -100 to -40 mV. Phenytoin (10 - 200 μM) was applied by rapid microperfusion using a five-barreled pipette array. No evidence for use-dependent block of the barium current (I_{Ba}) by phenytoin was observed, but the blockade of I_{Ba} was extremely sensitive to V_h, 100 μM phenytoin producing only 30% block at V_h = -100 mV, and >90% block at -40 mV. The tail current amplitude was twice as sensitive to phenytoin as the peak I_{Ba} evoked by depolarizing command steps, but no change in the I-V relations of either was observed. Phenytoin also produced an enhancement of the apparent rates of deactivation and inactivation, but had no effect on the kinetics of activation of I_{Ba}. These results suggest that a voltage-, but not use-dependent block of neuronal calcium currents recruited during paroxysmal discharges may substantially contribute to the therapeutic effectiveness of phenytoin in the treatment of generalized seizure disorders. Supported by NS25682 & NS23482.

EFFECTS OF ORGANIC CALCIUM ANTAGONISTS ON CALCIUM CURRENTS IN ACUTELY DISSOCIATED CA1 NEURONS: LACK OF EFFECT OF GTP-γ-S. J.M.H. ffrench-Mullen, J. Black, J.L. Barker and N.T. Slater. Dept. of Physiology, Northwestern University Medical School, Chicago, IL 60611 and Lab. of Neurophysiology, NINDS, NIH, Bethesda, MD 20814 U.S.A.

Activation of G-proteins by internal GTP-γ-S has been demonstrated to modulate both the gating kinetics of calcium currents and the responsiveness to organic calcium antagonists of peripheral sensory neurons (Scott & Dolphin, 1987). We have examined the effects of internal GTP-γ-S on the kinetics of the macroscopic calcium current in acutely dissociated CA1 hippocampal neurons, and their modulation by organic calcium antagonists. Neurons were enzymatically dissociated from the CA1 region of adult guinea-pig hippocampus and calcium currents were recorded using whole-cell patch-clamp methods with 3mM Ba as the external charge-carrying cation. Drugs were applied by rapid microperfusion from a multi-barrel array. The effects of the organic antagonists on the kinetic properties of the barium current (I_{Ba}) were assessed using holding potentials of -80 to -40 mV. D-600 and verapamil produced a highly voltage-dependent block, the degree of blockade increasing with membrane hyperpolarization. The blockade by nifedipine displayed the opposite voltage dependence, whereas blockade by diltiazam was not voltage-dependent. The potency ratio for blockade was (K_D, μM): nifedipine (5) > ±verapamil (10) > ±D-600 (50) > diltiazam (100). In the presence of internal GTP-γ-S (500 μM), no effects on the kinetic properties of I_{Ba}, and no apparent change in the potency or voltage dependence of blockade by the antagonists were observed. These results indicate that organic calcium antagonists exhibit similar mechanisms of blockade of hippocampal calcium currents to those previously observed in peripheral neurons. However, neither the calcium current kinetics, nor the effects of antagonists were modified by internal GTP-γ-S in CA1 neurons, suggesting differences exist in the regulation of calcium channels by G-proteins in central and peripheral neurons.

PEPTIDE TOXINS FROM AGELENOPSIS APERTA SPIDER VENOM BLOCK DEPOLARIZATION-INDUCED INCREASES IN CYTOSOLIC FREE CALCIUM IN RAT CEREBELLAR GRANULE NEURONS. L. D. Artman[1]*, N. A. Saccomano[2]*, R. A. Volkmann[2]*, E. F. Nemeth[1] and T. N. Parks[1] (SPON: W. Stevens). Natural Product Sciences Inc., Salt Lake City, UT 84108[1] and Pfizer Central Research, Groton, CT 06340[2].

Spider venoms contain several classes of toxin with a variety of targets in excitable tissues (Ann. Rev. Neurosci. 12; Ann. Rep. Med. Chem. 24,1989). Peptide toxins from the funnel-web spider A. aperta have been reported to act as calcium antagonists in vertebrate and invertebrate neurons and potently block synaptic transmission in chick cochlear nucleus and rat hippocampus (op. cit.). We studied the ability of five purified and sequenced 4200-5500 dalton peptide toxins (H1, H2, I, J, K) to inhibit depolarization-induced increases in cytosolic free calcium concentration ([Ca]i) in cultures of neonatal rat cerebellar granule neurons studied by fura-2 fluorimetry. In this preparation, increases in [Ca]i to depolarization with 10^{-2} M KCl or treatment with the dihyrdopyridine calcium agonist Bay K8644 (10^{-6} M) are completely blocked by 10^{-6} M nifedipine (see Nemeth and Parks, this meeting). Dose-response studies showed some of the spider toxins to be very potent in blocking depolarization-induced increases in [Ca]i; IC_{50}'s for the different toxins ranged from 25 nM to >1 μM. Thus, these toxins may be useful in studying voltage-sensitive ion channels in mammalian neurons (see also Albensi et al., this meeting).

ALTERATIONS OF RELATIVE DIVALENT CATIONIC INFLUX AND Ca^{2+}-CHANNEL LIGAND BINDING IN SYNAPTOSOMES BY METHYLMERCURY. T.J. Shafer, M.L. Contreras and W.D. Atchison. Dept. of Pharm./Tox., Mich. State Univ., E. Lansing, MI 48824.

Depolarization-induced influx of ^{45}Ca, ^{85}Sr and ^{133}Ba into rat forebrain synaptosomes was measured to determine the effects of MeHg on the relative influx of divalent cations through Ca^{2+} channels. In addition, the effects of MeHg on binding of the Ca^{2+} channel ligands [^{3}H]-nitrendipine and [^{125}I]-ω-conotoxin GVIA were measured in synaptosomes. When synaptosomes were depolarized in 42.5 mM K^+ solutions, the relative influx of ^{45}Ca:^{85}Sr:^{133}Ba was altered from 6:2:3 in the absence of MeHg to 6:1:3 in the presence of 100 μM MeHg. Equilibrium binding of [^{3}H]-nitrendipine was measured in non-depolarizing (5 mM) and depolarizing (77.5 mM) K^+ solutions and respective Scatchard values for K_D of 634±155 and 1092±299 pM were obtained. In the presence of 100 μM MeHg, the respective values for K_D were 2515±633 and 5327±2095 pM. After three experiments in non-depolarizing K^+ solutions, the K_D values for [^{125}I]-ω-conotoxin binding were 373±83 pM in the absence and 262±17 pM in the presence of 100 μM MeHg. MeHg did not alter B_{max} for either ligand. These results indicate that: 1) MeHg alters the relative influx of divalent cations through Ca^{2+} channels, and 2) concentrations of MeHg which block Ca^{2+} influx into synaptosomes also bind competitively at a dihydropyridine-sensitive binding site. (Supported by NIH grant ES03299; TJS is the recipient of a Student Fellowship sponsored by Hoffman-LaRoche, Inc.)

EFFECT OF IONIZING RADIATION ON CALCIUM CHANNELS IN RAT ILEUM MYENTERIC PLEXUS SYNAPTOSOMES. S.B. Kandasamy, W.A. Hunt* and A. Dubois.* Behavioral Sciences Department, Armed Forces Radiobiology Research Institute and Department of Medicine, Uniformed Services University of the Health Sciences, Bethesda, MD 20814-5145.

Radiation exposure induces increased gastrointestinal (GI) motility which is correlated with an increase in prostaglandin (PG) levels. The myenteric plexus (MP), which lies between longitudinal and circular smooth muscles of the gut, is the most important independent neural network responsible for GI motility in the absence of extrinsic innervation. Although MP is a part of the peripheral nervous system, it resembles in many ways the central nervous system. Exposure to ionizing radiation has been shown to reduce voltage-dependent sodium and calcium uptake into rat brain synaptosomes. The effect of ionizing radiation on voltage-dependent calcium influx was studied by measuring KCl-stimulated Ca-45 uptake into rat MP synaptosomes. Gamma irradiation (Co-60) (1-30 Gy) reduced calcium uptake after 3 sec in a dose-dependent manner similar to that found for brain synaptosomes. However, unlike in brain synaptosomes, PGE2, PGF2α and PGD2 (10 nM-1μM) increased the entry of calcium into non-irradiated and irradiated MP synaptosomes. These results suggest a radioprotectant effect of prostaglandins in reversing the reduced calcium uptake induced by radiation.

ISCHEMIA: EXCITABILITY AND NEUROTRANSMISSION

148.1

EXCITABILITY CHANGES OF RODENT HIPPOCAMPAL NEURONS AFTER TRANSIENT FOREBRAIN ISCHEMIA -IN VITRO STUDY. S. Miyahara *, N. Hori *, N. Doi * and K. Kinoshita *. (SPON: H. Kannan). Dept. of Neurosurgery, Miyazaki Med. College, Miyazaki 889-16 and Dept. of Pharmacology, Kyushu Univ., Fukuoka 812, JAPAN.

In order to clarify the mechanisms of delayed neuronal death of hippocampal CA1 neurons, we recorded responses of CA1 and CA3 neurons to orthodromic electrical stimulations in slice preparations obtained from rats and gerbils subjected to transient forebrain ischemia. Twenty-four hours after ischemia mossy fiber stimulations produced epileptiform burst discharges of CA3 neurons and Schaffer collateral stimulations evoked multiple population spikes superimposed on field EPSP in CA1 area. Seven days after ischemia evoked epileptiform burst discharges were still recorded in CA3 region and no responses in CA1 region where pyramidal cells were lost. In gerbils similar responses were obtained in CA1 and CA3 regions to those in rats after ischemia. However epileptiform burst discharges were recorded in CA3 region in sham-operated control gerbils. These results indicate epileptiform burst discharges of CA3 neurons after transient cerebral ischemia may cause delayed death of CA1 pyramidal neurons.

CHANGES IN MEMBRANE RESISTANCE AND CAPACITANCE INDUCED BY EXPERIMENTAL ISCHEMIA IN HIPPOCAMPAL SLICE. R.K. Rader, R.S. Wilkinson+ and T.H. Lanthorn (Spon: H. Sato+). CNSDR, G.D. Searle & Co., St. Louis, MO 63198 and Dept. of Cell Biology+, Washington Univ. School of Medicine, St. Louis, MO 63110.

We are utilizing a model of experimental ischemia which involves exposure of hippocampal slices to both hypoxia and hypoglycemia (2mM D-glucose). Synaptic responses of CA1 neurons, recorded intracellularly, fail within two minutes from the onset of hypoxia and this is followed by depolarization of the membrane potential toward zero (anoxic depolarization, AD). During reoxygenation, following AD, synaptic failure persists and the membrane potential ordinarily remains depolarized. This persistent depolarization can be blocked by NMDA antagonists.

Hyperpolarizing intracellular current pulses (0.1-0.6 nA) were used to construct an I/V plot from which membrane resistance of cells was measured. In addition, membrane impedance was estimated from frequency domain analysis (2-2000 Hz) of membrane responses to sinusoidal current (5-100 pA rms) measured with a phase-locked amplifier. Resting membrane potential (> -60mV, RMP) and resistance (45 ± 7 Mohms, Rin) were measured prior to hypoxia while in 2mM Glucose ACSF (n=13). At 15 min post-AD, RMP was -3.5 ± 2.4 mV and Rin was 110 ± 6% of its pre-hypoxic values. Similarly, at 30 min post-AD, RMP was -5.3 ± 4.6 mV and Rin was 101 ± 7% of control. Impedance measurements confirmed that Rin increased following AD, and indicated that the capacitive component declined from the onset of hypoxia, falling precipitously at AD. Membrane properties, including capacitance, recovered to pre-hypoxic values if the NMDA antagonist CPP (100 uM) was present. Our data suggest that although NMDA receptors are involved at the onset of AD, no significant increase in membrane conductance persists. Thus the failure of cells to repolarize following AD is not due to the continued opening of NMDA-associated ion channels.

148.3

SPREADING DEPRESSION-LIKE DEPOLARIZATION AND OTHER EFFECTS OF HYPOXIA ON MOUSE SPINAL CORD *IN VITRO*. G. Czéh* and G.G. Somjen, Dept. Physiol. Medical Univ. of Pécs, Hungary, and Div. Physiol. Duke Univ. Durham, NC 27710.

Spreading depression (SD) of Leão has been observed in almost all parts of the central nervous system of mammals, except the spinal cord. The reason for the "immunity" of spinal cord tissue is not known. We studied the effect of oxygen deprivation on isolated spinal cords of 9-16 day old mice maintained at 24°C. When exposed to N_2-saturated artificial CSF (ACSF), synaptic transmission was suppressed in 15 minutes except when the cord was bathed in ACSF with elevated $[Ca^{2+}]_o$ (2.4-3.6 mM) in which case synaptic failure was delayed to 30 min. Following 45 min hypoxia, transmission recovered to normal levels in 20-50 min. An hour or more after reoxygenation spontaneous discharges erupted in about 40% of the spinal cords. During hypoxia a 10-20 mV negative shift of extracellular potential, elevation of $[K^+]_o$ to 25-40 mM, and loss of axonal conduction, indistinguishable from SD, was seen in 1 out of 3 spinal cords. Reoxygenation restored V_o and $[K^+]_o$. SD occurred more frequently when O_2 was withheld for a second time in the same cord. We conclude that: 1. excess $[Ca^{2+}]_o$ retards hypoxic failure of synaptic transmission; 2. SD can, under certain circumstances, occur in spinal gray matter.

EFFECTS OF NMDA RECEPTOR ANTAGONIST ON POSTISCHEMIC SYNAPTIC PHYSIOLOGY OF CA1 HIPPOCAMPAL PYRAMIDAL CELLS. L. Urban*, K.H. Neill*, B.J. Crain, J.V. Nadler and G.G. Somjen (SPON: J.P. Vicedomini). Depts. Cell Biology, Pathology, Neurobiology and Pharmacology, Duke Univ. Med. Ctr., Durham, NC 27710.

Transient forebrain ischemia in the Mongolian gerbil leads to delayed degeneration of CA1 hippocampal pyramidal cells. Earlier experiments with hippocampal slices cut from previously ischemic brains showed that ischemia enhanced excitatory synaptic transmission in area CA1 before it abolished synaptic function. In the present study we tested the hypothesis that these effects require the activation of NMDA receptors during the postischemic period.

Gerbils were subjected to a 5-min occlusion of both common carotid arteries. Hippocampal slices were prepared 30-40 min or 4 h after the occlusion and superfused at 34.5 °C. Schaffer collateral-commissural input-output curves were constructed from recordings made every 30 min for 10-24 h.

Inclusion of the NMDA receptor antagonist CPP (2 or 10 uM) in the superfusion medium considerably prolonged the lifetime of control slices and it progressively increased both the initial slope of the focally-recorded EPSP (fEPSP) and the amplitude of the orthodromic population spike. In slices from animals subjected to transient ischemia, CPP completely prevented the loss of pyramidal cell excitability, even when the slices were prepared 4 h after ischemia. CPP also prevented the progressive increase in fEPSP duration normally observed after ischemia. Thus CPP both enhanced the viability of the preparation and halted the progression of ischemic damage. These results support the hypothesis that NMDA receptor activation during the postischemic period is one of the etiological factors in the delayed degeneration of CA1 pyramidal cells. (Supported by NIH grant NS 06233.)

148.5

EFFECTS OF THREE NMDA RECEPTOR ANTAGONISTS IN THE GERBIL CAROTID OCCLUSION MODEL OF TRANSIENT FOREBRAIN ISCHEMIA. M.A. Warner*, J.V. Nadler and B.J. Crain. Depts. Pharmacology, Neurobiology and Pathology, Duke Univ. Med. Ctr., Durham, NC 27710.

Excessive activation of the NMDA receptor has been suggested to play a key role in ischemic brain damage. We have tested the ability of three NMDA receptor antagonists, MK-801, CGS 19755 and MDL 27,266, to attenuate brain damage produced by transient forebrain ischemia in the Mongolian gerbil.

Animals were anesthetized with 2.5% halothane and both common carotid arteries were occluded for 5 min. When rectal temperature was maintained at 36-37 °C, transient ischemia consistently destroyed an average of 96% of the CA1 hippocampal pyramidal cells and damaged 32% of the striatum.

NMDA receptor antagonists were administered i.p. either 30-60 min before ischemia or after ischemia. Doses tested were: 1 and 10 mg/kg of MK-801 (pre- or postischemia); 30 mg/kg of CGS 19755 preischemia; four 25 mg/kg doses of CGS 19755 administered between 0.5 and 6.5 hours postischemia; and 40 mg/kg of MDL 27,266 (pre- or postischemia). All drug treatments markedly attenuated striatal damage, but only 10 mg/kg MK-801 (pre or post) and 40 mg/kg MDL 26,277 (pre only) significantly reduced the extent of CA1 pyramidal cell degeneration. CA1 damage varied widely from case to case and only 34-48% of the pyramidal cells, on average, was spared. The effects of NMDA receptor antagonists resembled those of hypothermia (29-32 °C). Most of the CA1 pyramidal cells that were protected from degeneration by an antagonist appeared abnormal, as judged by silver impregnation. From our electrophysiological work, it seems possible that these neurons were so damaged that, although viable, they were essentially non-functional. Our results therefore suggest that NMDA receptor antagonists will be less than ideal anti-ischemic drugs, at least when given by themselves. (Supported by NIH grant NS 06233.)

148.6

NON-COMPETITIVE NMDA ANTAGONISTS AND SIGMA-OPIATE LIGANDS BLOCK GLUTAMATE RELEASE FROM THE RAT HIPPOCAMPAL SLICE DURING ISCHEMIA. D. Lobner* & P. Lipton. Dept. of Physiol., Univ. of Wisconsin, Madison, WI 53706.

Exposure of rat hippocampal slices for 5' to buffer equilibrated with 95% N_2-5% CO_2 and devoid of glucose (ischemia) causes an ~500% increase in release of endogenous glutamate. This release is inhibited by high levels of the non-competitive NMDA receptor blockers (PCP EC_{50} ~50 μM, ketamine EC_{50} ~100 μM, and MK-801 EC_{50} ~100 μM). It is also inhibited by the sigma-opiate ligands ditolylguanidine (DTG) EC_{50} ~50 μM and haloperidol EC_{50} ~10 μM. The non-competitive NMDA receptor blockers also have sigma-opiate receptor affinity. The rank order of efficacy in inhibiting release by the above compounds is the same as the order of their binding affinities to the sigma-opiate receptor. We suggest the non-competitive NMDA receptor blockers inhibit ischemic glutamate release by acting at the sigma-opiate receptor.

The ability of different NMDA receptor blockers to protect against ischemic transmission damage in the slice depends on blocking both glutamate release and the NMDA receptor; that is, blockade of the NMDA receptor alone does not provide good protection while blockade of glutamate release and NMDA receptors protects very well. Therefore, we conclude that at glutamate levels reached during severe ischemia, damage occurs via both NMDA and non-NMDA glutamate receptors.

INCREASED CONCENTRATIONS OF GLUTAMATE AND ASPARTATE IN SUPERNATANTS OF HYPOXIC CNS CULTURES. I.E. Madl, D.H. Smullin, S.R. Skilling,* A.A. Larson and W. Raabe. Depts. of Vet. Biology and Neurology, U. of Minnesota, St. Paul, MN 55108.

Increased concentrations of extracellular Glu and Asp have been reported during ischemia *in vivo*, and are believed to mediate neuronal damage. The accumulation and possible origins of these excitotoxins was examined in cell cultures. Hippocampal and cerebellar cultures were obtained from 19 day rat fetuses and maintained *in vitro* for 17-18 days. Cells were washed with an electrophysiologic recording medium (ERM; in mM: NaCl 145, KCl 5, $CaCl_2$ 2, $MgCl_2$ 1, HEPES 10, glucose 5, pH 7.4, osmolarity 325) and then incubated in 91% N_2 with 9% CO_2 or ERM containing NaCN. In cultures exposed to hypoxia or NaCN, the concentrations of Glu and Asp in the ERM were increased more than 10 fold above controls while the concentrations of Gly, Asg and Gln increased less than 2 fold. The increases of Glu and Asp preceded neuronal cell death, as measured by trypan blue exclusion, and were potentiated by glucose deprivation. The increases were not inhibited by 1 μM tetrodotoxin or 10 mM Mg++, suggesting that the increases were not due to synaptic release. Hypoxia- and CN-induced increases in Glu and Asp were also obtained in C6 rat glioma and human astrocytoma cultures. The results indicate that glia contribute to hypoxia-induced increases in extracellular Glu and Asp *in vitro* and suggest that glia may play a major role in the extracellular accumulation of Glu and Asp during ischemia *in vivo*. Supported by NS01105, DA04090, DA04190, DA00124, CA01342.

CONCOMITANCE AND DEPENDENCE OF MASSIVE POTASSIUM FLUX TO EARLY GLUTAMATE RELEASE DURING CEREBRAL ISCHEMIA IN VIVO. Y.KATAYAMA, T.TAMURA*, T.KAWAMATA* AND D.P.BECKER. Division of Neurosurgery, UCLA Sch. of Med., Los Angeles, CA 90024.

An increase in the extracellular concentration of glutamate ([glu]e) during 10-min cerebral ischemia has been demonstrated by microdialysis in vivo. We tested the hypothesis that this early increase in [glu]e is responsible for massive potassium flux across the plasma membrane which is seen during the same period of ischemia. Changes in the extracellular concentration of potassium ($[K^+]e$) and [glu]e during initial 10 min period after the onset of decapitation ischemia were determined by 1-min fractions of microdialysis in young rats. An increase in [glu]e (1.8±0.2 fold baseline, n=5) occurred concomitantly with the sudden large increase in $[K^+]e$ which was observed 2-4 min (3.3±0.5 min) after the onset of ischemia, [glu]e decreased transiently thereafter. The onset of the massive increase in $[K^+]e$ was significantly delayed (1.3±0.2 min, n=8) by in situ administration of kynurenic acid (10 mM), an broad-spectrum antagonist of glutamate, through the dialysis probe. These results suggest that glutamate mediates a major component of massive potassium flux across the plasma membrane during cerebral ischemia in vivo.

DETECTION OF ISCHEMIC CELLULAR SWELLING IN VIVO WITH BRAIN MICRODIALYSIS: CHANGES IN CONCENTRATION OF ^{14}C-SUCROSE PERFUSED INTO THE EXTRACELLULAR SPACE. T.TAMURA*, Y.KATAYAMA, D.P.BECKER, AND T. KAWAMATA*. (Spon. N.Hayashi) Division of Neurosurgery, UCLA Sch. of Med., Los Angeles, CA 90024.

A cellular swelling and shrinkage of the extracellular space (ECS) during cerebral ischemia have been shown in vivo as an increase in concentration of ECS markers that can be continuously measured by electrodes. We attempted to detect the cellular swelling with brain microdialysis using similar principles. A dialysis probe was placed in the hippocampus of the rat, and perfused for 20 min with ^{14}C-sucrose (10 mM) as an ECS marker. The probes were perfused with Ringer solution thereafter, and $[^{14}C\text{-sucrose}]_e$ were determined from dialysis fractions. Concomitant with an abrupt increase in $[K^+]_e$ which occurred few minutes after the onset of decapitation ischemia, $[^{14}C\text{-sucrose}]_e$ was also elevated. This was taken as evidence of the shrinkage of ECS, i.e., water movement into the cells leaving the ECS marker behind. With in situ administration of Mg^{2+} (10 mM) through the probe, which blocks transmitter release, the onset of $[K^+]_e$ increase and the concomitant $[^{14}C\text{-sucrose}]_e$ increase were both delayed. Thus, the transmitter release appears to be involved in the ischemic cellular swelling.

ALTERATIONS AT THE N-METHYL-D-ASPARTATE (NMDA) RECEPTOR COMPLEX IN GERBIL HIPPOCAMPUS FOLLOWING SHORT-TERM (7 DAYS) AND LONG-TERM (32 DAYS) RECOVERY FROM 10 MIN FOREBRAIN ISCHEMIA. L.P. Miller* and T.R. Insel (SPON: D.C. Perry) Vet Adm Med Ctr, Wash D.C. 20422, Dept. Pharm., Georgetown Univ. Sch. Med., Wash D.C. 20007 & Lab. Clin. Sci., NIMH, Poolesville, Md. 20837.

It is well known that glutamate/aspartate act as excitatory amino acid (EAA) neurotransmitters in the CNS. In addition, there is support for the NMDA-receptor complex as a major site of action of EAAs. This complex has been shown to consist of: (a) glutamate recognition site, (b) glycine modulation site and (c) Ca^{++} channel site. All three sites have now been described using receptor binding technology in combination with autoradiography. The present series of experiments utilizes this combined technology to examine the individual components of the NMDA-receptor complex at the 7 and 32 days following a 10 min ischemic insult to gerbil forebrain. In addition we examined the other EAA receptor subtypes; quisqualate (QA) and kainate (KA). Ischemia in 10 - 12 week old female gerbil was induced by bilateral clamping of the common carotids for 10 min under 2.5% halothane anesthesia. At 7 and 32 days post-ischemia the animals were sacrificed by decapitation, brains removed and immediately frozen in isopentane/dry ice. Using 12 micron coronal sections EAA receptors and components of the NMDA-receptor complex were characterized in various subregions of dorsal hippocampus as: a) NMDA-displacable 3H-glutamate binding to the NMDA recognition site, b) 3H-glycine binding to the modulation site, c) 3H-TCP binding to the CA^{++} channel portion of the complex, d) 3H-AMPA binding to the QA subtype and e) 3H-KA binding to the KA subtype. Quanatitative autoradiography was performed using a LOATS RAS 1000 image analysis system. Within the strata radiatum our results expressed as percent of control were NMDA 75 & 40, TCP 79 & 49, Glycine 54 & 52, AMPA 62 & 58, KA(CA3 subfield) 88 & 97 at 7 and 32 days post-ischemia, respectively. Alterations within other hippocampal subregions will also be presented.

THE EFFECTS OF ISCHEMIA AND NMDA RECEPTOR BLOCKADE IN ORGANOTYPIC CULTURES OF RAT HIPPOCAMPUS. D. Newell*, A. Malouf and J. Franck. Department of Neurological Surgery, University of Washington, Seattle, WA 98195.

Hippocampal pyramidal cells, and particularly those in subfield CA1, are selectively vulnerable to experimental and clinical ischemia. In the whole organism, a variety of systemic, circulatory and endogenous neurotoxic factors may interact to confer this unique vulnerability. Likewise, agents which have been shown to block this cell death may do so on the basis of systemic effects and/or direct cellular effects. We are examining the effects of ischemia in organotypic roller tube cultures of hippocampal slices to determine if discrete vulnerability of specific populations of hippocampal neurons is maintained in a system where systemic effects are not operational.

Organotypic cultures were prepared from 4-day-old rat hippocampi according to the method of B.H. Gähwiler (*J. Neurosci. Methods*, 1981, 4: 329-342). Two- to four-week-old cultures were placed in glucose-free medium, and exposed to varying periods of anoxia. Following "ischemia" *in vitro* (anoxia + no glucose), the cultures were returned to normal growth medium for 48 hours. Cultures were then examined histologically for neuronal death. Additional cultures were made ischemic in the same fashion except the glucose-free medium also contained 30 μM MK-801 to block NMDA receptors. Our preliminary data suggest that (1) a gradient of vulnerability of hippocampal neurons to ischemia is maintained in this organotypic culture system, and (2) this vulnerability, as *in vivo*, may be dependent on activity at the NMDA-type glutamate synapse.

SELECTIVE SPARING OF NADPH-DIAPHORASE-SOMATOSTATIN-NEUROPEPTIDE Y NEURONS IN ISCHEMIC GERBIL STRIATUM. Y. Uemura*, N.W. Kowall, M. F. Beal, M. A. Moskowitz (SPON: J.H. Sandell). Neurology and Neurosurgery Services, Mass. General Hospital, Boston, MA 02114.

An increasing body of evidence has linked ischemic brain damage to a neurotoxic effect of glutamate acting at the N-methyl-D-aspartate (NMDA) receptor. In the present study we investigated the relative vulnerability of neuronal subsets in the gerbil striatum to ischemia induced by bilateral transient ligation of the common carotid. After 4 days survival, brains were evaluated histologically with histochemical methods (NADPH diaphorase and silver degeneration procedures) and radioimmunoassay for somatostatin (SS), neuropeptide Y (NPY) and substance P (SP) and measurements of amino acids and catecholamines using HPLC with electrochemical detection. NADPH diaphorase neurons were strikingly preserved in the ischemic dorsolateral portion of the striatum. NPY and SS concentrations were unchanged despite a 25% depletion of substance P and GABA. Aspartate, glutamate, taurine and dopamine concentrations were unchanged while homovanillic acid was significantly increased. Previous studies of NMDA excitotoxin lesions in striatum have shown a sparing of NADPH diaphorase-somatostatin neuropeptide Y neurons. The similar sparing of these neurons following ischemic lesions in gerbil striatum suggests that NMDA receptor activation plays a role in ischemic injury.

BLOOD AND BRAIN PHARMACOKINETICS OF MK-801 IN NEONATAL HYPOXIA/ISCHEMIA. P.H. Schwartz, L.M. Adams*, and C.G. Wasterlain. Epilepsy Res Lab, VAMC, Sepulveda, CA 91343 and Ped ICU Res, Child Hosp, Los Angeles, CA 90027.

Cardiopulmonary arrest in the adult rat decreases the clearance of MK-801 from plasma (Neurology 39(Suppl. 1):387, 1989). We examined the pharmacokinetics of MK-801 in both plasma and brain in a neonatal model of hypoxia/ischemia. 7-Day old rats underwent sham surgery or ligation of both carotid arteries under methoxyflurane anesthesia followed by a one hour exposure to 8% O_2. Sham animals received a 10 mg/kg i.p. injection of MK-801 5 hours after surgery while the animals exposed to hypoxia received it immediately after hypoxia. Trunk blood and brains were collected 2 to 240 minutes after the injection and the concentration of MK-801 in serum (μmol/L) and parietal cortex (μmol/kg) were determined by GC-NPD. Peak serum levels of MK-801 (3.3±1.3 μM) were attained between 20 and 30 minutes after i.p. administration. Neither the rate of appearance of MK-801 in the plasma nor the rate of elimination were affected by a previous hypoxic exposure although there was a non-significant trend towards a decreased elimination in the hypoxic animals. The half-life of elimination was approximately 100 min. Brain concentrations (21.6±7.1 μM) of MK-801 were significantly greater than plasma concentrations at all time points measured (6.8±1.6-fold) and a previous hypoxic exposure had no effect on this gradient. Thus, in a neonatal model of hypoxic/ischemic brain injury access to the brain by i.p. MK-801 is not hindered.

EXCITOTOXIC NEUROTRANSMITTER RELEASE IN AN INFANT CEREBRAL ISCHEMIA MODEL. JK Deshpande, SE Haun*, G Tsai, M Helfaer*, J Kirsch*, RJ Traystman, JT Coyle. Depts. of Anesthesiology & Neurosciences, The Johns Hopkins Medical Institutions, Baltimore, MD 21205

Intracerebral microdialysis was performed in dorsal hippocampus in pigs (8-12 mo; n=4) and piglets (2-3 wk; n=5) which underwent 10 min of global ischemia (ISC) by aortic cross clamp, and 1-2 hr recovery. Dialysis fractions were collected over 10 min periods: immediately after insertion (-60 min); 20 min and 10 min prior to ISC; ISC fraction; and every 10 min until the animal was sacrificed. Samples were assayed for aspartate (ASP), glutamate (GLU) and N-acetylaspartylglutamate (NAAG). ASP changed minimally during ISC and recirculation in both groups. GLU concentration increased in pigs from 2.8 to 19.4 uM (ISC), but changed minimally in piglets (8.2 to 6.4 (ISC) and 7.6 uM (10'recovery)). NAAG increased in pigs during ISC (172.7 to 296.8 nM), whereas the NAAG rise occurred in 10' and 20' recovery in piglets (89.0 to 252.7 and 333.0 nM). Our results in vulnerable brain regions varies with age. This finding may account for the disparity in outcome after global ISC in infants versus adults.

CHARACTERIZATION OF THE UPREGULATION OF LAMBDA OPIATE BINDING IN GERBIL HIPPOCAMPUS FOLLOWING FOREBRAIN ISCHEMIA IN GERBILS. D.C. Perry[1] & L. P. Miller*[2] (SPON. R. J. Walsh). [1]Dept. Pharmacology, George Washington Univ., 20037 & [2]Vet. Admin. Med. Ctr., 20422 & [2]Dept. Pharmacology, Georgetown Medical School, Washington, D.C.

We (Miller & Perry, Brain Res., in press) have shown that lambda opiate binding in mossy fiber terminal field of gerbil hippocampus is upregulated 7 days following forebrain ischemia. Ischemia was induced in 10-14 week old female gerbils by bilateral clamping of the common carotid arteries for 10 min under halothane anesthesia. Seven days post-ischemia brains were removed and frozen sections were cut. Lambda autoradiography was done with [^{3}H]naloxone plus 300 nM diprenorphine (Perry & Sadee, Eur. J. Pharmacol. 129: 147, 1986) using a Loats RAS1000 image analysis system. We examined binding in a coronal plane at six different regions along a rostral-caudal axis. The greatest increase in lambda binding with ischemia (41.2% greater than sham controls, $p<0.05$) was in the most rostral sections. More caudal regions showed smaller increases (14.5-31.7%). In a separate experiment we examined lambda binding in rostral hippocampus 32 days post-ischemia: the increase in lambda binding was still apparent (28.7%, $p<0.01$) but somewhat smaller than at 7 days. These studies support the possibility that endogenous opioids play a role in ischemia-induced neuronal damage. Supported by DA04191 (DCP) and VAMC (LPM).

GRADED HYPOTHERMIA PROTECTS AGAINST ISCHEMIC INJURY IN GERBIL HIPPOCAMPUS. F.A.Welsh and R.E.Sims*. Div. of Neurosurgery, Univ. of Penna. Sch. of Med., Philadelphia, PA 19104.

To define the degree of hypothermia required to ameliorate ischemic injury, we regulated brain temperature at 37°C, 35°C, or 32°C in three groups of gerbils during 5 min bilateral carotid artery occlusion. Normothermia was restored upon reperfusion, and the animals were permitted to recover for 1 week. The brain was quick-frozen, and alternate thin sections were stained for histologic scoring or freeze-dried for microassay of ATP and adenylate kinase. By all three endpoints, injury was reduced in CA_1 hippocampus of gerbils cooled to 35°C, compared to those at 37°C. Cooling to 32°C completely prevented CA_1 injury, as judged by each of the endpoints. Preliminary histologic evidence indicated that postischemic hypothermia (32°C) did not reduce CA_1 injury. These results demonstrate that hypothermia of 2°C during ischemia is sufficient to ameliorate injury in this model. In addition, ATP content and adenylate kinase activity are excellent measures by which to quantitate ischemic injury.

149.2

HYPERTHERMIC BRAIN ISCHEMIA: ACUTE MICROVASCULAR AND NEURONAL ALTERATIONS. M. Halley*, I. Valdes*, R. Busto and W. D. Dietrich. Cerebral Vascular Disease Research Center, Department of Neurology, University of Miami School of Medicine, Miami, FL 33101, U.S.A.

We have determined whether variations in brain temperature influence the acute response of microvessels and neurons to transient cerebral ischemia. Six animal subgroups were investigated, including rats whose brain temperatures were maintained at 30, 33, 36, or 39°C during 20 minutes of 4-vessel occlusion. Following a 1-hour postischemic recirculation period, rats were injected i.v. with horseradish peroxidase (HRP) and perfusion-fixed. Nonischemic control rats (36 or 39°C) showed no extravasation of HRP. Likewise, postischemic rats in which brain temperature was controlled at either or 30 or 33°C failed to demonstrate blood-brain barrier (BBB) alterations. In contrast, focal sites of HRP extravasation were seen in rats where brain temperature was maintained at either 36 or 39°C. Permeability alterations were most evident in the 39°C ischemic group, occurring in cortical, thalamic and hippocampal regions. In this ischemic group, dark-shrunken neurons were also observed in deeper cortical layers and CA1 hippocampus. These results demonstrate that brain temperature is a critical factor in determining whether BBB dysfunction is an acute consequence of a transient cerebral ischemic insult. In contrast to normothermic ischemic conditions, morphological indicators of acute neuronal injury are seen when intraischemic brain temperature is elevated.

149.3

HYPOTHERMIA BLOCKS ISCHEMIA-INDUCED INHIBITION OF CaM KINASE II. S.B. Churn,* R.E. Blair,* W.C. Taft and R.J. DeLorenzo. Dept. of Neurology, Medical College of Virginia-VCU, Richmond VA 23298.

Five minutes of bilateral carotid occlusion in the gerbil produces a brief episode of global cerebral ischemia and causes uniform death of hippocampal CA1 pyramidal neurons. An early event in the development of ischemia-induced cell death in this model is a pronounced and prolonged decrease in CaM kinase II activity (Brain Res. 447,159,88). In order to further investigate the relationship between CaM kinase II and ischemia-induced cell death we have examined the effect of hypothermia, a cerebroprotectant, on these two parameters.

Four groups of gerbils were subjected to 5 min of bilateral carotid occlusion. In all experiments, hippocampal temperature was directly measured by inserting an Omega hypodermic thermocouple probe through a guide cannula which was stereotaxically implanted in the hippocampus one day prior to ischemic insult. The groups studied were naive animals (unoperated), sham-operated animals (no ischemia), ischemic normothermic animals, and ischemic hypothermic animals. Two hours after ischemia, the animals were sacrificed and CaM kinase II activity was measured in vitro in forebrain homogenates. Percent phosphorylation of the 50 kDa subunit of CaM kinase II in each group was: naive (100.0), sham (87.8), ischemic normothermic (12), and ischemic hypothermic (109.7). Thus, CaM kinase II activity is substantially reduced by ischemia in normothermic animals, and this reduction is completely prevented by a decrease in intracerebral temperature to 32°C during ischemia. Cell counts showed total loss of CA1 pyramidal neurons in ischemic normothermic animals and complete preservation of neurons in the ischemic hypothermic group.

Chemical Adrenalectomy Protects Hippocampal Cells following Ischemia. J. K. Morse and J. N. Davis, V.A. Medical Center and Duke University Medical Center, Durham, NC 27710

It is well known that transient forebrain ischemia leads to a delayed hippocampal CA1 neuronal death. This delayed cell loss can be exacerbated by glucocorticoids and ameliorated by adrenalectomy. Previously we reported no hippocampal damage in 92% of hemispheres from adrenalectomized gerbils. We believe the sparing of hippocampal cells is in part due to the absence of adrenal glucocorticoids. To test this hypothesis an anti-glucocorticoid, metapyrone, was used in the present study. We used three different doses of metapyrone: 25 mg/Kg,50 mg/Kg, and 100 mg/kg (n=8 for all groups). Metapyrone was injected at 0 hours, 24 hours, and 48 hours after carotid occlusion. At 72 hours (day 4) all animals were killed. Increasing doses of metapyrone effectively reduced hippocampal cell loss. 69% of hemispheres had no hippocampal CA1 cell loss in the 100 mg/Kg group. In the 50 mg/Kg group 31% of the hemispheres were spared, while in the 25 mg/Kg group 6% of hemispheres were undamaged. These results imply that an anti-glucocorticoid, such as metapyrone, may be an effective treatment following ischemic injury. (Sponsored by NSO7274)

DEXAMETHASONE AFFECTS CEREBROSPINAL FLUID PRESSURE (CSF-p). B.A. Morrow*, V.P. Starcevic*, L.C. Keil* and W.B. Severs (Spon: J. Summy-Long). Dept. Pharmacol., Col. Medicine, Pennsylvania State University, Hershey, PA 17033

Dexamethasone (dex) is often used to treat elevated CSF-p. We examined it's effect on CSF-p elevated by a low rate infusion of artificial cerebrospinal fluid in conscious, relatively unrestrained adult male S-D rats. Rats were infused for 10 min with 4 µl/min into each lateral cerebroventricle; after a 10 min rest, when CSF-p was normal, they were infused with 0.25 µl/min into each lateral cerebroventricle for 8 h. CSF-p's (cmHOH) were similar to those previously reported in non-infused rats for about 2 h (Brain Res. 462:112,1988). Then, CSF-p rose during the 8 h period to levels about 3 x higher than at 1 h. Dex (0.04 mg i.m.) was given just prior to the preparatory infusion (20 min before starting the 1st h). CSF-p's of dex rats were lower throughout the entire period but still rose after the 2 h lag period. Dex may reduce an inflammatory response that contributes to the elevated CSF-p without affecting the temporal pattern of the infusion-induced increase in CSF-p. (NASA NCC-2-127, NIH TWO343-01)

CSF-p ± SEM	1st h	2nd h	4th h	8th h
Inf. (n=13)	15 ± 1	16 ± 2	35 ± 5†	46 ± 7†
Inf./dex (n=8)	10 ± 1*	9 ± 1*	19 ± 2*†	27 ± 3*†

2-way ANOVA (rep. measure) F(treatment) = 6.7, p < 0.05; F(subjects)= 35, p < 0.001; F(interaction)= 2.8, p < 0.05
* = p < 0.05 vs Inf., † = p < 0.05 vs 2 h CSF-p.

NEURONAL AND GLIAL NA,K-ATPases LOSSES: INDICATORS OF MEMBRANE FAILURE IN IRREVERSIBLE FOCAL CEREBRAL ISCHEMIA . V.A. Bharucha*, C.G. Wakade, S.E. Karpiak, and S.P. Mahadik. Div Neurosci NYS Psychiat Inst, Depts Psychiat, Biochem & Mol Biophys, P&S, Columbia U, NY, NY

Cerebral focal ischemia in rat alters tissue water, Na+ K+ and Ca++ levels and functional parameters. Since these changes reflect membrane failure we have analyzed the activities of neuronal and glial Na,K-ATPases since they are sensitive to membrane integrity. Enzyme activities were computed by their differential sensitivity to strophantin. Rats (4-7/group) were sacrificed at 24, 72, 120hrs after focal cortical ischemia (MCAo+CCAo). At 24hrs after ischemia there were no changes in glial or neuronal ATPase in the primary or peri-infarct cortical areas. After 72hrs there were significant decreases in both neuronal (-55%) and glial (-60%) ATPase activity in the primary infarct area. In peri-infarct areas at 72hrs decreases in enzyme activity were small while at 120hrs the enzyme activities were comparable to sham controls. Data indicate that there is irreversible failure of plasma membrane function in the primary infarct area, but recovery is seen in peri-infarct areas >72hrs after ischemia. Further, there is no gliosis in the primary infarct area since losses in glial ATPase persist. These effects of GM1 ganglioside on ATPase losses is being studied since GM1 has been shown to protect membrane changes following global ischemia [NINCDS NS-2525856].

FGF LEVELS AFTER STROKE. S.P. Finklestein, C.G. Caday*, M. Kano*, J. Foster*, C.Y. Hsu, P.H. Liu, M.A. Moskowitz, and M. Klagsbrun*. Massachusetts General Hospital, Boston, MA 02114.

We measured changes in levels of fibroblast growth factors (FGF) following focal cerebral infarction in the rat. Acidic and basic FGF are heparin-binding polypeptides with potent trophic effects on brain neurons, glia, and endothelial cells. Focal infarcts were made in the right cerebral cortex of mature male Long-Evans rats as per Chen et al. (Stroke, 17:738-743, 1986). At various times (0,3,7,14,21,30, and 60 days) after infarction, animals were sacrificed, and the right cerebral cortex was removed and assayed for total FGF. FGF levels were estimated as mitogenic activity on 3T3/Balb C cells in vitro, and expressed as mitogenic units/mg protein. More than 90% of this activity bound to a heparin-affinity column and reacted with specific anti-FGF antisera. We found a 1.5 - 2 fold increase in FGF levels in the first three weeks after stroke; this increase was sustained for at least two months after infarction. Given their multipotential trophic effects, such increases in FGF levels may play an important role in glial proliferation, neovascularization, and neural sprouting after stroke.

149.8

RETINAL GANGLION CELL VULNERABILITY AFTER ISCHEMIA IN THE CAT. EFFECTS OF NGF. R. Siliprandi*, R. Canella*, R. Zanoni* and G. Carmignoto* (SPON.: L. Facci). Fidia Research Laboratories, 35031 Abano Terme (PD), ITALY.

Electroretinographic (ERG) and morphological results obtained in this study 30 days following the induction of an episode of complete retinal ischemia (ranging from 60 to 90 minutes) in the cat, indicate that retinal ganglion cells (RGCs) are more vulnerable to ischemia as compared to the more distal retinal neurons.

Since intraocular (i.o.) administration of NGF has been proven to enhance the survival of RGCs following section of the optic nerve in the adult rat (Carmignoto et al., J. Neurosci, in press), we also assessed whether NGF could be effective in protecting RGCs from the ischemic damage. In order to address this issue, NGF was injected intraocularly in cats 30 minutes prior to the induction of the ischemic episode and following the ischemic injury every other day for 30 days, at dose of 30 μg, i.o.

Results obtained indicate that in NGF-treated cats, the ERG in response to a patterned stimulus, which reflects the functionality of RGCs, is less reduced as compared to controls. In addition quantitative morphological analysis performed on Nissl-stained whole-mounted retinae indicate that RGC loss is also reduced in NGF-treated cats, thus suggesting that NGF can in part prevent the neuronal damage following ischemia.

IMMUNOELECTRON MICROSCOPIC STUDY OF TUBULIN AND MAPS IN GERBIL BRAIN DURING PROGRESSIVE ISCHEMIA AND REPERFUSION. H. Tomimoto* and T. Yanagihara. Dept. Neurol., Mayo Clinic, Rochester, MN 55905

We previously observed prompt loss of the immunohistochemical reaction for tubulin and recently observed more prompt loss of micro-microtubule associated proteins (MAPs) in the vulnerable areas of the ischemic brain. We therefore investigated the immunocytochemical reaction for tubulin and MAPs (MAP1A and MAP2) by using immunoelectron microscopy. Mongolian gerbils were subjected to bilateral carotid occlusion for 10 to 30 min and reperfusion for up to 72 hours following ischemia for 10 min. After ischemia for 10 min, some dendrites in the stratum moleculare of the subiculum-CA1 region lost electron-dense precipitates for α-tubulin and MAPs associated with microtubules. Loss of the reactions advanced further and spread to the medial CA1 region during progressive ischemia for 30 min. In some dendrites electron-dense precipitates for MAPs were observed in the cytoplasm with little reaction product on microtubules but without alteration of the reaction for α-tubulin. After recirculation, loss of electron-dense precipitates for tubulin and MAPs as well as disintegration of microtubules propagated further to the medial CA1 region and to the proximal dendrites. The present study demonstrated prompt disintegration of microtubules and rapid disappearance of the reaction for MAPs which was probably caused by detachment of MAPs from microtubules.

149.10

CEREBRAL ISCHEMIA TRIGGERS NMDA RECEPTOR-LINKED CYTOSKELETAL PROTEOLYSIS IN HIPPOCAMPUS. P.Seubert*, K.S.Lee and G.Lynch (SPON: D.Arst). CNLM, Univ. of California, Irvine, CA 92717 and Dept. of Anat., Thomas Jefferson Med.School, Philadelphia, PA 19107.

Calcium-activated proteolysis of brain spectrin is detectable by immunoblot analysis following various neural insults including the activation of N-methyl-D-aspartate (NMDA) receptors. Using this assay we examined the effects of a 10 minute bilateral carotid artery occlusion on spectrin in various brain regions of the gerbil.

In common with other neurodegenerative events a massive proteolytic breakdown of spectrin occurred during the delayed cell death phase of hippocampal region CA1. In this vulnerable region 36% of the total spectrin immunoreactivity is present as the 155kDa and 150kDa spectrin breakdown products at 4 days post-ischemia. Interestingly, substantial breakdown (7.7%) is found in CA1 within 15 minutes of removal of the vascular clamps. Proteolysis is significantly higher in this region compared to other brain structures.

Since NMDA receptor activation has been implicated in both ischemic injury and spectrin proteolysis we examined the effects of MK-801, an NMDA antagonist with reported protective effects against ischemia. MK-801 significantly reduced both phases of proteolysis at a neuroprotective dosage (10 mg/kg) administered prior to the occlusion. These results suggest that NMDA receptor-linked proteolytic events may predispose vulnerable neurons to delayed cell death.

POST-ISCHEMIC MODIFICATION OF SYNAPTIC FACILITATION AND ADENOSINE INHIBITION IN THE CA1 REGION. K.S. Lee. Dept. of Anatomy, Thomas Jefferson University, Philadelphia, PA

Delayed neuronal death of CA1 pyramidal cells is a hallmark of transient forebrain ischemia. Increased neuronal activity during the post-ischemic period is thought to be a critical event contributing to the process of delayed neuronal death. The basis for this increased activity is unknown but is likely to reside in a disturbance of one or more of the endogenous factors which normally serve to control the output of CA1 neurons. Synaptic facilitation was examined in the stratum radiatum of CA1 in slices from control animals and from animals subjected to a 10 minute period of bilateral carotid artery occlusion and allowed to survive for 1-2 hours. Paired-pulse stimuli were delivered to the Schaffer collateral/commissural afferents with interpulse intervals ranging from 20 to 500 milliseconds. Paired-pulse facilitation was greatly reduced in slices from post-ischemic animals. As previously described (Urban et al., Neurosci. Abs. 14, 1988), single pulse evoked responses are enhanced in slices from post-ischemic animals, i.e. synaptic responses were larger for a given stimulus intensity during the early post-ischemic period. These data suggest that a modification of presynaptic mechanisms could be involved in altered neuronal activity following transient ischemia.

The effect of adenosine on synaptic facilitation was also examined in control and post-ischemic slices. Adenosine is a potent neuromodulator in the CA1 region which has been shown to inhibit evoked synaptic responses and to increase synaptic facilitation (Dunwiddie and Haas, J. Physiol. 369, 1985). The enhancement of synaptic facilitation by adenosine was reduced in slices from post-ischemic animals. It is proposed that reduced inhibition by adenosine at presynaptic sites contributes to enhanced synaptic responses and increased neuronal activity following transient ischemia. (Supported by NIH grant NS 24782 01A2).

PROTEIN SYNTHESIS INHIBITORS CAN PREVENT ISCHEMIC NEURONAL DEATH IN GERBILS. D.M. Ragan*, R.K. Rader and T.H. Lanthorn (SPON: J.M. Farah, Jr.). CNS Diseases Research, G.D. Searle & Company, 700 Chesterfield Village Parkway, St. Louis, 63198.

We have found that experimental ischemia, in vitro, induces a persistent depolarization which may be an early marker of impending neuronal death. The induction, but not the maintenance, of this persistent depolarization can be blocked by NMDA antagonists. Long-term potentiation (LTP) is another persistent process in which the initiation, but not the maintenance, can be blocked by NMDA antagonists. LTP can also be blocked by inhibitors of protein synthesis. We have investigated the possibility that compounds that inhibit protein synthesis can prevent ischemic neuronal death. Ischemic death of CA1 pyramidal neurons was induced by 5 min of bilateral carotid occlusion in gerbils and was assessed by cell counts on sections taken from the hippocampus 7 days following the ischemic insult. Anisomycin and emetine were able to significantly reduce the neuronal death when administered 30 min prior to, but not 24 or 48 hrs after, the ischemic insult. With 150 mg/kg anisomycin (30 min prior) there were 76.5 ± 10.2 (n=34) neurons remaining per field vs. 24.0 ± 6.8 (n=41) for controls ($p<.0001$). With 30 mg/kg emetine (30 min prior) there were 49.2 ± 14.8 (n=10) neurons remaining vs. 22.2 ± 14.4 (n=10) for controls ($p<.02$). These results suggest that the NMDA-initiated events underlying ischemic neuronal death and LTP may involve similar processes.

149.13

CHARACTERIZATION OF NOVEL PROTEINS IN THE HIPPOCAMPUS FOLLOWING ISCHEMIA. R.M. Leimgruber*, R.K. Rader, D.M. Ragan* and T.H. Lanthorn. CNS Diseases Research, G.D. Searle & Co., St. Louis, MO 63198.

In order to determine if protein synthesis may be involved in neuronal death, we employed two-dimensional polyacrylamide gel electrophoresis (2-D PAGE) to look for novel proteins in the brain after an ischemic insult. Proteins from brain extracts were fractionated by either isoelectric focusing or non-equilibrium pH gradient electrophoresis for the first dimension and by molecular weight using SDS-PAGE for the second dimension. Protein was obtained from the hippocampus of gerbils one hour following five minutes of bilateral carotid occlusion. Protein was also obtained from in vitro rat hippocampal slices one hour after anoxic depolarization induced by hypoxia plus decreased levels (2 vs. 10 mM) of D-glucose. The two-dimensional gel protein patterns obtained from the gerbil hippocampal slices were almost identical to those obtained from the rat hippocampal slices for all experimental conditions. Ischemia, or an in vitro model of ischemia, induced several proteins in the 20-45 KDa and 60-75 KDa molecular weight regions. These "novel" proteins were either absent or present in negligible amounts in untreated controls and in brain tissue which had been protected from the effects of ischemia by the use of the NMDA antagonist, MK-801, or the protein synthesis inhibitor, anisomycin.

EARLY IMPAIRMENTS IN HIPPOCAMPAL PROTEIN SYNTHESIS FOLLOWING GLOBAL CEREBRAL ISCHEMIA IN NEONATAL PIGS. J.M. Gidday and T.S. Park. Department of Neurosurgery, University of Virginia, Charlottesville, Virginia 22908.

There is evidence that protein synthesis shows a prolonged period of impairment following cerebral ischemia in adult animals even though energy metabolism and glucose utilization recover relatively rapidly. To investigate this phenomenon in the neonate, we assessed by autoradiography the regional incorporation of ^{14}C-leucine in hippocampal substructures of 6 isoflurane-anesthetized piglets (less than 5 days of age) following 10 minutes of global cerebral ischemia induced by subclavian and brachiocephalic arterial occlusion. After a 6 hour reperfusion period, a tracer dose of leucine (100μCi/kg) was given i.v. and the brains were transcardiac perfusion-fixed 30 minutes later. 30μm coronal sections were obtained at -20°C. Densitometric analyses of the autoradiographs revealed a depression in amino acid incorporation relative to controls of 22% in the granule cell layer of the dentate gyrus, 55% in the dentate hilus, and 57% in the pyrimidal cell layer of CA3. The greatest depression, 67%, occurred in the pyrimidal cell layer of CA1. Such early derangements in protein metabolism may play a key role in the delayed neuronal death experienced by these hippocampal cells following ischemic insults. (Supported by American Heart Association Virginia Affiliate; NS 00924 and NS 21045).

THE PHOSPHATIDYLINOSITOL SECOND MESSENGER SYSTEM AFTER TRANSIENT GLOBAL ISCHEMIA: AN AUTORADIOGRAPHIC STUDY. J.Deckert, M.B.Jorgensen* and D.C.Wright*. BPB, NIMH and SNB, NINCDS, NIH, Bethesda, Md. 20892, USA.

The hypothesis of excitotoxic neuronal cell death postulates increased intracellular Ca-concentrations induced by glutamate. This could occur due to increased phosphatidylinositol(PI)-hydrolysis and subsequent formation of inositoltrisphosphate (IP3) and diacylglycerol (DAG). We therefore decided to investigate binding sites for IP3 and DAG using a quantitative autoradiographic method and as ligands (3H)IP3 and (3H)phorboldibutyrateester ((3H)PDBU).

Male Sprague-Dawley rats were subjected to transient forebrain ischemia using a modification of the four-vessel occlusion model. (3H)IP3 (in the absence of calcium) and (3H)PDBU (in the presence of calcium) autoradiography were performed as originally described.

An early decline of (3H)IP3 binding after 6 hours of about 40% was measured in the CA1, the CA3, the Molecular Layer of the Dentate Gyrus and the Parietal Cortex. (3H) PDBU binding decreased by 20%-40% after 12 hours in the CA3 and the Molecular Layer of the Dentate Gyrus and only after 72 hours in the CA1 and the Parietal Cortex. Cell death was observed after 48 hours in the Dentate Hilus and after 72 hours in the CA1.

These data clearly implicate a role for the PI-second messenger system in the early stages of excitotoxic neuronal cell death.

149.16

SEPARATION OF INOSITOL PHOSPHATES IN RAT BRAIN BY CHROMATOGRAPHY. T.N. Lin*, G.Y. Sun, N. Premkumar*, R.A. MacQuarrie* and S. Carter* (SPON: Robert T. Zoeller). Biochem Dept. and Sinclair Research Farm, Univ. Missouri-Columbia; School of Basic Life Sci., Univ. Missouri-Kansas City; and Dionex Corp., Sunnyvale, CA.

In spite of great interest in understanding the signal transduction mechanism involving turnover of phosphoinositides and generation of inositol phosphates as second messengers, an inherent limitation to this type of study is the lack of sensitive method for quantitation of the inositol phosphates and isomers. To this end, a HPLC procedure has been developed in our laboratory for separating the inositol phosphates (IP, IP_2 and IP_3) and their isomers in brain. This procedure involves an Ion Pac AS5A-5u column together with an Anion Micro-Membrane Suppressor and subsequent detection using an Ion Conductivity detector (Dionex Corp.). In a typical study, Sprague-Dawley rats were killed by decapitation and the brain cortex removed and homogenized in chloroform-methanol (2:1, v/v). The homogenate was centrifuged to separate the protein layer and the organic solvent which was later discarded. The pellet was dried under nitrogen and resuspended in deionized water. Samples were subjected to a clean-up cartridge prior to injection into the column. Samples were eluted isocratically with 150 mM NaOH and H_2O in different proportions. Using this separation condition, the amount of IP, IP_2 and IP_3 observed in normal brain was 30-50, 150-200, and 4-7 nmole/g wet wt, respectively. Lithium treatment resulted in a 10-40 fold increase in the level of IP (depending on dose and time of treatment) but did not appreciably alter the levels of IP_2 or IP_3. Ischemic treatment also resulted in a time-dependent change in the levels of the inositol phosphates in brain. (Supported in part by NS 20836 from NINCDS and AA06661 from NIAAA).

TIME-DEPENDENT CHANGES IN PROTEIN KINASE C MEDIATED *IN VITRO* PHOSPHORYLATION IN ISCHEMIC SPINAL CORD. A. Kochhar*, J. A. Zivin, and T. Saitoh, Dept. of Neurosciences, School of Medicine, Univ. of California, and VA Medical Center, La Jolla, CA 92093.

Ischemia initiates a series of biochemical events that can eventually lead to cell death. We have previously shown that extended periods of ischemia (60 min) result in reduced *in vitro* phosphorylation of endogenous proteins by endogenous protein kinase C (PK-C). This ischemia duration produces irreversible neurological damage. In the present study, we examined the effects of shorter durations of ischemia on PK-C-dependent phosphorylation in rabbit spinal cord. Ten min of ischemia does not produce irreversible neurological damage, while 30 min of ischemia produces irreversible damage in 50% of the animals. Spinal cords were rapidly excised from control and ischemic rabbits and frozen. Tissue samples were homogenized and centrifuged. In *in vitro* endogenous protein phosphorylation assays, membrane and cytosolic fractions were incubated under phosphorylating conditions, in the absence or presence of PK-C activators, 4ß-phorbol 12-myristate 13-acetate and phosphatidyl serine. Proteins were separated by SDS-polyacrylamide gel electrophoresis, stained with Coomassie Blue, and phosphorylated proteins were detected by autoradiography. Ten min of ischemia did not affect endogenous protein phosphorylation mediated by PK-C in either fraction. However, the endogenous protein phosphorylation pattern under PK-C activating conditions was reduced 25 to 50% in both fractions after 30 min of ischemia. These studies show a temporal effect of ischemia on endogenous PK-C phosphorylation system. Short durations of ischemia (10 min) do not affect PK-C mediated phosphorylation, intermediate ischemia durations (30 min) can reduce protein phosphorylation by 50%, while long ischemia durations (60 min) result in almost complete loss of protein phosphorylation.

149.18

PROTEINKINASE C IS TRANSLOCATED TO THE PLASMAMEMBRANE DURING CEREBRAL ISCHEMIA. M. Cardell*, T. Saitho, J. Zivin, T. Wieloch* (SPON: B. Ehinger). Lab. for Exp. Brain Res., Lund University Hospital, 221 85 Lund, Sweden, Dept. of Neurosciences, UCSD Med School, La Jolla, CA 92093.

Transient periods of cerebral ischemia lead to selective neuronal necrosis in certain regions of the brain, including cerebral neocortex, hippocampus and striatum. We investigated protein kinase C (PKC) activity and PKC immunoreactivity (PKC-IR) in the membrane and cytosolic fractions from rat cerebral cortex and striatum. Activity of PKC was measured by incorporation of [32P] into histone III and endogenous phosphoproteins, and the amount of PKC was determined by Western blotting. Polyclonal antibodies directed against PKC α,β, or γ was used. Ischemia was induced either by cardiac arrest, or by bilateral occlusion of both common carotid arteries combined with hypotension.

Results:

1. During ischemia PKC-IR in cortex increased progressively in the membrane fraction and decreased in the cytosolic fraction.

2. Free arachidonic acid increased with time of ischemia.

3. *In vitro* phosphorylation of histone III and endogenous proteins in striatum decreased in the membrane fraction but was unaffected in the cytosolic fraction. No evidence for the formation of proteinkinase M (PKM) was seen.

Conclusions:

No partial proteolysis of PKC leading to the formation of PKM takes place during ischemia, despite elevated intracellular calcium concentrations. Proteinkinase C is translocated during cerebral ischemia to the cellular membranes possibly due to the accumulation of arachidonic acid, while the enzyme activity decreases which may be due to an inhibitor. Translocation of PKC could lead to changes in ion channel properties and gene expression, that may be of pathological significance in ischemia.

EFFECTS OF HYPOXIA ON ORNITHINE DECARBOXYLASE ACTIVITY IN BRAIN REGIONS OF NEONATAL RATS. A. Chicz-DeMet, V. Bjelajac*, B. Stoveken*, A. Gurnani*, and E.M. DeMet. State Dev. Rsch. Inst., Costa Mesa, CA 92626, Dept. Psychiatry, Univ. of California, Irvine, CA 92717

Ornithine decarboxylase (ODC), a rate limiting enzyme in the synthesis of polyamines, is normally induced during cellular replication and differentiation. Higher than normal levels may be induced in rats under conditions of stress, eg. separation from dam, toxic insult, or hypoxia, with maximum sensitivity on postnatal (pn.) day 8. Therefore, ODC levels may represent a sensitive measure of hypoxic exposure. The present study compared ODC responses to a 2 hr/7% oxygen exposure in male and female Sprague Dawley rats. Rats treated on day 8 pn. were sacrificed immediately following exposure and on days 13 and 20 pn. Brains were dissected into 9 regions and stored at -70°C for assay. Preliminary results of 5 brain regions confirm an earlier report that hypoxic treatment elevated ODC levels in all of these regions. Maximal increases were found on day 8 pn. in the hippocampus, midbrain, brainstem and cerebellum whereas levels in the cortex peaked on day 13 pn. Untreated female controls generally had higher levels than males, and ODC increases in treated females were greater than in males on days 8 and 13 pn. Treated rats of both sexes had lower than control levels on day 20 pn. with significant decreases only in the males. The possible relationship between ODC changes and neuronal damage will be discussed.

RELATION OF BLOOD-BRAIN BARRIER (BBB) CHANGES TO CALCIUM UPTAKE IN CEREBRAL ISCHEMIA. G.Nagashima*, J.Ikeda*, T.S.Nowak,Jr, F.Joo*, G.Mies*, C.Ruetzler*, J.Lohr* and I.Klatzo Lab. of Neuropathology and Neuroanatomical Sciences, NINDS, NIH, Bethesda, MD 20892.

The purpose of this study was to gain further insight into the nature of pathomechanisms operative following cerebral ischemia. Mongolian gerbils were subjected to repeated bilateral common carotid artery occlusions at 1 h intervals. The uptake of calcium in brain tissue was assessed by autoradiography using 45-Ca injected 7 h before sacrifice and by electron microscopy using an oxalate-pyroantimonate precipitation method. The permeability of the BBB was assessed with horseradish peroxidase or by immunostaining using a rabbit anti-gerbil albumin antibody. Autoradiographic observations after repeated insults revealed, in addition to hippocampus, conspicuous Ca uptake in the striatum, thalamus, medial geniculate and substantia nigra. The areas of calcium accumulation showed frequent association with immunocytochemical evidence of albumin extravasation in those regions. Electron microscopy revealed a pattern of abnormal calcium accumulation primarily in dendritic structures, similar to that described following convulsive seizures associated with neuroexcitation. Our studies suggest that neuroexcitatory mechanisms associated with cerebrovascular permeability changes and an increased calcium uptake may play an important role in development of postischemic lesions.

THE ROLE OF CALCIUM IN GLUTAMATE-ENHANCED HYPOXIC NEURONAL DAMAGE A. Schurr, C.A. West* and B.M. Rigor. University of Louisville School of Medicine, Louisville, KY 40292

Recently, the pathophysiology of cerebral hypoxia-ischemia has been attributed to neurotoxicity of the excitatory amino acids glutamate (Glu) and aspartate (Asp). Here we attempted to determine the role of Ca^{2+} in the enhancement of hypoxic-ischemic neuronal damage (HIND) by Glu, Asp and their analog NMDA. Extracellular recordings of orthodromic responses (population spikes) evoked in the CA1 stratum pyramidale of hippocampal slices were used as a measurement of neuronal function. Under normoxic conditions Glu and Asp (0.1-3.0 mM) had no adverse effect on neuronal function. However, when hypoxia was applied for 10 min, the recovery rate of neuronal function upon reoxygenation decreased with increasing concentration of Glu. In contrast to Glu and Asp, NMDA depressed normoxic neuronal function at concentrations above 50 uM. Under hypoxic conditions, 10 uM of NMDA induced a degree of neuronal damage equal to that of 3000 uM Glu. Elimination of Ca^{2+} from the perfusion medium during hypoxia completely abolished the neurotoxic effects of Glu, Asp and NMDA. Nevertheless, HIND could be detected in the presence of a standard concentration of Ca^{2+} (2.5 mM) and in the absence of an excitotoxin. APV, an NMDA antagonist, attenuated the NMDA-enhanced HIND. We concluded that Ca^{2+} influx and its intracellular accumulation are the major processes leading to HIND, whereas Glu and Asp, although enhancing such influx and damage, are by themselves innocuous.

ISCHEMIC CONDUCTION FAILURE IN RAT PERIPHERAL NERVE. J.D. Schmelzer* and P.A. Low. Neurophysiology Laboratory, Dept. of Neurology, Mayo Foundation, Rochester, MN 55905

Our rat model of severe nerve ischemia, produced by the temporary occlusion of the abdominal aorta and both iliac arteries for 1-3 hrs, consistently produced ischemic conduction failure within 30 min in both sciatic-tibial and caudal nerves. In the sciatic-tibial nerve, when submitted to 1 hr of ischemia, the muscle CAP recovered to >50% upon 3 hrs of reperfusion but when submitted to 3 hrs of ischemia the muscle CAP recovered to only 10% and 35% after 3 hrs and 1 wk of reperfusion, respectively. Three hrs of ischemia resulted in the recovery of nerve CAP to ~40% and ~60% after 3 hrs and 1 wk of reperfusion, respectively. In caudal nerve, following 1 hr of ischemia, recovery of the nerve CAP was prompt and 80% complete upon 2 hrs reperfusion and 90% upon 1 wk reperfusion. In contrast, muscle CAP recovered to only 20% and 30% upon 2 hrs and 1 wk of reperfusion. Following 3 hrs of ischemia, recoveries of the nerve CAP were 10%, 50%, and 80% upon 2 hrs, 1 wk, and 1 month of reperfusion. In contrast, the recoveries of the muscle CAP were 0%, 0%, and 28% upon 2 hrs, 1 wk, and 1 month of reperfusion. We conclude that the electrophysiological consequences of ischemia and reperfusion are better explained by conduction failure in muscle and/or nerve terminal rather than in peripheral nerve.

149.23

EFFECT OF CORTICAL BARREL-FIELD INFARCTION ON CYTOCHROME OXIDASE HISTOCHEMISTRY IN THE RAT. W.D. Dietrich, O. Alonso, and M. Halley*. Cerebral Vascular Disease Research Center, University of Miami, School of Medicine, Miami, FL, 33101.

Cytochrome oxidase (CO) histochemistry was used to obtain evidence for anatomical reorganization following focal brain injury. Young rats (25 days) underwent photochemically induced infarction of the left cortical barrel-field (BF). Three months later, rats were perfusion-fixed and processed for the light and electron microscopic visualization of CO histochemistry. In cleared Vibratome sections, abnormally dense CO staining was demonstrated in layers 4-6 of the somatosensory cortex contralateral to the BF infarct. Ultrastructural analysis of this area demonstrated a high frequency of large and darkly reactive dendritic mitochondria. The somata of many cortical neurons also contained large numbers of densely reactive mitochondria, while other neurons appeared dark with increased numbers of ribosomes. Astrocytes appeared swollen with clumped nuclear chromatin. Focal brain injury results in morphological indicators of altered mitochondrial function and protein synthesis in remote brain regions. Degeneration of transcallosal fibers following cortical infarction may lead to denervation of the contralateral hemisphere and subsequent neuronal reorganization at this relatively late post-injury period.

DENSE DEPOSITS IN RAT HIPPOCAMPAL CA1 NEURONS DURING POST ISCHEMIC DELAYED NEURONAL DEATH K Magnusson*, J Deshpande, T Linden*, H Kalimo* and T Wieloch*. (Spon: MC Rogers) Dept. of Anesthesiology, The Johns Hopkins Hospital, Baltimore, MD 21205 and Lab. for Experimental Brain Research, Lund University Hospital, Lund, Sweden.

Ultrastructural changes in hippocampal CA1 neurons were studied 1h, 6h, 24h, 48h, & 72h 10 min after cerebral ischemia with the 2 v-o model. Delayed neuronal death was observed on light microscopy. Until the appearance of frank necrosis, mitochondria appeared intact and nuclear chromatin was dispersed; nucleolus was unremarkable, the nucleolemma was irregular but no bleb formation of plasma membrane or cell fragmentation was observed on EM. At 6h, electron-dense fluffy material (DM) associated with tubular saccules appeared in soma and in dendrites immediately beneath the plasma membrane. The amount of DM increased progressively with recirculation. At 48h there was a gradient of DM with high density in soma and in the major trunks of dendrites and seldom in spines. DM did not correspond to Ca precipitates on oxalate-pyroantimonate stained sections. HSP-70 immunoreactivity (IR) was not observed in controls, but appeared at 24h and 48h. Ubiquitin IR found in control animals disappeared and never recovered in CA1. We propose that the DM represents aggregates of high turnover proteins which may induce disruption of cellular structure and function, ultimately leading to cell death.

FUNCTIONAL INTERACTIONS BETWEEN GABA AND GLIAL CELLS IN THE GERBIL FOREBRAIN AFTER TRANSIENT ISCHEMIA. C.S.Lin, K.Polsky and B.J.Crain Department of Physiology & Biophysics, Hahnemann University, Phila.,Pa. 19102 and Department of Neurobiology and Pathology, Duke University Medical Center, Durham, NC 27717

The present study was designed to investigate the functional relationships between the GABAergic neurons and the glial cells in the gerbil forebrain after transient ischemia. We used the immunostaining of the glial cells with GFAP and the GABAergic neurons with GABA and/or GAD to assess the interaction between GABA and glial cells by varying the survival time-i.e. from 1 day to 4 weeks after a 5 minute bilateral common carotid occlusion. An increase of GFAP reactivity after 4 days post-ischemic survival was noted mainly centered in the lateral septal nucleus, the dorso- lateral region of the striatum, the CA_1 sector of the hippocampus and the layer 3 of the somatosensory and auditory cortices. This reactive astrocytotic action was clearly noted beginning at 4 days and persisted up to 4 weeks. Further, the adjacent sections immunostained with GABA antiserium displayed a glial cell-like reactive change found in those most severely damaged areas after a 7 days survival. This glial cell-like reaction extended up to 4 weeks. However, this reactive change was not found in the adjacent sections stained with GAD antiserum. Our present finding suggests an intimate interaction between GABA and glial cells in the ischemic damaged gerbil forebrain. The functional significance of this phenomenon will be discussed. Supported by NIH NS 06233 and 1-SO7RR07241.

TRANSMITTERS IN INVERTEBRATES II

150.1

SUBSTANCE P-LIKE IMMUNOREACTIVITY IN A SUBPOPULATION OF THE FMRFamide-LIKE IMMUNOREACTIVE NEURONS OF *DROSOPHILA* AND *CALLIPHORA* D. R. Nässel and T. Lundquist*. Dept. Zoology, University of Stockholm, S-10691 Stockholm, Sweden.

For the understanding of peptidergic transmission in the insect CNS detailed mappings of neuron morphology and projections may be helpful. We have selected some peptidergic systems for such analysis. An antiserum against substance P immunolabels a small distinct population of neurons in the flies *Drosophila* and *Calliphora*. Double labeling shows that the substance P-like immunoreactive (SPLI) neurons constitute a subpopulation of the numerous FMRFamide-immunoreactive (FLI) neurons. In *Drosophila* there are 10 SPLI neurons in the brain and 10 in the fused thoracico-abdominal ganglia. In *Calliphora* the same 20 SPLI neurons are seen with about 30 additional smaller SPLI neurons. Six of the SPLI neurons in both species are thoracic neurosecretory neurons with terminals in a neurohaemal release site in the dorsal ganglion sheath and central processes connecting the thoracic neuromeres with the suboesophageal ganglia. In the brain SPLI neurons are projection neurons and large field amacrine neurons. Subpopulations of the FLI neurons are also recognized by antisera against CCK and enkephalins. Probably the FMRFamide- and CCK-antisera react with drosulfakinins [CCK-like peptides with the -MRFamide C-terminus in common with the *Drosophila* peptide DPKQDFMRFamide (Nichols et al., *J. Biol. Chem.* **25:** 12167, 1988; Schneider and Taghert, *Proc. Natl. Acad. Sci.* **85:** 1993, 1988)]. The FLI neurons may hence contain peptides similar to DPKQDFMRFamide and drosulfakinins, and some have colocalized substance P-like peptide. Functionally different types of neurons may use these peptides as neurotransmitters, modulators or neurohormones.

150.2

ISOLATION AND CHARACTERIZATION OF A **DROSOPHILA** AKH. M.H. Schaffer, B.E. Noyes*, C.A. Slaughter*, G.C. Thorne*, and S.J. Gaskell*. Depts. of Psychiatry and Biochemistry, U. Texas Southwestern Medical Center, Dallas, Tx., 75235-9070 and Center for Experimental Therapeutics, Baylor College of Medicine, Houston, Tx.

A member of the AKH - RPCH family of neuropeptides was isolated from **Drosophila melanogaster** based on the prediction that the **Drosophila** peptide would have physical properties and bioactivity on the grasshopper extensor tibialis similar to other family members. A peptide with these properties was extracted from thorax into methanol, acetic acid, water and purified by three steps of reverse phase HPLC. Its structure has been determined by a combination of automated Edman degradation sequencing (150 pmoles) and fast atom bombardment hybrid mass spectrometry with low energy collisional activation (150 pmoles). The structure has been confirmed by comparison of the fragmentation pattern to that of a synthetic standard. While the **Drosophila** peptide appears to be a typical family member in most respects, it is remarkable for the presence of an asp rather than an asn residue. Control experiments are required to document that this is not the result of hydrolysis during the purification, but this is unlikely since other family members subjected to the same purification are not degraded. Despite this change, the **Drosophila** peptide is clearly active on on the grasshopper leg.

150.3

ISOLATION, CHROMOSOME LOCALIZATION, AND EXPRESSION OF A cDNA CLONE FROM *DROSOPHILA MELANOGASTER* WHICH CODES FOR A PUTATIVE OCTOPAMINE RECEPTOR. [1]D.A. Urquhart, [1]L. M. Hall, [2]S. Arakawa* and [2]J. C. Venter*. [1]Dept. of Mol. Genetics, Albert Einstein Coll. of Med., Bronx, NY 10461 and [2]Sect. of Receptor Biology, NINDS, Bethesda, MD 20892.

Octopamine (OCTO) functions as a neurotransmitter and a circulating neurohormone in insects. At least two classes of receptors for OCTO can be distinguished pharmacologically; these receptors display properties similar to vertebrate a_2-adrenergic receptors (AR). Using a cDNA clone encoding a human b_2-AR, *Drosophila* genomic and cDNA libraries were screened under reduced stringency (Arakawa and Venter). A 3.3 kb cDNA clone encoding a protein of 601 amino acids was isolated. This protein expressed in CHO cells displayed high affinity ^{3}H-yohimbine binding (K_d = 6 nM) with a B_{max} = 1.5 pmol/mg membrane protein. Octopamine, synephrine, and clonidine were essentially equipotent in inhibiting yohimbine binding (K_i = 15-30 mM) while epinephrine, dopamine and isoproterenol were significantly less potent, suggesting that the protein encoded by this cDNA clone may be a *Drosophila* OCTO receptor. *In situ* hybridization studies using a biotinylated genomic clone has shown that this receptor gene maps to position 99A10-B1 on the right arm of the third chromosome. The relationship of this gene to exisiting mutants and chromosome aberrations in this region will be presented.

150.4

IDENTIFICATION OF GLUTAMATE NEURONS IN THE ABDOMINAL NERVOUS SYSTEM OF THE MOTH MANDUCA SEXTA. S.E. Fahrbach, Dept.Entomol., Univ. of Illinois, Urbana, IL 61801.

Glutamate (GLU) is the short-latency excitatory neurotransmitter at the insect NMJ. In studies of developmental neuron death in Manduca sexta, selective cellular markers would facilitate identification of neurons fated to die. (Of the cells that die in each abdominal ganglion after adult emergence, approximately 80 are motoneurons.) I have used a polyclonal antibody specific for GLU to identify GLU-IR neurons in whole ganglia and frozen sections of the moth abdominal nervous system. These studies have demonstrated not only that this antibody can recognize putative GLU-containing motoneurons in the moth nervous system, but have also revealed the surprising extent to which GLU must serve as an excitatory transmitter within the segmental ganglia, since it is expressed in numerous interneurons whose processes do not leave the CNS. The pattern of staining was reproducible from ganglion to ganglion. Staining for GLU should provide a label for this neuronal population as it undergoes a dramatic (50%), hormonally-regulated reduction in cell number.

150.5

THE DISTRIBUTION OF GABAERGIC LINEAGES IN INSECTS. J.L. Witten and J.W. Truman. Dept. of Zoology, University of Washington, Seattle, WA. 98195.

Using immunochemical methods (antiserum supplied by J. Hildebrand, U. Arizona), we have localized GABA to six identifiable postembryonic lineages in the thoracic ganglia of the moth, *Manduca sexta*. There are three ventral (K,M,N) and two dorsal (E,T) paired lineages and one dorsal unpaired (X) lineage. All the neurons within each lineage express the GABAergic phenotype. We found the same number of clusters of GABA - immunoreactive neurons in similar positions in the adult ganglia of the firebrat, grasshopper and beetle. In addition, the primary processes of cells in clusters that are in similar positions insert into the same tracts. These observations strongly suggest that these six clusters in the different insects are homologous lineages.

We are using this comparative approach to test the hypothesis that homologous lineages may serve similar functions in adult specific behaviors such as walking or flight. The size of individual lineages varies in different insects and we are trying to correlate this size difference with these particular species specific adult behaviors.

NEURAL REGULATION OF SEX PHEROMONE PRODUCTION IN FEMALE MOTHS. I. MORPHOLOGY. H. Itagaki, T.A. Christensen, and J.G. Hildebrand. ARL Div. of Neurobiology, Univ. of Arizona, Tucson, AZ 85721.

Recent work by Teal and Tumlinson (PNAS, in press) indicates that sex pheromone biosynthesis in female *Heliothis* moths is regulated by a two-step process. Pheromone biosynthesis-activating neuropeptide (PBAN, Raina & Menn, 1987) appears to be transported down the ventral nerve cord (VNC) from the subesophageal ganglion (SEG) to the terminal abdominal ganglion (TAG), where it acts on a second neural element that stimulates pheromone biosynthesis by the pheromone gland (PG), a specialized monolayer of cells in the intersegmental membrane at the abdominal tip. Using standard techniques, we have attempted to define the cellular elements of this system in female *Heliothis* moths.

Using paraldehyde-fuchsin staining for neurosecretory cells, we have identified one or two candidate PBAN-transporting cell(s) linking the SEG and the TAG. Specific staining was found in one axon in each connective, with terminals located in the pterothoracic ganglion and the TAG. We do not yet know if one or two cells are involved, as no soma(ta) have been found linked to these axons. We are planning further work using a PBAN-specific antibody to clarify this question.

We have also used cobalt staining followed by silver-intensification to characterize the neurons innervating the PG. Cutting and staining of TAG nerves revealed fibers projecting toward, and fine arborizations associated with, the PG. Cobalt backfilling from the PG toward the TAG has stained several small groups of cells located on the posterior margin of the TAG. Some of these cells also are stained by the vital dye Neutral Red, suggesting the possible presence of biogenic amine(s). This staining has led to a hypothesis about the transmitter used by TAG neurons to control pheromone biosynthesis (see next abstract). We are now trying to identify specific cells innervating the PG by intracellular staining using microelectrodes. [Supported by USDA, NIH, and Monsanto Co.]

NEURAL REGULATION OF SEX PHEROMONE PRODUCTION IN FEMALE MOTHS. II. PHYSIOLOGY AND NEUROCHEMISTRY. T.A. Christensen, H. Itagaki, P.E.A. Teal*, and J.G. Hildebrand. ARL Div. of Neurobiol., Univ. of Arizona, Tucson 85721, and USDA, Gainesville, FL 32604.

We are using standard anatomical, electrophysiological, and biochemical techniques to study the regulation of sex-pheromone production in the pheromone glands of the female *Heliothis* and *Manduca* moths. Anterograde staining of nerves from the terminal abdominal ganglion reveals several fibers with fine branches that appear to be associated with the gland (Itagaki et al., companion poster). The morphology of these terminals is easily distinguished from that of motorneurons or sensory neurons. Retrograde staining from nerve branches innervating the gland reveals a small cluster of cells at the posterior edge of the ninth neuromere. We are now using intracellular methods to record from and stain individual neurons in this cluster. These neurons stain selectively with the vital dye Neutral Red, suggesting the presence of biogenic amine(s).

Electrical stimulation of the gland nerves during the daylight hours can induce pheromone production in moths that ordinarily would not produce pheromone at this time of day. Several biogenic amines and an amino acid were then tested in isolated glands *in vitro* as candidates for the role of the transmitter mediating this action. We incubated denervated glands with DL-octopamine (OA), dopamine (DA), serotonin (5HT), or L-glutamate for 30 min (100 μg/10 μl saline solution). Only the three amines stimulated pheromone biosynthesis above control levels (OA, 100% above controls; 5HT, 61%; DA, 43%). Glutamate had no effect. Future experiments will focus on the possibility that OA is the efferent transmitter regulating the gland and on the effects of the pheromone biosynthesis-activating neuropeptide (PBAN, Raina & Menn, 1987) on the neurons innervating the gland. [Supported by NIH, USDA and Monsanto Company].

M1-LIKE MUSCARINIC RECEPTORS MEDIATE CHOLINERGIC ACTIVATION OF AN INWARD CURRENT IN ISOLATED NEURONAL SOMATA FROM LOCUST THORACIC GANGLIA. J.A. Benson. R & D Plant Protection, Agricultural Division, CIBA-GEIGY Ltd., CH-4002 Basel, Switzerland.

The response to acetylcholine in voltage-clamped, thoracic ganglion neuronal somata from *Locusta migratoria* comprises a fast, nicotinic (ACh1) component and a slow, muscarinic (ACh2) component (Benson, J.A. & Neumann, R., *Soc. Neurosci. Abs.*, 13:938, 1987). The current activated via the ACh2 receptor is inward at -30 mV and decreases with hyperpolarisation to zero at -80 to -90 mV. The ACh2 response is activated by muscarine, oxotremorine, arecoline and pilocarpine. It is blocked by quinuclidinyl benzilate and scopolamine at nanomolar concentrations, and atropine acts similarly at concentrations 10-fold higher. Gallamine, a weak nicotinic blocker and a potent antagonist of muscarinic m_2 but not m_1 receptors, and methoctramine, a specific m_2 blocker, are without effect on the ACh2 response at 10^{-4} M. In contrast, pirenzepine, a specific m_1 antagonist, blocks the ACh2 response (EC_{50} = 7.1 $\pm$ 4.5 x 10^{-7} M, m $\pm$ SD, n = 3). The pharmacological profile of the muscarine recognition site of this insect somal receptor thus resembles that of the vertebrate brain m_1 muscarinic receptor. These results are consistent with binding studies on locust neurones that reveal m_1 receptors on somal membranes and m_2 receptors at nerve terminals (Knipper, M. & Breer, H., *Comp. Biochem. Physiol.*, 90C:275, 1988), suggesting that the m_1 binding site corresponds to a functional receptor.

NEUROTRANSMITTERS OF THE CRAYFISH ABDOMINAL POSITIONING SYSTEM. B.F. Murphy* and J.L. Larimer. Department of Zoology, University of Texas, Austin, TX 78712

The abdominal positioning system of crayfish serves as a model for CNS control of simple behaviors, however, the major neurotransmitters of this system are largely unknown. We perfused isolated crayfish nerve cords with various neurotransmitters as well as some of their agonists and antagonists and monitored the effects by recording from the tonic positioning motor neurons. Each test consisted of a 15 minute prewash, a 30 minute treatment with neurotransmitter and a 15 minute washout period. Inhibition of motor neuron activity followed 10^{-3} M GABA while 10^{-4} M picrotoxin alone was stimulatory. Since neither glycine nor strychnine had an effect, we conclude that GABA probably serves as the major inhibitory transmitter in this system. Other neurotransmitters including glutamate and acetylcholine at 10^{-3} M as well as the agonist of acetylcholine, methacholine showed no effect. The acetylcholine agonist carbachol, however, stimulated the output at both 10^{-3} and 10^{-4} M indicating the presence of some form of acetylcholine receptor. The muscarinic agent atropine was more effective than the nicotinic drugs hexamethonium or curare in blocking the carbachol effect suggesting that the muscarinic receptor type is predominant. (Supported by NIH NS05423, JLL).

EFFECTS OF NEUROMODULATORS ON PROPRIOCEPTIVE NEURONS IN THE LIMBS OF THE CRAB, CANCER MAGISTER. R. L. Cooper and H. B. Hartman. Biocenter, Univ. of Basel, CH 4056 Basel, Switzerland and Dept. of Biology, Duquesne Univ., Pittsburgh, PA 15282.

Amines and peptides are known to play a variety of roles in crustacean neurophysiology. Serotonin, octopamine and proctolin have been the major compounds of interest in central neuromodulation. Kravitz's group (Beltz and Kravitz, J. Neurosci.,7:533, 1987) has carried out immunocytochemical studies identifing neurons containing these neuromodulators and shown behavioral changes that occur when modulators are injected into lobsters. Pasztor and Bush (Nature, 326:793,1987) have reported on peripheral modulation of mechanosensory neurons of the oval organ in lobster. We chose to study the effects of neuromodulators on the sensory neurons of proprioceptor organs within the limbs of the crab, Cancer magister.

The propus-dactylus (PD) organ was isolated in situ and responses to controlled movement of the organ by individual neurons were recorded using a suction electrode. The output of neurons responsive to joint extension, flexion, and static position was determined when octopamine, serotonin, proctolin, NMDA or GABA were present. The responses were quantified by the statistical index, eta^2. Serotonin (10^{-6}M) caused an increase in activity of the movement sensitive cells. This enhanced activity resulted in a loss of specificity to the stimulus. Octopamine and proctolin (10^{-4} and 10^{-6} M) did not produce any altered responses to the mechanical stimuli. The effects of NMDA and GABA will be described. Supported by NSF Grant BNS-8700506 to H.B.H.

BIOPHYSICAL AND THEORETICAL CHARACTERIZATION OF THE CURRENTS OF CRAB STOMATOGASTRIC GANGLION NEURONS: PROCTOLIN MODULATION. J. Golowasch, F. Buchholtz, I.R. Epstein, and E. Marder. Brandeis Univ., Waltham, MA 02254.

Many peptides and amines are now known to modulate the pyloric network of the crustacean stomatogastric ganglion (STG). Our aim is to determine the biophysical mechanisms underlying the modulation of identified neurons of the crab STG by the neuropeptide, proctolin. To this end we are using voltage clamp to characterize the time and voltage dependence of the currents in identified STG neurons. The Lateral Pyloric (LP) and Inferior Cardiac (IC) neurons are direct targets of proctolin. Both cells show similar currents. These are: 1) a Ca^{++}-dependent K^+ current, 2) a delayed rectifier-like current, 2) a A-type transient outward current, 4) at least one Ca^{++} current, 5) a slow inward rectifier that activates upon hyperpolarization, and 6) a novel voltage-sensitive current activated by proctolin and carried in part by Na^+ and Cl^-. The experimental data are then fitted with mathematical models to understand how proctolin modifies the excitability of these cells. Supported by NS17813, URI 49620-86-C-0131 and NSF DMB-8604794.

LOCALIZATION OF PIGMENT-DISPERSING HORMONE (PDH) -LIKE IMMUNOREACTIVITY IN THE CRUSTACEAN STOMATOGASTRIC NERVOUS SYSTEM. Lawrence I. Mortin and Eve Marder. Biology Department, Brandeis University, Waltham, MA 02254.

Pigment-dispersing hormone (PDH) acts to disperse pigments in crustacean chromatophores. We used a polyclonal antibody made against synthetic PDH from the crab Uca pugilator (Cell Tissue Res. 250:377, 1987) to characterize the distribution of PDH-like immunoreactivity in the stomatogastric nervous system of 5 decapod crustaceans: the crabs Cancer antennarius and Cancer borealis, the lobsters Panulirus interruptus and Homarus americanus, and the crayfish Procambarus clarkii. Staining was seen in the neuropil region of the stomatogastric ganglion (STG) of the lobsters and crayfish, but not in the crabs. None of the cells in the STG stained for PDH in any of these species, but cells and neuropil in the paired commissural ganglia (CGs) of all 5 species showed staining; the details of this staining were unique for each species. In each CG, PDH staining was seen in: one large cell in C. borealis; 3 cells, one large, one medium and one small, in C. antennarius; 3-7 medium to large cells in P. clarkii; 1-3 small cells in H. americanus; and 13-17 small cells in P. interruptus. In the lobsters, each CG contained 2 qualitatively different neuropil regions. Fibers from one neuropil region pass into each superior oesopha-geal nerve and travel towards the STG. Lucifer yellow backfills of the inferior oesophageal nerve (ion) combined with PDH antibody staining revealed that the smallest PDH cell in each CG of C. antennarius sends a process through each ion and the oesophageal ganglion (OG) to the opposite CG; these cells may act as bilateral coordinators of CG motor function. None of the cells in the OG showed PDH staining in any of these species. In all instances PDH staining was blocked by preabsorption of the antibody with 100μM PDH; preabsorption with other peptides did not block staining. A PDH-like peptide may act as a neuromodulator of the motor rhythms of the stomatogastric nervous system.

150.13

MODULATING RHYTHMIC MOTOR ACTIVITY WITH A PROCTOLIN- AND GABA-CONTAINING NEURON. M.P. Nusbaum[1,2], I. Cournil*[3], J. Golowasch[1] and E. Marder[1]. [1]Dept. Biol., Brandeis Univ., Waltham, MA 02254; [2]Dept. Biol., S.F. State Univ., San Francisco, CA 94132; [3]Lab. Neuro. Comparée, CNRS, 33120 Arcachon, France.

The modulatory proctolin-containing neuron (MPN) causes a state-dependent excitation of the pyloric rhythm in the crab stomatogastric ganglion (Nusbaum & Marder, J Neurosci, 9: In Press). Many MPN effects are mimicked by exogenously-applied proctolin. The intensity and time course of these proctolin effects are attenuated by amastatin-sensitive, aminopeptidase activity. One MPN effect that is not fully mimicked by proctolin is the short latency and long duration EPSPs produced by MPN in the LP and IC neurons.

MPN also exhibits GABA-like immunolabeling. Oesophageal ganglia containing Lucifer yellow-filled MPNs were fixed and sectioned. Alternate sections were processed for proctolin or GABA immunoreactivity. MPN showed both proctolin-like and GABA-like staining.

Focally-applied GABA (10^{-4}M) onto the STG neuropil causes short latency and short duration, mixed excitation and inhibition in LP and IC neurons. The $GABA_A$ agonist, muscimol (10^{-3} M), primarily excites these neurons. Depolarizing GABA responses were blocked by picrotoxin (PTX: 10^{-5} M). Hyperpolarizing responses were PTX resistant. In 10^{-4} M PTX, the early peak of the MPN-mediated EPSPs is reversibly reduced, suggesting a role for GABA. The remaining EPSP is likely to be proctolin-mediated. These ongoing studies will help determine how proctolin and GABA contribute to MPNs effects on the pyloric rhythm.

IDENTIFICATION OF ALL GABA IMMUNOREACTIVE PROJECTIONS TO THE LOBSTER STOMATOGASTRIC GANGLION. I. Cournil*, P. Meyrand* and M. Moulins. Lab. Neuro . Phys. Comp., Université de Bordeaux I et CNRS, Place Peyneau, 33120 Arcachon - France.

The rhythmic motor patterns generated in the stomatogastric ganglion (STG) are controlled by modulatory neurons projecting to the STG via the stomatogastric nerve (stn). Recent pharmacological results have suggested that some of these inputs are GABAergic (Cazalets et al, 1987, J. Neurosci. 7: 2884-2893). We have recently identified in rostral ganglia 8 neurons which represent all GABA immunoreactive inputs to the STG. Using GABA antibody and PAP detection on serial paraffine sections, it was found that the stn contains 10 immunoreactive fibers that terminate in the STG neuropile. The cell body location of these fibers have been identified by combining neuroanatomical methods with immunodetection. (1) stn backfills with Lucifer Yellow (LY) were performed to detect double-labelled cell bodies. (2) stn backfills with $NiCl_2$ (which selectively inhibits GABA immunolabelling) permitted detection of GABAergic neurons which do not project to the STG (Cournil and Moulins, in preparation). Identification has been finally confirmed for 4 (of the 8) neurons with electrophysiological techniques coupled with intrasomatic LY injection and subsequent GABA immunodetection.

SCPb AND FMRFamide IMMUNOREACTIVITIES IN *HOMARUS AMERICANUS* NEURONS: COLOCALIZATION OF TWO PEPTIDES --OR-- COLABELING OF A SINGLE PEPTIDE? Z. Kvitash* and B.S. Beltz. Department of Biological Sciences, Wellesley College, Wellesley, MA. 02181.

Virtually all of the SCPb immunoreactive neurons (ca. 60 cells) in the lobster also contain FMRFamide-like immunoreactivity. Preadsorption controls revealed that staining with each antibody is successfully preadsorbed with its specific antigen, while the normal staining pattern is retained using each antibody following preadsorption with the alternate peptide --potentially leading to the conclusion that these two antibodies are labeling distinct compounds that are colocalized in lobster neurons.

The lobster nervous system does not, however, contain authentic FMRFamide, but rather several FMRFamide-like compounds (Trimmer et al, *J. Comp. Neurol.* 266:16, 1987). The most abundant of these is peptide F, an octapeptide with some sequence homology to FMRFamide. Further preadsorption controls demonstrated that SCPb immunoreactivity is completely preadsorbed by synthetic peptide F, while FMRFamide immunoreactivity is partially blocked by preadsorption with this peptide. Preadsorption controls with met-enkephalin-ARG-PHEamide (an extended opioid peptide containing the FMRFamide sequence) also completely preadsorbs SCPb immunoreactivity. These results indicate that the SCPb antibody can bind to extended forms of FMRFamide-like molecules, and that these antibodies may be colabeling one or more peptide F-like molecules in lobster neurons. (Supported by NSF BNS-8718938 and the Howard Hughes Medical Institute).

ACTIVATION OF MEMBRANE-BOUND GUANYLATE CYCLASE BY PEPTIDE G_1, A PUTATIVE HORMONE PURIFIED FROM A LOBSTER NEUROSECRETORY GLAND. Michael F. Goy* (SPON: K. Dunlap). Department of Physiology, University of North Carolina, Chapel Hill NC 27599-7545.

The regulation of cyclic GMP metabolism appears to be especially important to the American lobster. The enzymes that control synthesis and breakdown of cyclic GMP, as well as the phosphoproteins and kinase that are targeted by cyclic GMP, are found at relatively high concentrations in many lobster tissues. In an effort to define the hormonal systems that control cyclic GMP metabolism, extracts of lobster neurosecretory glands were screened for endogenous cyclic GMP-promoting agents. Several different peptides were discovered, the most abundant of which has been named peptide G_1.

Peptide G_1 has been purified to homogeneity by sequential anion exchange and reverse phase HPLC. It is a large, hydrophobic peptide (approximately 8,000 daltons) with an acidic isoelectric point. A partial amino acid sequence has been obtained from the purified material, providing more than 60% of the total sequence. Based on this information, peptide G_1 appears to be unique, with no homology to any previously-characterized peptide. It affects cyclic GMP metabolism in many different kinds of tissue. Among the most responsive targets are muscle and hepatopancreas. When tested on muscle homogenates, purified peptide G_1 selectively activates the membrane form of guanylate cyclase, with little or no effect on the soluble cyclase. It shares this property with only a few other peptides, the best studied of which is the vertebrate Atrial Natriuretic Factor.

150.17

LOCALIZATION OF SUBSTANCE P-,SEROTONIN-, AND DOPAMINE-LIKE IMMUNOREACTIVITY IN CENTRAL GANGLIA OF THE HORSESHOE CRAB. Y. McClain* and R.F. Newkirk, Tennessee State University, Nashville, TN 37209-1561.

Evidence has been reported which suggests that neuroactive peptide substance P, serotonin and dopamine may serve as neurotransmitters in the horseshoe crab. In this study we have used techniques of immunocytochemistry to localize these substances in the circumesophageal ganglia. Fixed tissue was cryostat sectioned and reacted with an antiserum against substance P, dopamine or serotonin and the antibody complex was visualized using an indirect method. The results showed specific substance P-like immunoreactivity (SPLI) in fiber-like structures in the neuropil. Neurons were apparent throughout the ganglia also. Serotonin-like immunoreactivity (SLI) had a pattern distinctly different from that of substance P. Of particular note were groups of neurons exhibiting substance P-like immunoreactivity; no similar group was noted in the case of serotonin. Additionally, fibers exhibiting SPLI were noted in the walking leg nerves whereas SLI tended to maintain a central orientation. Dopamine-like immunoreactivity (DLI) revealed a pattern distinctly different from serotonin also. These results suggest substance P, dopamine and serotonin are localized in neurons and nerve fibers in the circumesopohageal ganglia of the horseshoe crab.

150.18

DETERMINATION OF ENDOGENOUS LEVELS AND LOCALIZATION OF SEROTONIN IN THE VENTRAL NERVE CORD OF LIMULUS POLYPHEMUS. B.S. McAdory* and R.F. Newkirk (SPON: S.M. Fredman). Tennessee State University, Nashville, TN 37209-1561.

The ventral nerve cord of Limulus polyphemus was studied using techniques of immunocytochemistry in an effort to determine the presence and localization of antiserotonin-like immunoreactivity. The chain of paraformeldehyde-fixed abdominal ganglia was exposed to a primary anti-serum (anti-5-HT) followed by treatment with a fluorescent labeled secondary antibody (FITC or rhodamine). The results revealed an extensive plexus of fibers and a pair of anteriorly positioned cell clusters consisting of six cells. A pair of posterior clusters of cells exhibiting less symmetry was also noted. Pretreatment of experimental animals with pargyline, colchicine or 5,7-dihydroxytryptamine (5,7-DHT) significantly enhanced visualization of cells and fibers. HPLC (with electrochemical detection) analysis confirmed the presence of endogenous serotonin in the abdominal ganglia of Limulus. These findings strongly suggest that serotonin is localized in cells and fibers of Limulus polyphemus where it may serve as a central neurotransmitter.

CHARACTERIZATION OF THREE FORMS OF PIGMENT-DISPERSING HORMONE FROM THE SHRIMP PANDALUS JORDANI. K. R. Rao, L. H. Kleinholz*+, and J. P. Riehm*. Dept. of Biology, Univ. of West Florida, Pensacola, FL 32514. + Dept. of Biology, Reed College, Portland, OR 97202.

Although crustacean pigment-dispersing hormone (PDH) occurs in multiple forms (Kleinholz, 1970, 1972), the structural basis of PDH heterogeneity in a given species remained unknown. Utilizing the previously described extraction methods (Fernlund, 1971) and chromatographic procedures (Rao et al., 1985), we have purified three forms of PDH from eyestalks of Pandalus jordani and determined their amino acid sequences. The deduced primary structures have been confirmed by chemical synthesis and by comparison of synthetic and native peptides in bioassays and HPLC. The sequences of these peptides are: NSELINSLLGLPKVMTDAamide, [Leu-8, Thr-16]-β- PDH; NSGMINSILGIPKVMADAamide, [Lys-13, Ala-16, Asp-17]-α-PDH; NSGMINSILGIPRVMTEAamide, α-PDH (identical to DRPH from Pandalus borealis). The β-PDH analog from P. jordani is as potent as β-PDH (Uca/Cancer PDH) in assays for melanophore pigment dispersion in Uca; these two peptides are about 20-fold more potent than α-PDH and 10-fold more active than the α-PDH analog. This indicates that several members of the PDH family, which show differences in relative potency and residue substitutions, account for PDH heterogeneity.

Supported by NSF Grant DCB-8711403.

RED PIGMENT CONCENTRATING HORMONE MODULATES THE CRAYFISH SWIMMERET RHYTHM. C. M. Sherff and B. Mulloney (SPON: H. Anderson). Dept. of Zoology, UC Davis, Davis, CA 95616.

While swimming, the crayfish beats its swimmerets with alternating power strokes and return strokes controlled by alternating bursts of power-stroke and return-stroke motor neurons. The crayfish can initiate and arrest this rhythm as well as alter the period and intensity of the beating. In isolated nerve cords, stimulation of different command neurons (Wiersma and Ikeda,*Comp. Biochem. Physiol.* 12:509-525, 1964) can activate or inhibit the swimmeret rhythm, but the neural mechanisms by which the animal varies its swimmeret rhythm over a wide range of frequencies and intensities have not been identified.

One transmitter that may be involved in this modulation is Red Pigment Concentrating Hormone (RPCH), a naturally occuring peptide in the crayfish nervous system. Perfusion with RPCH lengthened the period and the duration of the bursts in swimmeret motor neurons in a dose-dependent manner in both isolated nerve cords and semi-intact preparations. Perfusion of 10^{-6}M RPCH through the ventral artery led to changes in period and duration that were significant at the 95% confidence level.

Using an antibody raised against RPCH (gift of A. Madsen and R. Elde), we labeled three pairs of immunoreactive cell bodies in each abdominal ganglion and three pairs of immunoreactive interganglionic axons. These axons send branches into the lateral neuropil, regions that contain much of the circuitry for the generation of the swimmeret rhythm (Paul and Mulloney, *J. Neurophysiol.* 54:28-39). That these interneurons can modulate the swimmeret rhythm has not yet been determined.

150.21

A MAP OF NEURONS WITH HISTAMINE-LIKE IMMUNOREACTIVITY IN THE CRAYFISH NERVOUS SYSTEM. B. Mulloney and W.M. Hall. Zoology Dept., University of California, Davis, California 95616.

Histamine has been demonstrated biochemically to be the transmitter used by interneurons that modulate the stomatogastric ganglion (Claiborne & Selverston, 1984; Sigvardt & Mulloney, 1982), but the numbers and distribution in each segmental ganglion of neurons that use it as a transmitter have not been described. We used a well-characterized antibody to histamine (Panula et al., 1988) to map and to count neurons in the CNS that had histamine-like immunoreactivity (HLI).

To achieve good localization of HLI in these animals, we perfused the CNS for 20 min. through the sternal artery with a 4% EDCDI solution in crayfish saline that lacked Ca^{++}, followed by 4% formaldehyde in PBS. After removing the CNS from the animal, each ganglion was desheathed in 4% formaldehyde and left in that fixative over night. Ganglia were then washed, dehydrated to 70% EtOH, rehydrated, incubated in primary antiserum (1:150) for 24 hrs followed by secondary antiserum for 24 hrs.

Each Commissural Ganglion had one neuron brightly-labeled with HLI, and a dense labeling in its neuropil. The Stomatogastric Ganglion had labeled processes in its neuropil, but no labeled neuronal cell bodies.

The Subesophageal Ganglion and each Thoracic Ganglion had similar patterns of HLI; near the ventroposterior midline of each ganglion, one pair of brightly-labeled neurons were apparent. Each Abdominal Ganglion except the last had two pairs of neurons with HLI. The terminal ganglion had one pair. A few axons labeled brightly in each of the interganglionic connectives.

The antibody used was a gift from Dr. Panula (Helsinki).

151.1

THE GLUTAMATE ANTAGONIST,ϒ-D-GLUTAMYLGLYCINE, BLOCKS PERFORANT PATH STIMULATION-INDUCED INHIBITION OF DYNORPHIN SYNTHESIS IN RAT HIPPOCAMPUS. J.B. Daunais[1], C.W. Xie*, P.H.K. Lee, C.L. Mitchell,J.S. Hong, and J.F. McGinty[1]. [1]Dept. Anat. & Cell Biol. E. Carolina U. Sch. Med. Greenville, NC 27858 and LMIN, NIEHS/NIH, Res.Triangle Pk, NC 27709.

Unilateral stimulation of the perforant path (PPS) elicits wet dog shakes (WDS) and bilateral reductions in dynorphin A (1-8) immunoreactivity (DYN-IR) and prodynorphin mRNA (DYN mRNA) in rat hippocampus (see adjacent abstract). This study examined whether glutamate receptors mediate the above responses. In acute PPS experiments, the ventral hippocampus of rats was bilaterally injected with 25 μg/0.5 μl ϒ-D-glutamylglycine (DGG) or 0.5 μl of artificial CSF (ACSF) 10 min. before 4 consecutive PPS trials to establish the threshold for eliciting WDS. The rats were killed imediately after the last trial to determine DYN-IR in the hippocampus. The ACSF+PPS group had a mean of 73±4 WDS at a stimulus intensity of 0.46±0.03 mA as compared with significantly fewer WDS (x= 45±6, p<0.01) elicited at a significantly higher threshold (0.78±0.05, p< 0.001) in the DGG+PPS group. DYN-IR in the ACSF+PPS group was decreased by more than 40% in both dorsal and ventral hippocampus vs.sham controls. In contrast, the PPS-induced reduction in DYN-IR was antagonized by DGG in ventral but not dorsal hippocampus. In daily PPS experiments, rats received a daily unilateral injection of DGG or ACSF 20 min. prior to PPS delivered once per day for 6 days. In situ hybridization using a S^{35}-labeled oligonucleotide, demonstrated that the extent of decrease in DYN mRNA in dentate granule cells positively correlated with the number of WDS elicited by PPS. In rats treated with DGG before each PPS, no decrease in DYN mRNA was observed even in rats which experienced stage 3-4 seizures. These data indicate that DGG inhibits PPS -stimulated WDS and depletion of DYN-IR and mRNA in dentate granule cells. Supported in part by DA 03982 (JFM).

151.2

DIFFERENTIAL MODULATION OF STRIATONIGRAL DYNORPHIN AND ENKEPHALIN BY DOPAMINE RECEPTOR SUBTYPES. H.K. Jiang*, J.F. McGinty and J.S. Hong. Tri-Service Gen. Hosp., Taipei, Taiwan; Dept. of Anatomy, East Carolina Univ., Greenville, NC; & LMIN, NIEHS/NIH, RTP, NC.

The purpose of this study was to determine which dopamine (DA) receptor subtype(s) mediate the modulatory actions of DA on dynorphin (DYN) and enkephalin (ENK) in the striatonigral regions. Intact or unilaterally 6-hydroxydopamine (6-OHDA) lesioned rats were injected twice daily for seven days with the following compounds either separately or combined: D-1 agonist (SKF-38393, 5 mg/kg), D-2 agonist (LY-171555, 1 mg/kg), D-1 antagonist (SCH-23390, 0.05 mg/kg) and D-2 antagonist (sulpiride, 100 mg/kg). Sixteen hr after the last injection, levels of DYN and ENK in the striatum and substantia nigra were dertermined by RIA.The results indicate that D-1 receptors mediate excitatory control over the biosynthesis of striatonigral DYN and also exert a tonic inhibitory influence on the ENK system. Furthermore, stimulation of the D-2 subtype imposes an excitatory stimulus on ENK biosynthesis but has no effect on DYN.

151.3

MODULATION OF STRIATAL PREPROENKEPHALIN MRNA LEVELS BY THE D2 DOPAMINE RECEPTOR. **A.E. Pollack and G.F. Wooten. Dept. of Neurology, U.Va., Charlottesville, Va. 22908.**

Striatal preproenkephalin (PPE) mRNA levels increase ipsilaterally to a 6-hydroxydopamine (6-OHDA) lesion of the substantia nigra pars compacta both 5 days (d) (Eur. J. Pharm., 130:341, 1986) and 14 d post lesion (dpl) (PNAS 83:9827, 1986). We examined whether administration of quinpirole, a D2 agonist, could attenuate this elevation in striatal PPE mRNA ipsilateral to a nigral lesion. Rats received a unilateral sterotaxic injection of 6-OHDA (2 μl, 4 mg/ml) and their striata processed for RNA extraction. PPE mRNA of ipsi- and contralateral striata were compared by dot blot hybridization with a ^{32}P-labeled 30mer oligonucleotide probe complementary to PPE mRNA. Striatal PPE mRNA ipsilateral to the lesion increased 87% at 7 dpl and 25% at 14 dpl compared to the contralateral striatum. Rats killed 8 dpl that received quinpirole (1 mg/kg/2x day, s.c.) for 7 d demonstrated only a 47% increase in ipsilateral striatal PPE mRNA which was different from the untreated 7 dpl rats (p<0.01). In contrast, 14 dpl rats treated with quinpirole (5 mg/kg/2x day, s.c.) for the last 8 d demonstrated a 38% increase in ipsilateral striatal PPE mRNA which did not differ from controls. These results suggest that occupation of the D2 receptor for 7 d with quinpirole beginning 1 d following a 6-OHDA lesion attenuated the effect of dopamine denervation on striatal PPE mRNA levels, whereas quinpirole treatment for 8 d beginning 6 d following a 6-OHDA did not. This evidence suggests that striatal D2 dopamine receptor occupation regulates PPE gene expression.

PLASMA HYDROLYSIS OF [LEU]- AND [MET]ENKEPHALIN IN THE MOUSE. S. Shibanoki*[1], S.B. Weinberger[2], G. Schulteis[2], K. Ishikawa*[1], and J.L. Martinez, Jr.[2]. (SPON: C. Bakhit). [1]Dept. Pharmacol., Sch. of Med., Nihon Univ., Tokyo 173, JAPAN; [2]Dept. Psychol., Univ. of Calif., Berkeley, CA 94720.

Using HPLC-ECD, we determined the enzymatic hydrolysis of [leu]enkephalin (LE) and [met]enkephalin (ME) in mouse plasma in vitro by measuring accumulation of Tyr, Tyr-Gly (TG), and Tyr-Gly-Gly (TGG). Hydrolysis of both enkephalins yielded all three metabolites, although only very small quantities of TG were formed from either substrate. Hydrolysis of ME led to greater production of Tyr and TGG than did hydrolysis of LE. LE was hydrolyzed more slowly than was ME; the half-lives of the two enkephalins were 14 and 5 mins, respectively. By contrast, LE and ME have similar half-lives (1.5 mins) in the rat. TGG formation from both enkephalins was reduced approximately 90% by thiorphan (100 μM), an "enkephalinase" inhibitor. Captopril (100 μM), an angiotensin converting enzyme inhibitor, was less effective than thiorphan at reducing TGG formation. In addition, captopril produced a larger reduction in LE than in ME formation of TGG. Although "enkephalinase" does not hydrolyze LE in rat plasma (J. Pharmacol. Exp. Therap. 247, 129, 1988), this enzyme may be involved in the hydrolysis of LE and ME in mouse plasma.

151.5

PLASMA HYDROLYSIS OF [LEU]- AND [MET]ENKEPHALIN IN THE RAT. S.B. Weinberger[1], S. Shibanoki*[2], K. Ishikawa*[2], and J.L. Martinez, Jr.[1]. [1]Dept. Psychol., Univ. of Calif., Berkeley, CA 94720; [2]Dept. Pharmacol., Sch. of Med., Nihon Univ., Tokyo 173, JAPAN.

Hydrolysis of [leu]enkephalin (LE) and [met]enkephalin (ME) in rat plasma in vitro was determined using HPLC-ECD to measure Tyr, Tyr-Gly (TG), and Tyr-Gly-Gly (TGG) formation. LE and ME were rapidly hydrolyzed to form Tyr, TG, and TGG, and the half-lives of both enkephalins were approximately 1.5 min. Bestatin (500 μM), an inhibitor of aminopeptidase M, completely blocked formation of Tyr from both LE and ME. Puromycin, an inhibitor of aminopeptidase MII, only reduced Tyr accumulation at a concentration (5 mM) that also reduced TG and TGG formation, suggesting that puromycin was not selective at this concentration and that aminopeptidase MII does not participate in enkephalin hydrolysis in rat plasma. Although LE and ME did not differ in Tyr or TG formation, the formation of TGG from ME hydrolysis was greater than that from LE hydrolysis. Captopril (100 μM), an angiotensin converting enzyme (ACE) inhibitor, reduced TGG formation from both enkephalins, without reducing TG levels. These results suggest that similar enzymes are involved in the hydrolysis of LE and ME in rat plasma, although ACE plays a larger role in the hydrolysis of ME than it does in the hydrolysis of LE. (Supported by NIDA #DA04195 and #DA04795)

151.6

PLASMA HYDROLYSIS OF [LEU]ENKEPHALIN (LE) IN THE CHICK. G. Schulteis, K.A. Nudelman*, E.L. Bennett, M.R. Rosenzweig & J.L. Martinez, Jr. Dept. of Psychology, University of California, Berkeley, CA, 94720.

Prior to initiating studies on the effects of peripherally administered LE on learning and memory in chicks, we measured hydrolysis of ^{3}H-LE in plasma obtained from trunk blood of 2-day-old chicks. TLC was used to separate LE from its metabolites (Behav Neurosci, 102:404, 1988). LE was hydrolyzed with a 1/2-life of 1 min. The aminopeptidase M (Amino M) inhibitor bestatin (1.5 mM) inhibited 95-97% of LE hydrolysis. Either captopril (0.1-1 mM), an inhibitor of angiotensin converting enzyme (ACE), or thiorphan (1mM), an inhibitor of "enkephalinase" ("ENKase"), in combination with bestatin (1.5 mM) inhibited 10% of the remaining LE hydrolysis (<1% of total LE hydrolysis). The Amino MII inhibitor puromycin (5 mM) reduced LE hydrolysis 48-62%; the combination of puromycin (5 mM) and bestatin (1.5 mM) was no more effective in inhibiting LE hydrolysis than bestatin alone, suggesting a nonspecific action of puromycin on Amino M. In chick plasma, LE is degraded almost entirely by Amino M, ACE and "ENKase" activities account for <1% of LE hydrolysis, and Amino MII plays no detectable role in LE hydrolysis. This pattern of enzymatic LE hydrolysis differs from that seen in rat or mouse plasma (Shibanoki et al., Weinberger et al., this volume). (Supported by DA 04795, DA 04195, & DA 05334)

151.7

UPTAKE AND METABOLISM OF ^{3}H-[LEU]ENKEPHALIN AFTER EITHER I.P. OR S.C. INJECTION IN MICE. P.H. Janak, G. Schulteis, & J.L. Martinez, Jr. Dept. of Psychology, University of California, Berkeley, CA 94720.

In vitro studies of [leu]enkephalin (LE) hydrolysis in mouse plasma showed that LE has a half-life of 9.3 min. In order to characterize LE hydrolysis in vivo, mice received either intraperitoneal (IP) or subcutaneous (SC) injections of 30 µg/kg ^{3}H-LE. Trunk blood was collected by decapitation at 1,2,5,7.5,10,20 min after peptide administration. Total amount of ^{3}H was measured in 40 µl of each sample; the percent of LE hydrolysis was determined in another 40 ul of each sample using TLC to separate LE from its metabolites. Plasma uptake of ^{3}H differed between IP and SC injections, peaking at 5 min after IP, and 10 min after SC injection. By 1 min after IP injection, 95% of the ^{3}H in plasma was in the form of LE metabolites, while following SC injection the 95% metabolism level was not reached until 5 min postinjection. These hydrolysis rates are faster than those determined for mouse plasma in vitro and are similar to LE hydrolysis rates measured in the rat in vivo. These results are important for the interpretation of studies examining the behavioral effects produced by peripheral injection of LE. (Spon. by NIDA # DA 04195 and DA 05334)

CONFORMATIONAL CHARACTERISTICS OF PROENKEPHALIN PEPTIDES E, B, AND F. H.J. Hiddinga*, G.E. Katzenstein*, C.R. Middaugh*, and R.V. Lewis. Dept. of Molecular Biology, Univ. of Wyoming, Laramie, WY 82071.

The conformations of three adrenal medulla enkephalin containing polypeptides (ECPs) were investigated to gain an understanding of their potential structure-activity relationship. Secondary structure characteristics of peptides E, B, and F were examined by circular dichroism (CD) under conditions designed to mimic both their soluble state and the anisotropic environment which exists at the biological effector site. The conformational differences between the three peptides was further determined by Fourier Transform Infrared Spectroscopy (FTIR). Although all three peptides have similar structure and apparently exist in random configurations in aqueous solutions, they exhibit the potential to assume conformations which are unique to the individual peptide. The conformational differences may be important factors in determining their unique biological activities.

151.9

ROLE OF ARG 747 AND ARG 102 IN THE ACTIVE SITE OF NEUTRAL ENDOPEPTIDASE-24.11 (ENKEPHALINASE) INVESTIGATED BY SITE-DIRECTED MUTAGENESIS. A. BEAUMONT*, T. BENCHETRIT*, H. LE MOUAL*†, G. BOILEAU*†, P. CRINE*† and B.P. ROQUES*. (SPON: J.J. Vanderhaeghen). U 266 INSERM, UA 498 CNRS, UER des Sciences Pharmaceutiques, 4 av. de l'Observatoire, 75006 Paris, France. † Lab. Biochimie, Univ. Montreal, Québec H3C 3J7.

Neutral endopeptidase 24.11 (NEP) is a Zn-ectoenzyme which, in the central nervous system, participates in the inactivation of the opioid peptides, methionine and leucine enkephalin. Chemical modifying agents have been used to show the presence of an arginine residue(s) at the active-site of NEP, thought to participate in substrate binding, and Arg747 and Arg 102 have both been proposed to fulfill this role (Benchetrit et al., Biochemistry 27, 5921, 1987, L. Hersh, personal communication).

Met 747 NEP and Met 102 NEP have now been synthesized by site-directed mutagenesis and their activity compared to that of the wild-type enzyme. The Km of the substrate [^{3}H]-D-Ala^{2}-leucine enkephalin was increased for both enzymes as were the IC_{50}s of several NEP inhibitors. The activity of Met 102 NEP however was still affected by the arginine-modifying reagent butanedione, whilst that of Met 747 NEP was unchanged. It is suggested that both of these residues play a role at the active site of NEP.

151.10

A SOLUTION HYBRIDIZATION (SH) METHOD FOR THE QUANTITATION OF RAT PREPROENKEPHALIN mRNA (PPmRNA). Y.S. Zhu*, A.D. Branch*, H.D. Robertson*, T.H. Huang*, S.O. Franklin* and C.E. Inturrisi. Cornell Univ. Med. Coll. and The Rockefeller Univ., New York, N.Y. 10021.

To facilitate study of the regulation of opioid peptide gene expression, a SH method was developed for rapidly quantitating PPmRNA. A 32P-labeled riboprobe for rat PPmRNA was prepared from the pYSEA1 template and purified by use of a CF11 column. This riboprobe hybridized to a single 1.5 kb band using Northern blot analysis of total cellular RNA. For SH the labeled riboprobe is added to a tissue extract containing the mRNA of interest; unhybridized riboprobe is degraded with RNases; protected hybrids are collected by filtration and counted. A PPmRNA sense transcript is used as a calibration standard. Optimal hybridization conditions (16 hrs at 75°C) were defined and did not differ for the calibration standard and the PPmRNA of rat striatum. Both fully protect the 0.97 kb riboprobe. The hybridization conditions produced a linear curve ranging from 1.25 to 160 pg. PPmRNA was measured in total cellular RNA extracts from individual rat tissues that express PPmRNA and in explants of rat adrenal medullae. These results demonstrate the sensitivity and utility of this SH assay and its application to multi-sample analysis. (Supported in part by USPHS.NIDA Grants DA-01457 and DA-05130.)

POSTTRANSLATIONAL PROCESSING OF PROENKEPHALIN IN A HUMAN NEUROBLASTOMA CELL LINE, SK-N-MC. I.Lindberg and E.Shaw* Dept. of Biochemistry & Mol. Biol.,L.S.U. Med. Ctr., New Orleans, LA 70112

Several groups have recently shown that the SK-N-MC cell line contains enkephalins at concnetrations greater than any cell line yet described. We have analyzed the biosynthesis of enkephalins in this cell line and confirmed this finding. However, enkephalin biosynthesis in this cell line appears to be unusual in several respects. Firstly, these cells store an extremely small proportion of their enkephalins; more than 95% of total enkephalin is detected in the medium rather than in the cells after a two day incubation. Secondly, gel filtration of media samples in combination with radioimmunoassays for all of the penta- to octapeptide enkephalins revealed the presence of only two major immunoreactive species, namely peptides with elution positions corresponding to proenkephalin (2/3 of total) and Peptide B (1/3 total). Only trace quantities of other proenkephalin-derived peptides were observed. SK-N-MC cells thus apparently carry out only limited cleavage of proenkephalin. We also examined the potential phosphorylation and glycosylation of proenkephalin by incubation of cells with labelled inorganic phosphate and methionine followed by immunoprecipitation with Peptide B anitserum. These isotopes were incorporated into 34-38 kDa cellular and secreted polypeptides. The SK-N-MC cell line therefore represents an interesting system for the study of early processing events in enkephalin biosynthesis.

151.12

REGULATION OF CLEAVAGE OF THE N-TERMINUS OF BOVINE PRO-OPIOMELANOCORTIN BY GLYCOSYLATION. N.P. Birch*[1], H.P.J. Bennett*[2], F. Estivariz*[3], P.J. Lowry*[3] and Y.P. Loh[1]. [1]Lab. Dev. Neurobiol., NICHD, NIH, Bethesda, MD 20892, [2] Endo. Lab., Royal Victoria Hosp. and Depart. of Med., McGill University, Montreal, Quebec, Canada,[3] Dept. of Physiol. and Biochem., Univ. of Reading, Reading, England.

The amino terminus of bovine pro-opiomelanocortin (N-POMC1-77) is partially processed in the intermediate lobe of the pituitary to N-POMC1-49 and Lys-γ_3MSH. Seger and Bennett (*J. Steroid Biochem* 25:703, 1986) purified two species of N-POMC1-77 which were either glycosylated or non-glycosylated at Thr45. However, only non-glycosylated N-$POMC_{1-49}$ was detected leading to the proposal that differential O-linked glycosylation of N-POMC1-77 may regulate cleavage at the Arg49-Lys50 processing site. To test this hypothesis purified bovine intermediate lobe N-POMC1-77 enriched in either the O-linked or non-O-linked form was incubated with a purified bovine aspartic protease (POMC converting enzyme) which has previously been shown to cleave POMC at paired basic residues (Loh, Y.P. et al. *J. Biol. Chem* 260:7194, 1985) Analysis of the cleavage products using a γ_3MSH radioimmunoassay showed a 6- to 8-fold greater increase in generation of γ_3MSH immunoreactivity using the non-O-glycosylated substrate compared with the O-glycosylated form. High performance liquid chromotagraphic analysis demonstrated that this material co-migrated with Lys-γ_3MSH, indicating that cleavage occurred between the pair of basic amino acids. These data support a role for differential O-linked glycosylation in the regulation of processing of the N-terminus of bovine POMC.

THE ONSET OF PROOPIOMELANOCORTIN (POMC) PROCESSING AND IDENTIFICATION OF CLEAVED PRODUCTS IN DEVELOPING MOUSE EMBRYOS. R.A.RIUS*, T.CHIKUMA* and Y.P.LOH (SPON: J.S.GUTKIND). Lab. of Dev. Neurobiol., NICHD, Bethesda, MD 20892.

Previous findings using in situ hybridization have indicated that POMC mRNA expression during mouse development begins at embryonic day (E) 10.5; at the same time, immunocytochemical analysis revealed the presence of POMC-translated products in the CNS. Expression of POMC mRNA was seen in anterior pituitary at E12.5 and greatly increased by E14.5. In the intermediate lobe, POMC mRNA was first detected at E14.5 (Elkabes, S., Dev. Brain Res. 46:85, 1989). The aim of this study was to follow the post-translational modification of POMC during prenatal development. Embryos were obtained from pregnant mice at different gestational days and extracted for analysis of POMC-related materials by SDS-PAGE and h.p.l.c., followed by radioimmunoassay using several antibodies. Analysis with SDS-PAGE indicated that at E10.5 only POMC was present. Processed products were first seen at E11.5 although POMC was also present. By E12.5 only processed products were detectable. H.p.l.c. analysis of ACTH/MSH products present at E11.5 revealed the presence of ACTH 1-39, des-acetyl α-MSH and ACTH 1-14 but no α-MSH. A similar pattern of processed products were also observed at E12.5 except that the amounts were increased. By E14.5 there was a large increase in ACTH 1-39 consistent with the proliferation of anterior pituitary lobe cells seen at this stage. This study indicate that during development there is a time lag between POMC biosynthesis and processing. Proteolytic cleavage of ACTH 1-39 to ACTH 1-14 and formation of des acetyl α-MSH appear to occur as soon as POMC processing begins.

151.14

REGULATION OF OPIOID PEPTIDES AND NEUROTENSIN IN THE RAT BRAIN. M. E. Abood*, J. Eberwine*, E. Erdelyi*, J. D. Barchas and C. J. Evans, Nancy Pritzker Laboratory, Department of Psychiatry, Stanford University, Stanford, CA 94305.

Dopaminergic antagonists increase the levels of opioid peptides in the rat brain striatum and neurotensin in the nucleus accumbens and striatum. We were interested in determining the effect of dopaminergic agonists as well as antagonists on opioid and neurotensin peptide gene expression in these areas. In order to facilitate these studies, we have developed a method to measure peptides and mRNA from the same tissue extracts. Initially, we determined the effects of haloperidol and bromocriptine on preproenkephalin mRNA and total opioid peptides (as measured by an immunoassay directed to the N-terminus of all endogenous opioid peptides) in various rat tissues. We saw significant changes in striatum only. Subsequently, we examined the effect of a selective D1 antagonist, SCH23390, on opioid peptide gene expression in rat brain striatum. We have developed an immunoassay that allows us to measure neurotensin in extremely low concentrations in tissues, and have examined the regulation of neurotensin levels in striata of rats treated with dopaminergic drugs. In addition, we are examining the effects of these drugs on neurotensin mRNA levels in rat brain.

PAIN MODULATION: SPINAL OPIOID MECHANISMS

152.1

THE SPINAL ANALGESIC PROPERTIES OF THE MU AGONIST, DAMPGO, IN ACUTE AND CHRONIC PAIN. L.J. Spanos, J. Stafinsky and T. Crisp. Dept. of Pharmacology, N.E. Ohio Univ. Coll. of Med., Rootstown, Ohio 44272.

The present study: (1) evaluated the validity of computerized activity analysis to determine the spinal analgesic efficacy of the mu receptor-selective agonist, DAMPGO, in arthritic rats and (2) compared tolerance development to the analgesic effects of DAMPGO after repeated intrathecal (i.t) injections in arthritic (AA) and non-arthritic (NA) rats using the tail-flick assay (TFL). Male Sprague-Dawley rats (340-400 g) were cannulated with indwelling PE-10 catheters for i.t. drug injections, and were inoculated with Mycobacteriacum tuberculosis in Freund's adjuvant to induce arthritis. NA control animals were inoculated with incomplete adjuvant. Daily i.t. injections of DAMPGO (0.3 nmol/10μl) were administered to animals from day 7 to day 15 post-inoculation. Drug-treated AA rats displayed increases in locomotor activity when compared to saline-treated AA controls ($p<.05$). TFL scores in response to DAMPGO revealed that NA rats developed tolerance by the 12th injection while AA rats did not show significant tolerance development until the 14th injection of the drug.

152.2

LABELLING OF THE PROJECTION OF THIN AFFERENT FIBERS FROM A SINGLE DORSAL ROOT IN THE SUPERFICIAL LAYERS OF THE RAT DORSAL HORN USING A HIGHLY MU-SELECTIVE OPIOID LIGAND. D. BESSE, M.C. LOMBARD, J.M. ZAJAC, B.P. ROQUES and J.M. BESSON. INSERM U161 and EPHE 2, rue d'Alésia 75014 Paris and INSERM U266 4, av de l'Observatoire 75006 Paris.

Radioautographical and biochemical studies have demonstrated that opioid receptors are, to a large extent, located on thin primary afferent fibers. We have postulated that opioid binding sites could be putative markers to visualize and to quantify the distribution of thin afferent fibers in the rat superficial dorsal horn (laminae I and II). We labelled μ binding sites with (^{3}H)DAGO (3nM) and used a quantitative radioautographic technique. Previously, using the same ligand, we found that in the C7 segment, 76±1% of the total μ binding sites were located presynaptically. The extent of the projections of the C7 root in the spinal segments was evaluated by comparing the binding values in 4 experimental situations: intact rats and rats submitted to a variety of rhizotomies (C4-Th2, C4-Th2 sparing C7 and C7 alone). 8 days after the lesion, the projections of the C7 root, measured every 120 μm over 7 segments were as follows: 4% in C4, 8% in C5, 21% in C6, 42% in C7, 13% in C8, 8% in Th1 and 4% in Th2 segment. These measurements are highly reliable since similar results were obtained when comparing the paired lesions C4-Th2/C4-Th2 sparing C7 and intact/C7 alone. Results will be presented for 1, 2 weeks, 1, 3 months after the lesion.

152.3

INVOLVEMENT OF THE MU-OPIATE RECEPTOR IN PERIPHERAL ANALGESIA. Y.O. Taiwo* and J.D. Levine*. (SPON: T.J. Coderre) Dept. of Medicine, University of California, San Francisco CA 94143

Analgesic effects of opiates injected directly into injured and inflamed tissue suggest that they act at a peripheral as well as a central site. In this study we have evaluated their effect on the hyperalgesia induced by the inflammatory mediator prostaglandin E_2 (PGE_2). The intradermal injection of mu (morphine, DAGO and morphiceptin), kappa (U-50,488H) and delta (DPDPE and DSLET) selective opioid-agonists (10ng-10ug), by themselves, did not significantly affect the mechanical nociceptive threshold in the hindpaw of the rat. Intradermal injection of mu, but not delta or kappa opioid-agonists, however, produced dose-dependent inhibition of PGE_2 (1ng-1ug)-induced hyperalgesia. The analgesic effect of the mu-agonist morphine was dose-dependently antagonized by naloxone (10ng-10ug) and prevented by co-injection of pertussis toxin (1ug). Morphine did not, however, alter the hyperalgesia induced by 8-bromo cAMP (10ng-10ug). We conclude that the analgesic action of opioids on the peripheral terminals of primary afferents is via a binding site with characteristics of the mu-opioid receptor and that this action is mediated by inhibition of the cAMP second messenger system.

152.4

TOLERANCE TO THE ANTINOCICEPTIVE EFFECT OF INTRATHECAL MORPHINE IN INTACT AND CHRONIC SPINAL RATS. **C. Advokat, D. Flershem* and J. Siuciak. Dept. of Pharmacology, University of Illinois, College of Medicine, Chicago, IL. 60612.**

The antinociceptive effect of acute, daily intrathecal morphine injections on the tail flick (TF) withdrawal response was compared in intact rats and rats that were spinally transected for 20-30 days (chronic spinal rats). There was no difference in the initial antinociceptive response of intact and chronic spinal rats to acute intrathecal injections of either 5 μg, 15 μg or 30 μg of morphine. During four successive days of administration the response of chronic spinal rats declined significantly (became tolerant) to each of the three doses of intrathecal morphine. Intact rats did not become tolerant to these treatments. Spinal rats, made tolerant to repeated intrathecal morphine injections were not "cross-tolerant" to a subcutaneous injection of 6.0 mg/kg of morphine. The difference between intact and chronic spinal rats in the development of tolerance to spinal morphine administration suggests that supraspinal mechanisms mediate the development of tolerance to morphine-induced antinociception in the spinal cord.

152.5

ADENOSINE RELEASE FROM THE SPINAL CORD MAY MEDIATE ANTINOCICEPTION BY INTRACEREBROVENTRICULAR MORPHINE. M.I. Sweeney, T.D. White and J. Sawynok. Dept. of Pharmacology, Dalhousie University, Halifax, N. S., Canada. B3H 4H7.

Adenosine release from the spinal cord may mediate antinociception produced by intrathecal (i.t.) morphine (JPET 243:657, 1987). Recently it has been shown that antinociception produced by intracerebroventricular (i.c.v.) morphine is blocked by i.t. theophylline, suggesting that adenosine release also may be involved in antinociception by supraspinal morphine (JPET 239:88, 1986). In this study we have examined this hypothesis directly. For behavioral tests, drugs were injected via chronically implanted i.t. or i.c.v. cannulas in rats, and nociceptive latencies measured using the tail-flick and hotplate tests. In release studies, the i.t. space was perfused with artificial csf, and perfusates assayed for adenosine content using HPLC. Morphine 30μg i.c.v. produced antinociception in the tail-flick and hotplate tests which was inhibited by i.t. 8-phenyltheophylline 0.3μg, 3μg, and theophylline 5μg. However, the effect of theophylline was biphasic, since 50μg potentiated this action of morphine. Morphine 30μg i.c.v. released adenosine from the intact spinal cord in 5 of 8 rats. These data suggest that activation of descending systems by i.c.v. morphine produces an increase in the release of adenosine from the spinal cord which may contribute to antinociception. (Supported by MRC of Canada).

152.6

Spinal opioid effects are enhanced in a model of unilateral inflammation. J.L.K.Hylden, G.M.Herrera* and R. Dubner. Neuorbiology & Anesthesiology Branch, NIDR, NIH, Bethesda, MD. 20892.

The present work addresses the possibility that unilateral carrageenan (CARRA)-induced inflammation/hyperalgesia, and its concomitant alterations in spinal cord opioid peptides, is associated with an increase in the analgesic efficacy of opioid agonists at the spinal level. Opioid agonists were administered via intrathecal (i.t.) catheters to rats at 3 or 24 h after CARRA (2-6 mg in 0.2 ml saline, s.c. into the plantar surface). Rats were tested for cutaneous hyperalgesia or analgesia by measuring the paw withdrawal latency to a thermal stimulus. The dose-response curves of opioid agonists with mu- and/or delta-receptor selectivity (DADL, 0.3-3 μg; DAGO, 3.3-100 ng; DPDPE, 5-50 μg) were shifted to the left in rats with inflamed hindpaws, when compared to control. This enhanced analgesic effect was only observed in inflamed paws at the time of maximal inflammation (3 h) and was not apparent after the inflammation had resolved (24 h). The kappa agonist U50,488H (10-100 μg) was not analgesic in this assay. The opioid antagonist naloxone (10 μg, i.t.) failed to alter paw withdrawal latencies of either inflamed or non-inflamed paws. The long-term systemic antagonist naltrexone (5-10 mg/kg, s.c.) likewise had no effect on the hyperalgesic response of inflamed paws, but significantly decreased the withdrawal latencies of contralateral, uninflamed paws. The data show that mu- and delta-opioid agonists have enhanced analgesic efficacy at the spinal level during conditions of inflammation.

152.7

OPIOID BINDING IN RAT SPINAL CORD: EFFECTS OF EXCITATORY AMINO ACIDS. L. Lichtblau, S. Lei and G. L. Wilcox, Department of Pharmacology, University of Minnesota, Minneapolis, MN 55455.

Opioid agonists act within the spinal cord to produce analgesic effects, some of which involve selective interactions with excitatory amino acids. The properties of opioid binding sites in membranes from rat spinal cord were examined at physiological temperature and ion concentrations, and the susceptibility of this binding evaluated for modulation by excitatory amino acid agonists.

Adult male Sprague-Dawley rats were decapitated and their spinal cords removed to ice. The tissue was homogenized with a Dounce Homogenizer and centrifuged at 1000 x g for 10 min at 4°C. The supernatant was then centrifuged at 100,000 x g for 60 min at 4°C. The resulting membrane pellet was resuspended in 10 volumes of buffer and stored frozen at -70°C. Each assay tube (1 ml) contained approximately 500 μg membrane protein. [^{3}H]-naltrexone (NTX; 13.66 Ci/mmol) binding was carried out in a Krebs-HEPES buffer (pH 7.4 at 37°C) for 25 min. Saturation and competition data were analyzed by computer.

Under the above conditions, the apparent dissociation constant (K_d) of [^{3}H]-NTX was 0.77nM and the number of binding sites (B_{max}) was 52 fmol/mg protein. These data are comparable to other studies in mouse brain and spinal cord, but the binding conditions allow manipulations of agonist binding by other ligands. Competition for binding by various ligands (see table below) suggest that [^{3}H]-NTX binding in rat spinal cord under physiological conditions occurs with greatest affinity to μ receptors.

Ligand	Receptor	K_i (nM)
Naloxone	μ,κ,δ	1.4
[D-Ala^2, N-Me-Phe^4, Gly^5-ol]-enk (DAMGO)	μ	22.9
U50,488	κ	3007
[D-Pen^2, D-Pen^5]-enkephalin (DPDPE)	δ	5500

Further analysis suggests that DAMGO displaces NTX with two distinct affinities. NMDA but not AMPA increased the proportion of binding sites in the high affinity state.

OPIOID INHIBITION OF EXCITATORY AMINO ACID (EAA) AGONIST-INDUCED EXCITATION OF RAT SPINAL PROJECTION NEURONS. S. Lei and G. L. Wilcox, Dept Pharmacology, Univ Minnesota, Minneapolis, MN 55455.

We have previously observed excitation of spinal nociceptive neurons by N-methyl-D-aspartate (NMDA) and the quisqualate receptor agonist, (RS)-alpha-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid HBr, (AMPA), using electrophysiological techniques. The μ opioid agonist, [D-Ala^2, N-Me-Phe^4, Gly^5-ol]-enk (DAMGO) more uniformly inhibited NMDA-induced excitation than did morphine. The present study tested DAMGO for inhibition of EAA-induced excitation and the effects of EAA agonists on responses to natural peripheral stimulation.

Extracellular recordings were conducted *in situ* in the spinal cord of urethane-anesthetized male rats. 1.5 MΩ tungsten microelectrodes glued to seven barreled borosilicate glass microelectrodes were used to record from single spinal neurons and to apply various drugs iontophoretically. Thirteen of 22 cells tested dose-dependently responded to iontophoretically administered NMDA. DAMGO currents, superimposed on repeated NMDA pulses, inhibited NMDA-induced excitation in 8 of 11 neurons tested. Eleven of 18 cells tested showed increasing firing rate upon the ejection of AMPA, but AMPA-elicited excitation was reduced by DAMGO in relatively few cells (2 of 6). Four cells (all WDR) which responded to both NMDA and AMPA, were tested with DAMGO. Although DAMGO altered NMDA-elicited firing in all the cells, none of the cells' responses to AMPA was inhibited by DAMGO.

Subthreshold currents of NMDA increased peripheral stimulation-induced firing in six of eleven neurons tested. Subthreshold currents of AMPA increased stimulation-induced firing in 3 of 5 neurons tested. Subthreshold currents of iontophoretically applied NMDA greatly increased noxious thermal stimulation-evoked firing (50°C).

This evidence is in agreement with previous behavioral studies DAMGO to inhibit NMDA-elicited effects more selectively than AMPA-elicited effects. Thus, μ opioid agonists may selectively block NMDA receptor-mediated responses. That both NMDA and AMPA at subthreshold doses can increase responses to noxious peripheral stimulation supports the hypothesis that EAAs act as nociceptive neurotransmitters in the mammalian spinal cord and that NMDA and AMPA receptors have an important role in mediating spinal nociceptive transmission.

152.9

Differential tolerance between the spinal mu opioid agonists morphine and sufentanil, correlation with drug efficacy. *Sosnowski, M., Yaksh, T.L. (SPON P. Wilson). Dept of Anesthesiol, Univ. Calif. San Diego, La Jolla, CA 92093.

Chronic exposure of spinal opioid receptors to an intrathecal (IT) agonist results in a progressive loss of effect (tolerance). Speculatively, the degree of shift of the agonist dose response curve should be proportional to the magnitude of receptor down regulation and this in turn inversely related to the size of the spare receptor population. In previous work with the non-competitive mu receptor ligand, βFNA, we showed that for spare receptors: Suf > Mor (Soc Neurosci Abst: 14: 32, 1988). Rats pre-pared with IT catheters and osmotic infusion minipumps were infused with saline (Sal) or equiactive concentrations of Mor: 20 nmol/ul/h or Suf: 0.6 nmol/ul/h. After 7 days of IT infusion, IT dose response curves on the HP test for Mor or Suf were carried out in Sal, Mor and Suf infused animals. Each animal was used for one dose of one drug. After continuous infusion of Mor or Suf, the greatest shift relative to Sal infused animals (Tol Ratio) was observed in Mor infused animals and least in Suf animals.

Test drug	Sal Infused	Mor Infused	Suf Infused
Mor ED50 (nmol):	0.65	30.0	6.10
Tol Ratio		46.1	9.5
Suf ED50 (nmol):	0.07	0.68	0.21
Tol Ratio:		9.7	3.0

These observations are consistent with work indicating that Mor 1) possesses few spare receptors as compared to Suf and 2) down regulates more of its receptor population than Suf in producing an equivalent magnitude of analgesia. (DA02110).

DELTA RECEPTOR INVOLVEMENT IN MORPHINE SUPPRESSION OF NOXIOUSLY EVOKED ACTIVITY OF SPINAL WDR NEURONS IN CATS

K. Omote,* L.M. Kitahata, J.G. Collins, K. Nakatani,* Dept. of Anesth., Yale Sch. of Med., New Haven, CT 06510

Complex pharmacology associated with modulation of sensory information at the level of the spinal cord provides an opportunity for the development of more effective ways to block the processing of pain information. The purpose of this study was to evaluate the relative role of mu and delta opiate receptors in morphine suppression of noxiously evoked activity of spinal WDR neurons.

This protocol was approved by the Yale Animal Care and Use Committee. Extracellular single WDR neuronal activity evoked by noxious radiant heat was recorded in decerebrate spinally transected cats. All drugs were administered spinally. Pretreatment with B-FNA an irreversible, selective mu antagonist, antagonized the suppressive effects of the selective mu agonist DAGO, but not the selective delta agonist DPDPE. As expected, pretreatment with B-FNA significantly antagonized the effects of spinally administered morphine on noxiously evoked activity of WDR neurons. In addition, however, co-administration with morphine of ICI 174, 864, a selective delta antagonist, in the B-FNA pretreated animals produced an even greater antagonism of morphine's ability to suppress noxiously evoked activity than observed in the absence of the delta antagonist.

The results of this study support the hypothesis that morphine is capable of suppressing noxiously evoked activity at the level of the spinal dorsal horn, not only through an interaction with mu receptors, but also as a result of interaction with systems that are antagonized by ICI 174, 864 assumably delta receptors.

YOHIMBINE ADMINISTERED INTRATHECALLY (i.th.) REVERSES BOTH OPIOID AND NONOPIOID CONDITIONAL ANTINOCICEPTION (CA) IN RATS. A. H. Lichtman and M. S. Fanselow. Dept. Psych, Dartmouth College, Hanover, NH 03755, and Dept. Psych, UCLA, LA, CA 90024.

The present study examined whether the relative amount of training is a factor in activating opioid and nonopioid mediated CA. During the acquisition phase, a daily tail flick latency was assessed 2 min prior to 3 electric grids shocks (2 mA, .75 s duration, 20 s iti). Control animals were given a daily tail flick test followed by an equivalent period of time in the chamber. When a rat's tail flick latency exceeded 10% of the maximal possible analgesic effect it was tested either the next day or after 2 more acquisition days. On the test day, half the subjects in each group were administered naltrexone (7 mg/kg, ip) and the rest received saline. The efficacy of naltrexone in attenuating CA was inversely related to the amount of training that they had received during acquisition.

In Experiment 2, we examined the neurochemical mechanisms underlying CA at the spinal level. Both forms of CA were completely prevented by administration of the noradrenergic antagonist yohimbine (100 µg, i.th.). In contrast, neither quaternary naltrexone (10 µg, i.th.) nor the 5-HT antagonist methysergide (50 µg, i.th.) had consistent effects across the entire test session. These results indicate that a critical noradrenergic synapse, at the spinal level, is in the final common pathway of both opioid and nonopioid mediated CA.

152.12

INTRATHECAL OPIOIDS IN THE RAT MECHANICAL VISCERAL PAIN MODEL R.W. Colburn*, J.A. DeLeo, D.W. Coombs,C.J. Winfree*
Anesthesia Research Laboratory, Department of Anesthesiology, Dartmouth-Hitchcock Medical Center, Hanover, NH 03756

Pharmacologic profiles of the opiate receptor systems suggest a differential association of mu, delta, and kappa receptors with visceral chemical and cutaneous thermal stimuli in the rat. The current study attempts to profile the association of these opioid receptors with a visceral mechanical stimulus(duodenal distention).

Each 250g Holtzman rat was implanted with a duodenal balloon catheter and a PE-10 intrathecal(i.t.) catheter. Five to thirty minutes prior to testing rats were infused i.t. with 10 µl of drug or vehicle followed by 10 µl of saline flush. Testing consisted of 5 intraduodenal balloon pulses (0.5-0.85 ml) followed by one minute held inflation. Writhing response was graded on a 0-4 behavioral scale and reported as percent of control response(%CR) for each treatment group (n≥6rats/group). Agents studied were mu-agonists: morphine and [Tyr-d-Ala-Gly-(Me)Phe-Gly-ol] (DAGO), delta-agonist: [D-Pen^2, D-Pen^5] enkephalin (DPDPE), and kappa-agonists: U50-488H and beta-Funaltrexamine(b-FNA). Rank order of potency and ED_{60}(ug) were DAGO(.19)>> Morphine(.55)>b-FNA(1.53)>U50-488H(3.09) >DPDPE(5.41). At high doses(10-50ug) the antinociceptive effect of both kappa agonists plateaued (@50-60% CR), while both mu agonists continued with linear responses to the highest dose tested (@20-26% CR). These findings suggest even further differential association of the opioid receptor systems relative to the mechanical (mu mediated) or chemical (mu and kappa mediated) visceral stimulation. Supported by PHS Grant CA 33865 and Hitchcock Foundation Grant HF103.

152.13

EFFECTS OF DYNORPHIN ON THE RESPONSES OF NEURONS IN THE DORSAL HORN OF THE MEDULLA. S.S. Mokha. Dept. of Physiology Meharry Medical College, Nashville, TN 37208.

It has previously been reported that mu and delta opioid receptors are involved in modulating nociceptive input in the dorsal horn of the medulla (Mokha,S.S.,J.Physiol.,398: 85,1988). The present study investigated the effects of dynorphin A(1-13) on the responses of neurons in the dorsal horn of the medulla (trigeminal nucleus caudalis). Extracellular single unit recordings were made in rats anaesthetized with halothane. Nociceptive neurons were activated by thermal stimuli. The effects of intravenously administered dynorphin-(1-13) (0.4-1.6 mg/kg) were tested on the responses of 22 nociceptive and cold receptive neurons. Dynorphin reduced the responses of 8/8 selectively nocireceptive neurons in the superficial laminae of the dorsal horn of the medulla. It reduced the responses in 3/8 multireceptive neurons in the deeper laminae, enhanced the responses in 2/8 and produced a biphasic effect in 2/8 neurons. Dynorphin reduced the activity of 3/7 cold receptive neurons in the superficial laminae, enhanced the activity of 2/7 and produced a biphasic effect in 1/7 neurones. It is concluded that kappa opioid receptors exert a widespread influence on somatosensory informatiom from the face.

KAPPA AND DELTA-OPIOID AGONISTS SYNERGIZE TO PRODUCE POTENT ANALGESIA. C. Miaskowski*, Y.O. Taiwo* and J.D. Levine* (SPON: A.J. Miller), Schools of Nursing, Dentistry and Medicine, University of California, San Francisco CA 94143

A recent study from our laboratory suggests that the analgesic synergy produced by low-dose naloxone and pentazocine is the result of agonists action at delta and kappa opioid receptors, respectively. This study demonstrates that the simultaneous intrathecal administration of a selective kappa (U50,488H) and a selective delta ([D-Pen^{2,5}]-enkephalin, DPDPE) opioid agonist can produce analgesic synergy. The interaction of the analgesic effects of these two agents was studied, in the rat, using the Randall-Selitto paw-withdrawal test. Intrathecal administration of both U50,488H and DPDPE, as single agents, produced dose-dependent increases in mechanical nociceptive threshold. However, when the dose response curves for both U50,488H and DPDPE in the presence of a fixed low-analgesic dose of the other agent were compared with the dose response curves for the respective agonist administered alone, the curves for the combination regimens were shifted to the left. A statistically significant deviation from parallelism between the dose response curves of the single versus the combined agents demonstrates that the simultaneous administration of opioid agonists, that act at kappa and delta opioid-receptor sites, can produce analgesic synergy.

DIFFERENTIATION, MORPHOGENESIS AND DEVELOPMENT: NEUROMUSCULAR DEVELOPMENT

153.1

A QUANTITATIVE DEVELOPMENTAL ANALYSIS OF THE MORPHOLOGICAL ORIENTATION OF MOTONEURONS IN THE CERVICAL REGION OF THE SPINAL CORD. J.B. Taylor and W.J. Anderson. Indiana University School of Medicine, Terre Haute Center for Medical Education, Terre Haute, Indiana, 47809.

Previous investigations in our laboratory have morphologically described compact dendrite bundles in the lumbar and cervical spinal cord of the rat. The cervical dendrite bundle group is composed of three motoneuron dendrite columns including the medial dendrite bundle (MDB), the central dendrite bundle (CDB) and the lateral dendrite bundle (LDB).

A developmental study has been performed using Long Evans Hooded rats, the animals were sacrificed at days 1, 3, 5, 8, 10, 15, 20 and 30. Paraffin tissue was prepared at each of the above ages and stained with H&E. Golgi impregnation according to the method of Anderson and Felton was performed on each of the given ages while epon thick tissue was prepared for ages 5 day and 30 day. This study offers a complete quantitative analysis of the developmental orientation of the motoneurons in each of the three dendrite bundles using the Scholl Analysis technique on the Golgi-impregnated tissue. Results indicate motoneurons initially migrate to their destinations within small clusters of cells. the CDB has been identified at levels C3-C5 as the phrenic nucleus. The CDB cells at day 1 show extensive longitudinal interactions between the various cell clusters. The MDB cells present transverse fiber orientation early and then develop more extensive longitudinal interconnections. The LDB cells present few fibers at day 1, increased transverse projections and later increased longitudinal projections.

153.2

IMMOBILIZATION EFFECTS ON CHOLINERGIC ENZYME ACTIVITY IN EMBRYONIC CHICK LUMBAR SPINAL CORD. L.J. Haverkamp, J.L. McManaman, and S.H. Appel, Dept. of Neurology, Baylor College of Medicine, Houston, TX 77030.

Neuromuscular blockade has been demonstrated to prevent naturally occurring motoneuron death, alter patterns of muscle innervation, delay synapse elimination at poly-innervated junctions, and result in sprouting of stable junctions. We report here that such immobilization during embryonic development also increases choline acetyltransferase (CAT) activity in the lumbar spinal cord.

Daily injection of 2mg curare from E6-9, with sacrifice on E10, resulted in a mean increase of lumbar enlargement (LE) CAT activity to 171% of that of saline injected controls. Continuing the immobilization begun E6 on through E11 resulted in an increase of LE CAT to 240% of control, while immobilization from E10-13 resulted in an increase of LE CAT to 155% of control.

We interpret the increase in CAT seen after E6-9 curare treatment to be primarily the result of an increase in number of motoneurons, due to inhibition of naturally occurring cell death. However, since loss of motoneurons is largely complete by E10, we interpret the additional 70% increase in activity obtained by prolonging immobilization to E11, as well as the increase seen with treatment from E10-13, to be an increase in levels of CAT/motoneuron resulting from immobilization. Experiments are under way to document this possibility.

153.3

BRANCHING PATTERNS OF THE PHRENIC NERVE DURING DEVELOPMENT AND REINNERVATION. A.S. Norton*, P.K. Berger* and M.B. Laskowski. Dept. of Biological Sciences and WAMI Medical Program, Univ. of Idaho, Moscow, ID 83843.

Our previous studies have shown that the phrenic motor column projects topographically onto the surface of the diaphragm. This orderly map is present already at birth and is partially reestablished upon reinnervation. One potential mechanism for establishing topography lies in the choices that growing axons must make at branch points. In this study we asked whether nerves follow stereotypical patterns of branching early in development and upon reinnervation as a partial explanation for topographic specificity. Embryonic phrenic nerve-diaphragm preparations (E-15 to E-21) were aldehyde-fixed and stained with the silver/cholinesterase technique. Invariably even at the earliest stages, the phrenic nerve bifurcates into a rostral and caudal branch, and from the latter emerges a branch to the crus. After this primary bifurcation, however, further branching is asymmetric and variable between right and left sides of the diaphragm and between muscles of siblings. Within this asymmetry, we observed consistent patterns: 1) the complexity of branching increases dramatically with development, 2) higher-ordered branching occurs on the costal side of the primary branch, 3) the midcostal right side is far more arborized than the left. Three weeks after crush, the phrenic nerve remains bifurcated into rostral and caudal primary branches. However, secondary and higher ordered branching follows a markedly different pattern than normal. We conclude that both developing and regenerating phrenic nerves display consistent primary branching, but higher ordered patterns are highly variable. Thus axons in the phrenic nerve whether developing or regenerating are consistently offered a binary choice at the primary branch point. The selection to enter the rostral or caudal branch is not random and may be in response to positional cues.

153.4

FIBER-TYPE EXPRESSION IN RAT AND MOUSE SOLEUS DURING POSTNATAL DEVELOPMENT. D.J. Wigston, K.A. Shirley*, G. Schwartz*, and A.W. English. Departments of Physiology and Anatomy & Cell Biology, Emory University School of Medicine, Atlanta, GA 30322.

We analyzed the fiber-type composition of a mixed fiber-type muscle, soleus, in both rat and mouse, to determine whether the adult pattern of myosin expression is fixed soon after birth or whether it changes during maturation. We identified fast- and slow-twitch myofibers in muscles from animals varying in age from 1 week to 1 year, using monoclonal antibodies specific for fast and slow myosin isoforms. In cross-sections containing profiles of all myofibers in the muscle, we counted the fibers positive for fast myosin, and in adjacent sections, those positive for slow myosin. We also counted the total number of fibers in each section. Mouse soleus contained about 1,000 myofibers and rat 2,300 at all ages studied, suggesting that myogenesis ceases in soleus by 1 week after birth. In mouse, the relative proportions of fibers positive for fast and slow myosin were the same at all ages studied, 60% being fast and 40% slow. In rat, however, the proportions of fast and slow fibers changed dramatically. At 1 week after birth, 40% of rat soleus fibers were positive for fast myosin, whereas between 1 and 2 months, this value fell to 20% or fewer. The reason why 50% of the fast fibers present in rat soleus at 1 week are apparently converted to slow, whereas in mouse soleus fiber-type expression is constant, is unclear but may be related to differences in the amount of body growth between these two species.

153.5

MUSCLE FIBER TYPE DIFFERENTIATION IN THE OPOSSUM DURING POST-NATAL DEVELOPMENT. S. H. Astrow* and W. J. Thompson. Dept. of Zoology, University of Texas, Austin, TX, 78712.

Like other newborn marsupials, the anatomical structures of the opossum, Monodelphis domestica, are highly underdeveloped relative to other mammals such as the rat. Since much of the development of the hindlimb in the opossum takes place ex utero, it is a favorable preparation for studying the role of neuronal innervation in muscle development. In this study we used immunohistochemistry to examine the timetable of expression and distribution of muscle fiber types in the hindlimb of Monodelphis from birth until 2 weeks of age. Three myosin antibodies specific for embryonic myosin, slow myosin, and adult type IIa and neonatal myosin (fast/neonatal) were applied to cryostat sections. By postnatal day 3 (d3) muscle cleavage is largely complete and individual muscles can be identified. Prior to d7, all myotubes express slow as well as embryonic myosin. Fiber type heterogeneity is first detected at d7, when some of the primary fibers along the peripheral regions of muscles begin to express fast/neonatal myosin. By d9, fibers in the peripheral regions of tibialis anterior (TA) and extensor digitorum longus (EDL) no longer express slow myosin; labeling with the fast/neonatal and slow myosin antibodies appears to be complimentary in these regions. At d14 fast/neonatal myosin expression is also visible in the deep portions of TA and EDL. Small, presumably secondary myotubes expressing fast/neonatal myosin arise late in the second week of postnatal life. Thus, fiber type differentiation in the opossum is similar to, albeit more protracted than, that seen that in the rat. Myotubes assume a fiber type partially on the basis of birthdate: primary myotubes give rise to slow muscle fibers and secondary myotubes are largely determined to express fast myosin. In addition, some primary myotubes undergo a transformation of fiber type from slow to fast. It has been suggested previously that intramuscular position may determine which fibers undego this transformation, since the primary fibers which convert to fast are regionalized. However, in several muscles in the opossum, transformed fibers are intermixed with those which have not transformed, indicating that position alone can not account for the pattern of fiber types seen in the adult.

153.6

TIMING AND DIRECTION OF MUSCLE CLEAVAGE IN THE CHICK THIGH. S. Schroeter and K. W. Tosney. Department of Biology, University of Michigan, Ann Arbor, MI 48109-1048.

Individual muscles of the vertebrate limb are derived from two condensations of muscle cells, the dorsal and ventral muscle masses. In transverse sections at the light microscopic level, muscles appear to become separated from one another by "cleavage planes," regions of decreased cell density. These planes progress in a stereotyped pattern that was first recognized and broadly outlined by Romer (*J. Morphol. Physiol.*,43:347,1927).

We are re-examining the cleavage process in the thigh to more completely detail the temporal-spatial progression of cleavage during stages 27 to 32. We find that cleavage does not proceed in the same direction for all muscles. For instance, while the cleavage plane between the iliotibialis cranialis and iliotibialis lateralis progresses proximally, the cleavage plane between the adjacent ambiens and the iliotibialis cranialis progresses distally. We also find that cleavage is not necessarily uniform along the proximodistal axis. For instance, cleavage between the iliotibialis lateralis and iliofibularis is complete anteriorly while the muscles are still uncleaved posteriorly. We also detect cleavage slightly sooner than previously reported: muscles begin to cleave as growth cones begin to ramify within them. Our more detailed documentation reveals more complex separation patterns between muscles than previously described.

153.7

EFFECTS OF NEUROMUSCULAR BLOCKADE ON MYOTUBE DEVELOPMENT. B.J. Nelson and L.T. Landmesser. Dept. Physiology and Neurobiology, Univ. of Connecticut, Storrs, CT 06269.

Innervation has been proposed as necessary for development of the predominantly fast secondary myotubes, but not for primary myotube formation or their expression of fast and slow markers. The effect of curare-induced neuromuscular blockade on the development of myotube type was studied in chick iliofibularis muscle, which in adult has a fast posterior region and a mixed anterior region. Frozen sections of hindlimb were immunocytochemically stained with antibodies to slow muscle myosin (S58) and fast muscle Ca^{2+}-ATPase (5D2). From St 29 to 37, the antibodies recognized mutually exclusive myotube populations. At St 29-33, when only primary myotubes are present, 5D2 staining was restricted to the posterior (fast) region, whereas the anterior region was only labeled by S58. After St 33, small 5D2-positive cells appeared in the anterior IFIB, corresponding to secondary myoblast differentiation. The ratio of 5D2- to S58-positive cells increased tenfold between St 33 and 40. Chronic curare treatment dramatically decreased the number of both 5D2- and S58-labeled cells, but did not alter the fast/slow staining pattern, nor the normal increase in the ratio of 5D2- to S58-positive cells. This indicates that in IFIB, both slow primary and fast secondary myotubes are equally affected by activity blockade, thus leaving the spatial distribution of fiber types unaffected.

DELAYED SYMPATHETIC DENERVATION OF EMBRYONIC HEART MATURING IN OCULO COMPROMISES GROWTH. T.C. Love* and D.C. Tucker. Psychology Dept,Univ Alabama Birmingham,Birmingham,AL 35294.

Embryonic heart tissue grows less well in a sympathetically denervated eye chamber than in an intact eye chamber (Tucker & Gist, Circ. Res. 1986). By morphological criteria, hearts cultured in oculo resemble mature hearts after 4-5 wks in oculo. We tested whether sympathetic denervation of a mature graft would compromise growth in oculo.

Embryonic hearts grafted into intact eye chambers of adult male rats (Innervated, N=22) were compared to (a) grafts sympathetically denervated after 4 wks in oculo (Denervated, N=10) and (b) to grafts in eye chambers denervated before grafting (Noninnervated, N=14). Size and beating rate measurements were taken biweekly. Chronic recording electrodes were implanted at 8 wks to estimate autonomic controls of graft beating rate in unanesthetized hosts.

Noninnervated grafts grew less well than Innervated grafts (1.86 ± .33 vs 4.15 ± .61 mm^3). Growth was equally compromised in Denervated and Noninnervated grafts after 8 wks in oculo (1.73 ± .21 vs 5.08 ± .69 mm^3). Intrinsic beating rate, estimated after combined β-adrenergic and muscarinic blockade, was lower in Innervated grafts than in Noninnervated grafts (141 ± 28 vs 206 ± 24 bpm). Intrinsic beating rate did not differ between Denervated and Noninnervated grafts (214 ± 22 bpm). These results suggest that sympathetic innervation affects growth and intrinsic beating rate during the mature phase of growth rather than during early cardiac development.

154.1

ANATOMY OF THE NASAL CAVITY AND ITS FOREBRAIN PROJECTIONS IN THE AXOLOTL. H.L. Eisthen*, D.R. Sengelaub, and J.R. Alberts* (SPON: A. Strickholm). Dept. of Psychology and Program in Neural Science, Indiana University, Bloomington, IN 47405.

The axolotl (Ambystoma mexicanum) is an neotenic, aquatic salamander whose feeding and social behavior are influenced by chemical stimuli. To understand the sensory bases of these behaviors, we are conducting anatomical studies of the nasal cavity. Reconstructions reveal that the nasal cavity, which extends from the external naris on the dorsal snout to the internal naris in the roof of the mouth, is essentially an elongated tube with a lateral pouch. In cresyl violet-stained sections, we observe spatially separate and morphologically distinct receptor populations in the nasal cavity. The medial wall appears to contain ciliated olfactory receptors, and the lateral pouch contains a non-ciliated sensory epithelium, corresponding to the loci of olfactory and vomeronasal epithelia in other salamanders.

We examined the forebrain projections of these receptor populations using HRP (50% Sigma type VI, 5% DMSO), placed either by injection (0.3 µl) or implantation in crystal form into the appropriate region of the nasal cavity and visualized with TMB. After HRP placement into the medial nasal cavity, densely-fasciculated fibers could be seen throughout the olfactory nerve, terminating in discrete glomeruli in the main olfactory bulb. In contrast, labeling after lateral pouch placements was restricted to fibers on the lateral edge of the olfactory nerve. These fibers terminated in a small region lateral and caudal to the main olfactory glomerular field, corresponding to the accessory olfactory bulb described by Herrick (1921) for the tiger salamander (Ambystoma tigrinum), a closely-related species.

The existence of a vomeronasal system in the axolotl, an aquatic organism, is particularly striking because this system appears to have been lost in wholly-aquatic mammals and reptiles.

154.2

AN HRP STUDY OF PATHWAYS LINKING THE PREOPTIC AREA TO AUDITORY NUCLEI IN HYLA CINEREA. **J. D. Allison and W. Wilczynski. Dept. of Psychology, University of Texas, Austin, TX 78712.**

Cells in the ventral hypothalamus (VH) and preoptic area (POA) respond to acoustic signals, and pathways linking the VH to three auditory nuclei, the anterior (AN) and central thalamic nuclei (CN) and the secondary isthmal nucleus (SIN), have been described (see Neary, in Evolution of the Amphibian Auditory System, Fritzsch, et al., eds., Wiley, 1988). In the present study HRP was iontophoretically injected into the POA of the green treefrog to describe its auditory inputs. After a 4 day survival, the injected animals were sacrificed under anesthesia and the brains extracted, fixed, cut at 40µ, mounted, and reacted with standard techniques using TMB (Wilczynski & Allison, Brain Behav. Evol., in press). Heavy retrograde labeling in the ipsilateral AN and a few lightly labeled cells in the ipsilateral SIN were found. No connections with the CN were found. Anterogradely labeled fibers were seen bilaterally in the AN. In addition, we found bilateral reciprocal connections with the medial pallium and septal nuclei, unilateral reciprocal connections with the dorsal and lateral hypothalamus, afferents from the ventral hypothalamus, and bilateral efferents to the dorsal and ventral habenula. Compared with the VH, the POA has much stronger connections with the AN, much lighter connections with the SIN, and no connections with the CN. 154.3

ONTOGENY OF AMPHIBIAN LHRH SYSTEMS. L.E. Muske and F.L. Moore. Dept. Zoology, Oregon State Univ., Corvallis, OR 97331.

Immunocytochemical (ICC) studies were conducted on three anuran amphibians (genus Rana) during development from early tadpole to juvenile frog, using antisera to three different forms of LHRH (luteinizing hormone-releasing hormone). Antisera to chicken II and mammalian LHRH's revealed two anatomically and developmentally distinct LHRH systems. The forebrain-spinal cord system projects from the POA through the ventromedial brainstem into the spinal cord, and may be the source of LHRH in frog sympathetic ganglia. Intensity of labeling was robust in premetamorphic tadpoles, but decreased with age. Immunolabeling in the hypothalamic-hypophyseal (H-H) LHRH tract was first detected in late prometamorphosis and increased with age. Development of irLHRH in the H-H tract coincided with first appearance of irLHRH in the nervus terminalis (NT) in one species, suggesting species differences. Analyses of ICC developmental changes with different LHRH antisera support the conclusions that the forebrain-spinal cord system, hitherto undescribed in larval or neonatal vertebrates, develops first and synthesizes chicken II-like LHRH, and that the H-H system develops later and synthesizes mammalian LHRH. We suggest that LHRHir neurons of the forebrain-spinal cord and H-H systems are chemically, functionally, and embryonically distinct.

154.4

HISTAMINERGIC SYSTEM IN XENOPUS BRAIN: A COMPARATIVE AND DEVELOPEMENTAL STUDY. **M.S. Airaksinen and P. Panula. Dept. Anatomy, Univ. Helsinki, 00170 Helsinki, Finland.**

To study the evolution of the histaminergic system in vertebrates, we compared its distribution in adult and developing brain of Xenopus laevis, using an antiserum to carbodiimide-fixed histamine.

The histamine-containing cell bodies were located in the dorsal posterolateral hypothalamus. This area may be homologous to the tuberomammillary nucleus in mammals. Each cell had a thick process that terminated in the ventricle lumen. Analysis of adjacent sections indicated that the cells were not immunoreactive for GABA or serotonin.

The distribution of histaminergic fibers in Xenopus showed many similarities to mammals. The highest density was found in the medial amygdala and septum. In the primordial piriform cortex and striatum very few fibers were seen. There was a distinct, dense network of fibers around the cell bodies of nucleus accumbens. In diencephalon, highest fiber densities were found in the anterior and ventral thalamus, and preoptic and posterolateral hypothalamus. In hindbrain, the fiber density was highest in the central gray and the raphe area, as in most mammals.

Histamine-immunoreactive neurons appeared in the hypothalamus of Xenopus on the fourth embryonal day.

The results suggest that there is a widespread histaminergic system in the Xenopus brain. Besides, histamine may play a role in early developement of the nervous system.

DISTRIBUTION OF PIGMENTED CELLS AND PROCESSES IN THE BRAIN OF DEVELOPING TADPOLES. **N.J. Uray and P.S. Sexton. Dept. of Anatomy, Kirksville College of Osteopathic Medicine, Kirksville, MO 63501.**

In examining slides of brains of developing Rana catesbeiana tadpoles, we found pigmented neurons and processes with a specific distribution pattern from the caudal medulla to the telencephalon. In the medulla oblongata the pigmented cells comprise the ventrolateral cells of the motor column and cells in the octavolateral region. A different column of pigmented cells forms the ventralmost cells of the thalamic region, isolated cells in the dorsal infundibular nucleus and the lateral cell of the septum. Two kinds of pigment bearing processes are also present. One type appears to be the fine processes of the pigmented cells which ramify in the grey matter, the dorsal island of Kingsbury, the infundibulum of the hypothalamus and the neuropil of the habenula and epithalamus. A second course fiber type which is heavily pigmented is associated exclusively with the ventricular system terminating among ependymal cells and apparently contacting the CSF of the fourth ventricle. An anatomical "map" of these cells and processes may have significance in the interpretation of data that is generated in immunocytochemical procedures that utilize brown-black pigment granules. **Supported by NIAA Grant R01 AA07537-01.**

CARNOSINE-LIKE IMMUNOREACTIVITY IN THE RETINA OF AMPHIBIA. A.Fasolo&*, B. Mulatero&*, S.Biffo §&*, C. Artero&*, D. Cantinoδ* and F.L. Margolis§ (SPON: European Neuroscience Association). &Dip. Biologia Animale, δDip. Anatomia Fisiologia Umana, Universita' TORINO (I); §Roche Inst. Molec. Biol. Nutley, N.J. (U.S.A.).

The retina of frogs is rich in carnosine, an aminoacyl-histidine dipeptide (Margolis and Grillo, Neurochem. Int., 6:207-209, 1984). A polyclonal antibody against carnosine has been developed and used for localization of carnosine-like immunoreactivity (IR) in rodent and avian central nervous system (Biffo et al., in press). We used immunocytochemical methods to study the distribution of carnosine-IR in the retina of different amphibian species (Rana esculenta; Xenopus laevis; Ambystoma tigrinum; Triturus cristatus). In the retina of all these species an important carnosine immunopositive pattern was observed. Photoreceptor cell bodies were often stained as well as some bipolar elements. Moreover, an extensive network of fine cell processes was seen in the inner plexiform layer. These data suggest that the amphibian retina is a useful system in which to study the neural function of carnosine. (Supported, in part, by the Italian MPI.60-40%; NATO grant n.86/332; and CEE grant n.ST2J.0468).

MORPHOLOGY AND SYNAPTIC PHYSIOLOGY OF HIPPOCAMPAL NEURONS IN THE POND TURTLE STUDIED WITH WHOLE-CELL RECORDING. P. H. Desan, J. J. Lo Turco, A. R. Kriegstein. Dept. of Neurology, Stanford Med. Ctr., Stanford, CA, 94305.

The anatomy and synaptic currents of pyramidal cells in areas DM and M of the cerebral cortex of the pond turtle were studied with whole-cell recording and dye injection. These areas are analogous to the mammalian hippocampus. The medial wall of the cerebral hemisphere containing areas DM and M was dissected from adult pond turtles (Pseudemys scripta elegans), anchored in a petri dish with a plasma-thrombin clot and perfused with turtle physiological buffer. Whole-cell recording in both voltage clamp and current clamp modes were made as described elsewhere at this meeting (Kriegstein, Blanton and Lo Turco, 1989). Recording pipettes contained 120 mM CsF, 1 mM $MgCl_2$, 1 mM $CaCl_2$, 11 mM EGTA, 10 mM HEPES, 5 mM NaCl, and a saturating concentration of Lucifer Yellow CH. Intrahippocampal connections were activated with bipolar stimulation caudal to the recording site.

In successfully filled pyramidal cells, infrequently branching, spiny apical dendrites formed either a wide or narrow symmetrical arborization originating from 3-6 primary dendrites. The number of spiny basal dendrites was variable. In some cells profuse recurrent ascending axon collaterals were observed, and often one branch could be followed to the fornix. Frequent spontaneous synaptic current events were present: such events were uniformly inward at potentials more negative than -70 mV, either inward or outward at potentials near -40 mV, and uniformly outward at potentials more positive than 0 mV. Stimulation of intrahippocampal projections evoked a complex conductance, consisting of components reversing near either the chloride equilibrium potential or the nonspecific cation equilibrium potential.

REPTILIAN THALAMIC RETICULAR NUCLEUS. M.B. Pritz and M.E. Stritzel*. Div. Neurol. Surg., Univ. California Irvine Medical Center, Orange, CA 92613-4091.

All mammals possess a thalamic reticular nucleus. While its anatomy and physiology vary depending on the species investigated, the thalamic reticular nucleus shares at least two properties in all mammals so far examined. It projects to nuclei of the dorsal thalamus and its neurons are immunoreactive for GABA/GAD. We investigated whether such a nucleus is present in other amniotes.

Injections of horseradish peroxidase (HRP) were placed in a number of dorsal thalamic nuclei in reptiles, Caiman crocodilus. Tissue was processed using standard neurohistochemical methodology employing tetramethylbenzidine as the chromogen. Although not all dorsal thalamic nuclei have been injected with HRP, we have identified retrogradely labeled neurons in the nucleus of the dorsal peduncle of the lateral forebrain bundle (dpLFB) which are embedded within, for the most part, the telencephalic projecting thalamus axons. Injections of different parts of the dorsal thalamus retrogradely label different parts of the dpLFB. Dendritic visualization of such retrogradely labeled cells indicates that their processes are primarily distributed parallel to the entry zone of ascending dorsal thalamic axons. Additional immunocytochemical experiments using a polyclonal anti-GAD antibody and standard immunocytochemical methodology employing the avidin-biotin complex technique indicates that while some GAD (+) cells are present in the dpLFB, they are a population separate from those that project to the dorsal thalamus.

These results indicate that a thalamic reticular nucleus may be common to all amniotes and thus be a feature that has arisen early in evolution. Furthermore, the characteristics of these two cell populations in this reptilian thalamic reticular nucleus suggest that the intrinsic organization of the thalamus in Caiman may be organized quite differently from that of mammals.

154.9

DISTRIBUTION OF GABA-LIKE IMMUNOREACTIVITY IN TURTLE CEREBELLUM. D. Vyas, M. T. Clarke* and J. C. Houk. Dept. of Physiology, Northwestern University Medical School, Chicago, IL 60611.

It has been recognized from morphological and hodological studies that reptilian cerebellum is similar to that of mammals. The organization of GABA-ergic inhibitory neurons in mammalian cerebellum is well understood. However, the distribution of GABA in the cerebellum of lower vertebrates has not been studied.

We examined GABA-like immunoreactivity (IR) in 40 μm thick sections of turtle cerebellum using peroxidase-antiperoxidase method. The turtle was chosen because of our long range goal of correlating the neuroanatomy of the cerebellorubrospinal system with *in vitro* electrophysiological studies of motor pattern generation (Neurosci. Lett., 97:123,1989).

Our results demonstrate that all three layers of the cerebellum contained IR elements for GABA. In the molecular layer numerous bouton-like structures, somata and the processes of stellate cells contained dark reaction product. Parallel fibers did not display any IR for GABA. The perikarya of Purkinje cells showed weak GABA-IR. In the granular cell layer, Golgi cells and glomeruli were immunoreactive while granule cells were immunonegative. Both, medial and lateral cerebellar nuclei contained darkly stained terminals of Purkinje cell axons, and a few lightly stained small-sized neurons.

We conclude that stellate, Purkinje and Golgi cells are GABA-ergic neurons in the turtle cerebellum. The pattern of IR of these GABA-ergic neurons in the turtle cerebellum is comparable to that described in higher vertebrates including mammals.

154.10

MARGINAL NUCLEI IN THE SPINAL CORD OF THE BOA CONSTRICTOR. D. M. Schroeder, Medical Sciences Program, Indiana University School of Medicine, Bloomington, IN 47405.

Marginal nuclei are prominent in the spinal cord of reptiles, especially snakes, and recent evidence suggests that marginal neurons function as intrinsic mechanoreceptors. These neurons are located segmentally along the length of the spinal cord and are adjacent to the denticulate ligament. The ultrastructure of this nucleus has been described for snakes representing Viperidae and Colubridae families but not Boidae. The latter snakes represent an evolutionary older family. In the boa constrictor, each marginal nucleus extended about 800 μm rostrocaudally. In this area the collagen within the denticulate ligament, which is usually quite prominent, disappears for a distance of 100 μm. The nucleus consisted of a medial and lateral neuropil. The lateral neuropil, adjacent to the denticulate ligament, contained large neurons and many had short, stubby dendrites that extended towards the edge of the spinal cord; some neurons were immediately adjacent to the glia limitans. Within the neuropil fingerlike processes, originating from the stubby dendrites, were surrounded by glial processes and accompanied by an axonlike structure. Many dendritic profiles were present in the neuropil, as well as numerous boutons containing primarily round clear vesicles. Few myelinated fibers were present but unmyelinated axons were present throughout. The medial neuropil had fewer and smaller neurons and very few fingerlike processes. In general, the marginal nucleus of the boa had only minor differences compared to that of the other species. Supported by PHS S07RR7031J.

THE PARATYMPANIC ORGAN: MORPHOLOGY, INNERVATION, AND FUNCTION. C.S. Von Bartheld and E.W Rubel. Hearing Development Laboratories RL-30, Univ. of Washington, Seattle, WA 98195.

The paratympanic organ (Vitali organ) is a small sensory organ in the avian middle ear. The medial side of its lumen contains mechanoreceptors with afferent and efferent nerve fibers. We investigated the central connections of this organ by injections of fluorescent carbocyanine tracers (DiI, DiO) into the paratympanic organ of chick embryos and hatchlings. Approximately 40-50 ganglion cells in the facial ganglia give rise to paratympanic nerve fibers that enter the brainstem with the facial nerve, but project to the lateral, superior and descending vestibular nuclei. Approximately 40 efferent neurons are labeled ipsilaterally, adjacent to the superior olivary nucleus and the facial motor nucleus.

Two elastic ligaments attach to the paratympanic organ in the middle ear. The columellar-squamosal ("Platner's") ligament inserts at its caudal pole; the superior drum-tubal ligament attaches to the rostral tip of the organ. To study the effect of pressure and movement of the extracolumella on the configuration of the paratympanic organ, we perfusion-fixed embryonic and posthatch chickens while exerting positive pressure to the ear canal on one side and negative pressure on the other side. Serial sections were cut and stained with aldehyde fuchsin and neutral red. Parts of the lumen of the paratympanic organ expand differentially as a function of the tension of the ligaments and the position of the extracolumella; the displacement of fluid in the lumen may stimulate the paratympanic hair cells. This mechanism would explain the avian sensitivity to changes of atmospheric pressure and supports the hypothesis that this organ functions as a barometer and altimeter.

CHARACTERIZATION AND SPECIES DISTRIBUTION OF NEURONAL NADPH-DIAPHORASE. B.T. Hope and S.R. Vincent. Kinsmen Laboratory of Neurological Research, Department of Psychiatry, University of British Columbia, Vancouver, Canada.

NADPH-diaphorase is a histochemically defined enzyme found throughout the nervous system. It is found within somatostatin and neuropeptide Y neurons of the striatum and within cholinergic neurons of the mesopontine tegmentum of rats. Previous studies have found NADPH-diaphorase in several mammalian brains. We now report the presence of this enzyme activity in the striatum and mesopontine tegmentum, in the rat, cat, baboon, human, cow, pig, guinea pig, chicken, turtle, and frog. We have failed to detect any neuronal NADPH-diaphorase activity in the brains of any species of fish examined. Thus, NADPH-diaphorase appears early in the phylogenetic tree (ie. Amphibia) and its expression in particular neuronal populations is subsequently strongly conserved. The function of the enzyme is unknown. Histochemical characterization has demonstrated that the reaction is catalyzed by an enzyme which can utilize β-NADPH, deamino-NADPH, α-NADPH, but not β-NADH or 3'-NADPH. Electron microscopy indicates that the enzyme is associated with the membranes of the endoplasmic reticulum and nuclear envelope. Neither superoxides nor hydrogen peroxide are generated in the reaction. Under anaerobic conditions, all tetrazoliums with redox potentials more positive than NADPH can be reduced. The enzyme does not appear to be a metalloprotein, but may possess thiol groups which participate in the reaction mechanism. This novel enzyme appears to be distinct from any previously characterized NADPH-dependent oxidoreductases.

154.13

THE DISTRIBUTION OF NADPH-DIAPHORASE IN THE PERIPHERAL NERVOUS SYSTEM. S.R. Vincent, Y. Aimi* and H. Kimura*. Kinsmen Lab. of Neurological Research, Dept. of Psychiat., The Univ. of British Columbia, Vancouver, Canada, & Div. of Molecular Neuroanatomy, Shiga Univ. of Medical Sciences, Japan.

NADPH-diaphorase histochemistry has proven to be a useful tool for neuroanatomical studies of the central nervous system, where it selectively stains particular populations of neurons. We have now examined the distribution of this enzyme activity in the peripheral nervous system of the rat and guinea pig. In the enteric nervous system, many intensely staining neurons were found throughout the myenteric plexus, and many fibers were present in the circular muscle. A few stained cells were also found in the submucous plexus. NADPH-diaphorase positive neurons were not detected in the sympathetic ganglia, however, a dense network of stained fibers surrounded many of the principal cells in the prevertebral ganglia. Although the intermediolateral horn of the spinal cord did contain many strongly staining neurons, sectioning of the splanchnic nerve had no observable effect on the fiber staining in the guinea pig celiac-superior mesenteric ganglion complex. In contrast, interruption of the fibers from the gut drastically reduced the fiber staining in this ganglion. This indicates the presence of an NADPH-diaphorase containing projection from the myenteric plexus to the prevertebral ganglia. In the sensory system, a few positive neurons were seen in the dorsal root ganglia at cervical and lumbar levels. In contrast, the thoracic ganglia contained many positive neurons. NADPH-diaphorase histochemistry is an important technique for anatomical investigations of the peripheral nervous system.

CGRP IS AN EVOLUTIONARILY CONSERVED MARKER OF THALAMIC AUDITORY RELAY NEURONS. A. Reiner and S.E. Brauth, Dept. Anat. & Neurobiol., UT-Memphis, Memphis, TN; Dept. Psychol., Univ. of Maryland, College Park, MD

The distribution of calcitonin gene-related peptide (CGRP) in the auditory thalamotelencephalic pathways of turtles, caiman, pigeons, budgerigars and rats was examined using immunohistochemical techniques. In colchicine- treated turtles and pigeons, numerous CGRP+ perikarya were observed in the thalamic auditory relay nucleus, particularly in the periphery of the nucleus. In turtles, caiman, and pigeons, CGRP+ fibers were observed within the portions of the dorsal ventricular ridge (DVR) of the telencephalon previously reported to receive input from the auditory thalamus. In colchicine-treated rats, CGRP+ perikarya were abundant along the lower and medial edges of the medial geniculate nucleus (MGN) but sparse within the MGN itself. Fluorogold injections into auditory cortex retrogradely labeled some of these CGRP+ neurons, thus suggesting that at least some of these CGRP+ neurons are part of the rat auditory thalamus .

The present results are consistent with previous studies suggesting that the thalamic auditory relay neurons of reptiles and birds are comparable to parts of the MGN of mammals and suggest that these cell groups have been inherited at least in part by modern amniotes from their reptile common ancestor. Studies are needed to determine if CGRP is present in thalamic auditory relay neurons in modern amphibians, and on this basis may have been characteristic of the earliest land vertebrates. Supported by NS-19620 (A.R.) and MH-40698 (S.E.B.).

THE AVIAN LOBUS PAROLFACTORIUS: AN INTEGRATIVE BRAIN AREA PERHAPS INVOLVED IN STRESS. W.J. Kuenzel and S. Blaehser*. Poultry Sci. Dept. Univ. of Maryland, C.P.,MD 20742 and Anat. & Cytobiol.Inst.,Univ. of Giessen , Giessen, FRG.

Antibodies (ab) to corticoliberin (CRF), vasotocin (AVT), substance P(SP), neurophysin I and II(NP II) were used with immunocytochemistry to map the distribution of immunoreactive (i.r.) perikarya and fibers throughout the chick brain. It was found that the medial parolfactory lobe (LPO) from its rostral to caudal extent contained i.r. perikarya to CRF. When an ab to NP II was used, the entire LPO showed intensely stained i.r. perikarya. The entire LPO also showed i.r. fibers to SP. Since CRF is a well known neuropeptide that stimulates the release of pituitary ACTH and NP II is a carrier protein for AVT that likewise releases ACTH suggests that the LPO may have a neuroendocrine function. SP is involved in nociception as well as implicated in enhancing inflammatory reactions. Anatomically the LPO is a proposed component of the basal ganglia and an area involved with vocalization (area X). Hence the LPO can receive sensory as well as motor information, contains neural elements that would be regarded as neuroendocrine and adrenal-related and has direct neural connections to limbic structures. Perhaps the LPO is an integrative brain area involved in stress or emotional behaviour.

154.16

SEVEN MORE BRAIN TRAITS WHOSE VARIANTS ELUCIDATE MAMMALIAN PHYLOGENY. J.I. Johnson, Anat. Dept., Mich. State U., East Lansing, MI 48824; R.L. Reep, Dept. Neurosci., U. Fla., Gainesville, FL 32610; R.C. Switzer III, Depts. Pathol., Med. Biol., U. Tenn., Knoxville, TN 37920; J.A.W. Kirsch, Dept. Zool., and W.I. Welker, Dept. Neurophysiol., U. Wis., Madison, WI 53706.

We present seven additional traits which provide new evidence for assessing mammalian relationships. Four distinguish restricted groups from all other mammals: 1) Mirroring of the complete SI body representation (monkeys); 2) Rindenkerne, clumps of cell bodies in layer 6 of cerebral cortex (sirenians: manatees and dugongs); 3) Posteriorly-pointing digits in the SI body representation (bats, mega- and micro-); 4) Tectopetal connections from both, vs. contralateral, retinas (primates and megabats). Complex sortings are seen in : 5) Loss of lamination in dorsal cochlear nuclei, convergent in several lines where some species leave the ground (bats, monkeys, seals, dolphins and manatees); 6) Separation of claustrum from cortex is related to gyrencephaly but occurs in lissencephalic primates and marsupials, and 7) Lack of a distinct external cuneate nucleus in monotremes and sirenians.(Supported by NSF grant BSR 85-03687.)

THE INFLUENCE OF NODAL ANATOMY ON CONDUCTION VELOCITY IN MYELINATED NERVE FIBERS: A MODELING STUDY, J. A. Halter and J. W. Clark, Jr.[1], Division of Restorative Neurology and Human Neurobiology, Baylor College of Medicine, Houston, Texas, 77030 and [1]Rice University, Houston, Texas

A mathematical model of the myelinated nerve fiber was developed, representing the myelinated nerve fiber as a multi-axial electrical equivalent circuit including separate intra-axonal, peri-axonal and extra-axonal longitudinal conductive pathways with independent representations of the myelin sheath versus the underlying axolemmal membrane. The node is represented as a separate segment with an adjacent myelin sheath attachment region and a non-cylindrical fluted section transitioning to the stereotypical internodal region. The peri-axonal space extends to the nodal compartment, the nodal gap is represented and Na and K channels are included in the paranodal and internodal axolemmal membrane. Both amphibian and mammalian nerve fibers were modeled.

Results indicate that the peri-axonal conductive pathway and the axon radius present in the myelin sheath attachment region are sensitive parameters affecting conduction velocity. As the radius was decreased from that seen in the internode, the conduction velocity increased until a relative radius of 20% was attained after which the conduction velocity rapidly declined. This provides modeling evidence for the role of the nodal constriction in promoting higher conduction velocities.

PHARMACOLOGIC INFLUENCES ON SEXUAL BEHAVIOR IN MALE RATS. D. Yells*, S. Hendricks, B. Graber, and D. Fitzpatrick*. Depart. of Psychiatry and Psychology, Univ. of Neb., Omaha, NE 68182.

Previous research has suggested that manipulations of catecholamine and opiate metabolism can facilitate sexual behavior in male rats. The effects of these drugs are likelihood of copulating, e.g., sexually naive or castrated. Facilitation of sexual behavior in male rats has been reported to result from treatment with a number of drugs including Yohimbine (an alpha-2 antagonist), Naloxone (an opiate block), and Lisuride (a dopamine agonist). The present study evaluated the long-term effects of continual treatment with these drugs on post-castration sexual behavior of male rats. We also examined the effects of a combined injection of Yohimbine and Naloxone in this paradigm. Various components of male rat copulatory behavior were modified by drug treatments. The drug-induced facilitation became more obvious with increasing times post-castration.

155.2

DIFFERENCES IN PENILE REFLEX LEVELS AND SYNAPTIC COVERAGE OF SNB MOTONEURONS. M.G. Leedy, J.C. Bresnahan, and M.S. Beattie Depts. of Anatomy and Surgery, Ohio State Univ., Columbus, OH 43210.

Two groups of male rats were chosen based on their responses in three tests for penile reflexes: those exhibiting no reflexes in any of the tests (No Reflex group), and those six animals exhibiting the greatest number of reflexes (High Reflex group). Testosterone levels did not differ between these two groups. All animals, while gonadally intact, received bilateral injection of cholera toxin conjugated to HRP into the bulbocavernosus muscle, thereby labeling the motoneurons within the spinal nucleus of the bulbocavernosus (SNB). Analysis at the light microscopic level of these motoneurones showed no differences between the two groups, for dendritic lengths, somatic area, nuclear or nucleolar area. At the ultrastructural level, ANOVAs indicated that the High Reflex animals had significantly less synaptic coverage, measured as fewer terminals per 100 um membrane length, less synaptic apposition, less active site apposition, and more glial coverage, compared to the No Reflex group. (NS-10165)

155.3

EFFECT OF PERINEAL MUSCLE DENERVATION ON PENILE REFLEXES IN RATS. Edward P. Monaghan & S. Marc Breedlove. Psychology Dept., Univ. Calif., Berkeley, Berkeley, CA 94720.

The striated perineal muscles, bulbocavernosus (BC) and levator ani (LA) are involved in male reproductive function in rats, and, along with their innervating motoneurons in the spinal nucleus of the bulbocavernosus (SNB), are sexually dimorphic. Other researchers have performed muscle excision and electromyographic recordings to implicate the BC muscle in penile reflexes. As our initial step in investigating the SNB-BC system, we looked at the effect of BC/LA denervation on penile reflexes. By transecting the pudendal nerve just proximal to the BC/LA muscles we removed SNB input while leaving these muscles intact.

For behavior tests rats were held in a plexiglass cylinder with their ventral surface exposed. After five minutes the penile sheath is rolled back to expose the penis and the occurrence of erections, cups, and flips are recorded for a period of twenty minutes. Animals received at least two behavior tests prior to denervation and one final test two to three days after surgery. Denervation essentially eliminated the cups, reduced the number of erections, and had no effect on flips, thus supporting the findings of Hart & Melese-D'Hospital (1983) and Sachs (1982).

155.4

LOCALIZATION OF MOTOR NEURONS OF A SEXUALLY DIMORPHIC MUSCLE IN GUINEA PIGS. Louise M. Freeman* & S. Marc Breedlove, Psychology Department, University of California, Berkeley CA 94720.

The retractor penis (RP) muscle attaches between the penis and the pubis in adult male guinea pigs. An analogous but smaller muscle, the retractor clitoris (RC), is present in females. To determine the anatomical location of motor neurons innervating these muscles we used the retrograde tracer horseradish peroxidase (HRP).

Under ketamine anesthesia, adult guinea pigs were bilaterally injected (6.0-10.0 μL) with HRP (Sigma VI, 30% solution) in either the RP or RC. After three days, we perfused the animals and frozen-sectioned the spinal cords at 50 μm. Clusters of HRP-labeled motor neurons were found in the L5 to S1 levels of both sexes. Labeled motor neurons occupied the central region of the ventral horn. We will examine RP/RC motor neurons to determine whether they are sexually dimorphic in dendritic extent or number.

UNILATERAL ADMINISTRATION OF ANDROGEN TO BULBOCAVERNOSUS AND SUBSEQUENT EFFECTS ON SNB DENDRITIC LENGTH. Mark N. Rand & S. Marc Breedlove, Dept. Psychology, U.C. Berkeley, CA 94720.

Systemic administration of androgen has been shown to increase the length of dendrites in the sexually dimorphic spinal nucleus of the bulbocavernosus (SNB) in rats (Kurtz, Sengelaub & Arnold, Science 232:395, 1986) and in white-footed mice (Forger & Breedlove, J. Neurobiol. 18:155, 1986). We previously reported that local, lateralized administration of androgen to the SNB target muscles bulbocavernosus and levator ani (BC/LA) results in a lateralized anabolic effect mediated at or near the muscle (Rand & Breedlove, Soc. Neurosci. Abstr. 13:54, 1987). The present study tested the idea that such peripheral, unilateral administration of androgen to target musculature could increase dendritic length of SNB motoneurons in the ipsilateral spinal cord.

Adult male rats 90-120 days of age were castrated and implanted with two capsules, one containing testosterone (Sigma) and the other an anti-androgen (SCH16423, Schering Corp.). The capsules had a single diffusable surface and were sutured one on each side of the BC/LA so that the diffusable surface faced the muscle. After 30 days the capsules were removed and the medial BC on each side was injected with 1 μL of cholera toxin-HRP conjugate (CT-HRP). Four days later the animals were sacrificed and the BC/LA and spinal cord were dissected out. The lumbar spinal cord was frozen-sectioned at 50 μm and reacted with TMB to visualize the CT-HRP filled motoneurons and their processes. These were then traced without knowledge of steroid treatment, and lengths measured with a digitizing tablet and microcomputer. Dendritic length of motoneurons ipsilateral to BC/LA treated with androgen were compared with lengths ipsilateral to peripheral anti-androgen treatment. We are currently completing the measurement and analysis of SNB dendrites, and will present these data as well as muscle-half weights resulting from the peripheral, lateralized administration of androgen to the SNB system.

155.6

NO SEX DIFFERENCE IN SIZE OF MOTOR NEURONS WHICH INNERVATE M. SPHINCTER CLOACAE IN JAPANESE QUAIL. C.M. Seiwert and E. Adkins-Regan, Department of Psychology, Cornell University, Ithaca, NY 14853.

The foam gland complex of the Japanese quail (Coturnix japonica) is a sexually dimorphic structure located directly beneath the sphincter cloacae muscle (mSC) in the dorsal wall of the cloaca. The gland secretes a fluid that is whipped into a stiff foam in the male, possibly by the undulation of mSC (Klemm, R.D., J. Morph., 141:171, 1973). Motor neurons innervating mSC are located in lateral area IX of synsacral spinal segments 8 through 10. Foam production, gland size, and muscle size are androgen-dependent (Nagra et al., Anat. Rec., 133:415, 1959). Although present in both sexes, the gland and muscle are markedly reduced in females and no foam is produced. This research investigates whether the sex difference in musculature is reflected in the CNS.

Somal area of mSC motor neurons in males and females was measured with a computerized system following injection of .2% cholera-toxin conjugated horse radish peroxidase into the muscle. Labelled cells were visualized with a modification of the TMB technique. No sex difference was found in mean cell size [n=3 males, x+SEM=551.4μ+94.7μ, 12-45 cells per male; n=3 females, x+SEM=527.8μ+13.1μ, 15-31 cells per female]. There was, however, a sex difference in cell size variance: male cell size was more variable regardless of whether the bird or the cell was the unit of analysis ($F_{2,2}=52.6$, $p<.025$ or $F_{84,64}=2.1$, $p<.001$, respectively). The greater range of cell sizes in males raises the possibility of a sex difference in the number of cell classes. Cell number may also vary with sex. This possibility is currently under investigation. (Supported by NSF #BNS 88-09441).

155.7

RAT ANAL SPHINCTER MOTONEURON SIZE IS NOT TESTOSTERONE DEPENDENT. W.F. Collins, III, A.W. Seymour and S.P. Wargo*. Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, NY 11794.

The spinal dorsomedial nucleus [DMN or SNB] innervates the sexually dimorphic bulbospongiosus [BS] and the non-sexually dimorphic anal sphincter [AS] muscles (McKenna and Nadelhaft, '86). In adult males, somal cross sectional area and dendritic length of BS MNs is reduced in castrated animals compared to rats that are gonadally intact or castrated and given testosterone (Kurtz, et al., '86). In the present study, we have examined the effect of castration on AS MN size in adult male rats (Sprague-Dawley). Ketamine/Xylazine (90mg/10mg per Kg IM) anesthesia was used for all surgical procedures. Twenty-four 60 day old rats were separated into three treatment groups; (1) castration with testosterone propionate [C+TP] pellet implant, (2) castration with placebo [C+P] pellet implant and (3) sham castration. Thirty days following castration, the AS or BS muscles were injected with horseradish peroxidase (0.5-2.0 ul, 50%). After 2 days survival, rats were transcardially perfused with saline (27° C) followed by cold (4° C) perfusate (paraformaldehyde (4%) and glutaraldehyde (1.25%) in PBS). Frozen longitudinal sections (50 um) of spinal cord were cut and reacted using tetramethylbenzidine. Labeled MN profiles with nuclei were traced using a drawing tube attachment and cross sectional area measured using a digitizing tablet and computer. Measurements within treatment groups were pooled for comparisons. No significant difference in body weight was observed across treatment groups. The penis and attached muscles (weight) and the BS MNs (area) were significantly smaller in the C+P group compared to either the C+TP or sham groups. The C+TP and sham groups were statistically the same. In the case of AS MNs, no difference was observed in cross sectional area between treatment groups. Thus, in contrast to the sexually dimorphic BS motor system, AS MN size is not testosterone dependent in adult male rats. Supported by NS24206 (WFC) and NS14899 & NS16996 to L.M. Mendell.

INHIBITION OF TESTOSTERONE-INDUCED COPULATION IN QUAIL BY A NOVEL SPECIFIC AROMATASE INHIBITOR, R76713

L. Evrard*, C. Surlemont*, A. Foidart * and J. Balthazart, (SPON: A. Ghysen), Lab. General and Comparative Biochemistry, Univ. of Liège Belgium.

In Japanese quail, as in other higher vertebrates, the central aromatization of testosterone (T) seems to play a critical role in the activation of copulatory behavior. The strongest evidence supporting this idea comes from experiments showing that the aromatase inhibitor, androstatrienedione (ATD) blocks the T-induced behavior. However recent studies have questioned the specificity of ATD. It was shown that this compound inhibits the 5α-reduction of testosterone and also decreases the binding of androgens to their receptor. This might potentially explain the behavioral effects of ATD. A new triazole derivative, R76713 (Janssen , Beerse, B) was recently shown to inhibit selectively the aromatase without affecting other steroid-metabolizing enzymes and without interacting with the estrogen-, progestin- or androgen-receptors. This compound was tested here for its capacity to interfere with the induction by T of copulatory behavior. In a first experiment, R76713 inhibited in a dose-dependent manner (range 0.01 to 1 mg/kg) the activation by T silastic implants of sexual behavior and of the hypothalamic aromatase activity in castrated male quail. The 5α- and 5β-reductases were not systematically affected. Stereotaxic implantation of R76713 in the medial preoptic area similarly blocked the behavior activated by a systemic treatment with T demonstrating that the central aromatization of T is implicated in the activation of behavior. Finally the behavioral inhibition produced by R76713 could be reversed by the simultaneous treatment with a dose of estradiol which is not behaviorally effective by itself suggesting that the behavioral deficit induced by the inhibitor is specifically due to the suppression of estrogen production. These data confirm the critical role of the preoptic aromatase in the activation of reproductive behavior and demonstrate that R76713 is an ideal tool for the *in vivo* study of estrogen-dependent processes

VOLUNTARY EXERCISE MAY INCREASE CLEARANCE RATE FOR TESTOSTERONE. David Pieper, Providence Hospital, Department of Physiology, Southfield, MI 48037.

Voluntary exercise (EX) inhibits short photoperiod (SP) induced testicular regression in golden hamsters which is due, in part, to hyper-responsiveness to the negative feedback of testosterone on gonadotropin secretion. The following experiment was initially designed to determine whether exercise alters the responsiveness to testosterone (T) feedback. 40 hamsters were castrated, and placed on 14L:10D (LP) or 10L:14D (SP). One half of each group was given access to an exercise wheel while the other half was maintained in similar cages without wheels (SED). 8 w later, they were implanted with a 20 mm silastic capsule of T or an empty capsule. At 4 w after T capsule implant, T was much higher in the LP SED (5.62±0.33 ng/ml) and SP SED (6.62±1.06) groups than the LP EX (3.80±0.25) or SP EX (2.22±0.58) groups ($p<0.01$). The post-castration increase in serum LH was less pronounced in the EX (572±117 LP; 388±25 SP) than SED (1361±345 LP; 1487±353 SP) groups at 4 w ($p<0.05$). Similar results were obtained for serum FSH. T implants resulted in very low or non-detectable LH and FSH levels in all hamsters on SP. The LP EX animals with T generally had higher FSH and LH levels than the LP SED group. We conclude that exercise may inhibit the effect of SP by an independent influence of EX to increase the rate of T metabolism or clearance.

SEX DIFFERENCES IN RESPONSIVENESS OF RAT BRAIN TO ANDROGENS CORRELATE WITH REGIONAL DIFFERENCES IN ANDROGEN RECEPTOR CONTENT. C.E.Roselli and T.A.Fasasi*. Physiology Dept., Oregon Health Sciences Univ., Portland, OR 97201.

Males are generally more responsive than females to the behavioral and neuroendocrine actions of androgen. To determine whether this difference is associated with sex differences in the concentration and/or distribution of androgen receptors within brain, we measured cytosolic (ARc) and nuclear (ARn) androgen receptors in microdissected brain regions. We also measured microsomal aromatase activity (AA) as an index of tissue responsiveness to androgen. In the bed nucleus (n.) of the stria terminalis (BNST), periventricular preoptic area (PVPOA), medial preoptic n. (MPN) and ventromedial n. (VMN) testosterone induced greater amounts of AA in males than in females ($p<.01$). Except for MPN, this difference was correlated with significantly greater ARn levels in males compared to females ($p<.05$); no associated sex differences in ARc levels were observed. When we compared brain ARc levels in gonadectomized rats, we found that BNST from males contained significantly greater ARc levels than from females ($p<.05$). These results suggest that sex differences in androgen responsiveness may be due in part to sex differences in androgen-binding capacity in specific hypothalamic nuclei. Supported by HD 23293.

RESTORATION OF AGE-RELATED DEFICITS IN BRAIN ANDROGEN METABOLISM AND BINDING IN MALE RATS BY TESTOSTERONE TREATMENT. K. C. Chambers, J. E. Thornton, and C. E. Roselli. Dept. of Psychology, USC, Los Angeles, CA 90089 and Dept. of Physiology, OHSU, Portland, OR 97201.

Age-related deficits in male rat sexual behavior are accompanied by decreases in brain aromatase activity (AA), nuclear androgen receptors (ARn) and testosterone (T) levels. To determine if the deficits in brain androgen metabolism and binding in aged males are due to low T, we measured AA, ARn, and cytosolic AR (ARc) in the preoptic area, basal hypothalamus, and amygdala of old and young gonadectomized T-treated Fischer 344 males (GX-T). Untreated gonadectomized rats (GX) and intact young males (YI) also were studied for comparison. T levels in young and old GX-T were comparable and were higher than in YI males. In sexual behavior tests, all of the young but only 42% of the old GX-T males ejaculated. T-treatment stimulated AA in all brain areas to levels equivalent to YI levels. Although ARn levels in old GX-T were lower than in young GX-T, they were comparable to YI levels. No age or treatment related differences in ARc were observed. These data suggest that there is an association between decreased T levels in old males and decreased brain ARn and AA levels but no association between decreased T and decreased sexual behavior. Thus the age-related deficits in behavior are probably not due to changes in AA and ARn. HD 20970 and HD 23293.

155.12

SEX DIFFERENCES IN ANDROGEN RECEPTOR BINDING IN MICROPUNCHED BRAIN NUCLEI. M.Y. McGinnis and S.E. Katz*(SPON: J.E. Shriver). Dept. of Anatomy, Mount Sinai Sch. Med., CUNY, New York, NY 10029.

The biological basis of sex differences in male sexual behavior has been examined by measuring androgen receptors using various autoradiographic and biochemical methods. The results of these studies have been equivocal. To determine whether a more precise, localized measurement would reveal sex differences in androgen receptors, we examined cytosol androgen receptor binding in micropunched brain nuclei of male and female rats gonadectomized 1-3 weeks previously. Brains were sectioned in a cryostat at 300 u. Punches 500 u in diameter were obtained from MPOA, LPOA, BNST, ant HYPO, VMN, DMN, ARCUATE n., cort AMYG n., med AMYG n., parietal CTX, dorsal HIPPO, and lat SEPT. Samples were processed for cytosol androgen receptor binding using [^{3}H]R1881 as ligand. Results indicate that androgen receptor binding is significantly higher in the MPOA ($p\leq0.001$) and the ARCUATE n. ($p\leq0.05$) of males relative to females. Results suggest that sex differences in male sex behavior may be mediated, at least in part, by sex differences in androgen receptors. Supported by NSF grant BNS-8616996.

Androgen-binding in estrogen-receptor containing cells in the brain of the canary (Serinus canaria).
Manfred Gahr, University of Kaiserslautern, 3049, 6750 Kaiserslautern, FRG (Spon.: Maria Kaltwasser).

Even though there are many indications for interactions between estrogen-sensitive and androgen-sensitive neural circuits for the behavioural control the sites of interaction are unknown. This report combined in-vivo autoradiography (ARG) with the androgen 5a-dihydrotestosterone (DHT) and immunocytochemistry with the monoclonal estrogen-receptor antibody H222Spy to study the cellular basis for connections between estrogenic and androgenic circuits. Six adult male canaries were anesthetized and castrated. Birds 1 and 2 were implanted with estradiol benzoate (measured 17b-estradiol: 8ng/ml). Each animal was injected with 5µg (3µCi)/g body weight ^{3}H-DHT (SA=170 mM/Ci) 48hr after castration. In addition bird no.6 was injected with a 100x amount of untritiated DHT. ARG, immunostaining, and analysis (5x background criteria) were done as described in PNAS,85:7380,1988. Besides areas containing either tritium- or antibody-labeled cells or both,each animal (except no.6) contained antibody-labeled DHT-binding cells primarily in the nucleus ICo, Tn, OM, and the dorsal preoptic area. DHT is not convertable into estrogens. This fact, the double-labeling in animals with high estrogen levels, and the low affinity of estrogen receptors to DHT indicate a coexistence of androgen- and estrogen-receptors in the same neurons. Supported by DFG Gu/148-7,8.

CENTRALLY IMPLANTED TESTOSTERONE ACTIVATES SEXUAL BEHAVIOR IN CASTRATED MALE FERRETS. Y.P. Tang and C.L. Sisk, Neuroscience Program and Dept. of Psychology, Michigan State University, East Lansing, MI 48824.

This experiment assessed the ability of centrally implanted testosterone proprionate (TP) to reinstate sexual behavior in castrated male ferrets. The loss of sexual behavior after castration was confirmed in 30-min tests with receptive females in which the total amount of time spent engaged in three components of male sexual behavior (neck grips, mounts, thrusts) was quantified. Bilateral cannulae containing approximately 2 mg TP in cocoa butter were then stereotaxically aimed at the preoptic area (POA). Tests for sexual behavior were conducted on days 3, 7, 14, and 21 post-implantation. Based on histological evaluation of cannulae placement, ferrets were classified as either (1) Miss (n=3; implants not in POA), (2) Unilateral implant in POA (n=3), and (3) Bilateral implant (n=6). The amount of time spent neck gripping, mounting, and thrusting significantly increased between pre- and post-TP tests in the Bilateral group, but not in the Miss and Unilateral groups. Luteinizing hormone concentrations in blood samples collected on each day of behavioral testing were within the normal range of castrated ferrets, and did not significantly decline after TP implantation. These results demonstrate that central administration of TP into POA activates the neural substrates for sexual behavior in castrated male ferrets. Supported by the Whitehall Foundation.

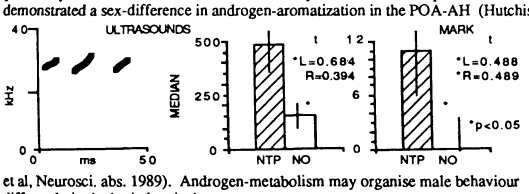
EFFECT OF TESTOSTERONE REDUCTION ON MALE SEIZURE SUSCEPTIBILITY. J. Thomas and J.H. McLean, Dept. of Psychology, Univ. of New Orleans, New Orleans, LA 70148.

The following study was conducted as part of research efforts to define more clearly the relationship between sex-associated gonad hormones and seizure susceptibility. On the basis of existing findings two hypotheses seem plausible in regard to the effects of testosterone in males: 1) that TT does not significantly modulate mechanisms underlying seizure susceptibility in males; or 2) that TT has a pro-convulsant effect in males. Naive, male Long-Evans hooded rats received either sham operations or orchiectomies under anesthesia (Nembutal, 65 mg/kg). After a 3 week recovery period, independent groups in each surgical condition were injected (sc) with picrotoxin (PIC) (3.0 or 7.0 mg/kg) and observed for behavioral signs of seizures. Castrated males were found to have significantly lower thresholds than sham- operates to all types of seizures. These results indicate that endogenous TT has anti- convulsant effects on PIC-induced seizures at the dose levels tested. This result contrasts with the effects of gonad hormones in females, where estrogen reduction was found to have different effects on susceptibility at threshold and supra-threshold levels of stimulation.

155.16



EXPRESSION OF THE EJACULATORY REFLEX IN THE CASTRATED MALE B6D2F1 HYBRID HOUSE MOUSE (Mus musculus) IS REDUCED BY THE AROMATASE INHIBITOR ATD. K. Sinchak* and L.G. Clemens. (SPON: B. Wee) Department of Zoology, Michigan State University, East Lansing, MI 48824.

This experiment investigated the hypothesis that retention of the ejaculatory reflex in B6D2F1 males following castration may be dependent on endogenous nongonadal steroid hormones. It has been shown some male B6D2F1 mice retain the ejaculatory reflex long after adrenalectomy and castration (Thompson An.Beh. 24:519, 1976), indicating expression of the ejaculatory reflex is independent of gonadal and adrenal hormones. Recent evidence with rats suggests dehydroepiandrosterone (which can be reduced or aromatized) may be synthesized in the brain (Corpechot Proc.Nat.Aca.Sci. 78:4704, 1981). To test whether such non-gonadal steroids may play a role in the retention of the ejaculatory reflex of B6D2F1 male mice, castrated males that continued to exhibit the ejaculatory reflex were administered 1,4,6-androstatriene-3,17-dione (ATD), an aromatase inhibitor that blocks the enzymatic conversion of androgens to estrogens via silastic capsule implanted subcutaneously in the nape of the neck. ATD implants significantly reduced the frequency of the ejaculatory reflex in the castrated B6D2F1 males. Copulatory behavior that results in an ejaculatory reflex, appears to be maintained by endogenous estrogen in castrated B6D2F1 males. The origin of this estrogen is unknown.

155.17

IS ASYMMETRIC BRAIN DEVELOPMENT RELATED TO SEXUAL BEHAVIOUR? S.D. HOLMAN, R. HUTCHISON,* A. WOZNIAK* and J. HUTCHISON. MRC Neuroendocrine Development and Behaviour Group, IAPGR, Cambridge, CB2 4AT, UK.

Sexual dimorphism of the brain is influenced by androgen and oestrogen metabolites formed as a product of aromatization in brain cells. Courtship ultrasonic calling is masculinized in females by implanting androgen into the neonatal preoptic-anterior hypothalamic (POA-AH) region (Holman and Hutchison, 107:355, 1985). Neonatal androgenization also masculinizes the Sexually Dimorphic Area pars compacta cells (SDA-PC) in the POA-AH (Yahr, Behav. Neur. Biol. 49: 119, 1988). This study relates the volume of the PC and androgen-metabolism in the POA-AH to sexually differentiated ultrasonics in Mongolian gerbils. Ultrasounds and courtship interactions were measured using MICRO. Females received either a 100µg testosterone propionate (NTP) or a vehicle (NO) injection neonatally, and TP in adulthood. Ultrasounds and scent-marking were masculinized by neonatal TP treatment. Marking shown by NTP and NO females was positively correlated with the PC volume on both sides of the brain. However, ultrasound emission was positively correlated with the PC volume only in the left hemisphere. Data also demonstrated a sex-difference in androgen-aromatization in the POA-AH (Hutchison

et al, Neurosci. abs. 1989). Androgen-metabolism may organise male behaviour differently in the brain hemispheres.

155.18

BRAIN AREAS FORMING BEHAVIORALLY EFFECTIVE ESTROGENS BY AROMATASE ACTIVITY CONTAIN IMMUNO-REACTIVE ESTROGEN RECEPTORS. J.B. Hutchison, M. Gahr*, R. Hutchison*, A. Wozniak* and S.D. Holman. MRC Neuroendocrine Development and Behaviour Group, Institute of Animal Physiology, Babraham, Cambridge, CB2 4AT, UK.

Estrogens as metabolites of androgens act on the preoptic area (POA) to influence specific components of behavior. POA aromatase activity is influenced by changes in circulating testosterone (T) and environmental stimuli. Formation of estrogens in POA cells depends on an active aromatase system which has both high affinity (K_m<10nM) for T as substrate and high activity (V_{max} >100 fmol.h^{-1}.mg tissue^{-1}). Aromatase activity (AA) in the gerbil POA is less active (Holman et al., Neurosci. abs. 1989). The distribution of AA in the dove and gerbil is compared. Estrogen-receptor containing cells (ERC) of the male dove were immuno-stained with a monoclonal antibody (H222Spy) which binds estrogen receptors in the avian brain (Gahr, B.Res. 402, 173, 1987). Aromatase assay of individual samples and ERC staining were carried out on the same coronal sections. High AA and ERC density overlapped in the POA and anterior hypothalamic areas of behaviorally active male doves. ERC density was also high in the tuberal complex and nucleus intercollicularis which showed low estrogen formation. Castration of doves reduced behavior and aromatase activity (>75%) in the POA, but ERC distribution underwent little or no change.T aromatized to estrogens in the POA could act on neurones via estrogen receptors. Local formation of estrogens, but not of estrogen receptors in the POA, appears to account for the effects of T on behavior in male doves. The aromatase system in the male gerbil is likely to be under a different type of control.

NEUROENDOCRINE RESPONSE TO, AND RECOVERY FROM, AGONISTIC ENCOUNTERS IN MALE GOLDEN HAMSTERS.
K.L. Huhman, L.M. Lambe*, E.H. Mougey*, & J.L. Meyerhoff
Dept. Medical Neurosciences, Walter Reed Army Institute of Reseach, Washington, D.C. 20307-5100.

The purpose of the present study was to characterize the neuroendocrine response to, and recovery from, an agonistic encounter in male golden hamsters. In Exp 1, we measured plasma adrenocorticotropin (ACTH), cortisol, beta-endorphin (B-EP), and beta-lipotropin (B-LPH) in pairs of hamsters sacrificed immediately after either a 5, 15, or 30 min encounter in which one of the hamsters established dominance. There were no differences in the three time points so the groups were pooled. In submissive hamsters, plasma ACTH & B-EP were significantly higher than in dominants or controls. Plasma cortisol & B-LPH were higher in submissives than in controls. Hormonal levels in dominants were not significantly elevated in any group. These results support the hypothesis that "losing" is more stressful than is "winning" in terms of pituitary peptide release.

In Exp 2, blood was collected immediately, 1 hr, or 3 hrs after a 30 min agonistic encounter. Plasma cortisol and ACTH returned to baseline levels in both dominant and submissive hamsters at 1 and 3 hrs. Further characterization of the neuroendocrine responses of dominant and submissive hamsters to both acute and chronic agonistic encounters is ongoing.

EFFECTS OF INTERLEUKIN-1-BETA ON IN VITRO RELEASE OF CATECHOLAMINES FROM THE HYPOTHALAMUS.
D.L.Palazzolo* and S.K.Quadri. Department of Antatomy and Physiology, Kansas State University, Manhattan, KS 66506.

Interleukin-1-beta (IL-1B) has been shown to alter the release of hypothalamic and pituitary hormones. This experiment was done to determine if IL-1B affects the release of norepinephrine (NE) from the hypothalamus since NE influences the release of hypothalamic and, in turn, pituitary hormones. Individual hypothalami from 5-6 mo. old male rats were incubated at 37°C in Krebs-Ringer Henseleit (KRH) medium in an atmosphere of 95%O_2-5%CO_2. The released NE was analyzed by high performance liquid chromatography after alumina extraction. Basal release was determined by incubating the hypothalami for 1 hr in KRH. This was followed by incubation for 1 hr in KRH (control), or in KRH containing 100 ng or 50 ng of IL-1B. There were no differences in the basal release rates among the three groups (21.0-25.8 pg/mg/hr). The presence of 100 ng of IL-1B in KRH increased the rate of NE release by 57±12%, whereas in its absence the release rate decreased by 13±10%. This difference was significant ($p<0.005$). The presence of 50 ng of IL-1B in KRH produced an increase of 18%, indicating a dose response. During the next hr, the hypothalami from the three groups were incubated in KRH alone. Under these conditions, the release rates in the experimental groups were the same as in the control group. The proof that the hypothalami remained viable during the entire procedure was obtained by challanging the hypothalami in the end with K^+ (60mM), which produced increases of >500% in all three groups. These results indicate that IL-1B stimulates the release of NE from the hypothalamus, providing further evidence of a neuroimmunoendocrine connection.

INTERLEUKIN-1 ENHANCES THE ACCUMULATION OF EPINEPHRINE AND VASOACTIVE-INTESTINAL POLYPEPTIDE IN CULTURED ADRENAL CHROMAFFIN CELLS.
R. Eskay*, A. Thiagarajan and L. Eiden* (SPON: C. Randall). Lab. of Clinical Studies, NIAAA and Lab. of Cell Biology, NIMH, Bethesda, MD 20892.

Recently, neural cells have been shown to be targets of the action of cytokines, including interluekin (IL)-1 alpha and beta and IL-6. 24-hr treatment of bovine adrenal chromaffin cells with 10^{-10} or 10^{-9} M recombinant human (rh) IL-1 alpha resulted in a dose-related increase in medium levels of vasoactive-intestinal polypeptide (VIP) and epinephrine (Epi). IL-1 alpha (10^{-9} M) increased the medium concentration of Epi (0.88+ 0.04; Mean + SE, N=8) and VIP (55.6 + 1.65) to 1.8 + 0.13 nMoles/well/24 hr and 117.1 + 11.02 pg/well/24 hr, respectively. Identical treatment of chromaffin cells with rh IL-1 beta (10^{-9} M) also resulted in a significant increase in the accumulation of VIP and Epi in the medium. In contrast to the stimulatory effects of IL-1, exposure of chromaffin cells to rh IL-6 (10^{-10} M) for 24 hr did not alter the accumulation of VIP or Epi, as compared to untreated cells. Continued exposure to rh IL-1 for an additional 48 hrs maintained elevated medium levels of VIP. Intracellular VIP levels were also elevated, indicating modulation of both synthesis and secretion of VIP by IL-1.

156.3

EFFECT OF INTERLEUKIN 1 ON PROLACTIN SECRETION, ADENYLATE CYCLASE ACTIVTY AND CALCIUM FLUXES IN RAT PITUITARY CELLS.
T.Florio*, O.Meucci*, E.Landolfi*, M.Grimaldi*, A.Marino* and G.Schettini. Inst. of Pharmacology, II School of Medicine, Univ. of Naples Via S. Pansini 5, 80131 Naples ITALY

Recent findings indicate that interleukin 1 (IL1) beta modulates neuroendocrine functions in a classical hormone manner. In this study we report IL1 modulation of prolactin secretion, evaluated by using reverse hemolytic plaque assay, of calcium fluxes and adenylate cyclase (AC) activity in rat normal pituitary cells. IL1 (10^{-14} to 10^{-8} M) reduced both basal and VIP-stimulated prolactin secretion. Similarly IL1 inhibited AC activty both in basal and VIP-stimulated conditions. Higher IL1 concentrations (10^{-10} to 10^{-8} M) restored the enzymatic activity to control value. IL1 also showed a biphasic effect on free intracellular calcium rise induced by maitotoxin (MTX). IL1 from 10^{-9} to 10^{-7} M potentiated MTX-induced increase of cytosolic calcium levels whereas lower concentration of IL1 (10^{-14} to 10^{-12} M) reduced MTX effect. Both the effects of IL1 on AC actvity and calcium fluxes were reverted by means of polyclonal anti-IL1 antibody, thus supporting the specificity of these findings. In conclusion our data show that IL1 modulates prolactin secretion through a direct action on pituitary cells, likely interacting with both AC activity and calcium flux.

MODULATION OF MAJOR HISTOCOMPATIBILITY COMPLEX (MHC) ANTIGEN EXPRESSION IN HUMAN NEURAL CELLS.
B. A. Boyer Kollas* and B. Wigdahl. Department of Microbiology and Immunology, The Pennsylvania State University College of Medicine, Hershey, PA 17033.

Previous studies by other investigators utilizing immunohistochemical techniques have demonstrated a low level of MHC class I and II expression in the human nervous system. However, in vivo animal model and in vitro studies have indicated that treatment of neural cell populations with (i) auto-antigens, (ii) interferon (IFN), or (iii) infection with neurotropic viruses induces the expression of MHC class I and II antigens. Expression of MHC proteins on cells of the human nervous system would potentially allow these cells to participate in immune response reactions. We examined human fetal dorsal root ganglia (DRG) isolated from aborted human fetuses ranging from 12 to 16 weeks gestation for their surface expression of MHC class I and II antigen by indirect immunofluorescence in conjunction with fluorescence-activated flow cytometric (FACS) analysis using monoclonal antibodies directed against the (i) heavy chain HLA- A, B, and C (class I), and (ii) HLA-DR region-associated, Ia-like bimolecular complex (class II). FACS analysis demonstrated that between 59 and 87% of human fetal DRG neural cells expressed detectable levels of MHC class I antigen while between 13 and 26% expressed class II antigen. Treatment of human fetal DRG neural cell populations for 48 hr with gamma-IFN (γ-IFN; 100 U/ml) enhanced the level of MHC class II expression by greater than 40%. These results were similar to those obtained in γ-IFN-treated U-373 MG human glioma cells. Current studies are examining the accumulation of MHC class I and II RNA in γ-IFN-treated human fetal DRG cells by RNA blot hybridization. These studies suggest that γ-IFN or other cytokines may alter the ability of specific human fetal neural populations to participate in immune reactions by modulation of MHC class I and II cell surface glycoprotein expression.

156.5

DUAL BINDING OF SEROTONIN AND N-ACETYL MURAMYL DIPEPTIDE TO SEROTONIN RECEPTORS. F.C. Westall. Institute for Disease Research, P.O. Box 1293, Alta Loma, CA 91701.

There are (Brain Res. Bull.,12: 485, 1984) structurally similar serotonin binding sites on the tryptophan peptide (phe-ser-trp-gly-ala-glu-gly-gln-arg) of the myelin basic protein, LHRH and MSH-ACTH 4-10. Furthermore, the adjuvant peptide, muramyl dipeptide (N-acetyl muramyl-L-ala-D-isogln) also binds to these sites (J.Inf.Ded.Biol.,2: 1,1986). Upon performing competition experiments using both muramyl dipeptide and serotonin with either LHRH or tryptophan peptide, we observed by nuclear magnetic resonance techniques that both compounds can simultaneously bind to either receptor. The serotonin is held predominantly through pi bonds to the aromatic rings, while the muramyl dipeptide binds to the more hydrophilic portions of the site. Our work helps to explain the contradictory effects of muramyl dipeptide and serotonin on neurological and immunological systems. Also, since both tryptophan peptide and LHRH are also autoimmune antigens, the results of the competition studies provide a model for how antigens are bound by the macrophage without interfering lymphocyte recognition.

156.6

INTERLEUKIN-1 ANTISERA DECREASES NEURONAL SURVIVAL IN DEVELOPING SPINAL CORD CULTURES. D.E. Brenneman, M. Schultzberg and I. Gozes. Lab. of Developmental Neurobiol., Clinical Neuroscience Branch, and Lab. of Molecular Genetics, NICHD and NIMH, Bethesda, MD 20892.

Interleukin-1 (IL-1), a protein that regulates the growth and activity of many cells including immune system cells, has been shown to occur in peripheral nerves and adrenal chromaffin cells in rodents, and in the human brain. In vitro studies have demonstrated the production of IL-1 by amoeboid microglia. Previous work has shown that nonneuronal cells stimulated by vasoactive intestinal polypeptide (VIP) secrete neuronal survival factor(s). We now investigate IL-1 as a possible mediator for these effects on neuronal survival in dissociated spinal cord cultures derived from fetal mice. After nine days treatment with antisera (1:2500 dilution) to holo murine interleukin-1 alpha, and to a synthetic peptide corresponding to amino acids 201-215 of the murine IL-1 alpha, neuronal cell counts were decreased to 40% of control cultures. Normal rabbit serum at the same dilutions had no effect on spinal cord neuron survival. Addition of VIP prevented the neuronal cell death associated with the antisera to IL-1. Immunoprecipitations utilizing the IL-1 antisera, followed by SDS polyacrylamide gel electrophoresis of the ^{35}S-methionine labelled proteins secreted by nonneuronal cell cultures in the presence of VIP, are now in progress to identify the endogenous peptide. In summary, the data imply that this cytokine or another substance that shares structural homology to IL-1, may have a role in the determination of neuronal survival during development. (MS is from Karolinska Inst., IG is on sabbatical from Weizmann Inst.)

ELECTROPHYSIOLOGICAL ANALYSIS OF THE ACTIONS OF PLATELET ACTIVATING FACTOR ON RAT MYENTERIC NEURONS IN CELL CULTURE. D.J. Fickbohm*[1], J.T. Wachsman*[2], D.W. Powell*[2,4] & A.L. Willard[1,3] (SPON: J. Dean). Curriculum in Neurobiology[1], Depts. of Medicine[2] and Physiology[3], and Core Center in Diarrheal Diseases[4], Univ. of North Carolina, Chapel Hill, NC 27599-7545.

Platelet Activating Factor (PAF), a lipid mediator of inflammation, stimulates Cl^- secretion by the intestinal mucosa by a process sensitive to tetrodotoxin and hexamethonium (Bern et al, *J. Clin. Invest. in press*, 1989). These observations suggest that PAF may trigger release of neurotransmitters from enteric neurons during inflammatory responses in the gut. We have used whole cell patch clamp methods to test directly the hypothesis that PAF excites rat myenteric neurons.

Myenteric neurons were dissociated from small intestines of newborn rats and grown in cell culture for up to 25 days. PAF was applied either by whole bath superfusion or by ejecting it from a micropipet. At concentrations ranging from 1 to 20 μM, PAF caused a reversible increase in membrane conductance and depolarizations as large as 30 mV. In addition, PAF often caused dramatic increases in nicotinic cholinergic synaptic activity (i.e. increased frequency of EPSPs).

The effects of PAF were not prevented by extracellular solutions that contained 0 (i.e no added) Ca, 2 mM Mg and 500 μM Cd (a concentration that completely blocks voltage-gated Ca currents in these cells). This suggests that influx of extracellular Ca is unnecessary for the actions of PAF. In a wide variety of other cell types (e.g. Kornecki & Erhlich, *Science* 240:1792, 1988), PAF causes elevation of intracellular Ca. We hypothesize that PAF causes release of intracellular stores of Ca in myenteric neurons and that the elevated Ca causes release of acetylcholine and activation of Ca-dependent cation channels. Supported by NIH grants to DWP (DK15350; DK34987) and ALW (NS24362).

METABOLIC EFFECTS OF GP120 IN BRAIN REGIONS RICH IN VIP RECEPTORS. A.S. Kimes, G. Szabo*, E.D. London, L. Raymon* and B. Tabakoff, Addiction Res. Ctr., NIDA, Baltimore, MD 21224 and Unit for Special Projects, IRP, NIAAA, Bethesda, MD 20892.

The glycoprotein (GP120) on the coat of the Human Immunodeficiency Virus (HIV) is toxic to neuronal cells in culture (Brenneman, D., et al., Nature 335:639, 1988), and binds to sites in the brain which have a distribution similar to VIP receptors (Hill, J., et al., Psychopharm. Bull. 22:690, 1986). In the present study, the effect of 1 pmole and 10 pmole GP120 administered intracerebroventricularly on regional metabolic rate(s) for glucose (rCMRglc) was measured using the 2-deoxy-D-[1-^{14}C]glucose method (Sokoloff, L., et al., J. Neurochem. 28:897, 1977) in rat brains. GP120 significantly decreased rCMRglc in the suprachiasmatic nucleus (1 pmole dose) and in the lateral habenula (10 pmole dose) by 19% and 12%, respectively, compared with controls receiving cerebrospinal fluid. The effects are consistent with the hypothesis that GP120 interacts with VIP receptors, as these regions have high densities of binding sites for VIP (Shafer, M.M. & Moody, T.W., Peptides 7:283, 1986). As the toxic effect of GP120 in cell culture had an inverted U-shaped dose response curve, we extended our studies to include lower doses of GP120. Preliminary results (N = 2/dose) indicate that 1, 10 and 100 fmole GP120 decrease rCMRglc in the above-mentioned regions and in several additional areas. The GP120-induced reduction in brain metabolism may be related to functional deficits in AIDS dementia.

GP120 was a gift from the National Cancer Institute.

SIGMA RECEPTORS IN LYMPHOCYTES: QUANTIFICATION ON T AND B CELLS AND DISTRIBUTION IN LYMPHOID TISSUES. S.A. Wolfe, Jr. and E.B. De Souza. Neurobiology Laboratory, Neuroscience Branch, NIDA/ARC, Baltimore, MD 21224.

The psychotomimetic drug phencyclidine (PCP) and several of its analogs suppress activity in *in vitro* immunologic functional assays. In addition, ^{3}H-PCP binds specifically to human peripheral blood leukocytes (HPBL). Since PCP binds to both PCP and σ receptors in brain, we previously surveyed rat spleen and HPBL, and found no evidence of PCP receptors, however we detected σ receptors in these tissues in densities equal to or exceeding that of brain. In the present study, we used fractionated lymphocyte populations and characterized cell lines to identify and quantify σ receptors on rat, human and mouse T_H, $T_{eff/suppr}$ and B cells. The highest density of σ receptors occurred on B cells, but T cells also displayed σ binding sites. In autoradiographic studies using the ligand d-3-(3-hydroxyphenyl)N-(1-propyl-2,3[^{3}H]piperidine) (^{3}H-3-PPP) and 3,4-[^{3}H]-(N)-[1(2-thienyl) cyclohexyl]-piperidine (^{3}H-TCP) to specifically label σ and PCP receptors, respectively, we confirmed the absence of PCP receptors, but detected σ binding sites in rat lymphoid tissues. Spleen contained a higher density of σ receptors than did thymus, mesenteric lymph nodes, or Peyers patches. In spleen, σ receptors were found in the white pulp areas, and were maximal in the outer (B cell) zones of the follicles. The presence of high densities of this brain/nerve receptor on lymphoid cells suggests a physiological role for endogenous σ ligands in modulating immune responses and in the integration of the CNS-endocrine-immune axis.

HUMAN NATURAL KILLER CELLS EXPRESS Na^+ CHANNELS. R.N. Mandler, L. Seamer*, A. Bankhurst*, M. Lennon*, E. Rosenberg* and D. Whitling*. Depts. of Neurology, Medicine and The Cancer Center, The Univ. New Mexico Sch. Med., Albuquerque, NM 87111.

We studied voltage-gated excitability of human purified natural killer (NK) cells using flow cytometry and the voltage-sensitive dye oxonol. Cells were obtained from normal volunteers after Ficol-Hypaque density gradient centrifugation, plastic adherence for macrophage removal, nylon-wool columns for B-cell removal and negative selection with monoclonal antibodies for T cells removal. The Na^+ channel agonists Batrachotoxin (BTX) (1-4 uM) and Veratridine (Ver) (100-400 uM) depolarized a population of highly purified (99%) human NK cells as determined by Leu 11-Leu 19 flow cytometric assay. BTX and Ver responses were concentration, time, temperature, and Na^+ dependent. The Na^+ channel antagonist tetrodotoxin (TTX) (1 uM) blocked BTX and Ver responses. Ver (100 uM) produced significant inhibition of cytotoxicity when purified NK cells were incubated with K562 tumor target cells in a 4 hr Cr^{51}-release cytotoxicity assay. These results strongly suggest presence of functional Na^+ channels in NK cells. Activation of voltage-dependent Na^+ channels depolarizes cells and reduces their cytotoxic function.

MODULATION OF CHANNEL ACTIVITY AND SECRETION BY NEUROTRANSMITTERS IN LACRIMAL GLAND LYMPHOCYTES. B.Walcott, E.J.Roemer* and P.R.Brink. Dept. of Anat. Sci., State University of New York, Stony Brook, NY 11794.

Anatomical studies have shown close physical proximity between AChE and catecholamine positive autonomic fibers and large numbers of plasma cells in the medulla of avian Harderian glands, suggesting a functional relationship. To test this, we have mechanically isolated plasma cells from the glands, suspended them in RPMI medium and treated them for 20 min. with 0.5 mg/ml collagenase. Plasma cells were identified by their morphology when compared to identical preparations stained with specific antibodies. Whole cell and cell-attached patch recordings were made within several hours of the isolation of the cells. Patch recordings revealed a maxi-K channel of 230 pS and, rarely, a small K channel of 40 pS. The maxi-K channel was Ca^{++} dependent. Carbachol ($1X10^{-5}$ M) caused a reversible increase in membrane current due to an increase in maxi-K channel open time. Norepinepherine ($2X10^{-7}$ M) caused a dramatic increase in cell current indicative of massive channel opening. In addition, carbachol ($1X10^{-5}$ M) caused pooled cells (approx. 10^5/ml) to transiently release 2 times the baseline amount of IgG into the medium. Thus, it appears that neurotransmitters have a direct effect on secretory functions of plasma cells.

DISTINCT SUBSETS OF LEWIS RAT T-HELPER LYMPHOCYTES RECOGNIZE THE 68-86 ENCEPHALITOGENIC REGION OF MYELIN BASIC PROTEIN. M. D. Mannie, P. Y. Paterson, D. W. Thomas, and R. Nairn (SPON: R. Holz). Department of Microbiology and Immunology, University of Michigan School of Medicine, Ann Arbor, MI 48109-0620.

T-helper lymphocytes which mediate experimental autoimmune encephalomyelitis (EAE) in Lewis rats recognize the 68-86 region of myelin basic protein (MBP). However, it is not known whether these T cells represent a homogenous population or a heterogenous population consisting of distinct subsets of T-helper cells. To address this question, we used six T cell hybridomas reactive with clonotypically unique epitopes in the 68-86 region of MBP to determine whether these hybrids required the same or different accessory signals for activation. When cultured with accessory cells (Lewis rat splenocytes) and MBP, all six hybrids were induced to secrete IL-2. Two observations indicated that these hybrids represented either of two exclusive subsets of T helper cells (designated THYB-1 and THYB-2). First, during a four hour preincubation of accessory cells with MBP, signals required for the activation of THYB-1 hybrids remained stable whereas those required by THYB-2 hybrids decayed rapidly. Second, radioresistant adherent cells were both necessary and sufficient for MBP-induced activation of THYB-1 hybrids. In contrast, both radioresistant adherent cells and radiosensitive nonadherent cells were required for MBP-induced activation of THYB-2 hybrids. These data indicate that at least two distinct subsets of MBP(68-86) reactive T helper cells can be defined by their distinct requirements for accessory cell signals. (Supported by a Postdoctoral Fellowship from the National Multiple Sclerosis Society, NIH grant AI-19273, and the Mulvihill Family Foundation.)

^{3}H-SPIPERONE LABELS SIGMA RECEPTORS IN LYMPHOCYTES. T. Coccini* and L.G. Costa. Department of Environmental Health, University of Washington, Seattle, WA

^{3}H-spiperone binds to dopamine D2 receptors in striatum and under the assumption that it labels the same receptors in lymphocytes, this binding site has been suggested as a biological marker for schizophrenia. We confirmed the presence of a specific, saturable and reversible binding of ^{3}H-spiperone to rat and human lymphocytes. However, although some dopaminergic drugs such as haloperidol, spiperone and pimozide were potent inhibitors of ^{3}H-spiperone binding, other specific dopaminergic compounds such as dopamine, apomorphine, sulpiride, eticlopride had minimal effects. The stereospecificity of butaclamol was the opposite of that expected for dopamine receptors. Serotoninergic drugs were weak inhibitors of ^{3}H-spiperone binding. On the other hand, drugs specific for the sigma receptors, such as pentazocine, SKF 10,047 and DTG were potent inhibitors of ^{3}H-spiperone binding in lymphocytes. Sigma receptors in lymphocytes were also identified with ^{3}H-DTG and ^{3}H-haloperidol: their binding characteristics are comparable to those of sigma receptors in brain tissue (cerebellum). Sigma receptor density in lymphocytes was similar with the three ligands (values of Bmax=77-95 fmole/10^6 cells), and a good correlation was found in a group of volunteers between the binding of ^{3}H-spiperone and ^{3}H-DTG. These findings indicate that sigma receptors are present in lymphocytes and that ^{3}H-spiperone binding in these cells occurs to these sites and not to dopamine D2 sites. (Supp. in part by grants from NIEHS, ES-04696, and Fondazione Clinica del Lavoro, Pavia).

AUTORADIOGRAPHIC LOCALIZATION OF BETA-2-ADRENERGIC RECEPTORS IN THE RAT THYMUS: ONTOGENESIS AND HORMONAL CONTROL. *B. Marchetti, *M.C. Morale, *U. Scapagnini, ▲G. Pelletier (SPON: M.A. Kling). Dept. of Pharmacology, University of Catania, 95125 Italy and ▲Molecular Endocrinology, CHUL, Quebec, G1V 4G2, Canada.

A substantial body of evidence suggests a feedback between the thymus and the brain, accomplished via direct innervation, thymic peptide secretion and endocrine-like pathways. We have used the potent beta adrenergic antagonist,iodocyanopindolol, to characterize and localize specific beta adrenergic receptors (ADR-R), of the beta-2 subtype, during thymus development and maturation of cell-mediated immune response. The density of beta ADR-R increases progressively between birth and 70 days of age, reaching half maximal levels at 17 days and a plateau at 40 days after birth. Castration sharply reduced the density of ADR-R, this effect being counteracted by estradiol alone or in combination with progesterone. T-cell blastogenic response to isoproterenol varied as a function of sexual maturity. Present data indicate that thymic ADR-R are involved in a regulatory system and suggest a clear interdependence between the development of neurendocrine and immune systems.

EFFECT OF PERINATAL THYMECTOMY ON ADULT SEXUAL BEHAVIOR. D.F. Bloom*, G.J. Bloch*, and R.A. Gorski (SPON: C. Duchala). Dept. Psychol., Dept. Anat./Cell Biol.; Lab. of Neuroendo., Brain Research Institute, UCLA, L.A., CA 90024.

The presence of the thymus appears necessary for the normal development of the reproductive axis, as perinatal thymectomy (thyX) of the female rodent results in ovarian dysgenesis and premature cessation of ovulation. The critical period for thyX coincides, perhaps significantly, with the critical period for brain sexual differentiation that results in sex-appropriate gonadotropin release and behavior. Thus far, no attention has been given to the effect of thyX on behavioral aspects of reproduction. Eight Long-Evans rat pups were thymectomized on day 3 of life; 11 (controls) were sham-thymectomized. All animals were ovariectomized in adulthood, and 2 wks later each received (s.c.) 2 ug of estradiol benzoate (EB) on day 0 and day 1 (day of test 1); 5ug EB was injected on day 2, and 2 ug EB was injected on day 3 (day of test 2). Test 3 was performed on day 4. On day 5, all rats were injected with 250ug of progesterone 5 hrs before test 4. For each test, a lordosis quotient (LQ, # responses per 20 male mounts X 100) was computed. On test 1, only 1 thyX rat (LQ=10%) and 2 control rats (LQ=20% & 40%) performed. With experience and repeated estrogen administration (test 2), behavior increased, and thyX animals revealed significantly lower ($p=.018$) LQ's than did controls (28.8±7.9% vs 64.5±11.1%). This trend continued (20±5.3% vs 65.5±9.2%, $p=.002$) on test 3. On test 4, all rats, except for 2 thyX animals (LQ's=10% & 90%) showed LQ's of 100%, revealing the physical capability of thyX females to perform high levels of lordosis. The apparently lowered estrogen sensitivity may result from the effect of thyX on the development of neural substrates of behavior.

SYNERGY OF cAMP PRODUCTION IN LYMPHOCYTES WITH DUAL BETA-ADRENERGIC AND MITOGENIC STIMULATION. S.L. Carlson, K. Trauth* and T.L. Roszman*, Dept. of Microbiology and Immunology, Univ. of Kentucky Medical Center, Lexington, KY 40536

Many reports have shown that manipulation of the autonomic nervous system can alter immune function via stimulation of the ß-adrenergic receptor (ßAR) on lymphocytes. To examine the mechanism of adrenergic effects on lymphocytes, we have studied the generation of second messenger signals within human T cells as a result of ßAR and mitogenic stimuli. The ßAR signals via the cAMP second messenger system whereas mitogens signal via the phosphotidylinositol pathway. We have found that stimulation of lymphocytes with both a ß-adrenergic agonist (isoproterenol, ISO) and mitogen (phytohemagglutinin or anti-T3 monoclonal antibody) results in a synergistic rise in cAMP compared to ISO alone. This effect is observed whether the mitogen is added several minutes before or after the ISO. In addition, the synergy follows a dose response depending on the concentration of mitogen added. Not only is cAMP accumulated more rapidly in T cells exposed to mitogen, but the levels of cAMP remain elevated for several hours compared to ISO stimulation alone. Both $T8^+$ and $T4^+$ T cells show a cAMP synergy with mitogen, however the absolute level of cAMP is higher in $T8^+$ cells, consistent with the higher number of ßAR expressed on these cells. Current studies are focused on determining the mechanism of the synergy. Stimulation of the ßAR results in a rapid desensitization of the ßAR. Receptor binding studies indicate that T cells incubated in the presence of the mitogen and ISO have less ßAR desensitization than cells incubated with ISO alone, which may be involved in the mechanism of the cAMP synergy. Other experiments have also suggested that increased intracellular calcium as a result of the mitogenic stimulus may be involved in the observed synergy.

THE CHARACTERIZATION OF NEURORECEPTORS DURING DYNAMIC PHASES OF IMMUNOCYTE DEVELOPMENT. K. Bulloch[1], T.I. Bonner[*2], R. Cassin[*3], D. Darko[*1], T. Rodojcic[*1] and M. Roman[*1]. [1]University of California, San Diego, La Jolla, CA 92093 [2]NIMH, Bethesda, MD 20982, [3]Helicon Foundation, San Diego, CA 92109.

The innervation of lymphoid tissues and organs implies that there are neuroreceptors on immunocytes that are capable of transducing signals from the nervous system to the immune system. We have focused our research on characterizing the types and function of these receptors at the cellular level as a first step in understanding the mechanisms of neuroimmune interactions. In order to gain a better understanding of the expression of beta adrenergic receptors (BAR) during the life cycle of a specific class of immunocyte, we have employed in vitro assays mimicing the in vivo phases of cell proliferation and differentiation. In an assay where Con A was used to stimulate thymocyte and splenic T-cell proliferation, BAR receptors were up regulated without changes in the Kd. PMA plus Ca^{2+} induced maturation of the monocyte cell line U937 down regulates their BAR receptors (Bmax) without affecting their affinity (Kd). Agonist induced levels of c AMP are proportionally reduced in PMA treated cells. Similar changes in BAR's Bmax are observed with PMA treatment of the thymocyte cell line, BW5147, as well as fresh thymocytes. However, no changes were observed in agonist stimulated c AMP levels. In characterizing the lymphoid muscarinic acetylcholine receptor (M AChR) on a B cell lymphoma, we have now demonstrated that carbachol specifically inhibits division. This phenomenon is not due to agonist toxicity. Using Northern Blot analysis our data indicates that the m-2 and m-5 M AChR probes hybridize to 1.9 kb and 3.0 kb mRNA isolated from this cell line. The results of these experiments advance our knowledge of the structure and function of the innervation and receptor fields of the immune system in dynamic models of normal physiological states as well as providing avenues for the development of new cancer therapies. Supported by a gift from the Kettering Foundation and grant #N00014-89-J-1256 of the ONR.

MODULATION OF ALVEOLAR MACROPHAGE FUNCTION BY NEUROPEPTIDES. I.Lemaire, M. St-Jean and S. Ouellet. (SPON: S. Lemaire). Lab. of Immunopharmacology, Dept. of Pharmacology, Fac. Health Sci., Univ. of Ottawa, Ottawa, Ont. Canada K1H 8M5.

Accumulating evidence suggest bidirectional communication between the nervous and the immune system. Alveolar macrophages (AM) present in the lung play a major role in immune reactions and inflammation. Since mediators of the nervous system are also present in the lung, we investigated the effects of neuropeptides on AM functions. Neurotensin (NT) (10^{-10}-10^{-6}M) as well as bombesin (BN) (10^{-9} -10^{-6} M) caused a significant enhancement of interleukin-1 (IL-1) production by activated AM whereas vasointestinal peptide (VIP) (10^{-9} -10^{-6} M) inhibited LPS-induced IL-1 production. NT also enhanced over the same range of concentrations tumor necrosis factor-α (TNF-α) production by activated AM. Furthermore, NT caused an increase in the proportion of large and mature macrophages as evidenced by AM morphology and sedimentation on Percoll density gradient. Our data demonstrate that neuropeptides present in the lung can exert dual regulation of AM functions associated with inflammatory response. (Supported by MRC).

SUBCORTICAL SOMATOSENSORY PATHWAYS I

157.1

BRAINSTEM PROJECTIONS TO SOMATOSENSORY THALAMUS IN THE MONKEY. H.J. Ralston and D.D. Ralston Department of Anatomy, University of California, San Francisco, CA 94143.

The somatosensory thalamus of the monkey receives projections from the dorsal column-lemniscal system (DCN), the spinothalamic tract and the trigeminal system (V), all of which interact with thalamocortical relay cells (TCR) as well as the GABAergic interneuronal population. These afferents are involved in both simple and complex synaptic arrays, exciting and modulating the output of the TCR cells. In addition, there are presumed to be afferent inputs from several other neuronal groups in brainstem which utilize various transmitters, including norepinephrine (NE), acetylcholine (ACh) and serotonin (5HT) to regulate the transfer of afferent information through the thalamus. These brainstem afferent projections to the thalamus have been shown in several mammalian species, but have been little studied in the primate.

In this study the somatosensory thalamus of the monkey (*Macaca fascicularis*) was physiologically characterized and injected with 5% wheatgerm agglutinin-horseradish peroxidase (WGA-HRP) or WGA-apoHRP-gold under sterile neurosurgical conditions. The animals were cared for using N.I.H. and U.C.S.F. Animal Care Committee guidelines. Subsequently, brainstem sections were processed to demonstrate retrogradely labeled neurons and some specimens processed for immunocytochemistry. In addition to labeling in DCN,V and nucleus solitarius, there was extensive labeling found in mesencephalic, pontine and medullary reticular formation. In particular, there were numerous labeled neurons in NE cell groups (locus coeruleus), cholinergic nuclei (nucleus cuneiformis) and neuronal groups containing 5HT (dorsal raphé). Thus, the primate somatosensory thalamus receives projections from brainstem neuronal nuclei which contain neurotransmitters shown in other species to have profound effects on the firing properties of thalamic neurons, influencing the transfer of information by thalamic neurons to the cortex.

ORIGINS OF CALCITONIN GENE-RELATED PEPTIDE (CGRP) IMMUNOREACTIVITY IN THE RAT SOMATOSENSORY THALAMUS. S.C. Ahlgren*, P.T. Ohara and A.M. Williamson. Dept of Anatomy, University of California, San Francisco, CA 94143.

Small injections of WGAapoHRP-Au (Basbaum A.I. and Menetrey,D., J.Comp.Neurol., 261:306, 1987) were made in lateral or medial thalamic nuclei. After 2 days survival the animals were perfused and reacted to visualize the WGAapoHRP-Au, then processed for immunocytochemistry using a primary antibody to CGRP (Sternini,C. and Brecha, N.C., Gastroent., 90:1155.). A second series of injections using PHA-L were made into various brainstem sites known to contain CGRP-positive cell bodies to determine thalamic projections from these sites.

As previously shown, CGRP immunoreactivity is largely confined to medial thalamic nuclei with nucleus submedius being heavily labelled. Following WGAapoHRP-Au injections into medial thalamic nuclei double-labelled cells are found in the medial and ventral portions of the parabrachial nucleus and in laminae I and II of the trigeminal nucleus caudalis. Injections into lateral thalamic nuclei resulted in some double labelled cells in the nucleus caudalis.

These results show that medial thalamic nuclei implicated in affective aspects of nociception receive CGRP innervation from several brainstem sites.

Supported by NS21445 and NS23347 from NIH

157.3

Distribution of GABA terminals on identified thalamocortical neurons in the VPL nucleus of the cat. X.-B. Liu*, C.N. Honda and E.G. Jones Department of Anatomy and Neurobiology, University of California, Irvine, California 92717. Spon. E. Davis, Jr.

We have used immunocytochemistry on vibratome sections containing thalamo-cortical relay cells, identified by intracellular recording and injection of HRP, to map the distribution of GABA synapses on the relay cells, after re-embedding and thin sectioning for electron microscopy.

Dense DAB reaction product in injected cell profiles contrasted with the less densely stained immunocytochemically defined GABA terminals. Serial thin section analysis confirmed the separate origins of the two types of profile. GABA terminals with features of presynaptic dendrites and presumed to derive from intrinsic neurons made symmetrical type synapses mainly on middle and distal segments of relay cell dendrites. More proximal dendrites and the cell soma received GABA positive terminals, not identifiable as presynaptic dendrites. These may derive from axons of reticular nucleus cells and of intrinsic neurons.

Supported by NIH grant NS22317.

157.4

ELECTROPHYSIOLOGICAL STUDY OF SPINO-THALAMIC INPUTS TO VL/VA. C.-T. Yen and E.G. Jones. Dept. of Zoology, National Taiwan University, Taipei, Taiwan, ROC and Dept. of Anatomy and Neurobiology, University of California, Irvine, CA 92717, USA.

The ventrolateral and ventroanterior nuclei of the thalamus (VL/VA) are known to receive direct inputs from spinothalamic tract fibers. This connection was studied by intra- and extracellular physiological techniques in cats. The animals were anesthetized with ketamine and barbiturates, and paralyzed with gallamine triethiodide. Their body functions were maintained within physiological ranges. Glass micropipettes filled with a buffered HRP solution were used to record from VL/VA neurons. Tungsten microelectrodes were used to activate the ipsilateral and contralateral spinothalamic pathways at the level of C2/3. Fifty-nine VL/VA neurons were recorded, 13 responded to spinal cord stimulation. Of these, 7 were inhibited and the other 6 had short latency excitatory responses. Their initial latencies varied from 3 to 10 msec (mode 6 msec). In experiments in which stimulation electrodes were also placed on the primary motor cortex, thalamocortical (TC) cells were identified. A small number of these cells responded to cord stimulation with 3 msec latency. This response could follow repetition rate higher than 20 Hz, indicating a monosynaptic connection between the spinothalamic tract fibers and some TC cells.

Supported by NIH grants TW03905 and NS22317.

THE RACCOON SPINOCERVICAL AND SPINOTHALAMIC TRACTS: AN HRP STUDY. Benjamin H. Pubols Jr., and John H. Haring. Good Samaritan Hospital & Medical Center, Portland, OR 97209, and St. Louis University, St. Louis, MO 63104.

In different raccoons, either the lateral cervical nucleus or the thalamic ventrobasal complex was injected with 1-2% solutions of WGA-HRP. Following 24 h or 4 d, respectively, the animals were sacrificed and both injection and target sites (spinal cord segments C_6-T_2) were processed using the TMB method. All labelled cells were counted in every fifth 50 μm section.

All labelled spinocervical tract (SCT) cells were located ipsilateral to the injection sites. Most were in laminae III and IV, with a few located more deeply or in lamina I. 50% of labelled cells were located in the medial 1/3 of the dorsal horn, the region of representation of the glabrous surfaces of the forepaw (Pubols, Hirata, and West-Johnsrud, 1989). The mean number of labelled SCT cells/section was 4.63.

75% of spinothalamic tract (STT) cells were located contralateral to the injection sites. Of these, 43% were in lamina I, the remaining 57% in laminae III-VI. Only 20-25% were located in the medial 1/3 of the dorsal horn. The mean number of labelled STT cells/section was < 0.50.

We conclude that the SCT plays a more critical role than does the STT in relaying tactile information from the glabrous surfaces of the forepaw to higher centers of the raccoon somatosensory system. [Support: NS-19486, USPHS.]

157.6

PRETECTAL NEURONS RELAY SPINAL INPUT TO CAT MOTOR THALAMUS. R.Mackel,H.Asanuma,A.Iriki* and E.Jorum*. The Rockefeller University, New York, NY 10021.

Lesioning the pretectal area (PT) abolishes spinal input to thalamic VL neurons (1). To confirm that PT neurons convey the spinal input, extracellular recordings were made from PT neurons identified as projecting to VL.

Experiments were performed on 10 cats anesthetized with chloralose. For antidromic stimulation of PT neurons, an array of stimulating electrodes was placed in VL. Spinal input was studied by stimulating the dorsal column(DC) and spinothalamic tract(ST) in the cervical spinal cord. Stimulation and recording sites were marked by lesion.

A total of 117 PT neurons were antidromically identified by their fixed latency, all-or-none responses and ability to follow high frequency trains. 62/86 PT cells (72%) tested for spinal input were activated by stimulation of DC and/or ST afferents. Of these neurons 56% received input from both spinal sources, 36% from DC only and 8% from ST only. The range of orthodromic latencies was wide (3-20ms). The PT neurons were located caudo-laterally in PT and projected to more caudal parts of VL.

These data indicate that PT neurons which project to motor thalamus process a considerable amount of somatosensory information which could play an important role during movement execution. (1) Brain Res (1989),47, 135-139.
The study was supported by NS-10705 and NS-26288.

GLUTAMATE IMMUNOREACTIVITY IN IDENTIFIED TERMINALS IN THE VENTRO POSTERO LATERAL NUCLEUS OF THE RAT THALAMUS. R. Spreafico*, A. Amadeo* and S. De Biasi. Dip. Fisiologia Ist.Neurologico "C.Besta" and Dip. Fisiologia e Biochimica generali, Sez.Istologia e Anatomia umana, Milano, Italy.

Although the synaptic organization of the ventro postero lateral (VPL) nucleus of the rat thalamus has been extensively studied, little is known about the neurochemical content of its terminals. In the present work experiments were carried out in rats a) to investigate whether the medial lemniscal pathway, the spinothalamic tract and terminals from brainstem nuclei may use glutamate (Glu) as neurotransmitter; and b) to study the relationship of the identified profiles with GABA immunoreactive terminals. Ultrastructural identification of synaptic terminals was performed by injecting WGA-HRP in the dorsal column nuclei, in the dorsal spinal cord and in the brainstem of deeply anesthetized rats. Single and double immunogold staining was then performed on thin sections of VPL from the injected rats, using polyclonal anti-Glu and anti-GABA sera. All the anterogradely labeled terminals are large and mainly contact proximal dendrites of VPL neurons. Most of these HRP-labeled terminals are stained by the anti-Glu serum. Glu-immunoreactivity is also in some small terminals not labeled by HRP, that contact distal dendrites. None of the HRP-labeled or Glu-positive terminals is immunoreactive for the anti-GABA serum, which stains medium sized boutons synapsing on proximal and distal dendrites.

MISMATCH BETWEEN NEURONAL RECEPTIVE FIELDS AND PROJECTED FIELDS EVOKED BY MICROSTIMULATION IN THE SENSORY THALAMUS OF PATIENTS WITH SPINAL CORD INJURY. F.A. Lenz, J.O. Dostrovsky, L. Lee', R.R. Tasker'. Dept. of Neurosurg., Johns Hopkins Hosp., Baltimore, MD. 21205 Dept. of Physiol. & Neurosurg., U of Toronto, Canada.

The sensory thalamus was explored in patients with central pain following spinal cord injury to determine the optimal site for implantation of deep brain stimulating electrodes for the treatment of pain. The same procedure was carried out in a control population of patients operated for treatment of dyskinesia. Receptive fields of thalamic single neurons were determined by standard methods. At the same sites where neurons were recorded, microstimulation was carried out to determine the part of the body where microstimulation (<25uA) evoked sensations (projected field). Receptive fields and projected fields were determined at 38 sites in 3 patients with spinal cord injury. In these patients, regions of the thalamus that represented parts of the body distant on the thalamic homunculus from the area of sensory loss were defined as 'unaffected' regions. Regions of thalamus that represented parts of the body adjacent to the area of sensory loss often exhibited increased representations of those parts of the body and were defined as 'affected' regions of thalamus. In control patients and in unaffected regions of thalamus in patients with spinal-cord injury there was usually a good match between receptive and projected fields. However, in affected regions of thalamus there was frequently a mismatch between receptive and projected fields. Projected fields were often referred to parts of the body where the patient experienced anesthesia as a result of the spinal injury. The activity of cells located affected regions of thalamus may be responsible for sensations referred to the anesthetic part of the body.

RELATIONSHIP OF THALAMIC NEURONAL RESPONSES AND MICROSTIMULATION EVOKED SENSATIONS ELICITED AT THE SAME SITES IN MAN. L. Lee*, J.O. Dostrovsky, R.R. Tasker* and F.A. Lenz (SPON: M.D. McClean). Dept. Physiology and Div. Neurosurg., Univ. of Toronto, Canada, and Dept. Neurosurg., Johns Hopkins Univ., Baltimore, MD, USA.

The use of both microstimulation and microrecording during stereotactic thalamotomy procedures provides a unique opportunity for correlating evoked thalamic neuronal responses with sensations evoked by electrical stimulation at the same site. In the present study thalamic ventrobasal complex neurons responding to sensory stimulation were recorded at 518 different sites in a total of 80 different electrode trajectories in 22 patients undergoing stereotactic thalamotomy for motor disorders. Most of the neurons had small cutaneous receptive fields (RFs) on the digits, lips and face. There were fewer neurons with RFs on other body regions such as leg, arm and torso and their RFs were larger. Stimulation at all of these recording sites (1 second, 300Hz, trains of 0.1ms pulses, <25uA) induced sensations (usually tingling) referred to a part of the body (projected field). In the well represented hand and face regions microstimulation usually resulted in identical or overlapping projected and receptive fields. However when the receptive fields were on less well represented regions of the body such as torso or leg the projected field was frequently different from the receptive fields of the neurons recorded at that site. The current thresholds necessary to evoke sensation were also usually higher at those sites where there was a large mismatch between the receptive and projected field. These findings indicate that the receptive and projected field sizes are inversely related to the degree of representation of that body region and that there is usually an excellent correspondence between the neuronal RFs and the projected fields in well represented regions.

BROADLY DISTRIBUTED INHIBITION IN VENTROPOSTERO-LATERAL NUCLEUS OF RAT. W.A. Roberts* and J. Wells. (SPON: W. W. Pendlebury) Department of Anatomy and Neurobiology, University of Vermont, Burlington, VT 05405.

We have studied the extracellular evoked response of single ventroposterolateral nucleus neurons using stimulation of brachial plexus and sciatic nerve. Thirteen percent of VPL projection neurons were responsive to both forelimb and hindlimb inputs. We also demonstrated the existence of mutually inhibitory interactions between inputs from forelimb and hindlimb in 45% of VPL units. The map of VPL we have obtained using direct nerve stimulation differs from that obtained with modality specific inputs in that a somatopically overlapping distribution was obtained. By appropriately timing the delivery of stimuli, forelimb inputs caused the inhibition of responses to hindlimb stimulation, and similarly, hindlimb inputs inhibited responses to forelimb stimulation. The inhibition had a duration that was variable and may reflect a combination of mechanisms including recurrent inhibitory collateral input from the thalamic reticular nucleus or an intrinsic hyperpolarizing inhibitory after potential of the VPL neuron. The responsiveness of VPL neurons to both forelimb and hindlimb inputs and an inhibitory correlate to this overlapping of inputs may explain the shifting of VPL maps following lesions of peripheral nerve, spinal cord or DCN.

LESIONING THALAMIC POSTERIOR GROUP (PARS MEDIALIS) IMPAIRS FOCUSED ATTENTION AND ONE OF ITS ECOG INDEX IN CAT M.H.Canu*, C.Durand*, M.F.Montaron*, J.J.Bouyer, A.Rougeul* and P.Buser*. *Institut des Neurosciences, Département de Neurophysiologie comparée, CNRS-Université P. & M. Curie, 9 quai Saint Bernard, F-75005 Paris.*

In the cat as in the monkey, motionless behavioural states of focused attention upon a target are accompanied by short volleys of fast electrocortical (ECoG) rhythms (ca 40 Hz) designated as "beta rhythms". Fronto-parietal beta rhythms mainly develop in two foci, one on the motor cortex, the other in the associative posterior parietal cortex (area 5a). The latter focus depends upon a thalamic rhythmic center located within the posterior thalamic nuclear group (pars medialis, POm). This issue was as yet mainly based upon simultaneous electrophysiological recordings from the thalamus and the cortex, including computing correlation and coherence functions between global rhythms and also comparing cortical waves and thalamic spikes using a "wave triggered" recording. We have now considered the effects of kainic acid lesions of the thalamic site. In the present study, kainic acid was injected bilaterally into the POm. The lesions have as yet been partial; however, very clear changes were observed concerning both ECoG and behaviour. The lesioned animals displayed for their behaviour an unusual distractibility : instead of remaining motionless during at least 60 mn with attention focused on the target (a mouse in a transparent box placed in front of them), their immobility was interrupted by numerous episodes of motor activity. Simultaneously, the beta rhythms, which appear only during attentive immobility, became much less frequent and their amplitude was reduced. These results support our previous findings and our hypothesis that integrity of the POm neurons (assuming that kainic acid mainly destroys cells and not passing fibres) both generate beta rhythms and are in some way governing attentive immobility. Other data from our group have indicated that the POm-parietal 5a cortex system is under a gating influence from the mesencephalic ventral tegmental area.

A GOLGI AND WGA-HRP STUDY OF THE RETICULAR THALAMIC NUCLEUS (RTN) OF THE RAT.

G. Battaglia , C. Frassoni , R. Spreafico , (SPON: European Neuroscience Association). Neurological Institute "C. Besta", 20133 Milano, ITALY.

Aim of the present study is to characterize the morphology of different cells types of RTN and to relate these data with those obtained by the axonal transport of WGA-HRP. Twenty rats' brains were used for silver impregnation methods by means of a Golgi-Kopsch technique, and cut in both coronal and horizontal 100 µm thick sections. In ten other animals WGA-HRP was injected in different areas of the somatosensory cortex and in the thalamus. Three morphologically different neurons were found in RTN: round-shaped neurons (R), with multidirectional dendritic arborization, large fusiform neurons (F), with dendrites arborizing in the horizontal plane; small fusiform neurons (f), mainly located in the medial and lateral border of RTN, with dendrites arborizing in the vertical plane. All cellular types were labeled after thalamic injections of WGA-HRP. Only labeled terminals were found in RTN after S_1 injections of the enzyme; they predominate in the most medial and lateral borders of the nucleus. It seems reasonable to conclude that axon collaterals of cortico-thalamic neurons synapse preferencially on the vertical dendritic arborization of "f" neurons. These data suggest a peculiar and precise intrinsic organization of RTN, subserving a more complex functional arrangement between the thalamus and the cortex in the rat.

A HIERARCHICAL NETWORK SIMULATION FOR MODELING INTERACTIONS IN THE SOMATOSENSORY PATHWAY. J.P. Utz and J.K. Chapin. Dept. of Physiol. & Biophys., Hahnemann Univ., Phila., PA 19102-1192.

A neuronal network simulation program has been developed as an aid for investigation of the mechanisms of information processing in the mammalian somatosensory system. Computation was done in C under Unix System V/68 on a 16 MHz MC68020 microprocessor. Initial studies have examined feedforward propagation of "sensory" volleys through a 5 layer serial network. Each layer contains a 12x12 array of neurons (720 total), each of which receives convergent excitatory input from 25 radially arranged neurons in the previous layer. The neurons in the first layer receive pseudorandom excitatory input, providing a background "noise". Neuronal characteristics were modeled using difference equations with initialized constants (e.g. membrane time constant, threshold and conductance decay constants) to calculate state variables (e.g. membrane potential, ion conductances, threshold, spike accommodation). Output of the network was recorded as membrane potential, and spike and synaptic events occurring at each neuron every cycle (1 ms). Parametric studies of this simplified network have shown that forward propagation through the network layers require sufficient: 1) background excitation of neurons, 2) synaptic convergence on target neurons, and 3) synaptic efficacy. Propagation of input volleys through the layers cannot occur in the absence of these factors, even if single input neurons fire rapidly. On the other hand, increasing these factors results in an amplification of the signal as it propagates forward through the layers. These results emphasize the importance of these factors in determining the threshold of transmission of sensory information, and also its pattern and amplification through successive layers. *Supported by PHS grants NS26722, AA06965, and AA00089.*

SOMATOSENSORY TRANSMISSION THROUGH THE LEMNISCAL SYSTEM DURING MOVEMENT IS FACILITATED AND THEN SUPPRESSED: VELOCITY DEPENDENCE . H.-C. Shin, B.K. Jin and J.K. Chapin, Dept of Physiology/Biophysics, Hahnemann U., Phila., PA 19102

We have previously shown that cutaneous sensory transmission from the forepaw to single neurons in the rat somatosensory (SI) cortex is strongly suppressed during treadmill locomotion. To determine the level in the lemniscal somatosensory system at which this modulation may occur, we have here simultaneously recorded single neurons in the forepaw areas of the cuneate nucleus (nC), ventroposterolateral (VPL) thalamus, and the SI cortex in awake rats. Modulation of sensory transmission to these cells was tested by stimulating through electrodes chronically implanted under the skin of the palmar forepaw. Evoked unit responses to this stimulation were measured during resting behavior as a control, and during three standardized speeds of locomotory movement: Slow (1.0 steps/s), Medium (1.5 steps/s), and Fast (2.0 steps/s). These studies confirmed the strong suppression of neural responses in the SI cortex to such stimuli during movement. However, neural responses in the nC were facilitated, and in the VPL were similar to control. Furthermore, at all levels, greater speeds of movement produced increased sensory suppression. Thus, responses of neurons in the nC were facilitated by $+59.4 \pm 29\%$, $+54.9 \pm 7\%$, and $+23.6 \pm 38\%$ during slow, medium, and fast running speeds, respectively. Responses of neurons in the VPL were facilitated by $3.9 \pm 11\%$ during slow running, but were suppressed by $-7.3 \pm 6\%$ during fast running. By contrast, in the SI cortex neuronal responses were suppressed by $-44.2 \pm 3\%$, $-55.9 \pm 3\%$, and $-55.8 \pm 5\%$ during slow, medium, and fast running respectively. These results suggest that afferent feedback ascending through the lemniscal somatosensory system during movement may be first facilitatated in the dorsal column nuclei before being suppressed at thalamic and then cortical levels. *Supported by PHS grants NS26722, AA06965, and AA00089.*

SUBCORTICAL SOMATOSENSORY PATHWAYS II

158.1

RAT TRIGEMINAL GANGLION NEURON RESPONSES TO WHISKER MOVEMENTS IN DIFFERENT DIRECTIONS. S. Lichtenstein*, G.E. Carvell*, and D.J. Simons. Depts. of Physiology and Physical Therapy, University of Pittsburgh, Pittsburgh, PA 15261.

Extracellular recording electrodes were used to study the response properties of 123 trigeminal ganglion cells in barbiturate anesthetized rats. All units displayed single-whisker receptive fields, determined manually. When the distal end of the whisker was displayed 5.7 deg (1 mm) from its neutral position using controlled stimuli, 81% of cells responsed with statistically more spikes/stimulus to movements in 1-3 of 8 cardinal directions than to the others. The more directionally selective the cell, the more vigorous was its response. Seventy-five percent of the cells were slowly adapting, 25% rapidly adapting. A number of quantitative analyses indicated that the former were more directionally selective than the latter. This difference is consistent with the hypotheses of Rice et al. (JCN: 252, 154-174, 1986) concerning structure-function relations in the vibrissal follicle. Specifically, lanceolate endings, which are associated with the ringwulst and mesenchymal sheath, are proposed to mediate less directionally selective, rapidly adapting responses; Merkel cell endings, which are interposed between the rigid glassy membrane and the hair shaft, are proposed to mediate more directionally selective, slowly adapting responses.

Quantitative comparisons between the response properties of peripheral and central neurons in the whisker/barrel system indicate that the afferent signal is progressively and substantially transformed by mechanisms that function to integrate information arising from different peripheral receptors and from different, individual vibrissae. Supported by NS-19950.

TERMINATIONS OF CERVICAL PRIMARY AFFERENTS ON SPINOTHALAMIC, PROPRIOSPINAL AND SPINOCEREBELLAR NEURONS. P.S. Bolton* and D.J. Tracey, School of Anatomy, University of New South Wales, Kensington NSW 2033, Australia.

The possibility of direct contact between primary afferents and neurons in the upper cervical spinal cord (C1-C4) was investigated in the rat. Primary afferent fibers and their terminals were diffusely filled with horseradish peroxidase (HRP). Neurons in the upper cervical spinal cord projecting to the thalamus, cerebellum and thoracolumbar cord were labelled by retrograde transport of HRP, and putative contacts between primary afferents and the soma or proximal dendrites were identified under the light microscope.

Spinocerebellar neurons were found in the central cervical nucleus (CCN) and in laminae 5-7. Approximately 90% of cells in CCN received apparent synaptic contacts from primary afferents, while 9-16% of spinocerebellar cells in lamina 5-7 received such contacts. This underlines the difference between the spinocerebellar pathways involving CCN and other neurons in the cervical spinal cord.

Propriospinal neurons descending to thoracolumbar levels of the cord (T9-L3) were located in laminae 7-8. Approximately 20-40% of these long descending proprospinal neurons received apparent synaptic contacts from primary afferents. This connection is probably an important component of the pathway mediating neck reflexes.

Spinothalamic neurons were found in three main groups in lamina 1, laminae 4-6, and laminae 7-8. Approximately 8-10% of spinothalamic neurons in laminae 4-6 received apparent synaptic contacts on the soma or proximal dendrites, suggesting that a significant proportion of these neurons are monosynaptically activated by primary afferents.

158.3

MAPPING OF PRIMARY AFFERENTS FROM FORELIMB DIGITS TO THE CERVICAL SPINAL CORD IN THE RAT. S. Maslany*, D.P. Crockett, J. Zhang* and M.D. Egger. Dept. of Anatomy, UMDNJ-Robert Wood Johnson Med. Sch., Piscataway, NJ 08854-5635.

A mixture of 25% free HRP and 2.5% WGA-HRP was injected intracutaneously into individual forelimb digits in 13 adult rats. After 3 days, the rats were perfused transcardially; transverse sections (60-μm thick) were cut through the cervical spinal cord. The tissue was reacted for HRP using the TMB-method.

The labeled cutaneous primary afferents projected to Rexed's laminae I - III, with the densest label in lamina II. The label was distributed in fusiform columns which, at their greatest width, extended from the medial border of the dorsal horn to approximately 50-60% of the distance across it. Projections from digit 1 extended rostocaudally from caudal C4 to caudal C6; projections from digit 5 extended from caudal C6 to rostral C8. Comparisons of the projection maps from each of the five digits indicated that, in the cervical spinal cord, there is extensive overlapping among the cutaneous primary afferent fibers from these digits. Such overlapping projections contrasted sharply with our earlier findings of discrete projections to the cuneate nucleus from the cutaneous primary afferent fibers from each digit.

We also examined projections to the cervical spinal cord and to the cuneate nucleus in adult rats in which some digits had been deafferented neonatally (PD0, n=3; PD2, n=1) or in adulthood (n=2). Labeling from the intact digits in the deafferented rats was similar to that found in the normal adults.

LOCALIZATION OF INTRINSIC NEUROTRANSMITTERS IN THE SUPERFICIAL FELINE MEDULLARY DORSAL HORN. M.A. Henry[1,2,3], L.E. Westrum[1,2,3], N.A. Nousek-Goebl*[1], and L.R. Johnson[4]. Depts. of Neurological Surg.[1], Biol. Struct.[2], and Restor. Dent.[3], Univ. of Wash., Seattle, WA 98195; and Depts. of Surg. Dent. and Cell and Struct. Biol., Univ. of Colo.[4], Denver, CO 80262.

The localization of neurotransmitters intrinsic to the medullary dorsal horn (MDH) was done as part of a study examining the organization of the trigeminal system. Sections from the caudal medulla were incubated with primary antibodies to neurotensin (NT), met-enkephalin (ENK), serotonin (5-HT), tyrosine hydroxylase (TH) and glutamic acid decarboxylase (GAD), the synthesizing enzyme for gamma-aminobutyric acid. Axons and terminal puncta are labeled by each antibody in specific patterns and densities, whereas NT, ENK, and GAD also show cell bodies, mainly in laminae III and IV. Lamina I and outer II (IIo) show the greatest amount of label in each case, with a reduction in inner II (IIi) and occasional axons or puncta deeper (III-IV). TH and NT label is modest as compared to very dense label for GAD, ENK, and 5-HT. These findings emphasize the importance of the superficial laminae (I and IIo) as specific regions for internal neurochemical modulation of nociceptive stimuli and suggest particular systems (TH and NT) as optimum candidates for studies of deafferentation remodeling by intrinsic pathways. 158.5

TOPOGRAPHIC ORGANIZATION OF THE DORSAL COLUMN NUCLEI PROJECTION TO THE INFERIOR OLIVE IN MONKEY AND RAT. K.E. Schultze*, H.H. Molinari, and N.L. Strominger. Department of Anatomy, Albany Medical College, Albany, NY 12208

It is known that the dorsal column nuclei (DCN) project to precerebellar structures, such as the inferior olive and pontine nuclei. Studies of the pontine projection have demonstrated distinct species differences in DCN input. A study by Kalil (1979) in primates suggested that the projection to the inferior olive might likewise differ across species. The present study investigated this possibility by examining the topography of the projection from DCN to the inferior olive in cynomolgous monkeys and albino rats.

Wheat germ agglutinin conjugated with horseradish peroxidase was injected into either the gracile or cuneate nucleus. The antero-gradely transported tracer was visualized with tetramethylbenzidine. The projection to the rostral dorsal accessory olive (DAO), where the topographic organization of the DCN input is most distinct, was analyzed in detail and compared with published data from cats.

In contrast to Kalil's results, both the cuneate and gracile nuclei in monkeys were found to project to DAO. The cuneate projection, revealed with injections in the caudal part of the nucleus, terminated primarily in medial DAO. The gracile projection in both monkeys and rats terminated most heavily in lateral DAO. These data parallel findings in cat and suggest that the organization of the DCN projection to the inferior olive does not show significant interspecies variability.

158.6

SYNAPTIC RELATIONSHIPS BETWEEN GABAERGIC TERMINALS AND CUNEOTHALAMIC NEURONS IN THE RAT CUNEATE NUCLEUS. C.Y. WEN, J.Y. SHIEH* and K.N. CHEN*. Dept. of Anat., Col. of Med., Nat'l. Taiwan Univ., Taipei, Taiwan 10018.

Cuneate nucleus comprises several types of neurons in mammals. The major cells of this nucleus were the neurons projecting to the contralateral ventrobasal thalamic nuclei. Synaptic activities are very complicated within the nucleus. It is believed that the inhibitory activity might be mediated by the GABA. Some GABAergic terminals may be intrinsic in the cuneate nucleus. It seems that the intranuclear inhibitory interneurons release GABA as a hyperpolarizing inhibitory neurotransmitter upon cuneate relay neurons.

Young adult albino rats were used for the present study. The cuneothalamic neurons (CTN) were labelled with HRP and GABAergic terminals were identified by postembedding immuno-gold protocal. Retrograde axon transport of HRP study showed that some of the postsynaptic neurons were the CTN, which were large and were rich in cytoplasmic organells. GABAergic terminals and CTN were found forming direct axo-somatic synapse. It may be morphologically a postsynaptic inhibitory basis. [Supported by NSC78-0412-B002-140, ROC].

LONG ASCENDING UNMYELINATED PRIMARY AFFERENT SYNAPSE IN THE NUCLEUS GRACILIS. K. Chung, J.T. Patterson*, W.T. Lee* and R.E. Coggeshall, Marine Biomed. Inst. and Dept. Anat. & Neurosci., Univ. Texas Medical Branch, Galveston, TX 77550

The dorsal funiculus of the mammalian spinal cord is thought to consist of large primary afferent fibers, but recent studies have shown large numbers of unmyelinated fibers in this path. This study dertermines the presently unknown destination of these fibers. To eliminate all primary afferent fibers in the fasciculus gracilis (FG), anesthetized rats were unilaterally deafferented from the midthoracic cord caudally. One week later, the numbers of unmyelinated fibers in the FG at the 2nd cervical level of the cord were counted in eletron micrographs and compared to normal counts. The numbers of CGRP immunostained (primary afferent marker) unmyelinated axons in the C2 FG and terminals in the nucleus gracilis (NG) also estimated in normal and deafferented rats. The data indicate that 80% of the unmyelinated axons in the C2 FG are removed following dorsal rhizotomy, and thus are presumably ascending primary afferent. Approximately 10% of the unmyelinated fibers were CGRP immunostained and 90% of these were eliminated after deafferentation. The majority of CGRP immunostained terminals in the NG were also eliminated after deafferentation. These data suggest that large numbers of unmyelinated fibers in the FG in rat are long ascending primary afferent fibers and they make synapse in the NG. Thus there is a possible noxious input to the nucleus gracilis. (Supported by NIH NS11255 & NS10161)

158.8

INGROWTH AND DEVELOPMENT OF SOMATOSENSORY AFFERENTS IN THE RAT DORSAL COLUMN NUCLEI. J.R. Norris*, H. Dickinson-Anson*, S. Catalano*, & H.P. Killackey Dept. of Psychobiology, Univ. of California, Irvine, CA 92717

The recently developed carbocyanine, fluorescent tracers (e.g., DiI), which can be used for tracing neural connections in *fixed* tissue, provide a number of advantages for studying the developmental anatomy of neural systems. In the present study, DiI was used to study the ingrowth and development of ascending somatosensory afferents to the dorsal column nuclei (DCN) of rat.

Pre- and postnatal rats were perfused with phosphate buffered, 4% paraformaldehyde. The brainstem and cervical spinal cord were exposed and small DiI crystals were implanted in the dorsal fasciculus of the spinal cord. Following transport times of 1-6 weeks, the brains were removed and sectioned at 75 um with a vibratome. The sections were mounted in buffer, sealed under a coverslip, and examined with an epifluorescent microscope.

Approximately 3-4 days prior to birth, fibers, generally organized into small fascicles of 2-5, exit the dorsal fasciculus at right angles and enter the DCN. Initially, the fibers are relatively straight, simple, and unbranched. Between E19 and the day of birth, few qualitative changes occur, and the fibers are still relatively simple and unbranched in structure. During the first postnatal week, the fasciculation of the fibers becomes less apparent, the course of the fibers becomes more irregular, and the fibers become branched. These results indicate that a significant amount of development of the ascending somatosensory afferents in the rat DCN occurs postnatally. (NSF grant BNS 87-19311)

158.9

DISTRIBUTION AND ORIGIN OF CGRP-IMMUNOREACTIVITY IN THE CAT DORSAL COLUMN NUCLEI. M. Fabri and F. Conti. Institute of Human Physiology, University of Ancona, Ancona, Italy.

Adult cats were used to study the distribution of calcitonin gene-related peptide (CGRP) immunoreactivity in the dorsal column nuclei (DCN). Animals were perfused with 4% paraformaldehyde, and 25 μm-thick vibratome sections were reacted with an antiCGRP serum (Sternini et al., Gastroenterology, 1987).

CGRP-positive fibers and terminals were present in the DCN (mostly in the cuneate nucleus; CN) of all animals: they were denser in the middle than in the caudal and rostral CN. In the middle CN, CGRP-positive fibers were mostly concentrated in the dorsal and ventrolateral portions, sparing the ventral CN. In colchicine-treated animals, CGRP-positive neurons were present in the CN (1.1%) and in the external CN (14.3%), but not in the gracile nucleus. In three additional animals, WGAapoHRP-Au was injected (2 ul) in the CN and dorsal root ganglia (DRG) were embedded in wax, cut in 7 μm-thick sections and reacted first for the retrograde tracer and then for CGRP. DRG neurons were observed which contained both black grains of WGAapoHRP-Au and CGRP immunoproduct.

158.10

SPECIALIZATION OF THE PARATRIGEMINAL NUCLEUS IN THE MUSKRAT MAY RELATE TO THE DIVING RESPONSE.
S. M. DeLisa* and S. O. E. Ebbesson (SPON: D. Feist) Institute of Marine Science, University of Alaska Fairbanks, Alaska 99775,USA.

The apnea, bradycardia and peripheral vasoconstriction of the diving response are elicited upon immersion of the nose. In a preliminary search for primary afferent connections of the pathway mediating the diving response, we traced projections from the rhinarium in muskrats and compared them with projections in rats. Horseradish peroxidase (HRP) and wheatgerm agglutinin-HRP were injected into the skin lateral to the naris. After 48 h survival, perfused brains were removed and frozen, sectioned and reacted with tetramethylbenzidine. The muskrat differed from the rat with respect to one structure, the paratrigeminal nucleus (Pa5). The Pa5 is massive in muskrats and receives a much greater input from the rhinarium in muskrats than in rats. We also found terminal labeling of Pa5 in muskrats following HRP injections in the soft palate and larynx. Stimulation of these structures produces a response similar to the diving response. The intensity of projections to Pa5 from the rhinarium, the overlapping of trajectories from the rhinarium, soft palate and larynx, and the prominence of Pa5 in muskrats, suggest that this structure may play a role in mediating the diving response.

Our findings, combined with the description of the Pa5 as an extension of the marginal zone of the caudal part of the spinal trigeminal nucleus (Gobel and Hockfield 1977), suggest a thermoafferent function for the Pa5 in the production of the diving response. Kilduff *et al.* (1983, 1987) proposed a similar function for the Pa5 in ground squirrels during hibernation, when it is the only structure to increase its relative 2-deoxyglucose uptake. Specialization of the Pa5 for thermoafferent function in these situations may be comparable to specialization of a similar nucleus, the lateral descending trigeminal nucleus, for infrared reception in pit vipers and boids (Molenaar 1974, 1978; Schroeder and Loop 1976).

VIBRISSA PRIMARY AFFERENT ARBORS HAVE DIFFERENT PROPERTIES IN ROSTRAL AND CAUDAL PRINCIPALIS AND ROSTRAL ORALIS. J.W. Moran*, W.M. Panneton & M.F. Jacquin (SPON: E.R. Shuter). Dept. of Anatomy & Neurobiology, St. Louis University School of Medicine, St. Louis, MO 63104.

Vibrissae are represented throughout the rat trigeminal (V) brainstem complex, yet metabolic staining and receptive field patterns vary along its rostrocaudal axis. Such intersubnuclear variations may reflect differences in the way single primary afferent axons arborize in different brainstem regions. 4 vibrissa-sensitive primary afferents were stained with HRP. Heavily labeled collaterals in rostral (N=6) and caudal (N=21) principalis (PrV) and rostral oralis (N=6) were compared quantitatively (means ± SD's).

	Rost. PrV	Caud. PrV	Rost. Oralis
# end swellings	6.8±6.6	25.3±16.5	13.7±8.2
# fiber swellings	6.8±4.9	31.1±26.3	9.2±5.3
Arbor area (u^2)	3308±1914	7889±3365	17015±12947
Arbor diameter (u)	62.8±16.2	97.8±21.8	138.9±48.5
Arbor volume (u^3)	41472±44916	156420±130354	272192±226296
Arbor limits in X	57.2±7.5	120.7±39.2	171.7±77.1
Arbor limits in Y	96.5±39.2	118.8±42.4	133.0±32.8

Thus, collaterals from single axons have different properties along the rostrocaudal axis of the rostral V brainstem complex. These data suggest that peripheral and central target factors dictate arbor structure in the V brainstem complex, and that physiological distinctions between rostral V brainstem regions may reflect differing primary afferent arbor morphologies. TRIGEMINAL PROJECTIONS TO THE CONTRALATERAL DORSAL HORN ARISE FROM SUPRAORBITAL AND MENTAL NERVES. L. Pavaloti*, W.M. Panneton & M.F. Jacquin (SPON: J. Gibbons). Dept. of Anatomy & Neurobiology, St. Louis University School of Medicine, St. Louis, MO 63104.

Primary afferent fibers in the ophthalmic and mandibular divisions of the trigeminal nerve project into lamina III-V of the contralateral medullary and rostral cervical dorsal horns (Barcia et al., Neurosci. Abst. 13:187, '87). We have previously shown that these crossing fibers do not innervate cornea, dura or nasal mucosa. Retrograde double labeling methods were used to determine if these fibers originate in midline hairy skin. Multiple injections of diamidino yellow (DY) were made into the rat medullary and cervical dorsal horns on the right and a mixture of HRP solutions was injected into the supraorbital nerve on the left (N=2). Up to 94 ganglion cells in a single case were labeled with DY in the ophthalmic portion of the left trigeminal ganglion. 79% (N=105) of these ganglion cells also contained HRP. Their size did not differ from non-crossing single labeled cells (mean diameter of 23.6μ vs 24.8μ). Similar experiments were done to test if fibers in the mental nerve contribute to the crossed primary afferent projection (N=2). Significantly fewer cells were labeled with DY in the mandibular ganglion (N=9) but some (N=3) were double labeled with HRP. These data indicate that a substantial portion of the trigeminal primary afferents that project to contralateral dorsal horn innervate midline hairy skin via the supraorbital nerve. Support: NIH DE07762, DE07734, HL38471.

PATTERNS OF CONTRALATERAL DEGENERATION AFTER UNILATERAL PRIMARY DEAFFERENTATION OF TRIGEMINAL NUCLEI. L.E. Westrum and M.A. Henry. Depts. Neurosurg., Bio. Struct., and Restor. Dent., Univ. of Washington, Seattle, WA 98195.

As a part of a larger study on anatomical remodeling in the trigeminal nuclei (TN) after different types of trigeminal nerve lesions, we present here observations following complete primary deafferentation with emphasis on contralateral and possible transneuronal changes in the caudal subnuclei. Total unilateral retrogasserian rhizotomy in adult felines was followed by survival times of 3-20 days and the TN was studied by LM silver stains or conventional EM. All survival times showed massive ipsilateral degeneration and in each case contralateral degeneration localized to the partes interpolaris and caudalis. EM preparations revealed axonal and synaptic terminal degeneration in the same sites. Shorter survivals (3-5 days) had degenerated round-vesicle (R) terminals with type I contacts onto dendrites whereas longer survivals showed degenerated flat-vesicle (F) terminals at type II sites. Dendrites showed minimal alterations suggestive of transynaptic degeneration. The findings confirm contralateral terminations which might be initially primary afferents (R terminals) and subsequently second-order afferents (F terminals). This may represent a new form of selective transynaptic change affecting mainly axons with minimal dendritic alterations.

PRIMARY AFFERENT NEUROTRANSMITTER LOCALIZATION IN THE FELINE MEDULLARY DORSAL HORN. L.R. Johnson[1], L.E. Westrum[2], M.A. Henry[2] and N.A. Nousek-Goebl[1,2]. [1]University of Colorado, Denver, CO 80262, [2]University of Washington, Seattle, WA 98195

As a part of studies of primary afferents within the trigeminal nuclei, neurotransmitter localization in the medullary dorsal horn (MDH) is being analyzed. Sections from the caudal medulla of adult cats were incubated with primary antibodies to calcitonin gene-related peptide (CGRP), somatostatin (SOM) and substance P (SP). The isolectin Griffonia simplifolia (I-B4) that co-localizes with FRAP was also used. CGRP and SP labeling is similar although SP labeling shows more discrete terminal puncta while CGRP reveals varicosing axonal arrays. Label is heaviest in the islets of Cajal, laminae I and outer II (IIo). Labeled fibers leave IIo to enter inner lamina II (IIi) and III. Scattered fibers and puncta occur in laminae IV and V. SOM labeling of axons and terminals is heaviest in IIi, reduced in laminae I and IIo, and sparse in III and IV. Labeled cell bodies are present in laminae III-VI. I-B4 labeling of axons and terminals is greatest in lamina IIo and less in IIi, with some axons in laminae I, IV and V. The observed variations in the distribution and character of the axonal and terminal labeling suggest a distinct sublaminar organization of these neurochemically defined primary afferents. (Supported by NIH grants DE04942 and DE00219. LEW is affiliated with CDMRC.)

158.15

CORTICOTRIGEMINAL AXONS AND THEIR ROLE IN INTERPOLARIS RECEPTIVE FIELDS. M. Wiegand*, W.E. Renehan, S. Stansel* & M.F. Jacquin. Anatomy & Neurobiology, Univ. of Louisville Sch. Med., KY 40292 & St. Louis Univ. Sch. Med., MO 63104.

PHA-L and WGA-HRP anterograde tracing methods were used to study corticotrigeminal axons in 22 adult rats. Deposits restricted to SI barrel cortex labeled crossing fibers in the pyramidal decussation that terminated heavily in caudal medullary and rostral cervical dorsal horns laminae III-V, and the caudal half of interpolaris. Moderately dense label occurred in rostral portions of caudalis and interpolaris. A small number of terminals were labeled in the substantia gelatinosa. Pontine terminals arose largely from other fibers that crossed in the pons and provided few terminals in oralis and moderate numbers through all of principalis. A small number of axons did not decussate and ended in all ipsilateral trigeminal subnuclei. Cortical projections were topographic; connections were heaviest between matching whisker representations. Single axon arbors had longitudinal orientations and stringy shapes, with terminal and en passant boutons. Many axons ascended through caudal trigeminal subnuclei and gave rise to multiple collaterals.

The receptive fields of 190 interpolaris cells contralateral to acute ablation of SmI cortex were also studied with single unit recording methods. As with chronic cortical lesions (Neurosci. Abstr. 13:145, '87), most cells had normal response properties. However, a small % of local circuit and projection neurons expressed unusual convergence of tactile inputs. Support: NIH DE07662, DE07734.

158.16

ULTRASTRUCTURE OF CGRP IMMUNOREACTIVITY IN TRIGEMINAL NUCLEUS. N.A. Nousek-Goebl*,[1] M.A. Henry,[1,2,3] L.E. Westrum,[1,2,3] and L.R. Johnson.[4] (Spon: R. Haschke) Depts. Neurosurg.,[1] Biol. Struct.[2] and Restor. Dentistry,[3] Univ. of Wash. Seattle, WA 98195, and Depts. of Surg. Dent. and Cell and Struct. Biol, Univ. of Colo.,[4] Denver, CO 80262

Calcitonin gene-related peptide (CGRP) has been shown to be an important neuropeptide in peripheral sensory systems in general and in dental-trigeminal pathways in particular. We are studying the light microscopic (LM) distribution and fine structural (EM) localization of this neurotransmitter in the brainstem trigeminal nuclei. Special emphasis is on patterns of label in the laminated pars caudalis (PC) and medullary dorsal horn (MDH). LM shows heavy labeling of fibers and especially axonal varicosities with some isolated terminal puncta. Reactivity is greatest in outer layer II, less in I and inner II, and sporadic in lamina III. By EM, label occurs in thinly myelinated and unmyelinated axons, often in clusters. Terminals are frequently labeled and have round synaptic vesicles with type I contacts onto small dendrites. They are sometimes associated with flat-vesicle terminals in a complex. The EM findings confirm an extensive CGRP-positive axonal plexus in specific PC/MDH laminae and identify a class of CGRP synapses consistent with primary afferent terminals. SOMATOSENSORY NEURONS IN THE INTERCOLLICULAR NUCLEUS OF THE CAT. A.Blomqvist, I.Danielsson* and U.Norrsell*, Dept. Cell Biol., Univ. Linköping, and Dept. Physiol., Univ. Göteborg, Sweden.

The intercollicular region of the midbrain contains neurons which respond exclusively to somatosensory stimuli. The location of these neurons appears to correspond to the nucleus intercollicularis (INC), which receives dense projections from somatosensory nuclei of the brain stem and spinal cord. The purpose of the present investigation was to characterize the response properties and determine the location in the intercollicular region of somatosensory-responsive neurons.

Extracellular sampling of unitary activity was made with tungsten electrodes in the intercollicular region of cats anesthetized with chloralose. Single units were characterized with adequate somatosensory, visual and acoustic stimuli, as well as electrical nerve stimulation by forelimb and hindlimb electrodes, and their stereotaxic coordinates noted. With the aid of the coordinates the units' positions were determined by means of unbiased, cytoarchitectonic identification of the structures which contained the electrode tracks.

Out of 494 units, 138 were activated exclusively by somatosensory stimuli. INC was found to be the only structure in the intercollicular region that exclusively contained neurons solely responsive to somatosensory stimuli. The somatosensory-responsive units in INC had shorter response latencies than somatosensory units outside INC and could follow higher stimulation frequencies.

The findings suggest that INC constitutes a specific mesencephalic structure for somatosensory function.

158.18

CONVERGENCE PATTERNS ON SOMATOSENSORY NEURONS IN CAT SUPERIOR COLLICULUS. H. R. Clemo and B.E. Stein. Department of Physiology, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298-0551.

Somatosensory information reaches the superior colliculus (SC) from a variety of sources. However, the specific convergence patterns that give rise to SC cell receptive field properties are not yet known. To begin examining these convergence patterns, stimulating electrodes were implanted in the contralateral dorsal column (DCN) and trigeminal (nV) nuclei and ipsilateral somatosensory cortex (SIV) in nembutal-anesthetized animals. The receptive fields of SC neurons antidromically activated from any one or combination of these sources were studied.

The majority (57/97; 59%) of somatosensory SC neurons studied received converging inputs from multiple sources. Most (39/57; 68%) of these were activated from both ascending (DCN and/or nV) and descending sources (SIV), but a substantial proportion (18/57; 32%) were activated from the two ascending sources. Regardless of the specific source or number of different inputs a given SC neuron received, in the majority of cases there was always a close correspondence between the afferent receptive fields and that of the target neuron on the SC: afferent receptive fields either matched or were included within the SC receptive field. However, in 26% of the SC neurons studied, afferents that could be demonstrated electrically were not apparent when natural stimuli were used (i.e., SC neurons with facial receptive fields were sometimes activated from the DCN).

158.19

RESPONSE PROPERTIES AND SOMATOTOPY OF VIBRISSA-ACTIVATED NEURONS IN RAT SUPERIOR COLLICULUS. C.-Q. Kao*, J.G. McHaffie & B.E. Stein. Dept. Physiol., Med. Col. Va., Richmond, VA 23298.

Receptive fields (RF's) of vibrissa-activated neurons (n=59) in the superior colliculus (SC) always consisted of multiple (2-12) contiguous contralateral mystacial vibrissae; small rapid displacements of any single vibrissa was sufficient for activation. All were rapidly-adapting, and the majority (91%) required high velocity stimuli. Few exhibited direction selectivity (10%) or spatial summation (32%), and none showed spatial inhibition. Their distribution revealed only a crude somatotopy: upper rows were generally located rostromedial and lower rows caudolateral. Even less topographic fidelity was evident in the columns. Multiple-vibrissa RF's and crude somatotopy are in contrast to the precise vibrissa representation reported elsewhere in the CNS. The data indicate that while these SC neurons are poorly suited for feature detection, they can signal the occurrence and general location of transient stimuli.

DISSOCIATION OF TACTILE AND ACOUSTIC COMPONENTS IN AIR-PUFF STARTLE. SEPARATION OF MOTOR AND CARDIOVASCULAR RESPONSES. B.K. Taylor*, R. Casto* and M.P. Printz. Dept. Pharmacology M-036, Univ. Ca. San Diego, La Jolla, CA. 92093

Complex cardiovascular and behavioral (motor) responses result from tactile (air-puff) or acoustic startle stimulation. Motor, pressor, tachycardic and bradycardic responses in conscious, unrestrained, chronically-catheterized rats arise from tactile stimuli (12.5 psi, 100 msec, 30 trials). An acoustic component of this stimulus was characterized (range 84-94 dB between 1-31.5 KHz). To evaluate this component, the tympanic membranes of adult, male, Sprague-Dawley rats were ruptured under halothane anesthesia using standard procedures for stereotaxic placement. Treated rats exhibited minimal response to acoustic startle (116 dB). Importantly, the motor response to air-puff startle was nearly abolished (groups stat. sig. with $F(9,297)=2.75$, $p<.004$; 1st trial control = 66+6.1 units, punctured = 18+6 units). In contrast, there was only minor, non-significant attenuation of the cardiovascular components from control values. Control vs punctured, trial 1: BP = +32.2±2.4 vs +25.0±2.9 mmHg; bradycardia = -18±4 vs -20±6 bpm; tachycardia = 9±3 bpm vs +11±4 bpm.

These results indicate that air-puff startle may contain both tactile and acoustic components. Further, we conclude that the motor and cardiovascular responses may be separated through discriminatory afferent stimuli.

NEUROANATOMICAL INTERCONNECTIONS OF AVIAN BRAINSTEM LOCOMOTOR REGIONS. D.M.S. Webster, G.N. Sholomenko and J.D. Steeves. Depts of Zoology and Anatomy, U.B.C. Vancouver, Canada, V6T 2A9.

Previous studies have shown that electrical or neurochemical stimulation of localized regions in the avian mid- and hindbrain will evoke locomotion in acute decerebrate geese and ducks. These locomotor sites are situated within the ventromedial medullary and pontine reticular formation, dorsolateral pontobulbar locomotor strip (PLS), medial mesencephalic reticular formation and dorsolateral midbrain reticular formation. The purpose of this study was to examine, using a variety of neuroanatomical retrograde tracers, afferent projections to the locomotor regions of the ventromedial pontobulbar reticular formation and PLS. The major findings were: 1) that the ventromedial pontobulbar reticular formation receives the majority of its afferent input from other regions of the reticular formation; 2) that the PLS projects medially into the ventromedial pontobulbar reticular formation; 3) that the most prominent input from the mesencephalon is from the dorsolateral mesencephalic reticular formation which projects to both the ventromedial pontobulbar reticular formation and the PLS. These results demonstrate that, similar to other vertebrates, rostral brainstem locomotor regions have the appropriate connectivity to exert control over more caudal locomotor sites which, in turn, give rise to direct reticulospinal pathways that are important for the initiation and ongoing control of voluntary locomotion. Supported by NSERC of Canada and the Rick Hansen Man in Motion Foundation.

SPINAL CORD AND CRANIAL NERVE PROJECTIONS TO LAMPREY BRAINSTEM NUCLEI REVEALED BY USING ANATOMICAL TRACERS IN VITRO. R. Dubuc, Y. Ohta* and S. Grillner. The Nobel Institute for Neurophysiology, Karolinska Institutet, Box 60400, S-104 01, Stockholm, Sweden

The lamprey nervous system is a useful model to study the cellular bases of vertebrate locomotion and other patterns of behaviour. Not only physiological, but also anatomical techniques are important to establish interactions between different cells or cell groups. To trace the inputs to the brainstem from the spinal cord and cranial nerves, anterograde and retrograde tracers (cobalt-lysine, HRP and dextran-amines) were used under *in vitro* conditions. This has the important advantage of providing better control for local application of the tracers. Cobalt-lysine was applied for periods ranging between 18 to 60 hours and axonal transport of the tracer occurred, on an average, at a rate 1.25 cm/day. Dorsal column (DC) fibres were anterogradely labelled within the alar plate. Terminal branches were observed in a longitudinal cell group in the medial margin of the alar plate, extending from just caudal to the obex to the nucleus octavolateralis dorsalis. When cobalt was applied iontophoretically within the posterior rhombencephalic reticular nucleus, cells within the area of termination of DC fibres were retrogradely labelled, as well as cells within the nuclei octavomotorius ventralis and posterior. Cobalt-lysine is a useful anterograde and retrograde tracer in the lamprey nervous system, filling extensively terminals, cell bodies and dendritic arborization, somewhat better than HRP and dextran-amines. (R.D. receives a Centennial fellowship from the Canadian MRC)

159.3

EFFECTS OF 5-HT ON RETICULOSPINAL NEURONS AND DISTRIBUTION OF 5-HT IMMUNOREACTIVE FIBERS IN THE LAMPREY BRAINSTEM. G. Viana Di Prisco, R. Dubuc, P. Wallén* and S. Grillner. The Nobel Institute for Neurophysiology, Karolinska Institutet, Box 60400, S-104 01 Stockholm, Sweden

5-HT affects the locomotor pattern by decreasing the late after-hyperpolarization (AHP) due to Ca^{2+} dependent K^+ channels in spinal neurons in the lamprey (Wallén *et al.*,1989, *J. Neurophysiol.* 61). Immunohistochemical studies have shown the presence of a rich 5-HT innervation both in the spinal cord (Van Dongen *et al.*,1985, *J. Comp. Neurol.* 234:501) and the brain including reticulospinal (RS) neurons (Brodin *et al.*,1986, *Neurosci. Lett.* 67:53). This study investigates the possible role of the brainstem innervation by local extracellular application of 5-HT onto presumed glutamatergic RS neurons recorded intracellularly. 5-HT elicited, in most cases, a small membrane hyperpolarization. Moreover, a specific reduction of the late AHP was observed in some cells without a concomitant hyperpolarization, as in spinal neurons. Cells were subsequently filled intracellularly with Lucifer Yellow and the brainstem was processed for 5-HT immunohistochemistry. Close appositions between 5-HT immunoreactive fibers and 5-HT responsive RS cell bodies and dendrites were observed. Interestingly however, the distribution of labeling revealed the most dense 5-HT innervation within the alar plate and also 5-HT fibers in several cranial nerve trunks.

R.D. receives a Centennial fellowship of MRC Canada.

RUBROFACIAL PROJECTIONS IN THE CAT. AN ANTEROGRADE L.M. AND E.M. STUDY UTILIZING WGA-HRP AS A TRACER. Gert Holstege and Diane Daly Ralston, Dept. Anatomy, Univ. Calif. San Francisco CA 94143

It has recently been shown that the red nucleus (RN) not only projects indirectly, but also directly to motoneurons innervating distal limb muscles (Holstege 1987 in cat, Holstege et al. 1988; Ralston et al. 1988 in monkey). In the brainstem RN projects also directly to the intermediate facial subnucleus containing orbicularis oculi muscle motoneurons and to a lesser extent to the dorsal portion of the medial facial subnucleus, containing motoneurons innervating ear muscles. There is no agreement whether RN projections terminate in the lateral facial subnuclei, innervating peri-oral muscles. Therefore we investigated RN projections to the intermediate and lateral facial subnuclei at LM and EM levels. In two cats relatively large injections of WGA-HRP were made in RN and dorsally adjacent tegmentum. At the LM level many labeled fibers were observed in the intermediate and dorsal part of the dorsomedial facial subnuclei, but the impression was gained that in the lateral facial subnuclei only fibers of passage were present. At the E.M. level many labeled myelinated axons were found in the lateral facial subnuclei, but only a very small number of labeled terminals. They contained rounded synaptic vesicles and formed asymmetric contacts upon proximal and distal dendrites. On the other hand, the intermediate facial subnucleus contained a very dense population of terminals, at least 200 times as many as the in lateral facial subnuclei. Most terminals were large in diameter, filled with primarily rounded synaptic vesicles and forming asymmetric contacts with the somata and proximal dendrites of the motoneurons. Only occasionally, contacts were seen upon small diameter dendrites. The results indicate that RN has a strong excitatory influence upon orbicularis oculi motoneurons in the same way as its projections to the distal limb inter- and motoneurons. The direct RN influence on peri-oral muscle motoneurons is negligible.

159.5

GABAERGIC SYNAPSES IN THE MACAQUE RED NUCLEUS REVEALED BY IMMUNOGOLD ELECTRON MICROSCOPIC TECHNIQUES. D.D. Ralston and A. M. Milroy. Department of Anatomy, University of California, San Francisco, CA 94143.

The red nucleus of the primate is known to be composed of two divisions, a parvicellular or rostral two thirds of the nucleus and a magnocellular or caudal one third. Both divisions of the nucleus contain a population of small neurons (10-20 µm in diameter) considered to be interneurons, many of which may use gamma aminobutyric acid (GABA) as the neurotransmitter. Although the rat and the opossum contain a population of small neurons within the nucleus, these have not been identified as GABAergic interneurons. However, immunohistochemical analyses in the cat have demonstrated the presence of glutamic acid decarboxylase (GAD) in the red nucleus at a light and ultrastructural level.

In this study we are demonstrating the results of an immunohistochemical analysis of antibodies to GABA conjugated to 10 nm gold particles in the macaque monkey. The animals were cared for following N.I.H. and University of California Animal Care Facility guidelines. Electron microscopic analysis has revealed the presence of small labeled neurons as well as labeled synaptic profiles upon rubral neurons in both divisions of the normal nucleus in the macaque monkey. The majority of the profiles are small to moderate size, contain flattened to pleomorphic vesicles and form symmetric contacts with all regions of the dendritic arbor. Many of these profiles have been shown to be dendritic in origin due to the presence of ribosomes. Occasional GABAergic profiles contain dense cored vesicles. Labeled myelinated axons have also been observed, suggesting the presence of two sources of GABAergic interaction within the nucleus: one from axons of GABA positive neurons; the other from the dendrites of these neurons which form presynaptic dendrites (PSD's).

These results demonstrate the presence of GABAergic interneurons that interact with rubral neurons by means of axonal and dendritic synaptic input.

PROJECTIONS OF THE PARVOCELLULAR RETICULAR FORMATION TO NUCLEI OF THE MEDULLA OBLONGATA. G.J. Ter Horst*, J.C.V.M. Copray*, S.B.R. Liem* and J.D. Van Willigen* (Spon: European Neuroscience Association). Dept. Neurobiology, Univ. of Groningen, Groningen, NL9712KZ The Netherlands.

Anatomical investigations gave evidence that the parvocellular reticular formation (PCRt) is an intermediate area in nervous ciruitry for limbic control of food-intake. In previous studies globally the connections of PCRt with brainstem nuclei for autonomic and orofacial motor control were identified with retrograde tract tracing techniques. Now, we would like to know all projections of PCRt and their precise sites of termination in the nuclei of the brainstem. Therefore, we studied the projections of PCRt in the rat with Phaseolus vulgaris leuco-agglutinin (PHA-L) as a tracer. In this presentation we describe the efferent connections of the rostral PCRt to nuclei of the brainstem. Projections of PCRt were traced to motor neurons of the jaw closing muscles, the mesencephalic trigeminal nucleus, and to the dorsal parts of the principal, oral, interpolaris and caudal spinal trigeminal nuclei. Terminal boutons of PCRt were also identified in the parabrachial, facial, solitary and hypoglossal nuclei, and in the dorsal gigantocellular nucleus, the caudal PCRt dorsal to nucleus ambiguus and in nucleus linearis. Efferent connections of PCRt to the dorsal motor nucleus of the vagus and nucleus ambiguus were not found. These data show that neurons in the rostral PCRt may participate in neural networks that underlie orofacial motor activity such as jaw and tongue movement. Anatomical evidence for involvement of the rostral PCRt in regulation of the autonomic nervous system was not found.

BRAINSTEM RETICULAR NUCLEI WHICH PROJECT TO THE CEREBELLUM-A QUANITTATIVE STUDY IN THE RAT. D.B. Newman and C.Y. Ginsberg* Department of Anatomy, USUHS, Bethesda, MD 20814-4799

The nuclear origins of projections from the brainstem reticular formation (RF) to the cerebellum were determined in rats using retrograde transport of 1% WGA-HRP, 10% HRP, or 2.5% Fluoro-Gold. Counts of retrogradely labeled cells were done on a large number of select cases whose injection sites comprised a wide sampling of vermal, hemispheric, and nuclear regions. The strongest reticulocerebellar projections arose from the classic precerebellar lateral reticular, paramedian and reticulotegmental nuclei. However, strong cerebellar projections also arose from catecholamine cell groups such as A6 (locus ceruleus), A5, and C1, from the serotinergic raphe nuclei (particularly raphe pontis and obscurus), and from the cholinergic pedunculopontine nucleus. Labeled cells were also seen in several non-aminergic isodendritic reticular nuclei involved in visuomotor activity (e.g. paragigantocellularis dorsalis, raphe interpositus, and the paramedian pontine RF), as well an RF nucleus associated with the trigeminal system (reticularis dorsalis). Injections into the deep nuclei produced more labeled cells in skeletomotor RF nuclei such as gigantocellularis, magnocellularis, and pontis caudalis. Supported by USUHS-DOD Grant RO7059 to D.B.N.

LESIONS OF MEDULLARY RAPHE NUCLEI IN TWO ANIMAL MODELS OF MOVEMENT DISORDERS. S. Wieland, M.S. Kreider, and I. Lucki. Dept. of Psychiatry, Univ. of Pennsylvania , Philadelphia, PA 19104.

Administration of the neurotoxin 3-acetylpyridine (3-AP) produces spontaneous involuntary motor dysfunctions in rats. We previously reported that rats treated with 3-AP demonstrated increased sensitivity to the 5-HT_{1A} agonist 8-OH-DPAT and the 5-HT_2 agonist DOB without concurrent changes in 5-HT content or receptor densities (Soc. Neurosci. Abstr. #404.11, 1988). We further studied the effects of 3-AP on the morphology of the serotonergic (5-HT) system by visualizing the 5-HT-containing neurons using immunocytochemistry. There was a large reduction in the number of 5-HT immunoreactive neurons in the raphe obscurus of 3-AP-treated rats as compared to saline-treated rats. In contrast, 3-AP treatment did not affect any other 5-HT-containing nucleus in the brain stem.

We also studied the role of 5-HT in the genetically dystonic rat (*dt*). The *dt* rat displays slow, twisting movements of the limbs and trunk, similar to that seen in rats treated acutely with 3-AP. The *dt* rat was more sensitive to 8-OH-DPAT as seen by a 5-fold shift to the left of the dose-response curve in 8-OH-DPAT's ability to produce the 5-HT behavioral syndrome. The *dt* rats showed a significant decrease in the number of head shakes produced by the 5-HT_2 agonist DOB. Immunocytochemical analysis of 5-HT-containing neurons revealed a large decrease in the number of 5-HT immunoreactive neurons in the raphe magnus of the *dt* rat as compared to the phenotypical control littermate. No other 5-HT-containing cell group in the brain stem was visibly different in the *dt* rat as compared to the control group.

These results suggest that the 5-HT system is altered in these two animal models of movement disorders.

NATURALLY AND ELECTRICALLY EVOKED BURST ACTIVITY IN THE RED NUCLEUS OF ANESTHETIZED TURTLES. *R. Sarrafizadeh*, J. Keifer, and J.C. Houk.* (Spon: K. McKenna) Department of Physiology, Northwestern University Medical School, Chicago, IL 60611.

Bursts of red nucleus discharge are associated with commands that specify movement velocity in the awake monkey (Gibson et al, J. Physiol. 358: 551, 1985). Recently we developed an *in vitro* turtle hindbrain preparation to study mechanisms that may underlie burst generation in the cerebellorubrospinal system (Keifer & Houk, Soc. Neurosci. Abs., 1989). To explore the relation between bursts recorded from the *in vitro* turtle brain and motor commands recorded during movement, we studied naturally and electrically elicited responses of red nucleus cells in anesthetized turtles.

Single rubral units were recorded with tungsten microelectrodes in turtles (*Chrysemys picta)* anesthetized with sodium pentobarbitol (10mg/kg). A total of 61 cells responded to single pulse stimulation of the spinal cord with latencies characteristic of antidromic (3-4msec, 19% of sampled cells) or synaptic (6-24msec, 81% of sampled cells) activation. This is similar to our *in vitro* results except that a larger percentage of units was activated at longer synaptic latencies (14-24msec, 45% *in vivo* vs 4% *in vitro).*

Bursts of action potentials were obtained in response to single pulse stimulation of the spinal cord in 58% of the excited cells, approximately twice the percentage found in *in vitro* studies. Brief trains delivered to the cerebellum, natural somatosensory stimulation, and execution of a scratch reflex also evoked bursts of activity in these cells. A second population of units was inhibited by spinal cord, cerebellum, and somatosensory stimulation, and also during the scratch reflex. Short latency responses to spinal cord stimulation could not be obtained from the inhibited units.

In conclusion, burst activity of red nucleus neurons recorded *in vivo* to natural and electrical stimuli is similar to that evoked electrically *in vitro*. This suggests that the *in vitro* preparation will be useful in studies of the mechanisms that may underlie the generation of motor programs in the cerebellorubrospinal system.

159.10

BURST GENERATION IN RED NUCLEUS IS BLOCKED BY EXCITATORY AMINO ACID RECEPTOR ANTAGONISTS IN THE *IN VITRO* TURTLE BRAINSTEM. J. Keifer and J.C. Houk. Dept. of Physiology, Northwestern University Medical School, 303 E. Chicago Ave., Chicago, IL 60611.

In vivo studies in mammals have suggested that the cerebellorubrospinal circuit functions as a recurrent excitatory loop that generates motor commands and transmits them to the spinal cord via the rubrospinal pathway. Bursts of activity recorded from magnocellular red nucleus (RN) neurons in the monkey are associated with commands that specify movement velocity (Gibson et al., J. Physiol. 358: 551, 1985). We have developed an *in vitro* preparation from the turtle that exhibits functional synaptic connections between the cerebellum, brainstem and spinal cord in which to study burst generation in the RN (Keifer & Houk, Neurosci. Lett., 97: 123, 1989).

Bursts of activity lasting several seconds recorded extracellulary from single units in the RN were triggered by single pulse stimulation of the contralateral spinal cord, or brief train stimuli to the cerebellar cortex. Bath application of specific excitatory amino acid receptor antagonists APV (DL-2-amino-5-phosphonovaleric acid, 100μM, 9/9 cells), a specific NMDA (N-methyl-D-aspartate) receptor antagonist, CNQX (6-cyano-7-nitroquinoxaline-2,3-dione, 10μM, 3/3), a specific non-NMDA receptor antagonist, and AP4 (DL-2-amino-4-phosphonobutyric acid, 100μM, 6/6), an agonist of a presynaptic receptor, blocked burst activity in the RN. Using a multibarreled pipette for ejection of drugs and recording, iontophoresis of APV (12/16) or CNQX (7/7) into the RN blocked bursting while AP4 (5/5) did not.

These data suggest that turtle RN neurons have both NMDA and non-NMDA receptors and that excitation mediated by these receptors has an important role in the generation of burst activity in the RN. The site of action of the AP4 sensitive receptor appears to be elsewhere in the cerebellorubrospinal circuit. The possibility that bursts are produced by a combination of bistable membrane properties induced by NMDA channels and positive feedback will be explored.

159.11

ALTERATIONS OF RUBRAL SINGLE UNIT ACTIVITY AND MOVEMENT PARAMETERS AFTER INJECTIONS OF GABA OR SEROTONIN IN CAT RED NUCLEUS AREA.
Schmied A.*, Farin D*., Dormont J.F.*, Amalric M.
UPS CNRS UA 1121, Neurobiol. Bat 440 91405 ORSAY, FRANCE.

The motor impairments and the neuronal inactivations previously observed with injections of muscimol in the Red Nucleus (RN) area support the inhibitory GABAergic control of rubral activity through GABA A receptors. However, injections of bicuculline, intended to block the action of endogenous GABA, depressed most of the rubral neurons, with a dysruption of the motor performance. These unexpected results might be explained by the release of a second inhibitory rubral input, possibly serotoninergic. The presence of a dual inhibitory control was tested by comparing the neuronal and motor effects of GABA or 5HT, injected into the RN area of cats performing a Reaction Time (RT) task. GABA injections (0.1-1 ug) produced inactivations of 6/7 neurons, followed (1ug) by an increase of RTs, with a slowed down movement velocity, as observed with the muscimol. 5HT injections (0.4 ug) produced also an increase of RTs, with a delayed movement initiation, as observed with bicuculline. 5HT injections (0.2-0.4 ug) had depressing (4/7), activating (2/7) or mixed (1/7) effects on the neuronal activity. Experiments are in progress to further differentiate the GABAergic and serotoninergic inhibitory control of rubral neuronal discharges in relation to the movement parameters.

SENSORY PROPERTIES OF RUBROMOTONEURONAL (RM) CELLS. K. Mewes* and P.D. Cheney (SPON: T.J. Imig). Dept. of Physiol., KU Med. Ctr., K.C., KS 66103.

RM cells were identified by their postspike facilitation (PSF) of target muscle emg activity in rhesus monkeys trained to make alternating wrist movements. The sensory properties of 19 RM cells were studied using passive flexion and extension movements of the wrist. In addition, 16 of these cells were tested in relation to flexion and extension torque pulse perturbations applied during active movement. Eighteen of 19 RM cells showed brisk (mean depth of modulation, DOM: 62±28 Hz) responses to passive movement at short latency. Sixteen cells had bidirectional and two unidirectional responses, while one cell was unresponsive. Most RM cells also responded to torque pulses (15 of 16). Cell discharge was even more brisk for torque pulses (mean DOM of 161±53 Hz) and showed a similar predominance of bidirectional patterns (13 of 16). The mean onset latencies for responses to torque perturbations was 31±11 ms. Target muscle stretch in association with either torque perturbations or passive movements was not consistently the most effective stimulus direction. This contrasts with corticomotoneuronal cells which respond either exclusively or preferentially to target muscle stretch (Cheney and Fetz, J. Physiol. , 349:249, 1984). Only 2 of 13 RM cells had cutaneous receptive fields. Supported by NSF grant BSN-8216608 and NIH Grant NS 25646.

LOSS OF MUSCLE TONE AFTER ELECTRICAL OR CHEMICAL STIMULATION OF THE MEDIAL MEDULLA IN THE INTACT CAT. E. Schenkel*, Y.Y. Lai and J. M. Siegel. Sepulveda VAMC, UCLA Sch. Med., Sepulveda CA 91343

Electrical and chemical stimulation of the medial medulla have been found to produce suppression of muscle tone in decerebrated cats. However, several reports have indicated that medial medullary stimulation in intact cats does not produce such suppression. We now report success in inducing suppression of muscle tone with both electrical and chemical stimulation of the medial medulla of the intact cat. Guide cannulas were implanted as previously described (E. Shenkel and J. M. Siegel, Neurosci. Lett. 98:159-165, 1989). Concentric bipolar stimulating electrodes or 29 g cannulas were inserted through the guides to targets at P 9-15, H 5-8, L 0-1.5. Electrical stimulation (500 msec to 5 sec trains at 100-150 Hz and 80-150 μA) caused suppression of muscle tone at effective sites, often followed by excitation. Microinjection of acetylcholine (0.2-0.5 μl @ 200 μg/μl) caused similar but longer lasting effects. When administered in a waking, standing cat, the animal would rapidly collapse to the floor, in association with reduction but not complete abolition, of nuchal muscle tone. Suppression of muscle tone was not associated with PGO spiking. We hypothesize that we are activating a medullary relay in the pontomedullary descending pathway responsible for suppression of muscle tone in REM sleep. MUSCLE TONE SUPPRESSION ELICITED BY CORTICOTROPIN-RELEASING FACTOR MICROINJECTED IN MEDIAL MEDULLARY RETICULAR FORMATION. Y.Y. Lai and J.M. Siegel, UCLA, Sch. Med. and VAMC, Sepulveda, CA 91343.

The medial medullary reticular formation (MMRF) is thought to mediate muscle atonia in REM sleep and in cataplexy. Previous studies in our laboratory (J. Neurosci., 8:4790, 1988) have found that muscle atonia could be elicited by L-glutamic acid and cholinergic agonists microinjected in rostral and caudal MMRF, respectively. In the present experiment, we found that corticotropin-releasing factor (CRF) microinjected in rostral MMRF also produced decreases of muscle tone or atonia. Experiments were performed on unanesthetized, decerebrated cats. Neck muscles were dissected and implanted with bipolar EMG electrodes. Injection sites were identified by electrical stimulation (500 ms trains with 100 Hz, 0.2 ms, and 20-70 μA rectangular cathodal pulses). Sites which produced inhibition of muscle tone were microinjected with 0.5 μl of a range of concentrations of CRF. Injections with concentrations as low as 0.1 nM were found to produce muscle inhibition. The magnitude of the muscle inhibition was dose dependent. The latency and duration of muscle suppression were 18.8 ± 16.9 sec (n = 12) and 4.4 ± 3.1 min, respectively. This finding suggests that CRF may play a role in MMRF mediated suppression of muscle tone in REM sleep and in other states. (Supported by the Veterans Administration and PHS grants HL41370 and MH43811.)

PONTO-GENICULO-OCCIPITAL WAVES FACILITATE THE STARTLE REFLEX: EFFECTS OF PCPA. M.-F. Wu and J. M. Siegel. Neurobiol. Res., VAMC, Sepulveda, CA 91343 and Dept. Psychiat., UCLA Med. Ctr., Los Angeles, CA 90024.

PGO waves have been hypothesized to be a correlate of a central alerting process. Such alerting would be expected to modulate the sensorimotor processing associated with the startle response. We tested this hypothesis by presenting startle-eliciting stimuli following spontaneous PGO waves during waking and non-REM sleep, after the animal has been treated with *p*-chlorophenylalanine (PCPA), which releases PGO waves during waking and non-REM sleep.

Cats were given PCPA methyl ester HCl (125 mg/kg/day, ip) for 6 days. Tests were done between Day 4 and Day 6 when spontaneous waking PGO waves occurred. Startle-eliciting stimuli (115 db, 20 msec noise pulse) were presented between 0 and 400 msec after the peak of the PGO wave, or randomly without association with the PGO wave.

Startle amplitude was increased by 50-200% following the PGO wave, an effect most evident within 200 msec of the peak. Baseline startle response was also enhanced by PCPA as compared to pre-drug level. The present results support the hypothesis that the PGO wave facilitates the sensorimotor response to external stimuli. (Supported by PHS Grants MH43811 and NS14610 and the Veterans Administration.)

ELECTRICALLY EVOKED STARTLE-LIKE REFLEXES IN RATS: COLLISION EFFECTS BETWEEN BILATERAL RETICULAR FORMATION SITES. C.M.E.Hempel* and J.S.Yeomans (SPON:N.Wiener).Dept. Psychol., U. Toronto, Canada M5S 1A1.

Startle-like responses were elicited by stimulation of pontine reticular formation (RPC) with single, 0.1 ms duration pulses of 400-1000 uA. A second (T) pulse delivered to the same site always reduced current thresholds as interpulse (C-T) intervals increased from 0.3-0.6 ms, suggesting that short-refractory-period reticulospinal neurons mediate this response. When the first (C) pulse was delivered to one RPC site and the second (T) pulse to the contralateral RPC, current thresholds decreased sharply at C-T intervals of 0.4-1.0 ms, suggesting axonal connectivity between startle-mediating RPC sites on either side of the brainstem. The difference between unilateral and bilateral stimulation conditions suggests conduction times of 0.15-0.55 ms between the two sides, or conduction velocities of 5-18 m/s assuming straight-line conduction. These conduction velocities are much slower than large reticulospinal axons, so smaller axon collaterals passing through both stimulation fields may be responsible for the observed collision. The size of the collision was greatest (almost 100%) when both electrodes were in the center of the RPC. This connection may allow bilateral coordination of reflexes evoked from one RPC. (Supported by NSERCC grant to J.Y.)

NMDA-INDUCED LOCOMOTION IN THE RAT AND CAT. Y. Ishikawa*, Y. Atsuta*, R.D. Skinner and E. Garcia-Rill, Dept. of Anatomy, University of Arkansas for Medical Sciences, Little Rock, AR 72205

Previous studies from this lab showed that controlled locomotion can be induced by electrical and chemical stimulation of the mesencepahlic locomotor region (MLR) and the medioventral medulla (MED) in the rat and cat. In the present study, we used the precollicular transected preparation and assessed forelimb and hindlimb locomotion using EMGs. A cannula/electrode ensemble was used to establish the locations of the locomotor regions by electrical stimulation before injecting any agents. We found that localized injections of the excitatory amino acid agonist, N-methyl-D-aspartic acid (NMDA) induced locomotion when injected into either the MLR or MED. Low concentrations of NMDA (lmM or less) failed to induce locomotion. Four-limb locomotion was induced in 50% of cases by 5mM , in 63% of cases by 10mM and in 78% of cases by 20mM NMDA. Higher concentrations of NMDA had long lasting effects, inducing locomotion for more than 2 min. (longest 24 min.) in most cases. Similar effects were obtained after injection of NMDA into the MLR and MED of the rat and cat. NMDA-induced locomotion could be blocked by injection of similar concentrations of the NMDA antagonist APV5. These results suggest that NMDA receptors play a role in the control of locomotion by the brainstem. Preliminary results suggest that injection into the MLR of the rat and cat of the cholinergic agonist, carbachol, can block NMDA- and electrically-induced locomotion. This effect can be reversed by atropine, pointing to the presence of an inhibitory cholinergic input to the MLR in both species. Supported by USPHS grants NS21981 and NS20246.

ENTRAINMENT OF WINGBEAT AND RESPIRATION DURING FREE-FLIGHT, "FICTIVE" FLIGHT AND PASSIVE WING FLAPPING IN GEESE. G.D.Funk, W.K.Milsom & J.D.Steeves. Dept. Zool., U.B.C., Van. B.C. V6T 2A9.

To describe the relationship between wingbeat and respiratory pattern, wingbeat frequency (f_w) and breathing frequency (f_v) were recorded during free-flight in 5, 4-5 month old, trained Canada geese. The two patterns were predominantly coupled at 3 wingbeats per breath. To assess whether afferent activity stimulated through wing flapping could account for the coupling of the two systems, we examined the relationship between f_v and f_w during passive wing flapping. Results indicate that; (1) passive flapping will entrain respiratory rhythm, and (2) removal of wing afferent activity through dorsal root section of the brachial plexus has no effect on this entrainment, implicating a role of chest wall and/or lung afferents in this coupling.

We were also interested in whether the afferent activity associated with wing flapping, although sufficient to entrain respiration and wingbeat, was necessary for this coupling. Flapping was induced in decerebrate birds through electrical stimulation of the dorso- and ventrolateral medullary reticular formation and the medial mesencephalic reticular formation. The birds were then paralyzed and pectoralis nerve (main wing depressor nerve) and respiratory nerve (internal and external intercostal) discharges were recorded during "fictive" flight. A very tight coupling between pectoralis and intercostal nerve discharge was observed. These results suggest that, although afferent activity will entrain respiration to locomotion, there is a central program synchronizing the outputs of the two systems. Supported by the NSERC of Canada.

CLASSIFICATION OF JAW-MUSCLE SPINDLE AFFERENTS
D. Dessem and A. Taylor. Washington Univ. Dental School, St. Louis, MO 63110 and St. Thomas's Hospital, London, UK SE1 7EH.

The responses of jaw-muscle spindle afferents were studied in rats (300-350g) deeply anesthetized with sodium pentobarbital supplemented with chlorpromazine. Ninety-three afferents (47 masseter, 24 temporalis, 8 other) were studied in the mesencephalic nucleus of the trigeminal nerve during ramp muscle stretches prior to and following the infusion of the depolarizing drug suxamethonium, and during constant muscle stretch. Thirty-one percent of the afferents had initial dynamic indices <10 imp/sec, showed no increase in dynamic responsiveness following suxamethonium, had low coefficients of interspike-interval variation and therefore were classified as secondary afferents. Seventeen percent of the afferents showed dynamic indices >100 imp/sec following suxamethonium, higher coefficients of interspike-interval variation and therefore were considered to be clear primary afferents. Fifty-two percent of the afferents showed intermediate responses. This large percentage of intermediate-type responses may be due to the considerable morphological variability of afferent terminations on the intrafusal fibers.

MANY SPINAL NEURONS HAVE DIFFERENT FIRING PATTERNS DURING LOCOMOTION EVOKED FROM THE MIDBRAIN VS. THE MEDULLA.
N.A. Bernau and R.B. Leonard. Marine Biomed. Inst., Univ. of Tex. Med. Branch Galveston, Tx 77550.

We are using the Atlantic stingray, Dasyatis sabina, to study spinal cord cells involved in generating locomotion. Swimming can be evoked by electrical stimulation in both the medulla and the midbrain. Previously we reported data showing that half of the cells whose activity was modulated during swimming, fired tonically during swimming evoked from the medulla. These tonic cells received a shorter latency input from the medullary locomotor region than phasic cells. Consequently, we thought that the tonic cells may be following the tonic stimulation used to evoke locomotion. We used extracellular recording in paralyzed, decerebrated animals to show that 60% of the tonic cells became phasic during midbrain-evoked or spontaneous locomotion. Conversely, 50% of the cells that fired phasically during spontaneous or midbrain-evoked locomotion, fire tonically during locomotion evoked from the medulla (phasic-tonic). The other 50% fired phasically during locomotion, regardless of how it was evoked (phasic-phasic). The proportion of phasic-tonic cells that were phase transition cells vs. those that fired in phase with the motor nerves was similar to that of the phasic-phasic cells. Some cells continued to fire tonically during locomotion, regardless of how it was evoked. These cells may not be involved in generating locomotion. Supported by NS 11255.

CONTROL OF POSTURE AND MOVEMENT IV

160.1

DYNAMIC POSTURAL RESPONSES IN THE CAT INVOLVE INDEPENDENT CONTROL OF LIMB LENGTH AND ORIENTATION.
C. Maioli* and R. Poppele (SPON: F. Lacquaniti). Istituto di Fisiologia dei Centri Nervosi, CNR, 20131 Milan, Italy.

Tilt in the sagital plane induces active postural adjustments involving reciprocal changes in fore- and hindlimb lengths and a maintenance of limb axes nearly vertical. When animals are subject to tilt of the visual environment alone or together with the base of support, their responses suggest that the two geometric components, limb length and limb orientation are controlled separately.

Tilt of the visual environment alone evokes postural adjustments in limb orientation only. Limb lengths remain constant while the orientation of the limbs deviates in the direction of the stimulus. In contrast, simultaneous tilting of the platform with the visual environment (a conflict stimulus) evokes changes in both limb length and orientation. The changes in limb length are indistinguishable from responses to platform tilt alone. However, the changes in limb orientation differ from those evoked by platform tilt alone, consistent with the conflicting visual stimulus.

BILATERAL LABYRINTHECTOMY DOES NOT IMPAIR QUIET STANCE IN THE CAT.
D. Thomson*, J.M. Macpherson, J.T. Inglis and R.H. Schor†. Dept. of Anatomy, Queen's Univ., Kingston, Ont. K7L3N6 and †Dept. of Otolaryngol., Univ. of Pittsburg Med. Sch., Pittsburg PA 15261

The vestibular system is thought to play an important role in the maintenance of stance posture. We compared stance in the quadrupedal cat before and after bilateral labyrinthectomy. Analysis was limited to periods of quiet stance, with head stationary and facing forward. Data included ground reaction forces (3D) and the tonic activity of selected limb and trunk muscles. Cats were labyrinthectomized by drilling into the canals and vestibule on both sides. As soon as the animals could stand (1-2 days post-op), they were tested on the force platform. After the lesion, there was no change in stability of quiet stance. The distribution of vertical forces did not vary; excursions of the centre of pressure (body sway) did not increase. Horizontal plane forces became more laterally directed and increased in amplitude, transiently. Surprisingly, EMG activity of limb and trunk extensors increased transiently. Stance only became unstable during movements, such as head turning. Supported by the MRC.

160.3

DESCENDING PROJECTIONS OF THE DORSOLATERAL PONTINE CHOLINERIGIC NEURONS TO THE PARAMEDIAN RETICULAR NUCLEUS IN THE CAT
P. Shiromani, Y.Y. Lai and J. M. Siegel. Dept Psychiatry, UCSD, Sepulveda VAMC and UCLA.

Microinjections of acetylcholine into the *paramedian reticular nucleus* (PRN) of the medulla produces loss of muscle tone in the decerebrate cat. Activation of this pathway may also produce the atonia during physiologic REM sleep. In order to determine the source of the cholinergic innervation to the PRN we injected *WGA-HRP* (1%, 0.05 ul) into the PRN of three anesthetized cats. The tissue was processed for HRP using TMB as the chromagen and the sections were processed for ChAT immunohistochemistry. Counts were made of HRP-positive, ChAT positive or HRP+ChAT cells.

HRP labeled cells were found in the *pedunculopontine tegmental* (PPT) cholinergic field and in the *lateral dorsal tegmental* (LDT) nucleus. Of the HRP labeled cells in the PPT, 10-25% were also ChAT positive on the ipsilateral side while contralaterally 10-24% were ChAT positive. In the LDT, 8-16% were ChAT positive ipsilaterally while contralaterally 5-21% were ChAT positive. Of the ChAT cells, only about 0.9-1.5% of ChAT PPT cells, and 0.5%-1.4% of ChAT LDT cells project to the PRN. Thus, even though the LDT and PPT do not heavily innervate the PRN, of those cells that do project, about 15% are cholinergic. This further elucidates the networking subserving REM sleep and muscle tone.

160.4

HINDLIMB MUSCLE SYNERGIES DURING BACKWARD WALKING IN THE CAT.
J. A. Buford, J. L. Smith, and R. F. Zernicke. Laboratory of Neuromotor Control, UCLA, Los Angeles, CA 90024.

Last year we described kinematics of backward (BWD) walking, and here we describe synergies for flexor-extensor pairs at the hip (iliopsoas, IP; anterior biceps femoris, aBF), knee (semitendinosus, ST; vastus vateralis, VL), and ankle joints (tibialis anterior, TA; lateral gastrocnemius, LG). For BWD and forward (FWD) treadmill walking at 0.6 m/s, step cycles began and ended at paw off and swing occupied 35% of the cycle. Cycle periods were shorter for BWD (582 ± 43 ms) than for FWD (663 ± 75 ms) walking. EMG was digitized (1000 Hz) and muscle onset and offset latencies were calculated from paw off times determined from high-speed (100 fr/s) ciné film.

Grillner's (1981) prediction of coactivation between hip flexors and knee extensors during BWD stance was not supported by our data. For BWD and FWD walking, extensor muscles (aBF, VL, LG) at the three joints were coactive during stance. Swing phase recruitment was different as LG and aBF onsets came at mid swing during BWD walking but near paw contact during FWD walking. VL onsets just before paw contact and offsets just before paw off were similar for both directions, but average VL burst amplitude was greater during BWD walking.

For BWD and FWD walking, onsets of the three flexors (IP, ST, TA) preceded paw off by 5-10% of the cycle period. Offset of IP came early in BWD swing but late in FWD swing. A second IP burst sometimes appeared at the end of BWD swing. TA offset came just after paw contact for BWD walking but just before paw contact for FWD walking. ST had one burst throughout BWD swing compared to the two-burst ST pattern during FWD swing.

The locomotor synergy of extensor activity during stance and flexor activty during swing dominated both BWD and FWD walking, suggesting similar motor control for both directions. The change in central pattern generator coupling proposed by Grillner does not appear necessary for BWD walking. The differences in BWD and FWD synergies occurred mostly during swing, when muscle torques interact with joint torques related to gravity and segment inertias. Feedback may monitor these torque-related factors and help control swing phase recruitment by interacting with a common central pattern generator that is used for both BWD and FWD walking. Research supported by NIH NS19864.

160.5

RHYTHMIC FLUCTUATIONS OF MEMBRANE POTENTIAL AND ANTIDROMIC DISCHARGES OF IDENTIFIED MUSCLE PRIMARY AFFERENTS DURING FICTIVE LOCOMOTION IN THE CAT. J.-P. Gossard, J.-M. Cabelguen* and S. Rossignol, Centre de Recherche en Sciences Neurologiques, Université de Montréal, Québec, Canada.

Our previous experiments with intra-axonal recordings revealed that the membrane of cutaneous primary afferents was depolarized twice during the fictive step cycle and that phasic antidromic discharges were rare. The present study focusses on presynaptic mechanisms with similar intra-axonal recordings of identified muscle primary afferents of the hindlimb during fictive locomotion spontaneously occurring in decorticated cats or induced by Clonidine (chronic spinal cats) or Nialamide and DOPA (acute spinal cats). On the basis of conduction velocities and stimulation threshold, 62% of recorded units were classified as group I afferents (33/53). Muscle stretches and twitch contractions indicated that 75% of all units were presumably spindle afferents (40/53). Results showed that the membrane potential of all muscle afferents fluctuated (amplitude of up to 1.5 mV) at the rhythm of the fictive locomotion. All units had a flexor-related depolarization and 79% had an additional, but usually smaller, extensor-related depolarization. Phasic discharges, related to the parent locomotor efferent activity, were seen in 9 units despite additonal large doses of Flaxedil. Those discharges, considered as antidromic because of the absence of phasic peripheral input, were found in afferents innervating flexor (5/18) and bifunctional (4/16) muscles but were never encountered in extensor afferents (0/19). Similar results were obtained in decorticated and spinal preparations. The results thus indicate that patterns of presynaptic depolarization during fictive locomotion are similar in all muscle afferents. However, the absence of antidromic discharges in extensor afferents suggest that presynaptic mechanisms and efficacy of transmission may be controlled differently in specific afferent pathways by the spinal locomotor network. (Supported by the MRC and the FRSQ).

160.6

INFLUENCE OF PHASIC PROPRIOCEPTIVE INPUTS ON FICTIVE FORELIMB LOCOMOTION IN THE CAT. P. Saltiel and S. Rossignol, CRSN, Université de Montréal, Québec, Canada.

After decortication or decerebration and spinalization at T13, locomotor-like activity can be recorded after paralysis using cuff electrodes placed around the nerves of the right (R) and left (L) long heads of Triceps (Tri) in the forelimbs. This study examines the changes in the fictive pattern when the R forelimb was suddenly protracted or retracted at different moments of the R Tri burst. These shoulder movements, in the order of 10-15 degrees, were produced with the scapula and the elbow fixed and were monitored with a potentiometer.

Retraction early in the R Tri burst, before L Tri has ended,markedly shortened R Tri while frequently prolonging the L Tri until the next R Tri burst as if to assume weight support which the R forelimb is unable to accept. Retraction during the R Tri, after termination of the L Tri, shortened the R Tri and prematurely activated the L Tri. This response would normally speed up weight transfer to the L forelimb, before the R forelimb reaches the end of its stance and is no longer able to support weight. The L Tri silence almost never decreased below 50% of its normal duration. This might ensure that the L forelimb has swung forward enough to assume weight support upon contacting ground.

Protraction prolonged the R Tri burst when occurring during the first two-thirds of the burst and delayed activation of L Tri. This prolongation could imply that landing on the L forelimb is delayed until the R forelimb is ready to transfer weight. No significant changes occurred when the R forelimb was protracted in the last third of the R Tri burst. Such a protraction would more or less mimick the normal sequence of events whereby the R forelimb is protracted during swing when the L forelimb can accept the body weight.

These results suggest that, even in fictive locomotion, proprioceptive perturbations that could threaten the equilibrium in real locomotion may evoke strong bilateral responses which seem to be best understood in terms of providing adequate weight support or weight transfer. (Supported by the MRC).

160.7

ACTIVITY OF RETICULOSPINAL NEURONES DURING FICTIVE LOCOMOTION IN THE DECEBRATED CAT. M.C. Perreault, T. Drew and S. Rossignol, Centre de Recherche en Sciences Neurologiques, Univ. de Montréal, Montréal, Québec, Canada.

Neurones of the medial medullary reticular formation (mMRF) have been shown to discharge rhythmically during locomotion in both intact and decerebrated preparations (see Drew et al., J. of Neurophysiol., 55 375-401, 1986). However, as the respective contribution of rhythmical peripheral feedback and central drive to such a modulation is difficult to establish when movements are present, the aim of the present work was to study the discharge of reticulospinal neurones (RSNs) in paralysed cats.

RSNs recorded from the mMRF with glass-tungsten electrodes (AP:-5 to -15, L:0.8 to 2.5), were antidromically identified by stimulation of their axon through wire electrodes inserted in the spinal cord at the level of L1-2 in six decerebrated and curarized cats. The fictive locomotor rhythm, either occurring spontaneously or evoked by stimulation of the mesencephalic locomotor region, was monitored with cuff electrodes placed around the proximal part of sectioned nerves supplying extensor and flexor muscles of the four limbs.

Of a total of 38 identified RSNs, 79% (30/38) were active while 21% (8/38) were silent during fictive locomotion. 67% (20/30) of the active RSNs showed phasic increases in the discharge frequency which could be related to the rhythmical activity of nerves from the anterior (11/20) or posterior (9/20) limbs whereas the activity of the remaining 10 RSNs was found to be unrelated to the locomotor rhythm. Strong relationships were observed with both the onset and the duration of the activity of nerves to either extensors or flexors lying both ipsilaterally and contralaterally to the recording site.

Thus, even in the absence of phasic peripheral afferent input, RSNs display rhythmic patterns of activity which are similar to those observed during locomotion in unparalysed animals. This suggests that the modulation of RSNs is in part of central origin and probably occurs, directly or indirectly, through the spinal central pattern generator. (Supported by the FRSQ and MRC).

160.8

ADAPTATION TO TREADMILL SPEED OF CHRONICALLY IMPLANTED CATS BEFORE AND AFTER SPINALISATION. M. Bélanger, T. Drew and S. Rossignol, CRSN, Univ. de Montréal, Montréal, Québec, CANADA.

An increase in walking speed can be achieved by altering the step length and/or the step duration. Whereas intact cats can easily reach speeds of upwards of 2.5 m/s on a treadmill, spinal cats are generally incapable of following speeds above 0.8 m/s. The purpose of this study was to examine and compare, in the same chronically implanted adult cats (N=5), the changes in kinematics and EMG activity before and after spinalisation during changes in treadmill speed. Before spinalisation (BS), an increase in treadmill speed from 0.2 to 0.8 m/s resulted in a decrease of the step cycle duration together with a parallel reduction in the duration of the extensor activity (VL, LG). Correspondingly, there was an initial increase in the stance length which reached a plateau at a speed of 0.6 m/s. In addition, there was a progressive and steep increase in the amplitude of the extensor muscle activity. The amplitude of the flexor muscle activity (St, TA) slightly increased whereas its duration remained constant throughout. After spinalisation (AS), although the step cycle and the extensor activity, for any given speed, were generally of shorter duration than BS, there was a similar, although less pronounced, reduction in their durations as treadmill speed increased. However, both reached a plateau at approximately 0.7 m/s. The stance length, although comparatively shorter at slower speeds, increased to BS values at 0.8 m/s. Furthermore, in contrast to BS, the amplitude of the extensor muscle activity, which was generally smaller AS, remained relatively constant as the speed of locomotion increased. Changes in the amplitude of flexor muscle activity and duration were similar to those seen BS. In conclusion, the spinal cat adapts to changes in treadmill speed (in the range of 0.2 to 0.8 m/s) by increasing its stance length up to the BS value attained at 0.8 m/s and by decreasing its cycle duration. However, the spinal cat cannot walk much faster than 0.8 m/s because it appears to lack the capability of increasing the amplitude of its extensor output which would allow it to shorten its stance duration further as seen BS. (Supported by MRC and FRSQ).

160.9

EFFECTS OF NORADRENERGIC, SEROTONERGIC AND DOPAMINERGIC DRUGS ON THE INITIATION OF LOCOMOTION IN THE ADULT SPINAL CAT. H. Barbeau and S. Rossignol. Centre de recherche en Sciences Neurologiques, Univ. de Montréal, and School of Physical & Occupational Therapy, McGill Univ.

The effects of noradrenergic, serotonergic, and dopaminergic precursors and agonists on the initiation of locomotion were investigated within the first week after complete spinalization at Th13 in adult cats. The electromyographic (EMG) activity of Vastus Lateralis (VL) and Semitendinosus (St) was recorded bilaterally through percutaneously implanted copper wires in 6 spinal cats for a total of 13 experiments. The movement of the hindlimbs on the treadmill was also simultaneously video-recorded before and after the injection of drugs.

Without drug injection, strong and continuous perineal or abdominal stimulation did not induce any episodes of coordinated stepping on the treadmill during the first week after spinalization. St was continuously active as opposed to VL in which minimal or no activity was present. Injection of apomorphine (0.3 to 0.5 mg/kg, n=3), a dopaminergic agonist, failed to induce locomotion in such an early stage after spinalization. After injection of DL-5-HTP (50 mg/kg, n=2), a serotonergic precursor, a marked tonic increase in both St and VL amplitude was induced by the movement of the treadmill belt without triggering the locomotor pattern. In contrast, injection of either L-Dopa (50-60 mg/kg, n=1), a noradrenergic precursor, or clonidine (150 µg/kg, n=2), a noradrenergic agonist, induced locomotion on the treadmill. The animal demonstrated a bilateral foot placement on the sole and a complete weight support of the hindquarters. The spinal cat could follow the treadmill speed up to 0.80 $m.s.^{-1}$. The triggering effect of L-Dopa (n=2) or clonidine (n=3) was also observed when combined with 5-HTP or apomorphine.

The present results confirm previous studies showing that the locomotor pattern cannot be expressed spontaneously in the acute stage after spinalization. We further demonstrate that L-Dopa or clonidine, but not apomorphine nor 5-HTP, are capable of inducing locomotion in the first week after spinalization. This supports the importance of the noradrenergic system for the initiation of locomotion. (Supported by a group grant from the MRC. H.B. received a scholarship from the FRSQ.)

FICTIVE MOTOR PATTERNS IN CHRONIC SPINAL CATS. K.G.Pearson and S.Rossignol. CRSN, Universite de Montreal, Quebec, Canada.

Following transection of the spinal cord at T12, adult cats have the capacity to step with their hindlegs on a treadmill. We have recorded the fictive motor patterns in hindleg motor nerves following decerebration and immobilization at different times after spinalization. In cats in which hindleg stepping on the treadmill had recovered (between 30 and 40 days post-spinalization) fictive rhythmic motor patterns could be generated in response to stimulation of the perineum in the absence of drugs. The pattern consisted of short duration flexor bursts alternating with longer extensor bursts. Usually the durations of the bursts in different flexor nerves was not identical. Gentle stimulation of a paw sometimes gave high frequency bursts (up to 10/s) in ipsilateral motor nerves. This activity appears to be related to paw shaking. Squeezing of the paw gave rise to relative long duration bursts in ipsilateral flexor nerves. In animals spinalized between 1 to 10 days prior to recording, vigorous bilateral rhythmic activity was elicited by perineal stimulation following the administration of Clonidine. This activity was characterized by synchronous bursts in ipsilateral flexor motor nerves alternating with synchronous activity in extensor motor nerves. The administration of DOPA following Clonidine resulted in a spontaneous and more complex pattern. In all animals leg flexion decreased the duration of flexor bursts and reduced the frequency of the rhythmic motor activity. We conclude that the complexity and basic features of the fictive motor pattern in chronic spinal cats depends on numerous factors such as time after spinalization, drug treatment, site of stimulation, and leg position. (Supported by the MRC of Canada).

HINDLIMB KINEMATICS AND MUSCLE SYNERGIES DURING SCRATCHING. P. Carlson Kuhta, J.L. Smith, and R.F. Zernicke. Neuromotor Control Lab., Department of Kinesiology, UCLA, Los Angeles, CA 90024-1568.

Although the hindlimb kinematics of 'air' scratching in decerebrated cats are described (Deliagina et al., *Brain Res.* 100:297, 1975), nothing is known about interlimb coordination during a scratch response in which the pinna is contacted by the hind paw. To determine the hindlimb kinematics of scratching in normal cat, we filmed the response at 100 fr/s, and EMG from selected flexor and extensor muscles at the hip, knee, and ankle joints was synchronized with the film.

During a scratch response, the cat stood with the thigh elevated and held nearly horizontal to the floor. The paw was held above the ankle and generally made elliptical excursions about the pinna, usually making contact during each cycle. The range of motion was: ankle, 55 deg; knee, 45 deg; hip, 10 deg. The ankle and knee joints changed from flexion to extension simultaneously, followed by the hip joint about 20 ms later. Reversal from extension to flexion was sequential; the knee joint led, followed by the ankle and hip joints.

The kinematic cycle period (CP), defined as the time from one peak ankle flexion to the next, averaged 188±32 ms (5-7 cycles/s). At the ankle joint, time from peak flexion to peak extension was 62±8% of CP. Paw contact (PC) at the pinna normally occurred 20-40 ms after peak ankle flexion, and paw-off (PO) usually coincided with peak ankle joint extension. On average, PC duration was 48% of the CP.

Extensor EMG was largely coactive and reciprocal with flexor EMG. Usually extensor EMG occurred prior to or near peak flexion, while flexor EMG occurred prior to peak extension. At the ankle, extensor activity occurred prior to PC and remained active for most of PC, while flexor usually occurred about 20 ms prior to PO. Ankle extensor EMG was variable and related to PC duration. These results are consistent with our hypothesis that the duration of extensor muscle recruitment is modulated by motion-dependent feedback during PC. During 'air' scratching, in contrast, the absence of this modulation may account for the brief extensor bursts and prolonged flexor bursts in the decerebrated cat. Funded by NIH NS19864.

KINETIC AND KINEMATIC ANALYSIS OF LOCOMOTOR CAPABILITIES OF POSTURALLY TRAINED ADULT SPINAL CATS. K.L. Perell,* R.J. Gregor, E.G. Fowler, J.A. Hodgson,* and R.R. Roy. BRI and Kinesiology Dept., UCLA, LA, CA 90024-1568.

We have demonstrated that cats spinalized as adults (T12-T13) and subjected to standing postural therapy (Sp-S)(30 min/day, 5 days/ wk) for 6 months have pronounced locomotor output deficiencies when compared to nonexercised (Sp) spinal cats (Soc. Neurosci. Abstr., 14:64, 1988). In order to describe these deficits in detail, force transducers (J. Biomech, 14:489, 1982) were implanted on the distal tendons and EMG electrodes in the muscle bellies of the soleus (SOL) and medial gastrocnemius (MG). Bone pins were implanted as muscle endpoint markers for muscle length and joint kinematic measures (J. Biomech, 17:685, 1984). Additionally, the tibialis anterior (TA) muscle was instrumented for EMG. Peak forces in SOL and MG were similar in Sp-S and Sp cats, while the MG force impulse was significantly shorter in the Sp-S. Timing of TA EMG was more variable in the Sp-S cats with shorter burst durations than in Sp cats. In general, deficits in locomotor output in the cats trained in postural therapy were manifested in two ways. While the SOL maintained its output, the MG did not contribute to increased locomotor speed. This extensor deficit coupled with premature onset of TA EMG, i.e., occurring much sooner relative to the end of stance in the Sp-S than Sp cats, resulted in poor propulsive capabilities in the Sp-S cats and the inability to walk at speeds above 0.2 $m \cdot s^{-1}$.

DIFFERENTIAL MODULATION OF SHORT-LATENCY EPSPS FROM SUPERFICIAL PERONEAL AND MEDIAL PLANTAR NERVES IN SPINAL MOTONEURONS DURING FICTIVE STEPPING IN THE DECEREBRATE CAT. G. N. Sholomenko, A. K. Moschovakis and R. E. Burke, Lab of Neural Control, NINDS, NIH, Bethesda, MD 20892.

Short-latency (< 3 ms) EPSPs produced in flexor digitorum longus (FDL) motoneurons by electrical stimulation of low threshold (<2.5xT) afferents in the superficial peroneal (SP) nerve are systematically increased in amplitude during the early flexion phase of fictive stepping in unanesthetized, decerebrate cats (Schmidt et al., *Exp. Brain Res.* 71:568, 1988). We have now shown that EPSPs with similar latencies and thresholds, produced by stimulation of the medial plantar nerve (PLANT; innervating the central plantar pad and the ventral surface of the toes), are modulated in a completely different manner during fictive stepping. When recording intracellularly from FDL motoneurons in precollicular decerebrate cats, short-latency PLANT EPSPs are markedly reduced or completely suppressed throughout the flexion phase of fictive stepping, at the same time that SP EPSPs are increased in amplitude. This indicates that the two species of EPSPs are produced by separate interneuronal pathways that are subject to differential control by the central pattern generator for locomotion. It seems possible that excitatory interneurons in the PLANT reflex pathway may play a role in the irregular "facultative" action of FDL during the stance phase of normal walking, which apparently acts to help stabilize the animal during perturbed step cycles in intact cats (O'Donovan et al., *J. Neurophysiol.* 47:1126, 1982).).

EFFECT OF PERTURBATION PROFILE ON VISCOELASTIC AND REFLEX PROPERTIES OF CAT HINDLIMB MUSCLES. R.F. Kirsch and W.Z. Rymer Northwestern University Medical School, Chicago, IL. 60611.

Stochastic inputs are frequently used to characterize the properties of muscle and reflex systems, but the impact of perturbation bandwidth on these properties has not been directly addressed. We have examined the force and EMG responses of isolated soleus and m. gastroc. muscles of the decerebrate cat to controlled stochastic length perturbations of three amplitudes (±0.4, ±0.8, and ±1.6 mm) and bandwidths (0-10, 0-30, and 0-100 Hz). These responses were collected for a variety of background force levels modulated by the crossed-extension reflex, both before and after deafferentation (L5-S2). Viscoelastic properties were summarized by fitting the data to a model of the form $f(t) = f0 + K*x(t) + B*v(t)$, where f(t)=total force, f0=mean force, x(t)=muscle length, v(t)=velocity, K=elastic stiffness, and B=viscous stiffness. Velocity was calculated numerically from the length record and K and B were estimated using standard multiple regression techniques.

Although this simple model fit the data of individual trials surprisingly well (85-98% variance accounted for), the values of the viscoelastic parameters K and B were found to depend on the form of the perturbation. For matched mean force levels, K decreased with increasing amplitude, while B decreased modestly. Increasing bandwidth caused a slight increase in K, but a large decrease in B, especially between the lowest and middle bandwidths. The elastic component dominated the response to low bandwidth perturbations; the viscous component accounted for <5% of the variance in this case. Deafferentation caused a decrease in K and an increase in B, but this effect was dependent on bandwidth as well, being rather significant (30% decrease in K) for the lowest bandwidth but essentially imperceptible for the widest bandwidth. Increasing the bandwidth of the perturbation also had adverse effects on force production in the muscle; for example, mean force dropped by more than 50% upon application of the widest bandwidth and largest amplitude perturbation, even though the EMG was most strongly modulated by this perturbation.

The above results suggest that (1) reflexes actively enhance muscle stiffness for relatively restricted bandwidth (<15Hz) perturbations and (2) the viscoelastic and contractile properties of muscle itself are highly dependent not only on mean force but also on the nature of the applied perturbation.

Motor cortex activity in the hindlimb region of the cat during a task which requires a voluntary modification of locomotion. Witold WIDAJEWICZ* and Trevor DREW. Centre de recherche en sciences neurologiques, Université de Montréal, Québec, CANADA. H3C 3J7

We have recently shown (Brain Res. 457 181-187, 1988) that identified pyramidal tract neurones (PTNs) recorded from the forelimb region of the cat motor cortex may markedly increase their discharge when the cat has to voluntarily make a modification of its gait in order to step over obstacles attached to a moving treadmill belt. The present study was designed to determine whether the motor cortex plays a similar role in controlling the trajectory of the hindlimbs which have to make changes in trajectory similar to those of the forelimb but without the benefit of direct visual control.

Recordings were made from the hindlimb region of the motor cortex of two chronically implanted, unrestrained, intact cats using conventional glass-insulated micro-electrodes. PTNs were identified by stimulation of their axon in the pyramidal tract at P7 with microwires while EMGs were recorded from flexor and extensor muscles acting around the hip, knee and ankle.

51 PTNs with receptive fields on the contralateral hindlimb were recorded while the cat stepped over the obstacles on the moving treadmill belt. 13/51 (26%) showed a marked increase in their discharge frequency immediately prior to, and/or during, the changes in EMG activity associated with the modification of the hindlimb gait. Temporal relationships between cell discharge and muscle activity were made on the basis of raster displays and showed that all 13 neurones were best related to flexor muscle activity of the contralateral hindlimb. Microstimulation in the region of the recorded neurones normally caused EMG activity in the contralateral hindlimb at currents of 25μA or less.

These preliminary results, taken together with the observation that stimulation within the hindlimb areas of the cortex may modify EMG activity during locomotion, suggest that the motor cortex may play a direct role in controlling hindlimb activity in circumstances which require a voluntary modification of gait. (Supported by the MRC and the FRSQ).

161.1

THE INFLUENCE OF HEAD POSITION AND TASK SPEED ON STANCE DURING VOLUNTARY ARM MOVEMENT. C.L. Kaiser* and S.S. Palmer. Dept. of Kinesiology, University of Illinois at Urbana-Champaign, Urbana, IL 61801

This study investigated stance during shoulder flexion in response to a tone stimulus using a force platform computerized system. A ratio of integrated torque during initial upward and forward movement over subsequent downward and backward movement was called the ratio of anticipatory torque to volitional torque. Twelve subjects performed 60 trials, with three head positions, and at both self-paced and ballistic speeds. A univariate and multivariate repeated measures analysis determined significance of torque ratios and response times. A linear correlation coefficient between the two variables was -0.693. The mean torque ratio for self-paced trials was 1.29, for ballistic 1.64 (p=.06). In head-neutral and head-extended trials, ratios were significantly greater for ballistic versus self-paced trials. Mean response time for all head-extended trials was 1008 ms, faster than that of other head positions (1090 ms).

EMG was recorded from leg, shoulder and neck muscles. In all conditions, hamstrings was activated before deltoid, trapezius and sternocleidomastoid. In ballistic trials, a second burst of EMG in deltoid occurred simulatneously with that of hamstrings and neck muscles (neck flexor and extensors were coactivated). The relative timing of torques and EMG patterns supports the theory that a simple motor task during stance utilizes adaptive and integrative strategies.

THE PRE-MOVEMENT SILENT PERIOD IN AN ANTAGONIST MUSCLE. R. Agostino,* M. Hallett and J. N. Sanes, Human Motor Control Section, Medical Neurology Branch, NINDS, NIH, Bethesda, MD 20892.

During a rapid voluntary movement, a silent period (SP) can be recorded in tonically activated antagonist muscles prior to any detectable change in limb position. The present study investigated the effects of changing the peak velocity, movement size and pre-load on the SP in antagonist muscles.

Subjects performed visually guided wrist flexion movements by moving a handle attached to a torque motor. A pre-load assisting flexion was used so that the extensor muscles had to be contracted tonically to maintain an initial position of 20° of extension. The surface electromyogram was recorded from wrist flexor and extensor muscles. Thirty movements were collected for each experimental condition, each after some practice.

In one series of experiments, subjects performed a 40° movement at three different peak velocities (300°, 450° and 600°/sec). The SP was longer and larger during the slower movements. The SP size correlated positively with movement duration (MT) and timing of the antagonist (ANT) burst, relative to the onset of voluntary movement. The SP size correlated negatively with the sizes of the first agonist (AG1) and ANT bursts. In a second series of experiments, subjects performed movements of different sizes (20°, 40° and 60°), each with a peak velocity of 450°/sec. The SP was longer and larger during the larger movements. The SP size correlated positively with MT and the ANT burst timing. The SP size correlated negatively with ANT burst size. In a third experimental series, subjects performed 40° movements at a peak velocity of 450°/sec, while three different pre-loads opposed extension (0.23, 0.42 and 0.63 Nm). The SP was larger with heavier pre-loads. The SP size correlated negatively with AG1.

These results suggest that subjects initiate movement by a combination of agonist activation and ANT inhibition, which is not simply reciprocal inhibition. These relationships are predicable to a certain extent by the intended peak velocity, movement size and initial activation of the muscle. Furthermore, the timing and size of ANT excitation and the intended MT strongly influenced SP.

STIMULATION TRIGGERED ENHANCEMENT OF "YIELD TASK" INHIBITION OF M2 LATENCY PERTURBATION EVOKED EMG ACTIVITY J.S. Thomas, Department of Physiology, Meharry Medical College, Nashville, TN 37208.

Subjects instructed to either "YIELD to" or "ASSIST" handle movement produced by a step increase in the torque load applied to elbow prime movers, are typically able to effect a marked reduction in the amplitude of the "M3" latency (75-100 ms) component of the EMG activity evoked to the load change, as compared with that of a "RESIST" task. YIELD task reductions in "M2" latency (50-75 ms) activity are far more modest and variable, unless preceded by a visual, auditory, or cutaneous conditioning signal 20-50 ms prior to the test loading torque step. Since there is no change in EMG activity to the conditioning signal alone (at the same latency as the reduction in M2 amplitude), it is argued that the effect of the conditioning pulse on M2 transmission must occur prior to the motoneuron, possibly at a relay site in a "long loop" pathway of M2 latency excitatory transmission. On this interpretation, it may be possible to use this technique to asses the relative amplitudes of "long" and "short" loop contributions to M2 latency activity in specific subjects and disease processes.

161.4

KINESTHETIC THRESHOLD IN THE THUMB INTERPHALANGEAL JOINT. M.A.Sabbahi, D. Judy. School of Physical Therapy, TWU, 1130 MD Anderson Blvd., Houston, TX 77030.

Kinesthetic sensation has been tested primarily in large joints, despite its importance in rehabilitation of movements after injury. This study investigated passive kinesthetic sensation in the thumb interphalangeal (IP) joint.

Thirty-five normal subjects aged 8-75 years were tested. Subjects' thumbs were positioned in a kinesthesiometer (K) with the distal phalanx moulded in putty. Subjects were blindfolded and audio white noise was applied. The IP joint was passively moved 2^{o} into flexion or extension from neutral position using a variable speed electric motor. Forty random flexion and extension movements were recorded in each subject on a chart recorder and the amplitude and output velocity were calculated. Kinesthetic threshold (KT) was calculated as the speed at which the subject was 70% correct in identifying movement direction. Flexion, extension and combined thresholds were calculated for different age groups.

KT was directly correlated with age (r=.71) for subjects over 23 years. A Kruskal-Wallis ANOVA demonstrated significantly lower KTs for the 23-40 age group ($\bar{X}=10^{o}$/min) as compared to either the 15 ($\bar{X}=27^{o}$/min) or 40 ($\bar{X}=22^{o}$/min) age groups. A Wilcoxon Signed Ranks test showed significantly lower flexion KTs within the 23-40 age group (.01 level. These results indicate that thumb flexion kinesthesia is more sensitive during movement. These kinesthetic sensation vary directly with age.

161.5

EFFECTS OF STATIC LIMB POSITION ON EMG EVOKED BY CERVICAL AND CORTICAL MAGNETIC STIMULATION IN MAN B. Day*, D. Cros*, K.L. Kerman*,B.T. Shahani and J.P. Donoghue, Dept. of Neurology, Mass. General Hospital, Boston, MA 02114 and Center for Neural Science, Brown University, Providence RI 02912

The effect of motor cortex output upon the motor apparatus may be shaped by state of the motor neuron pool. In the present study we used magnetic stimulation to evaluate the effect of different limb positions on the electromyogram (EMG) evoked by cortical stimulation and to compare this effect with that evoked by cervical stimulation. Cortical stimuli were delivered with a magnetic coil centered at the vertex in awake human subjects . Surface electrodes were placed over the flexor and extensor carpi radialis muscles (FCR and ECR). Single magnetic stimuli approximately 1.2x threshold were delivered with the wrist fixed in each of three positions: 30^{o} flexion, neutral, 20^{o} extension with the subjects seated and relaxed. Responses were measured as the integral of 10 trial averages of rectified EMG. Cervical stimulation was used to estimate the effect of peripheral factors upon EMG amplitude.

Position effects were evident after either cortical or cervical stimulation. The cervical-evoked EMG in FCR decreased with wrist extension to 33-77% compared to flexed position, without significant effect in ECR EMG. In ECR, cortical stimulation (after correction for peripheral effects) with wrist extended resulted in 150-180% larger activity than in flexed position; FCR showed inconsistent results in different subjects, but did vary with position. Thus, cortical stimulation evokes larger activity with the muscle at a shorter length for the wrist extensor. The studies suggest that motor cortex output may have different effects on neuron pools depending on initial limb position and that this effect may be muscle specific. These results also show that limb position must be controlled when examining stimulation effects. (Supported by NS 25074)

RESPONSES OF WRIST MUSCLES ELICITED BY PERTURBATION ABOUT THE ELBOW JOINT. G.F. Koshland, L. Gerilovsky* and Z. Hasan Dept. Of Physiology, Univ. of Arizona, Tucson, AZ 85724.

It has been shown that long latency (70 ms) responses occur in elbow muscles even when these muscles are not stretched by perturbations of the upper or lower arm segments (Gielen, CCAM et al. *J Physiol.* 407:275, 1988; Lacquanti, F & Soechting, JF *Exp. Brain Res.* 61:482, 1986). To test the generality of this phenomenon for other inertially coupled joints, we examined the response of wrist flexor and extensor muscles, elicited by a perturbation that extended the elbow.

The subject's forearm was affixed to a frame connected to a torque motor and was free to move in a vertical plane. Surface EMG recordings were obtained from biceps and triceps brachii, brachioradialis, and flexor and extensor carpi ulnaris muscles. With the wrist free to move and the forearm in a supinated position, the elbow perturbation (extension) caused the wrist to flex. A long latency response occurred in the wrist flexor, which was not evoked by stretch of the wrist flexor and occurred too late to cause wrist flexion. Moreover, its latency did not vary with increased amplitude of the perturbation or with increased initial activity of the wrist flexor. When the forearm was repositioned in pronation, the same elbow perturbation caused the wrist to extend, and a long latency response occurred in the wrist extensor.

Similar responses were obtained for perturbations after the wrist and fingers were immobilized in a contoured splint. Taken together, the results support the notion that long latency responses depend on initial limb configuration, but with unchanged configuration, the responses are obligatory, even when the muscles cannot have a mechanical effect as in the case of immobilization. Supported by U.S. grants INT-8520863 (NSF), 2R01-NS19407 & 5T32-NS07309 (NIH).

WRIST-AIRJET SYSTEM FOR IDENTIFICATION OF JOINT MECHANICAL PROPERTIES OF THE UNCONSTRAINED HUMAN ARM. Y. Xu*, D.J. Bennett, J.M. Hollerbach, and I.W. Hunter. Depts. Aero. & Astro. Engrg. and Brain & Cognitive Sciences, MIT, Cambridge, MA, and Biomedical Engrg. Unit, McGill U., Montreal, PQ.

We describe a wrist-mounted airjet system for determining the human arm's joint mechanical properties that is simple and unencumbering. The airjet creates thrusts in opposite directions alternated at high frequencies, and consists of a nozzle, a fluidic flip-flop, two light-weight solenoids, a force sensor and a wrist cuff. Based on the Coanda effect, the nozzle and fluidic flip-flop are specifically designed to generate large thrusts under high flow rates, pressures and frequencies. The solenoids control the flip-flop, which operates under bistable modes to generate pseudorandom binary force sequences. The thrust frequency response is a flat 4 N up to 75 Hz, and useable thrust exists beyond 100 Hz. The rise time in a step response is between 1-2 msec. The static pressure at the nozzle inlet is about 80 psi, generated by air cylinders. These specifications were carefully selected for efficient and robust system identification of the arm's joint mechanical properties. Individual forearm/wrist casts are created for each subject, and the airjet system is rigidly clamped to a cast. Arm displacements are measured very accurately by an Optotrak System (Northern Digital Corp.). Calibration tests with a high-performance linear motor and LVDT have verified the performance of the system. This research is supported by a Whitaker Foundation Biomedical Engineering Grant and NIH Grant AM26710.

161.8

IDENTIFYING THE MECHANICAL IMPEDANCE OF THE ELBOW JOINT DURING POSTURE AND MOVEMENT. D.J. Bennett, Y. Xu*, J.M. Hollerbach, and I.W. Hunter. Depts. Brain & Cognitive Sciences and Aero. & Astro. Engrg., MIT, Cambridge, MA, and Biomedical Engrg. Unit, McGill U., Montreal, PQ.

Our goal is to characterize the human arm's joint mechanical properties during unconstrained posture and movement. As described in an accompanying poster, we have developed a wrist-mounted airjet system for this purpose. As the first step in these studies, we present preliminary results on elbow joint mechanical impedance. For these studies, the airjet system is configured for a uni-axial thrust of 4 N, switched at rates of up to 100 Hz as a pseudorandom binary sequence. We record force, position, acceleration and EMG during the perturbation. Data are analyzed with linear system identification techniques to identify the impedance transfer function between force and position. Two basic experiments were performed, one studying posture and the other movement.

The posture experiment investigates the changes in the mechanical impedance while controlling (1) the subject's instructions ("resist," "resist lightly," or "do not resist"), (2) the size of the perturbations, and (3) a constant bias force (10 to 40 N) against which the arm operates. The second experiment characterizes the time course of the impedance changes during elbow flexion and extension. To this end, repeated trials are ensemble averaged, and a linear perturbation model is identified at each instant in time. This research is supported by a Whitaker Foundation Biomedical Engineering Grant and NIH Grant AM26710.

THE FORCE:FATIGABILITY RELATIONSHIP IN SINGLE MOTOR UNITS:1. A SYSTEMS APPROACH TO THE STUDY OF MUSCLE FATIGUE. D.G. Stuart, Y. Laouris* and L. Bevan. (SPON: Z. Hasan). Department of Physiology, University of Arizona, Tucson, AZ 85724.

Most research on muscle fatigue has focused on the study of mechanisms of action at single failure sites within the CNS and peripheral neuromuscular system. However, a systems approach (cf. Bigland-Ritchie et al., J. Physiol. 379:451, 1986) is also required because, under normal circumstances, fatigue results from failures at several sites, as determined by the task at hand. A systems approach of potential impact is to determine the circumstances under which there is, or is not, a clear association between the magnitude of muscle/motor-unit force output and fatigability, across and within different fatigue-inducing tasks. For whole muscles, this association is close during voluntary and imposed activations of varying strength and duty cycle at varying muscle length, and even in muscles subjected to imposed chronic stimulation. For single motor units, the force: fatigability relationship is also strong at varying levels of force output and activation rate, and when comparing the two parameters' values across a muscle's unit population. However, the association is not evident when comparing values for units of similar type (particularly S). In one disuse paradigm, the association breaks down, when comparing force/fatigability across unit types (normal vs reduced-use). A force-optimization paradigm also alters the force:fatigability relationship within a single unit, when fatigued by regular vs force-optimized activation trains. Similarly, the literature on associations between single-fiber histochemistry/ biochemistry, fiber size and muscle/ motor unit force/ fatigability indirectly reveals examples both in support and against a close association between force and fatigability. In summary, the force:fatigability relationship provides a rubric for further systems studies on muscle fatigue. (Supported in part by USPHS grants NS 25077, HL 07249, NS 07309 and RR05675).

161.10

THE FORCE:FATIGABILITY RELATIONSHIP IN SINGLE MOTOR UNITS:2. A NEW EXPERIMENTAL PARADIGM SUPPORTED BY SIMULATIONS. Y. Laouris*, L. Bevan, R.M. Reinking* and D.G. Stuart (SPON:D. Blask). Department of Physiology, University of Arizona, Tucson, AZ 85724.

A method was developed to compare the effects of different activation patterns on the force production and fatigability of single motor units. Preliminary experiments revealed that delivering two different activation patterns to the same unit sequentially was impractical, because the depression in force output following the first test lasted several (4-6) hours (cf Jami et al, J.Physiol., London, 340:129, 1983). As an alternative, we used a random alternation of two activation patterns delivered to the same motor unit, and decomposed the force profile to assess the contribution of each pattern to the overall force record (cf Cooper et al, J.Physiol.,London, 397:585, 1988). Before proceeding, it was necessary to consider the potentially complicating effects of history-dependent behavior brought on by the temporal effects of one activation pattern on the other. Modeling and simulation were used to: 1) show that short-term, history-dependent effects could be minimized by randomly alternating triple- rather than single trains of the two test patterns; and 2) predict the time course of experimentally derived, decomposed force profiles. With this strategy, it was possible to proceed with the experimental paradigm. (Supported in part by USPHS grants NS 25077, HL 07249, NS 07309 and RR05675).

161.11

THE FORCE:FATIGABILITY RELATIONSHIP IN SINGLE MOTOR UNITS: 3. SIGNIFICANCE OF THE UNIT-ACTIVATION PATTERN. L. Bevan, Y. Laouris*, R.M. Reinking*, S.J. Garland*, N. Radicheva*, and D. G. Stuart. Department of Physiology, University of Arizona, Tucson, AZ 85724.

The goal of the present work was to compare the effects of activation patterning on force production during fatigue in single motor units of the cat hind limb. The stimulus trains used to produce force were relatively similar, i.e., a constant number of stimuli/train (10-20), and train duration (500 ms) and rate (1/s), but subtle changes in the activation pattern produced different force. Two activation patterns (one regular, one optimized) were delivered in random alternation to axons of functionally-isolated motor units, restricted to the type FF category. The force produced by each activation pattern was extracted from the overall force record, so that profiles of fatigability for the two activation patterns could be compared (cf J.Physiol., London, 397:585,1988). It was shown that the optimized activation pattern, which significantly augmented force production initially, maintained the ability to enhance force production throughout the fatiguing procedure. This result suggests that a subtle change in activation patterning is a potential mechanism by which the nervous system can adjust force during fatigue. Furthermore, use of such a strategy would imply that a unit's force:fatigibility relationship is task dependent.(Supported in part by USPHS grants NS 25077, HL 07249, NS 07309 , NSF Int 8520863, RR005675 and the Ontario Ministry of Health).

BEHAVIOR OF MOTOR UNITS IN HUMAN BICEPS BRACHII MUSCLE DURING FATIGUE. S.J. Garland*, L.P. Serrano*, G.A. Robinson, and R.M. Enoka. Departments of Exercise & Sport Sciences and Physiology, University of Arizona, Tucson, AZ 85721.

Motor units maintain force differently over time (i.e., fatigability varies), so we examined the influence of fatigue on the behavior of 12 motor units from 8 human biceps brachii muscles with a subcutaneous branched-bipolar electrode. We measured: (1) recruitment and derecruitment threshold forces and discharge rate during a ramp-and-hold task; (2) discharge rate during a fatigue-inducing, sustained, submaximal voluntary contraction. During fatigue, 11/12 motor units could be followed. Of these, 6 showed an initial increase in discharge rate that subsequently declined. The other 5 motor units showed steady decreases in discharge rate. These behaviors were evenly distributed between high threshold (>25% of a maximum voluntary contraction (MVC)) and low threshold (<25% MVC) motor units. During the fatiguing contraction, 1 low threshold and 3 high threshold motor units failed to discharge tonically, 2 low threshold motor units maintained their rates, and the remainder showed decreased rates. After fatigue, recruitment forces decreased 11-72% from prefatigue forces in all but 2 motor units; both failed to be recruited. Thresholds for derecruitment decreased 20-70% in 7 motor units, increased 18% in 1 motor unit, and did not change in the others. During the ramp-and-hold task, postfatigue recruitment and derecruitment forces changed irrespective of threshold force while discharge rate during holding declined more in high threshold motor units (44-87%) than low threshold motor units (15-48%). Thus, high threshold motor units were more likely to drop out or to reduce discharge rate during a fatiguing contraction. CHARACTERIZATION OF MOVEMENT RELATED VARIABLES OBTAINED FROM SCALP-RECORDED CEREBRAL ACTIVITY IN MAN. D.H. York, D. Fousek*, T. Spagnolia* and M. Schafe*. Dept. of Physiology, School of Medicine, University of Missouri, Columbia, MO 65212.

This study was aimed at characterizing specific components of scalp recorded activity associated with a movement, relative to specific movement variables. Subjects performed a ballistic thumb flexion movement over a fixed displacement, against a known load. Cerebral activity was segregated based on different movement times for comparisons across load and displacement. Five major waveform components were defined across 7 subjects, which are related to the movement task. The amplitude of an initial N1-P1 component was correlated with acceleration. Its onset latency was correlated with the load. The latency of a third component, termed N2 correlated with peak velocity of flexion. The completion of movement was correlated with a fourth component, termed P2, following which, a fifth component termed N3 was consistently defined. In experiments involving passive thumb flexion, performed over the same displacement, load and movement time, only P2 and N3 were defined, suggesting that these two components may represent sensory feedback. TASK INFLUENCE ON TIMING AND GRASP PATTERNS IN HUMAN PREHENSION. T. Iberall, M.J. Preti* and R. Zemke*, Departments of Computer Science, Neurobiology, and Occupational Therapy, University of Southern California, Los Angeles, Calif 90089.

Examining task effects on prehension has raised important questions about the underlying neural mechanisms. While Fitts' law suggests an important constraint that relates task index of difficulty to movement time (MT), Marteniuk et al, CJP, 1987, show the influence of intent and task context, arguing that increased MT is due to an extended deceleration time. In addition, Newell et al, in press, show the effect of object size on the number of fingers used to grasp the object.

Subjects were instructed to either place (easy task) an upright cylinder on a platform or balance it on two horizontal dowels (difficult task). Four light weight cylinders of different heights were used (3-9 cm). MT was analyzed from the start of the movement to the time that the cylinder was grasped. Kinematic analysis using a WATSMART system revealed a significant difference in this MT for the easy vs difficult task. More time was spent in the deceleration phase (time from wrist peak resultant velocity to time of grasp) during the difficult task than the easy task. More fingers were used as cylinder height increased. These data support the results cited above, suggesting the powerful influence of task and object properties.

To model the neural controller, we simulated the grasping component with an adaptive neural net. Using these experimental data as a training set, the network learned to use a different number of fingers depending on task and object properties.

EFFECT OF LOAD MAGNITUDE PREDICTABILITY ON AUTOMATIC COMPENSATORY GRIP FORCE ADJUSTMENTS.
C.J. Winstein, F.B. Horak, and J.H. Abbs. Speech and Motor Control Laboratories, Waisman Center, Univ. Wisconsin, Madison, WI 53705. R.S. Dow Neurological Sciences Institute of Good Samaritan Hospital, Portland, OR 97209.

Effective object grasp requires precise modulation of neuromuscular outputs by cutaneous and muscle mechanoreceptors. Automatic precision grip force responses have been observed within 60-90 ms in response to natural object slips (Westling & Johansson, 1984), and to slips induced by object load changes (Cole & Abbs, 1988; Winstein et al., 1988). In this study, the effect of predictability on these grip force adjustments was evaluated in eight subjects. Different magnitude load perturbations were delivered to an object held between the thumb and index finger. Two load orders (random, blocked) were combined with two pre-load grip conditions (unconstrained, constrained). With random order, the load magnitudes were unpredictable, whereas, in blocked conditions, the same load was presented consecutively ten times allowing load magnitude to be predicted. In constrained conditions, initial grip forces were maintained near the natural minimum level necessary to prevent pre-loaded object slippage, while no initial grip force restrictions were imposed in unconstrained conditions.

Generally, compensatory grip force responses were scaled to load magnitude in all four conditions. However, the initial rate of these grip force responses were more closely related to load magnitude in the predictable than in the unpredictable conditions (r = 0.65 vs 0.48), and most closely related to load magnitude when initial grip forces were maintained near the minimum natural level. These results suggest that anticipatory processes pertaining to load magnitude permit the response gain of these rapid grip force adjustments to be set, at least partially, prior to perturbation onset. Moreover, this response gain setting appears to be independent of the prevailing level of motoneuron pool excitability. (Supported by NIH grants NS-13274, HD-03352, AG-06457, NS-01094.)

161.16

SINGLE MOTOR UNIT ACTIVITY PATTERNS OF HUMAN INTRINSIC LARYNGEAL MUSCLES DURING RESPIRATION. C.M. Chanaud and C.L. Ludlow. Speech and Voice Unit, NIDCD, NIH, Bethesda, MD 20892.

Multiple patterns of activation have been recorded from laryngeal muscles during respiration, suggesting that these muscles may be functionally complex. The purpose of the current study was to determine whether different discharge patterns occur across single motor units within these muscles.

Bipolar concentric EMG needles were percutaneously inserted into the left and right thyroarytenoids (TA) and cricothyroids (CT). EMG and respiration signals were recorded in normal volunteers. Single motor units were identified in records containing a few, distinct units and repeat firings were selected by waveform shape and peak amplitudes.

During respiration, the patterns and rates of discharge of TA and CT units were modulated relative to the phase of the respiratory cycle (inspiratory vs. expiratory). Multiple discharge patterns were found across TA and CT units: of the TA units, 45% had inspiratory bursts, 45% had inspiratory and expiratory bursts and 10% had an expiratory burst; of the CT units, 40% had inspiratory only and 60% had inspiratory and expiratory bursts. Discharge rates ranged 5-30 Hz, usually varying between 10-25 Hz, depending on the respiratory phase.

Multiple activity patterns were found across motor units within the human TA and CT laryngeal muscles. These two muscles may contribute to multiple mechanical or kinematic functions of the human larynx.

ANTICIPATED AND PERIPHERALLY INDUCED EMG ACTIVITY IN ACTIVITY IN SIMULATED CHEWING. F. Bosman, A. van der Bilt*, M.A. Koks*, and H.W. van der Glas. Dept. of Oral Pathophysiology, Univ. of Utrecht, Padualaan 14, 3584 CH Utrecht, The Netherlands.

Additional elevator muscle activity (AMA) is necessary to overcome the resistance of the food during the closing phases in chewing movements. Preceding research on chewing an artificial testfood suggested that peripheral stimuli play an important role in the origin of the AMA.

Eleven subjects participated in the experiments. The AMA was evoked by an external force supplied by a solenoid in a magnetic field. The solenoid was attached to the mandible of the subjects who performed open-close movements at a natural rate controlled by a metronome. At a preset level of jaw opening a force in downard direction was applied. Jaw movement and EMG activity of masseter, temporal and digastric muscles were recorded.

In the cycles wherein a force was applied the EMG of the closing muscles increased about 100 ms before application of the force. About 60 ms after the onset of the force the EMG activity showed a much larger increase. In the first cycle without force the EMG activity started at the same degree of jaw-opening as in the previous cycles. However, the second EMG burst did not occur.

The results suggest that in chewing the texture of the food is anticipated for, whereas the main part of the AMA is induced by peripheral stimuli.

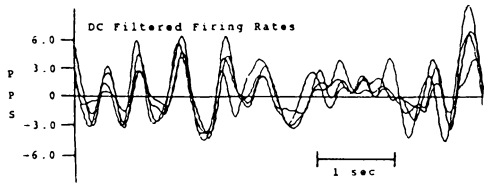
KINESTHETIC THRESHOLDS DURING ACTIVE PRODUCTION OF OROFACIAL AND FINGER MOVEMENTS. L.F. De Nil and J.H. Abbs (SPON: M.A. McCall), Speech & Motor Control Laboratories, Waisman Center, Univ. Wisconsin, Madison, WI 53706.

Previous studies of finger and orofacial kinesthesia have typically been done using a paradigm in which positional changes around a joint were externally imposed. In real life, however, organisms normally have active control over their movements. Such movements may be characterized by enhanced kinesthesia, as is suggested by the observation that increased muscular tension and velocity result in higher kinesthetic acuity.



In the present study, 12 subjects were instructed to make the smallest possible vertical movement with their jaw, lower lip, and tongue. Preliminary data were collected also for the right index finger. To separate the motor from the sensory component, the movement task was performed both with and without visual feedback. The Just-Noticeable-Difference (JND) was significantly larger without visual feedback, indicating that performance in this condition was mainly limited by sensory processes. In the nonvisual condition, the JND for the jaw was more than 2 times smaller (.699 mm) than previously found for passive positioning. The JND's for the lip and tongue were .698 mm and 1.411 mm, respectively. A directional difference was found for the finger, flexion yielding a significantly smaller JND (.814 mm) than extension (1.298 mm). Similarly, a directional trend was apparent for the lip with downward movements (.590 mm) yielding smaller JND's than upward ones (.806 mm).

The data indicate that, at least for orofacial systems, kinesthetic acuity is notably higher during active movements than during more passive positioning. As a result, data from passive positioning tasks should be interpreted cautiously in terms of the sensory information available to the organism during actively controlled movements. Also of interest is the fact that the magnitude of the JND was independent of whether a motor system was endowed with joint receptors or muscles spindles. THE COMMON DRIVE OF MOTOR UNITS IN HUMAN ORBICULARIS ORIS MUSCLE. G. Kamen, N. Paul*, C.J. De Luca. NeuroMuscular Research Center, Boston Univ., Boston, MA 02215.

We have previously identified a phenomenon of motor control termed "common drive", in which human motor unit firing rates are positively correlated when a subject attempts a constant-force isometric contraction. In the present study, we endeavoured to identify the role of spindle afferents in this common drive behavior by recording from the orbicularis oris, a muscle which is reportedly devoid of muscle spindles. Recordings were made using a specially-designed needle electrode while the subject maintained a contraction of the perioral sphincter muscle. The firing occurrences of individual units were identified using our motor unit decomposition technique. The figure shows the common modulation observed among DC-filtered motor unit firing rates, and suggests that common drive behavior can occur in muscles devoid of muscle spindles.

LINKAGE BETWEEN ORBICULARIS OCULI ACTIVITY AND VOLUNTARY MOVEMENTS. I.C. Bruce and P.W.P. Poon*, Department of Physiology, University of Hong Kong, Hong Kong.

As a prelude to a study of eye-hand co-ordination, activity of the eye-closer, orbicularis oculi (OO), was examined during simple movements.

EMG was recorded from OO and wrist flexors during a simple reaction task. Subjects made rapid wrist flexions in response to a low-intensity tone while fixating on a stationary target. Sessions were repeated with cued responses from axial or ankle muscles. Rectified EMGs were averaged with respect to the cue.

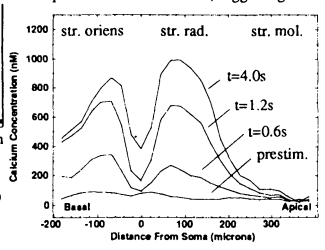
In all subjects, EMG activity in OO was linked to that of the muscle involved in the reaction task. In a given subject, the same EMG pattern was found in OO related to wrist, axial or ankle activity, although the pattern varied between individuals. In the simple excitatory pattern shown by most subjects, OO activity showed a single peak in parallel with that of the responding muscle. The onset latencies of the OO patterns were shortest for wrist, preceding the onset of voluntary EMG by up to 70 ms, intermediate for axial, and longest for ankle, following voluntary EMG onset by at least 55 ms. Control experiments, in which the subject did not respond to the cue, showed no "startle" effect of the auditory cue on OO activity. Processing of the video image of the eye during some sessions indicated that OO activity was not associated with eye movements.

The findings suggest that motor "programmes" for simple reaction tasks include a component affecting eye-closure.

LONG-TERM POTENTIATION III

162.1

NMDA RESPONSES OF SMALL NEURONAL NETWORKS IN CULTURE M.B.Gordon*, S.P.Fracek and G.W.Gross, Dept. of Biological Sciences and Center for Network Neuroscience, University of North Texas, P.O. Box 5218, Denton, Tx, 76203



The NMDA (n-Methyl-D-Aspartate) receptor is known to participate in long term potentiation in hippocampal slices, and could play an important role in information storage. This study was undertaken to ascertain the effects of NMDA on small neuronal networks obtained from embryonic mouse spinal cord (SC), olfactory bulb [OB], cerebellum [CB], and hippocampus [HC]. The dissociated tissues were grown as monolayer minicultures (1mm diam., 500-800 neurons) on multimicroelectrode plates which make possible simultaneous spike sampling from up to 64 extracellular electrodes photoetched onto a glass plate. This allows the long term monitoring of spatio-temporal patterns across the monolayer culture.

Our initial studies, (n=20), show that responses to NMDA concentrations ranging from 20 to 150 µM are best described in terms of 3 distinct phases. Phase 1 represents an abrupt and immediate replacement of pre-stimulus burst patterns by intense tonic spiking on all electrodes. Phase 2 is characterized by an initial inhibition of Phase 1 spiking, gradual increase in spiking, emergence of spike clusters (i.e. bursts), and gradual increase of burst frequencies. Phase 3 starts when bursts fuse to yield intense tonic spiking. In SC and OB cultures, this phase lasted until washout, however, in the HC and CB we observed cycling through Phases 2 and 3 until washout. Variability within each phase was seen among the different tissues tested and among channels, particularly in SC and CB. In the SC, entrained (i.e. directly coupled) pre-stimulus bursting among channels ranged from 70 to 95%, but was reduced to 30 to 60% in Phase 2. Initiation of alternating activity between channels was also observed in SC subsequent to NMDA washout. The tissue-specific differences consisted primarily of the variability in Phase 2, the appearance of cycling through Phases 2 and 3, and the degree of entrainment between channels. Both classes of NMDA antagonists, represented by ketamine and 2-aminophosphonovalerate (2-APV), were effective in these cultures in concentrations ranging from 20 to 90 uM. Above 90 µM, all activity was reversibly inhibited. Supported by a grant from W.W. Caruth (Dallas) via the Communities Foundation of Texas (to GWG) & NSF grant BNS-8719319 (to SPF).

OPTICAL IMAGING OF ION CONCENTRATION DYNAMICS IN PYRAMIDAL CELLS IN HIPPOCAMPAL BRAIN SLICE. D.W. Tank & W.G. Regehr*, AT&T Bell Laboratories, Murray Hill, NJ 07974.

CA1 neurons in guinea pig hippocampal slices were iontophoretically microinjected with the fluorescent calcium indicator fura-2 or the fluorescent sodium indicator SBFI. Low magnification images acquired at two excitation wavelengths with a large dynamic range CCD camera were used to construct maps of ion concentration in soma, apical dendrites and basal dendrites. Fura-2 measurements demonstrate that stimulation of Schaffer collateral afferents produces widespread dendritic accumulation to micromolar levels in the proximal apical and basal dendrites, corresponding to stratum radiatum and stratum oriens, respectively (See Fig.). Accumulation in distal apical dendritic regions located in stratum moleculare is greatly reduced. Most of the response appears to result from activation of voltage-dependent calcium channels (Regehr & Tank, accompanying abstract). Similar experiments with SBFI-filled neurons demonstrate stimulation-induced increases in the ratios of fluorescence excited at 340nm and 380nm in basal and apical dendrites and soma, suggesting mM changes in monovalent cation (Na^+ and K^+) concentration. We are attempting to determine the contribution of synaptic and voltage-dependent conductances to these changes.

Increasing calcium accumulation in a CA1 hippocampal cell during stimulation (20 Hz;10 sec) in stratum radiatum versus distance to soma along representative dendrites. Stimulation begins at t=0s.

162.3

CALCIUM IN HIPPOCAMPAL PYRAMIDAL CELLS DURING TETANIC STIMULATION: IMPLICATIONS FOR LTP. W.G. Regehr* & D.W. Tank, (SPON: R. Cholewiak) AT&T Bell Labs, Murray Hill, NJ 07974.

Popular models for the induction of long-term potentiation (LTP) presume a calcium influx through postsynaptic NMDA receptor channels. Only localized postsynaptic sites that have the necessary conjunction of presynaptic transmitter release and sufficient postsynaptic depolarization are envisaged to accumulate calcium to levels necessary for induction, thus predicting that well localized calcium accumulations only occur near activated afferents. Using microfluorometric imaging techniques and the calcium indicator fura-2, we have measured intracellular free calcium levels in CA1 hippocampal pyramidal cells during (a) intracellular microelectrode stimulation, and during tetanic afferent stimulation of fiber tracts in (b) stratum moleculare, (c) stratum radiatum, and (d) stratum oriens. Similar widespread calcium accumulations in proximal dendrites (described in preceding abstract) with peak calcium levels in the micromolar range were observed for (a)-(d), both in normal saline and in the presence of the NMDA-receptor antagonist APV. Our measurements suggest that calcium accumulations are primarily due to influx through voltage-dependent non-NMDA calcium channels. The lack of appreciable accumulation in distal apical dendrites suggests a different learning or computational role for afferent inputs in stratum moleculare. While the role of influx through voltage-dependent calcium channels in the induction of LTP remains unclear, the resulting accumulations should be taken into consideration in models of LTP induction.

162.4

OPTICAL MONITORING OF LTP AND RELATED [Ca2+]i CHANGES WITH A 256CH PHOTODIODE ARRAY SYSTEM. T.Iijima*, M.Ichikawa and G.Matsumoto (SPON:T.Shiida). Electrotechnical Laboraory, Tsukuba, Ibaraki 305, Japan

We developed a compact optical recording system of 256 ch photodiode array to study neuro-plasticity. We applied this system to a hippocampal slice to observe the neuronal activity change in LTP. A stimulation of the Shaffer-commissural path evoked double-peak optical signals in the dendritic portion of CA1 pyramidal cell; the first peak originated from the activity of input fibers and the second one from the electrotonic potential change of somatic excitation. A tetanic stimulation (100Hz, 1s) increased the both peaks (150-200%) to be sustained for over 3 hrs. An application of phorbor ester also changed the optical signal. However a large increase was detected, along with the increased second peak, only in the dendritic portion within 90 um from the soma. This may indicate the activity change in presynaptic terminal in the definite region. Propagation characteristics of electrical signal from mossy fiber - CA3 region - CA1 region was also studied. The LTP induced in CA3 region largely affected the signal transmission. The [Ca2+]i change concerned with LTP was investigated in a single cell level with this system.

162.5

TWO DIMENSIONAL ANALYSIS OF THE CHANGES IN $[Ca^{2+}]i$ IN THE RAT HIPPOCAMPAL SLICE DURING LONG TERM POTENTIATION. Y. Kudo*, E. Ito* and A. Ogura* (Spon: H. Akagi). Department of Neuroscience, Mitsubishi Kasei Institute of Life Sciences, 11 Minamiooya, Machida, Tokyo 194, Japan

The cytosolic concentration of Ca^{2+} ($[Ca^{2+}]i$) is suggested to play a key role in the establishment of the long term potentiation (LTP) of synaptic transmission in the hippocampus. Here we applied a microscopic image analysis system to the rat hippocampal slices loaded with fura-2 to examine the spatial and temporal changes of $[Ca^{2+}]i$ in the CA1 and CA3 regions during tetanic stimulations. The effects of glutamate receptor agonists were examined in addition to know which subtype(s) of glutamate receptor is(are) responsible for the $[Ca^{2+}]i$ increase. An LTP-inducible tetanization (50 Hz, 5 sec) of the Schaffer collateral caused a small but significant increase in the $[Ca^{2+}]i$ of the st. radiatum of CA1, while those of stt. oriens and pyramidale remained unaltered. A tetanic stimulation to the mossy fiber also resulted in the $[Ca^{2+}]i$ elevation of the CA3 region. The application of any of the agonists (50 μM), NMDA, quisqualate and kainate, caused the increase of $[Ca^{2+}]i$ in TTX-treated preparations. The increase was most remarkable in the layer of st. radiatum in both of the CA1 and CA3 regions. The response to quisqualate and kainate was observed after the treatment of APV (10 - 50 μM). These results further support the requirement of Ca^{2+} for the establishment of LTP and suggest that all subtypes of glutamate receptor participate in the $[Ca^{2+}]i$ elevation.

162.6

ELECTRICAL TEST STIMULI WERE REQUIRED FOR CALCIUM-INDUCED LTP. K.Uruno*, K.Kato*, K.Saito* and H.Kato* (SPON: M.Sato). 2nd Dept. of Physiol., Yamagata Univ. Sch. of Med., Yamagata, 990-23, Japan.

To examine properties of calcium-induced long-term potentiation (LTP), Guinea pig hipocampal slices (400um) were perfused with high calcium (4mM) and low magnesium (0.1mM) solution for 10-20 min. Test stimuli were delivered every 20 sec to Schaffer collateral /commissural pathway. Population spike and field EPSP were monitored in pyramidal cell layer and in radiatum of CA1, respectively. 10 min perfusion of high calcium and low magnesium solution produced LTP of both pop.spike and EPSP. Perfusion for 20 min without test stimuli resulted in only transient potentiation, which was sometimes succeeded by depression of population spike. These results suggest that synaptic transmission and subsequent events are required for calcium-induced LTP. Further, since MK-801 blocks calcium-induced LTP, calcium influx through receptor mediated channels may play a key role as in post-tetanic LTP.

162.7

DIFFERENT SUSCEPTIBILITIES TO DRUGS OF LTPS IN THREE INPUT SYSTEMS TO HIPPOCAMPAL CA3 REGION. M. Satoh, S. Kaneko*, K. Ishihara*, H. Katsuki* and M. Sugimura*. Dept. of Pharmacology, Fac. of Pharm. Sci., Kyoto University, Kyoto 606, Japan.

We have demonstrated *in vitro* that long term potentiation (LTP) in the mossy fiber(M)-CA3 system was augmented by anti-amnesic drugs and inhibited by pro-amnesic drugs. On the other hand, it is well known that the hippocampal CA3 region receives inputs from the fimbria (F) and commissural/associational fiber (C/A) besides F. Thus, we compared effects of several drugs on LTPs in the M-, F- and C/A-CA3 systems. Slices of the hippocampus, 400-500μm thick, were prepared from adult guinea-pigs. A single slice was perfused in a recording chamber with artificial CSF (35° C). Test and tetanic stimui were given at 0.2Hz and 33Hz, respectively. D-APV (a NMDA-antagonist: 10μM) suppressed LTPs in F- and C/A-CA3 systems, but did not affect LTP in M-CA3. However, naloxone (an opioid antagonist:1μM) and scopolamine (a muscarinic cholinergic blocker: 10μM) depressed LTP in M-CA3 system but did not LTPs in F- and C/A-CA3 systems. These findings indicate that mechanisms of production of LTP in M-CA3 system are different from those in F- and C/A-CA3 systems.

162.8

Hippocampal Mossy Fibers Induce LTP of Select Heterosynaptic Afferents. ***J. E. Bradler and G. Barrionuevo*, Depts. of Behavioral Neuroscience & Psychiatry, University of Pittsburgh, Pittsburgh, PA 15260**

We have previously reported that tetanization of the mossy fibers reliably induces heterosynaptic LTP of non-mossy fiber afferents, but tetanization of non-mossy fiber afferents induces a heterosynaptic depression of mossy fiber responses (1). Tetanization of a subset of mossy fibers has been reported to heterosynaptically potentiate a separate, nontetanized subset of mossy fibers (2,3). More recently, however, an absence of heterosynaptic LTP in a nontetanized subset of mossy fibers following tetanization of a separate set of mossy fibers has been demonstrated (4). The resolution of this discrepancy is essential for determining if heterosynaptic LTP represents a non-specific enhancement of all heterosynaptic afferents, or whether it is a potentiation of only select heterosynaptic afferents. Three stimulation sites were used to evoke EPSCs in hippocampal CA3 neurons maintained in an *in vitro* slice preparation. Two sets of separate mossy fibers were stimulated: one electrode was placed in the ventral blade of the dentate granule cell layer, a second was placed in the dorsal blade of the granule cell layer. A third electrode was placed in the fimbria, to stimulate non-mossy fiber afferents. Other methods were similar to those used in our previous report (1). In all cells tested (n=12), tetanization of the mossy fibers induced homosynaptic mossy fiber LTP (mean 85±18%), heterosynaptic fimbrial LTP (91±17%), and heterosynaptic depression of the nontetanized mossy fiber response (38±17%). Supported by NS01196 and NS24288.

162.9

VOLTAGE-DEPENDENCE OF LTP AT THE HIPPOCAMPAL MOSSY FIBER SYNAPSE. *D.B. Jaffe* and D. Johnston*, Div. of Neurosci., Baylor College of Medicine., Houston, TX 77030.

Recent work in our laboratory suggests that postsynaptic, voltage-gated Ca^{2+} channels may modulate the induction of mossy fiber LTP. We tested the hypothesis that the induction of mossy fiber LTP is dependent upon the activation of postsynaptic Ca^{2+} channels, and therefore dependent upon the postsynaptic membrane potential during high-frequency stimulation (HFS). Intracellular recordings were made from CA3 pyramidal cells in the hippocampal slice preparation. An artificial CSF bath containing 10 μM picrotoxin was used to reduce synaptic inhibition and 20 μM APV to block any NMDA evoked potentiation. HFS was applied as 8 trains (50 msec duration) of 100 Hz stimulation at 0.2 Hz. LTP was induced in 5 of 10 control cells (>20% increase in synaptic response 15 minutes post HFS) with a mean increase in EPSP amplitude of 15 ± 8%. Voltage-clamping of CA3 pyramidal cells (holding potential -80 mV) during HFS blocked the induction of mossy fiber LTP in 17 of 18 cells. HFS delivered under current-clamp paired with depolarizing current pulses (3 nA, 50 msec, square pulse) induced LTP in 8 of 10 cells (mean increase in EPSP amplitude 47 ± 14%), which was significantly greater than control cells (unpaired t-test, $p < 0.05$). Postsynaptic depolarization (8-20 square pulses, 3-6 nA injected current, 0.2 Hz) alone or paired with single EPSPs had no effect on synaptic responses. These data suggest that mossy fiber LTP has a Hebbian-like mechanism which is not dependent upon NMDA-receptor activation. A rise in $[Ca^{2+}]_i$, possibly through voltage-dependent Ca^{2+} channels, may be the initial trigger for the expression of LTP at the mossy fiber synapse (Williams & Johnston, this volume). However, a second factor, dependent upon high-frequency synaptic stimulation, may also be required for LTP induction. (NIH grants NS11535 & HL31164, and AFOSR 88-0142)

162.10

HIPPOCAMPAL CA3 MOSSY FIBER LTP IS BLOCKED BY POST-SYNAPTIC CALCIUM CHELATORS. *S.H. Williams & D. Johnston*, Division of Neuroscience, Baylor College of Medicine, Houston, Tx 77030.

Long-term potentiation (LTP) of the hippocampal CA1 Schaffer collateral synapse requires postsynaptic Ca^{2+} influx, which is mediated by glutamate gated, voltage-sensitive, Ca^{2+} permeant, NMDA channels. At the CA3 mossy fiber (MF) synapse, however, the NMDA antagonist APV does not prevent LTP. While NMDA receptor activation is not required, a postsynaptic Ca^{2+} increase may still be necessary. We have tested this hypothesis using postsynaptic injections of the Ca^{2+} chelator BAPTA.

Single electrode current- and voltage-clamp techniques were used to study single CA3 cells in hippocampal slices. Picrotoxin was routinely added to the saline to reduce inhibition. Tetanic stimulation of MF (3 episodes, 100 Hz, 1 sec) induced LTP (> 20% increase 15 min after tetanus) in 6/6 control cells. In a further 4/5 cells, LTP was seen in the presence of 50μM D-APV. In contrast, cells that were iontophoretically loaded with BAPTA (10 mM in the recording pipette) showed LTP in only 2/9 cases. The magnitude of LTP in control cells (EPSP +61 ± 12%, EPSC +58 ± 13%) did not significantly differ from APV treated cells (EPSP +39 ± 4%, EPSC +45 ± 16%), but both control and APV groups showed significantly greater LTP (ANOVA) than BAPTA loaded cells (EPSP +4±9%, EPSC 0±14%). BAPTA did not affect resting potential, input resistance, and membrane time constant. The EPSP was stable with time in control and BAPTA treated cells. Quin-2, a Ca^{2+} chelator similar to BAPTA, blocked LTP in 75% of cells ($n = 4$).

A postsynaptic rise in Ca^{2+} appears necessary for MF LTP. The Ca^{2+} source could be intracellular stores or influx through voltage gated ion channels. The second possibility appears the most likely (Jaffe & Johnston, this volume).

(NIH grants HL31164 & NS11535, and AFSOR 88-0142).

162.11

THE NMDA RECEPTOR IS NOT INVOLVED IN Ca^{2+}-INDUCED LTP IN THE RAT HIPPOCAMPAL CA1 REGION. A. Obenaus, J.A. Shacklock, K.G. Baimbridge, Dept. of Physiology, Univ. of British Columbia, Vancouver, B.C., Canada V6T 1W5.

The effect of D-(-)-2-amino-5-phosphonovalerate (D-APV) on Ca^{2+}-induced long-term potentiation (LTP) has been examined in the in vitro rat hippocampal slice. Additionally, the effect of a transient increase in $[Ca^{2+}]_o$ on $[Ca^{2+}]_i$, has been determined using hippocampal pyramidal cell cultures loaded with the Ca^{2+} sensitive fluorescent probe, Fura II.

D-APV (50uM) affected neither the baseline population spike and EPSP amplitudes, nor did it prevent the induction of LTP by a transient (10min) perfusion with ACSF containing 4mM Ca^{2+}. In cultured hippocampal neurons perfused with a medium containing 2mM Ca^{2+}, the resting $[Ca^{2+}]_i$ was 105nM. Perfusion of 4mM Ca^{2+} for 10min doubled the $[Ca^{2+}]_i$ to 314nM. Neurons observed during the transition to high Ca^{2+} revealed a rapid and sustained increase in $[Ca^{2+}]_i$ which persisted after the return to 2mM $[Ca^{2+}]_o$. D-APV (50uM) when applied prior and during the high $[Ca^{2+}]_o$, did not effect the changes in $[Ca^{2+}]_i$.

Our results suggest that NMDA receptors are not involved in the underlying mechanism(s) seen in Ca^{2+}-induced LTP in the CA1 region. Rather a sustained increase in $[Ca^{2+}]_i$ may be the critical feature.

POSITIVE MODULATION OF LONG-TERM POTENTIATION BY GLYCINE.
D. L. Tauck and G. A. Ashbeck*. Department of Biology, Santa Clara University, Santa Clara, CA 95053.

Long-term potentiation (LTP) is the increased synaptic efficacy induced by a brief burst of high frequency afferent stimulation. Accumulated evidence suggests that calcium influx through the NMDA receptor/channel is required for the development of LTP. In micromolar concentrations, glycine potentiates numerous responses of the NMDA receptor including calcium flow through the channel. The present study documents the role of glycine as a positive modulator of LTP.

Slices of rat hippocampus were prepared and maintained in vitro by standard techniques. A stimulating electrode positioned in stratum radiatum evoked field potentials in stratum pyramidale of area CA1. Baseline responses were recorded for 20 minutes at a frequency of 0.05 Hz and a stimulus intensity which elicited a 1.5 mV population spike. To induce LTP, the stimulus was applied at a frequency of 100 Hz for 1 second. Twenty minutes after the burst, the average control response had increased to 4.0 mV while the response in 1 micromolar glycine had increased to 8.9 mV. This modulation of LTP by glycine was insensitive to strychnine.

CALCIUM-INDUCED CHANGES IN SYNAPTIC EFFICACY IN THE RAT VISUAL CORTICAL SLICE Borroni, A. & Teyler, T. NEOUCOM, Rootstown, Ohio 44272

Long-term potentiation has been studied as a cellular mechanism underlying learning and memory. In the hippocampal slice, LTP can be induced by transient exposure to an extracellular medium containing higher than normal levels of Ca^{2+} (4mM) and K^+ (6.25mM). This result, along with other studies, suggests that the activation of voltage gated Ca^{2+} channels may be required for the induction of LTP in some areas of the hippocampus. In the present experiment, elevated levels of calcium (4mM) and potassium (6.25mM) were used to investigate the similarities between neocortical and hippocampal LTP induction.

White matter stimulation, 1 mm lateral to a recording tract through Oc1 of the rat neocortical slice (400um thick), was sampled every 2 minutes. The slice was exposed to elevated levels of extracellular calcium and potassium for 20 minutes at a rate of .5ml/min. This manipulation produced increases in the evoked response which lasted at least twenty minutes (duration of experiment) after returning to normal medium. Current source density analysis will be used to elucidate the laminar distribution of the Ca^{2+}-K^+ induced changes in the evoked response.

SYNAPTOLOGY OF NEUROPEPTIDE Y (NPY) IMMUNOREACTIVE NEURONS IN THE HILAR AREA OF THE RAT HIPPOCAMPUS.
T.Deller*[1] and C.Leranth[1,2]. (SPON: R. J. Austin-LaFrance) Dept of OB/Gyn[1] and Section of Neuroanat[2], Yale Med Sch, New Haven, CT 06510

Synaptology and morphology of NPY-immunoreactive neurons in the fascia dentata were studied using an antiserum against NPY. Transection of the perforant pathway and fimbria fornix transection were used to study extrinsic afferents. Retrograde tracing technique was applied to determine the possible commissural projections of NPY-cells. Results: The majority of NPY terminals were found in the outer molecular layer of the dentate gyrus where they established exclusively symmetric synaptic contacts on dendritic shafts and occasionally on spines of the granule cells. A moderate number of NPY synapses were also found on dendrites in the inner molecular layer and on the cell body of granule cells. Numerous symmetric NPY synapses were also found in the hilar area, some of them on the cell body of neurons which project to the contralateral hippocampus. At least three types of NPY-neurons could be distinguished: Type 1: pyramidal shaped cells in the subgranular and granular layer with long apical dendrites reaching into the outer molecular layer of the dentate gyrus. After transection of the perforant pathway degenerated boutons were found on distal dendritic shafts of the type 1 NPY-neurons. Type 2: multipolar cells located in the polymorph layer of the hilus. They receive mossy axon collaterals. Type 3: Fusiform neurons, some of which could be retrogradely labeled with HRP-injected into the contralateral hippocampus. This study provides a basis for further electrophysiological studies on the controversial effect of NPY on cells in the dentate hilar area. Supported by NIH grant NS26068 (to C.L.) and Cusanuswerk Fellowship (to T.D.)

163.2

HIPPOCAMPAL AFFERENTS, VASOPRESSIN-, AND MONOAMINE-IMMUNOREACTIVE FIBERS TERMINATE ON THE SAME "SOMATO-SPINY" TYPE OF LATERAL SEPTAL AREA NEURONS.
R.L. Jakab*[1] and C. Leranth[1,2]. (SPON: S. Diaz-Cintra) Yale Univ., Med Sch. Dept. Ob/Gyn[1] and Section of Neuroanatomy[2], New Haven, CT. 06510 U.S.A.

A population of lateral septal area (LSA) neurons is believed to be a pacemaker for hippocampal theta rhythm generation. Vasopressin (VP) can inhibit the depression of spontaneous rhythmic activity of these LSA neurons evoked by monoamines, and enhance their excitatory responses to glutamate (M. Joels and J.A. Urban, 1985). In order to elucidate the synaptological relationships of neuronal elements responsible for the aforementioned physiological phenomena, the combination of EM immunostaining and acute axonal degeneration techniques were used. The fimbria-fornix in adult male Sprague-Dawley rats was transected and after a 36 hours survival period vibratome sections of the ipsilateral septal area were immunostained for either VP or the monoamine marker tyrosine hydroxylase (TH). Distribution of degenerated axon terminals (representatives of hippocampo-septal excitatory amino acid containing afferents) and VP- or TH-immunoreactive boutons was examined by electron microscopy. A population of LSA neurons which established asymmetric synapses with degenerated hippocampal afferents were observed to have characteristic spines on their soma, and the same neurons in most cases were also found to form symmetric synapses with VP- or TH-immunoreactive boutons. These results suggest that the VP, monoamine, and hippocampal excitatory amino acid containing fibers terminate on the same "somato-spiny" LSA neurons. Therefore, VP may act monosynaptically as a modulator in the responsiveness of these neurons to monoamines and glutamate. Supported by NIH grant NS 26068 (to C.L) and Soros Foundation Fellowship (to R.L.J).

163.3

POSSIBLE ANATOMICAL BASIS OF THE HYPERSENSITIVITY OF FASCIA DENTATA SOMATOSTATIN NEURONS IN EXPERIMENTALLY INDUCED- AND TEMPORAL LOBE EPILEPSY.

C. LERANTH and A.J. MALCOLM*. Yale Univ., Med. Sch. Dept. Ob/Gyn, and Section of Neuroanat., New Haven, CT. 06510 U.S.A. (C.L.) and MRC Reg. Peptide Group, Univ. of British Columbia, Vancouver, B.C. Canada (A.J.M.)

A selective loss of somatostatin (SS) immunoreactive neurons has been reported in the fascia dentata of patients with temporal lobe epilepsy (R. Robbins et al., 1987). Experimentally-induced epilepsy in rats also dramatically decreases the number of SS neurons in the same hippocampal area (R.S. Sloviter, 1987). The aim of the present study was to determine whether SS neurons of the fascia dentata are involved in a specific excitatory circuitry which results in their selective damage by non-physiological hyperstimulation. Perforant pathways were transected in anesthetized adult Sprague Dawley rats and after a 28-32 h surviving time, animals were sacrificed. Ipsilateral fascia dentata Vibratome sections were immunostained for SS using a monoclonal antibody (SS_8). Correlated light- and electron microscopic analysis demonstrated that both granule cell dendrites and SS immunoreactive dendrites which extend up to the outer third of the molecular layer are densely covered with degenerated perforant pathway axon terminals. Furthermore, other deep hilar area dendrites of the same SS neurons were found in postsynaptic position to granule cell axon collaterals. These observations suggest that a single perforant pathway stimulus can doubly excite SS neurons. First by a direct excitatory synapse on the outer molecular layer dendrites of SS neurons, and secondly by an indirect pathway involving the mossy axon collaterals of granule cells receiving perforant pathway stimulation. This study was supported by an NIH grant (NS 26068) of C.L.

163.4

CHANGES IN SOMATOSTATIN-IMMUNOREACTIVITY OF NON-PYRAMIDAL CELLS IN THE KAINIC ACID LESIONED RAT HIPPOCAMPUS.(SPON: BRA UK)

R.C. Bruce* and H.V. Wheal. Department of Neurophysiology, Univ. of Southampton SO9 3TU. UK.

The CA1 pyramidal cell region in the kainic acid (ICV) lesioned hippocampus exhibits epileptiform activity that is associated with a loss of synaptic inhibition and GABA mediated IPSPs(Ashwood et al.Exp Brain Res.62:189-198,1986). In the normal rat hippocampus neurones exist in which GABA and somatostatin(SOM) are colocalised (Kosaka et alExp Brain Res.71:388-398,1988). We have investigated the effects of the chronic KA lesion on the numbers of SOM-immunoreactive(SOM -I) neurones in the hippocampus at 7 and 28 days post lesion. A monoclonal antibody to SOM-10 was used(Vincent et alJ Comp Neurol. 238:169-186,1985).

When the ipsilateral and contralateral hippocampi were compared at 7 days post lesion, there was a highly significant difference in the number of SOM-I non-pyramidal cells found in the stratum oriens of CA1(n=8). This reduction in the number of SOM-I cells in the lesioned hippocampus was still apparent at 28 days post lesion(n=9). No changes in the numbers of SOM-I cells in the stratum oriens of the contralateral hippocampus were observed.

In contrast, no difference was observed in the SOM-I of cells in the hilar regions 7 days post lesion(n=5). However by 28 days a highly significant reduction in the immunoreactivity of the hilar region in the lesioned hippocampus had developed(n=7). There was also a progressive loss of activity in the hilus of the contralateral hippocampus.

This project was funded by the Wellcome Trust.

163.5

ULTRASTRUCTURAL LOCALIZATION OF SOMATOSTATIN-LIKE IMMUNOREACTIVITY IN THE RAT DENTATE GYRUS.

T.A. Milner and C.E. Bacon*. Div. of Neurobiology, Dept. of Neurology and Neuroscience, Cornell Univ. Med. Coll., New York NY 10021

Antisera to somatostatin (SOM) were localized ultrastructurally in the hilus (H) and molecular layer (ML) of the rat dentate gyrus by the peroxidase-antiperoxidase (PAP) method. Two types of perikarya with SOM-like immunoreactivity (SOM-LI) were in the hilus: (1) ovoid (6-10μm) and labeled cytoplasm with an accumulation of PAP-reaction product in some Golgi apparatus; and (2) larger (11-16 μm) and a more abundant cytoplasm than the first type, but lacking labeled Golgi. The majority (96% of 374) of synapses on perikarya and dendrites with SOM-LI were from unlabeled terminals forming both asymmetric and symmetric junctions. The remaining pre-synaptic terminals contained SOM-LI and made primarily symmetric synapses. In both the H and ML, terminals with SOM-LI were associated: (1) with single unlabeled perikarya and dendrites (49% of 215 H; 76% of 326 ML); (2) with two unlabeled perikarya and dendrites simultaneously (5% H; 4% ML); and (3) with SOM-containing perikarya and dendrites (6% H; 3% ML). In all three cases, the majority of terminals with SOM-LI formed symmetric synapses on the shafts of small dendrites. The remaining SOM-labeled terminals (40% H; 17% ML) were without any detectable synaptic relations. However, a few of these terminals were in direct apposition to other terminals; some also contained SOM-LI. We conclude that in the dentate gyrus, SOM: (1) may be synthesized and/or packaged in the Golgi of only type of neuron; and (2) most likely inhibits (symmetric synapses) SOM-containing neurons and non-SOM-containing interneurons and granule cells. (Supported by NIMH MH42834 and NIH 18974.)

163.6

MEMBRANE PROPERTIES OF INTERNEURONS IN STRATUM ORIENS/ALVEUS OF THE CA1 REGION OF RAT HIPPOCAMPUS.

J.-C. Lacaille and S. Williams. Centre de recherche en sciences neurologiques, dép. de physiologie, Université de Montréal, Montréal, Qc, H3C 3J7.

Despite their profound influence on hippocampal pyramidal cells, little is known of the intrinsic properties of interneurons. Intracellular recordings were obtained from interneurons (n=19), located at the border of stratum oriens and the alveus (O/A) in rat hippocampal slices, to analyze their membrane properties. Results (n=14/19) indicate that RMP ranged between -52 and -73 mV, R_{in} between 29-83 MΩ and action potential (AP) amplitude between 48-87 mV. 2 types of interneurons with short (<1.0 ms; n=10) or long-duration (>1.2 ms; n=4) APs were encountered. Interneurons displayed single spike after hyperpolarizations (AHP) (amplitude -8 mV, duration 32 ms) and burst AHPs (amplitude -4 mV, duration 700 ms). V-I relationship in response to 200 ms hyperpolarizing pulses showed time-dependent inward rectification and anodal break excitation (8/11 neurons).

In 5 interneurons, exponential curve fitting and peeling was used to estimate passive cable properties from the charging function of averaged responses to small hyperpolarizing pulses. The membrane time constant t_0 ranged between 6.18-12.0 ms, and the equalizing time constant t_1 between 1.15-2.33 ms. Estimates of ρ, the dendrite to soma conductance ratio, varied between 0.44-4.40 and of L, the electrotonic length, between 1.06-1.31. In 5 interneurons, repetitive discharge during long (700 ms) depolarizing pulses was examined. Spike frequency adaptation was present in each cell and the ratio of final to initial interspike frequency varied between 0.32-0.45.

O/A interneurons have distinctly non-pyramidal membrane properties. They are electrically compact and display spike frequency adaptation. Physiologically more than one type of interneuron may be found in O/A region.

MORPHOLOGY AND SYNAPTIC ORGANIZATION OF PHYSIOLOGICALLY IDENTIFIED INTERNEURONS IN SLICE CULTURES OF RAT HIPPOCAMPUS.

D.D. Kunkel, A.T. Malouf and P.A. Schwartzkroin. Department of Neurological Surgery, University of Washington, Seattle, WA 98195.

Hippocampal slices retain their basic structural and connective organization when cultured by the roller tube technique. Previous physiological and morphological studies have shown that slice cultured hippocampal pyramidal cells exhibit typical pyramidal cell characteristics. Information on the intrinsic interneuron populations and the overall synaptic organization of hippocampal organotypic cultures is generally lacking.

Interneurons were first identified physiologically in CA1 stratum oriens, and then injected intracellularly with biocytin, and examined at the electron microscopic level. Numerous fusiform and multipolar-shaped interneurons were found in stratum oriens and at the stratum oriens/stratum pyramidale border. Both types of cells possessed an extensive multipolar dendritic tree extending approximately 200 μm from the soma. Dendrites were slightly varicose, aspiny, and had numerous synaptic contacts (both asymmetric and symmetric) along their length. The axon and its collaterals projected towards CA1 pyramidal cells and made numerous synaptic contacts. Synaptic contacts from these interneurons appeared to be of the symmetric type. Synaptic contacts were also observed making contact with other interneurons in this region. Studies are on-going to examine the immunoreactive nature of these cells, and the overall synaptic organization of organotypic hippocampal cultures.

PARVALBUMIN IMMUNOREACTIVITY IS LOCALIZED TO ALL FIVE TYPES OF BASKET CELL IN THE RAT DENTATE GYRUS.

C. E. Ribak, L. Seress*, S. F. Bullock* and K. G. Baimbridge. Dept. of Anatomy and Neurobiology, Univ. of Calif., Irvine, CA 92717 and Dept. of Physiology, Univ. of British Columbia, Vancouver, BC, V6T 1W5.

Previous studies have indicated that many GABAergic neurons in the hippocampal formation contain immunoreactivity for the calcium-binding protein parvalbumin (PAR-ir), including two types of basket cell in the dentate gyrus. These studies did not determine whether all five types of basket cell that are GABAergic contain PAR-ir and what the ultrastructural features of PAR-ir basket cells are. Light and electron microscopic immunocytochemical studies were made to resolve these issues. In light microscopic preparations, PAR-ir was localized to many pyramidal and fusiform basket cells as previously described. In addition, horizontal, inverted and molecular layer basket cells were less frequently observed to contain PAR-ir. Electron microscopic preparations revealed that cells containing PAR-ir in the granule cell layer displayed the characteristic features of basket cells, such as Nissl bodies, intranuclear rods, nuclear infoldings, asymmetric and symmetric axosomatic synapses and aspinous dendrites. A variety of axon terminals that form synapses with the PAR-ir dendrites was observed. These results indicate that all five types of basket cell have PAR-ir. (Supported by NSF Grant BNS 86-15579)

CONDITIONING PULSES REDUCE PAIRED PULSE INTERACTIONS IN THE RAT DENTATE GYRUS. D.D. Mott* and D.V. Lewis. Depts. of Pharmacology, Neurobiology and Pediatrics (Neurology), Duke University Medical Center, Durham, NC 27710.

Heterosynaptic afferent input has been shown to alter the response of dentate granule cells to perforant path excitation. We used paired perforant path stimuli to investigate this phenomenon.

Paired pulse effects were studied in hippocampal slices from adult, male Sprague-Dawley rats. Perforant path stimulation evoked an EPSP and a population spike in the dentate gyrus granule cell layer. Responses to paired perforant path stimuli exhibited an early (10 msec) inhibition, an intermediate (50 msec) facilitation and a late (400 msec) inhibition. Paired pulse effects were quantified as the percent change in the amplitude of the perforant path-evoked population spike.

Conditioning pulses (1-4 pulses, 50 Hz) delivered to the alveus or stratum lucidum of CA3 had marked effects on the responses of granule cells to paired PP stimulation. Conditioning pulses reduced early (10 msec) inhibition, converting the response to one showing facilitation. In addition, they reduced the intermediate (50 msec) facilitation but had no effects on the late (400 msec) inhibition. The effect of conditioning pulses lasted for up to 1000 msec with a maximal effect at 200 msec. Phaclofen (1 mM, bath-applied) but not naloxone (10 uM, bath-applied) antagonized the effects of the conditioning pulses. In the presence of phaclofen, conditioning pulses only slightly reduced the early inhibition and caused no change in paired pulse facilitation. Phaclofen reduced the amplitude of the perforant path-evoked population spike but had no consistent effect on paired pulse interactions. All drug effects were reversible.

These results suggest that heterosynaptic input can affect granule cell responsiveness through a $GABA_B$ receptor dependent mechanism.

Supported by NIH grant NS 22170 and the Chemical Industries Institute of Toxicology Predoctoral Fellowship.

163.10

RELATIVE CONTRIBUTIONS OF FEEDBACK AND FEEDFORWARD INHIBITION IN THE DENTATE GYRUS OF THE RABBIT HIPPOCAMPAL SLICE. T.P. Harty, T.W. Berger and G. Barrionuevo. *Departments of Behavioral Neuroscience and Psychiatry, University of Pittsburgh, Pittsburgh, PA, 15260.*

We evaluated the relative contributions of feedback and feedforward GABAergic inhibition to paired-impulse activation of population spikes evoked by perforant path stimulation of granule cells of the dentate gyrus. Using a rabbit hippocampal slice preparation, antidromic (activates feedback elements only) and orthodromic (activates feed-forward and feedback elements) conditioning impulses were paired with orthodromic and antidromic test impulses. These testing procedures were performed using short interstimulus intervals (10-50 ms) in the presence of alphaxalone (an allosteric GABA agonist) and bicuculline (a GABA antagonist). In the presence of alphaxalone, antidromic and orthodromic conditioning impulses reduced orthodromic test responses by 34% and 83%, respectively, relative to comparable test responses in the presence of bicuculline. This suggests that feedforward inhibition can account for as much as 50% of orthodromically activated inhibition. However, neither orthodromic nor antidromic conditioning impulses significantly reduced antidromic responses. One possible interpretation of these findings is that feedforward and feedback interneurons selectively project to a population of granule cells that are activated orthodromically but not antidromically. The population of granule cells activated antidromically excite feedback interneurons but are not inhibited by them. It remains possible that GABAergic feedback inhibition is unable to reduce antidromically activated population spikes. Intracellular studies will be necessary to clarify this issue. These studies were supported by grants from the ONR, AFOSR, NIH and NIMH.

163.11

COMPARISON OF DIRECT AND INDIRECT INPUT TO THE HIPPOCAMPAL REGIO INFERIOR FROM THE ENTORHINAL CORTEX USING TRANSSYNAPTIC TRANSPORT OF WGA-HRP. T.W. Berger and P.M. Rice*, *Departments of Behavioral Neuroscience and Psychiatry, University of Pittsburgh, Pittsburgh, PA 15260.*

Transsynaptic transport of WGA-HRP injected into the entorhinal cortex (Van Hoesen et al., Brain Research, 398, 1986) of adult New Zealand white rabbits was used to compare the distributions of direct (presumed monosynaptic) and indirect (presumed disynaptic, mediated by entorhinal monosynaptic afferents to the dentate gyrus) entorhinal input to the CA3 pyramidal cell region of the hippocampus. While animals were maintained on halothane anesthesia, WGA-HRP (2-3%) was pressure injected into the entorhinal cortex. Animals were allowed 3-5 days of survival, after which time they were perfused and the tissue prepared, sliced, and reacted with tetramethyl benzidine, as described by Gibson et al. (Brain Research, 298, 1984).

Densely labeled processes indicative of axonal and terminal labeling were localized within the outer two-thirds of the molecular layer of the dentate gyrus and in the stratum lacunosum-moleculare of CA3. In addition, labeling was observed within somata of the granule cell layer, and not within the inner one-third of the molecular layer, indicating transsynaptic transport of WGA-HRP from entorhinal terminations in the dentate. Less dense, but clearly detectable labeling also was localized in the stratum lucidum of CA3, consistent with transsynaptic transport of WGA-HRP along granule cell mossy fiber axons. Particularly notable was the lack of correspondence between the dense monosynaptic innervation of CA3 and the disynaptic input indicative of those CA3 cells receiving indirect input as part of the trisynaptic pathway.
Supported by NSF, NIMH, ONR, and AFOSR.

163.12

LONG-TERM POTENTIATION OF MONOSYNAPTIC ENTORHINAL CORTICAL INPUT TO CA3 PYRAMDIAL NEURONS OF THE HIPPOCAMPUS. M.F. Yeckel and T.W. Berger, *Depts. of Behavioral Neuroscience and Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA 15260.*

The CA3 and CA1 pyramidal cell regions of the hippocampus receive both a direct, monosynaptic input from the entorhinal cortex (EC) and an indirect, di- and/or tri-synaptic input via EC projections to the dentate gyrus (DG). We recently have demonstrated that for any given subpopulation of pyramidal neurons, EC excitation through monosynaptic afferents predominates over the di- or tri-synaptic input (Yeckel et al., Soc. Neurosci. Abstr., 14, 1988). Additionally, activity in both CA3 and CA1 can be evoked when DG cell activity was inhibited, indicating that EC-induced excitation of pyramidal cells can occur independently of DG excitation. We have investigated further the functional characteristics of the direct EC-to-CA3 projection, and specifically, its ability to express long-term potentiation (LTP).

Ten trains of 10 impulses (400 Hz) were delivered to the angular bundle of halothane anesthetized rabbits while recording from the cell body layers of DG, CA3, and CA1. Recordings from CA3 revealed that short-latency (4-6 ms) monosynaptic population spike responses to angular bundle stimulation were potentiated for at least 1 hr following high frequency stimulation. Comparison of input/output functions for EC-to-DG and EC-to-CA3 projections revealed a greater magnitude increase in CA3 spike amplitudes in response to low intensities, and a greater magnitude increase in DG spike amplitudes in response to high intensities. Increases in both di- (EC-CA3-CA1) and tri-synaptic (EC-DG-CA3-CA1) activation of CA1 also were seen post-LTP. These observations support the conception that excitation of EC afferents initiates a two-phase feedforward excitation of hippocampal pyramidal cells, and demonstrate that these feedforward pathways also are modifiable by high frequency stimulation. Supported by NSF, ONR, AFOSR, and NIMH.

QUANTITATIVE ESTIMATION OF THE NUMBER AND DISTRIBUTION OF ACTIVE DENTATE GRANULE CELLS IN THE HIPPOCAMPUS AS A FUNCTION OF IMPULSE ACTIVITY OF ENTORHINAL AFFERENTS. G. Chauvet*, G. Barrionuevo, and T.W. Berger (SPON: G. Barrionuevo). *Lab. of Theoretical Biology, School of Medicine, Angers, France, and Depts. of Behavioral Neuroscience and Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA.*

A mathematical model based on a two-level field theory[+] is described that relates the number and distribution of active neurons in a volume to the extracellular current density they generate during action potential discharge. The anatomical structure includes a density-connectivity function, $\pi(s,r";r)$, that describes the density of synapses at s with density ρ_0 in postsynaptic neurons localized in r and which are connected to presynaptic neurons with density ρ_1 in r". The physiological problem is the determination of active spaces and density functions, as dependent on stimulus intensity.

The specific geometrical model considered is of entorhinal perforant path innervation of the hippocampal dentate gyrus. The model describes the interaction between a set of active afferents, assumed to be a cylinder with a diameter dependent on stimulation intensity, and conically shaped dendritic trees of granule cells. It is assumed that perforant path afferents provide topographically organized, excitatory input through en passage synapses.

It is shown that information from specifically defined experiments allows an estimation of the minimum (space element) and maximum active volumes, active density-connectivity and granule cell density functions as a function of the number of active perforant path fibers. Full experimental implementation of this model should allow extracellular field potentials recorded from the dentate gyrus to be interpreted in terms of the number of granule cells activated and the strength of the synaptic input responsible for the activation. [+]Chauvet, G., Correlation principle and physiological interpretation of synaptic efficacy, in Systems with Learning and Memory Abilities, J. Delacour and J.C.S. Levy, Elsevier (1988). RESPONSE PREDICTION FOR THE HIPPOCAMPUS OF THE RABBIT. *J. M. Solomon, D.N. Krieger, T.W. Berger, and R. J. Sclabassi. Departments of Neurosurgery, Electrical Engineering, and Behavioral Neuroscience, University of Pittsburgh, Pittsburgh, PA 15213. (Spon: M. Bennett). We have been characterizing the nonlinear functional properties of the hippocampal formation in the rabbit utilizing the kernels from an orthogonalized functional power series. Using both *in-vivo* and *in-vitro* preparations, we have experimentally estimated the first four kernels (h_0, h_1, h_2, h_3), by cross-correlating the evoked population spike activity with a random point process input. The resulting functions are interpreted both as generalized recovery functions and as n^{th} order impulse responses. These kernels are then utilized in N^{th} order convolution integrals to model the system response to alternative inputs. This paper reports on experiments from both classes of preparations where, besides the random trains, the perforant path was stimulated with doublets and triplets over a range of interstimulus intervals from 10 ms to 1000 ms, and the observed responses were predicted using an input/output model based on the previously measured kernels. Both the twin pulse and triplet experiments had prediction mean square errors of less than 5%, when modeled utilizing kernels through the third order for both the *in-vivo* and *in-vitro* experiments.

163.15

FREQUENCY DOMAIN PROPERTIES OF SECOND ORDER KERNELS FROM THE HIPPOCAMPUS OF THE RABBIT. R. J. Sclabassi, D. N. Krieger, T. Biedka,* and T.W. Berger Departments of Neurosurgery, Electrical Engineering, and Behavioral Neuroscience, University of Pittsburgh, Pittsburgh, PA 15213.

This paper examines the frequency domain characteristics of second order kernels of a functional power series expansion. Experimental data was obtained by stimulating the medial and lateral bundles of the perforant path, both *in-vivo* and *in-vitro*, using random stimulus trains, and recording the evoked population spike in the granuale cell layer. Second order kernels were obtained by cross-correlation. The second-order kernels were transformed into the frequency domain using a two dimensional dFT The results are presented in the ω_Δ and ω_τ plane, with the maximum frequency component in either axis being 500 Hz. All three classes of preparations studied demonstrated significant activity in the frequency domain. Medial perforant path data demonstrated a 1/f fall-off in the ω_Δ dimension, terminating in a notch at $\omega_\Delta = \omega_\tau$. Lateral perforant path data demonstrated a similar fall-off, again terminating in a notch at $\omega_\Delta = \omega_\tau$, with a parallel notch occurring at $\omega_\Delta + 50Hz. = \omega_\tau$. In contradistinction, the slice data was nearly constant in the τ but demonstrated significant periodicities in the Δ dimension.

163.16

NONLINEAR RESPONSE PROPERTIES OF HIPPOCAMPAL DENTATE GRANULE CELLS ARE NOT DEPENDENT ON MEAN FREQUENCY AFTER LONG-TERM POTENTIATION OF ENTORHINAL CORTICAL INPUT. J.R. Balzer*, R.J. Sclabassi, and T.W. Berger (Spon: S. Wolff). *Departments of Behavioral Neuroscience, Neurological Surgery, and Psychiatry, University of Pittsburgh, Pittsburgh, PA 15260.*

In previous experiments (Robinson et al., Soc. Neurosci. Abstr., 11, 1985), we have used nonlinear systems analysis to characterize the transformational properties of the hippocampal perforant path-dentate projection (PP-DG). Perforant path fibers were stimulated with trains of impulses having a Poisson distribution of inter-impulse intervals; different distributions having mean frequencies (λ) of 1.0, 2.0, 3.3, 5.0, and 10.0 Hz were used. First, second, and third order kernels were computed by cross-correlating intervals of the stimulus train with amplitude of the granule cell population spike. Results showed that first order kernels, which reflect the average population spike amplitude per impulse, were not altered by changes in λ. In contrast, second and third order kernels, which reflect the nonlinear response of granule cells as a function of intervals within the train, varied substantially depending on λ.

We examined the effect of LTP on the relationship between granule cell nonlinearity and λ. Results showed that after the induction of LTP, nonlinear response characteristics were much less dependent on λ. Together with our previous findings that LTP decreases the dependence of nonlinear characteristics on the intensity of random train stimulation, these data show that the dentate component of the hippocampus provides much less transformation of entorhinal input after induction of LTP, and that the transformation that does occur is the same for most levels of synchrony and mean firing rate of entorhinal neurons. THE USE OF WAVEFORM RELAXATION IN COMPARTMENTAL MODELLING OF HIPPOCAMPAL CA1 PYRAMIDAL NEURONES H.V. Wheal and E.W Stockley*. Department of Neurophysiology, University of Southampton. SO9 3TU, UK.

The interpretation of electrophysiological data related to synaptic function in the CA1 region of the hippocampus is limited by a lack of knowledge of the spatial distribution and efficacy of synapses. In order to overcome this limitation we have developed a compartmental model based on the 3-dimensional morphology of pyramidal cells and their dendrites.

Intracellular electrophysiological data was obtained from CA1 pyramidal cells that were subsequently filled with HRP. After histological processing the cells were optically sectioned, digitised and reconstructed in 3-dimensions. This database provided the structure for the generation of a multi-compartmental model. We have written a circuit simulator based on waveform relaxation (WR) specifically to solve the resulting large (>2000 nodes) equivalent circuits. The program was first tested by simulating idealised structures with analytic solutions. Our simulations showed that waveform relaxation converged slowly when applied to the tightly coupled compartments of a typical cell structure. However, significant improvements in solution time were obtained using succesive over relaxation and by combining WR and sparse matrix gaussian elimination into a hybrid simulator.

Comparison of simulated and measured input resistances and time constants has enabled us iterate towards a consistent set of passive model parameters. We are now adding active membrane conductances to the modelling scheme based on modified Hodgkin/Huxley dynamics and data obtained from dissociated pyramidal cells.

SIMULATIONS OF SYNAPTIC POTENTIALS USING REALISTIC MODELS OF HIPPOCAMPAL PYRAMIDAL NEURONS. J. Wathey, W. Lytton, J. Jester and T. Sejnowski, Salk Institute, La Jolla, CA.

Different portions of a pyramidal cell may operate independently along one physiological dimension while interacting along another. Parameters that may be involved include voltage changes, second messengers, ion fluxes, morphological and metabolic changes. To assess the relative contribution of these influences, we have modeled an anatomically realistic CA1 pyramidal cell at different levels of physiological detail. We used the simulation program "CABLE" (M. Hines and J. Moore) with morphological data provided by D. Amaral.

Initially, we determined whether passive properties could produce asymmetrical voltage responses in apical and basilar dendritic fields to synaptic input on the opposite side. With low membrane resistance, a basilar tetanus showed 30% less influence on the apical region than a normalized apical tetanus produced in the basilar region. Even with maximal synaptic input, however, the resulting depolarization in the other compartment was only 5-10 mV with these parameters, too low to be significant. With passive somatic and dendritic membranes, the addition of a spike-generating axon had virtually no effect on the membrane potential elsewhere in the cell. Soma-generated spiking was reflected throughout the neuron and transformed a low frequency signal in the apical dendrites into passively conducted spikes in the basilar dendrites. Slower Ca^{++}-mediated spiking in the apical dendrites smoothed the signals received via the soma from the basilar dendrites to produce more consistent depolarization in the apical dendrites. These possibilities can be tested by studying interactions between different parts of pyramidal cells in slice preparations.

COMPUTER SIMULATION OF HIPPOCAMPAL PLACE CELLS. Patricia E. Sharp, SUNY Health Sciences Center, Brooklyn, N.Y.

It has been suggested that the hippocampus is involved in configural learning and that deficits seen on spatial and other tasks after hippocampal damage are due to a configural component of these tasks (Sutherland & Rudy, *Psychobiol.*,1989). Hippocampal pyramidal cells show location-specific firing thought to be crucial in the hippocampus' role in spatial learning. It has been suggested that this firing results from the 'local view' available in a cell's field (McNaughton, In *Neural Connections, Mental Computation*, Nadel *et al.*, 1989).

Here, these ideas are combined in a model in which pyramidal cells are the output layer of a competitive learning pattern classification device (Rumelhart & Zipser, In *Parallel Distributed Processing*, Rumelhart *et al.*, 1986). The inputs are 'configurations' of environmental stimuli as viewed from various locations. These patterns are 'classified' on the basis of their similarity. Since views available from contiguous regions of space are similar, single cells come to fire in a circumscribed region (place field).

In these simulations, computerized rats run 'sessions' of continuous locomotion in a 'cylinder' with discrete 'stimuli' on its walls. For each input cycle (at 8 Hz): 1) the distance and angle of each stimulus to the rat's current head position is calculated 2) these results establish activity in 'neocortical' units which have a .16 probability of responding to a given stimulus when that stimulus is in its receptive field 3) these units establish activity in 'entorhinal cells' to which they project and 4) these, in turn, project to 'hippocampal cells'. Hebb-like changes in synaptic weights occur for active cells. Firing-rate maps for these theoretical units show place fields remarkably similar to those of actual cells (Muller, *et al., J. Neurosci.*, 1987; Quirk *et al., Soc. Neurosci. Abstr.*, 1988).

BACK-PROPAGATION CALCULATIONS OF HIPPOCAMPAL PLACE CELL FIRING FIELDS. R.U.Muller*, G.J.Quirk and J.L.Kubie. (Spon. M. Halpern) Dept. of Physiol. SUNY Health Sciences Center, Brooklyn, N.Y. 11203

The spatial firing patterns of hippocampal (HP) place cells and entorhinal cortex (EC) cells were recorded under identical conditions. The firing patterns of HP cells were crisper than those of EC cells. This is not unexpected, since EC is likely the route by which processed sensory information reaches HP.

We used back-propagation of error (Rumelhart et al, 1986) to calculate spatial firing patterns of place cells with EC cells as inputs. With 40 each of EC, "hidden" and place cells, the total error sum of squares (TSS) decreased along an exponential-like path. After 500 iterations, the patterns calculated for place cells strongly resembled the "teaching" patterns. Another run with place cells as inputs gave similar results, except that TSS was lower at each iteration than with EC inputs. In both cases, the decay of TSS was associated with large variations of TSS around the running average, an indication of "chaotic" behavior.

A third calculation was done with randomized versions of EC firing patterns as inputs. The decay of TSS was slower than with the original EC patterns, but the form of the decay was the same, and the computed patterns again strongly resembled the teaching patterns. Thus, back-propagation does not require a spatial signal in the inputs to yield close facsimiles of place cell spatial firing patterns, and may therefore be too powerful (due to the teaching input?) to serve as a method for investigating the origins of place cell properties. In contrast, it may be possible to generate testable connectivity schemes between EC, the dentate gyrus and the hippocampus by minimizing differences between the computed properties of hidden cells and the measured spatial firing properties of dentate cells.

THE FIRING OF ENTORHINAL PLACE CELLS IS MORE SENSORY-BOUND THAN THAT OF HIPPOCAMPAL PLACE CELLS.
G.J. Quirk, and R.U. Muller*, SUNY Health Sciences Center, Brooklyn, N.Y.

The entorhinal cortex (EC) is the main path for conveying sensory information to the hippocampus (HP), and cells there show location-specific firing when examined in freely-moving rats (Quirk and Ranck '86, *Neurosc. Abstr.* 12:1524). Place cells in both structures fire most rapidly in a single region of the apparatus; this region rotates with the controlling cues. To further understand environmental control over the firing of cells in the two structures, recordings were made in differently shaped chambers. Previous work showed that changing apparatus shape dramatically alters the firing patterns of HP cells, i.e. the firing pattern in a cylinder does not predict the firing pattern in a square (Muller and Kubie '87, *J. Neurosc.* 7:1951-1968).

28 EC and 19 HP cells were examined in a cylinder (76 cm diam) and a square (69 cm on a side) that were uniformly gray save for a white cue-card attached to the wall in each chamber. Mean firing rate and 3 measures of location-specificity (spatial autocorrelation, field size, no. of high-rate patches) were compared in the cylinder and square for the EC and HP cells. In all measures, the firing patterns of EC cells were significantly more similar in the two apparatuses than were HP cells. Unlike HP cells, the location of EC firing-fields in the two apparatuses often occupied a similar position relative to the cue-card.

These data suggest that the firing of EC cells is more tightly controlled by the cue-card than HP cells, and that the extraordinary sensitivity of HP cells to the shape of the chamber is a property that arises after the EC.
