The cerebellar cortex contains five major cell types. These cell types have been differentiated from one another by their location, size and shape and in some cases by molecular characteristics. Another less numerous cell type, the Lugaro cell, has been identified by its shape and location. Lugaro cells are long, horizontally-oriented, fusiform cells that are located in or slightly below the Purkinje cell layer. Their principle dendrites emerge from opposite poles of the cell body and extend long distances in the horizontal plane. Despite their distinct morphology, Lugaro cells have not been differentiated from the Golgi cells of the granule layer by many authors, who classify all the large neurons of the granular layer as Golgi cells.

In the present study, we sought to differentiate the Lugaro cell by its molecular characteristics. We used cell-type specific antibodies against the three large cell types located at the junction of molecular and granular layers: Cat-301 and Cat-304 for Lugaro cells; Rat-303 for Golgi cells; and anti-calbindin for Purkinje cells. Double-label immunocytochemistry on cat cerebellar sections with subclass- or species-specific secondary antibodies showed that each class of neuron was identified by only one cell-type specific antibody. These results demonstrate that Lugaro cells are molecularly distinct from Golgi and Purkinje cells with respect to their surface and intracellular antigens. This molecular characterization of Lugaro cells resolves the question of whether they make up a distinct cell type and should permit further studies to determine their role in cerebellar circuitry and information processing. MORPHOMETRIC ANALYSIS OF FUSIFORM CELLS IN THE GRANULAR LAYER OF THE RAT CEREBELLAR CORTEX.
J. LAINE*, B. BERTHIE* & H. AXELRAD* (SPON: W.R. WEBSTER) Lab. de Physiol.-CHU Pitié-Paris 13- FRANCE

The fusiform neurons, present in the granular layer, form the less known cell type of the mammalian cerebellar cortex. Since their description by Lugaro (1894) only qualitative studies on their morphology have been published, the exact target of their occasionaly impregnated axon is still under debate and there has been no functional recording of these interneurons. In view of a complete morphofunctional study of these cells- necessary to apprehend the full dynamics of the cerebellar network- we present here some quantitative data obtained from 40 Golgi impregnated neurons of the rat vermis, using the modification of Gabbott & Somogyi (J. Neurosci. Methods., 11:221;1984). 1-Cell localization: 16 had their soma at the level of the Purkinje Cell layer(PCl),21 were located about 4 µm beneath the PCl, intermingled between the basket cell's terminal "pinceaux", and 3 were more deeply situated in the depth of the granular layer. 2- The cell soma has a great axis parallel to the PCl with a mean length of 16.6µm and mean small axis of 9.7µm (mean ratio:1.8; range: 1.18-2.57). 3- The mean number of dendrites is 4.2(range 2-8) with 89% of them arising at either pole,thus giving the cell it's specific bearing. 4- Due to the fact that 84% of the 167 dendrites were cut the total spatial span of these is difficult to assert, nevertheless the longest ones had their termination farther than 320µm from the soma. 4-Of the 21 complete polar dendrites 14 branched dichotomously with a mean of 3 branches.No clear correlation for the branching point distances was found. 5-In our series , as for other groups, unfortunately no axon was impregnated for more than 20-30µm.These cells appear therefore as a relatively homogeneous type.

164.3

PROJECTIONS FROM THE BRAINSTEM NUCLEI TO VENTRAL PARAFLOCCULUS (vPFL), DORSAL PARAFLOCCULUS (dPFL) AND FLOCCULUS (FL).
S.A. Azizi, A.J. Painchaud* and D.J. Woodward, *Dept Cell. Bio. U. T. Southwestern Medical Center, Dallas, TX 75235*

This study was undertaken to demonstrate the organization of detailed projections from brain stem nuclei to visual-vestibular areas of the lateral cerebellum. Small quantities (.01 to .2µl) of HRP-WGA were pressure/iontophoretically-injected into discrete areas of the cerebellar cortex in 45 rats. The sensitive chromogen, tetramethyl benzidine, was used to visualize labelled neurons. Three-dimensional images of the PFL and FL were obtained with the aid of a computer. Results of this investigation demonstrated that with regard to olivary projections, the FL receives almost exclusively from the dorsal cap, a portion of the vertical lamella. The vPFL receives from the rostral lamella of the medial accessory olive and the ventral lamella of the principal olive, while dPFL receives mainly from the principal olive (for nomenclature see Azizi and Woodward, JCN 263:467, 1987). With regard to mossy fiber afferents, FL receives mainly from the vestibular nuclei and lateral zones of the basilar pons. The vPFL receives from lateral zones of the rostral basilar pons, while dPFL receives from the medial zone of the rostral basilar pons, among other minor projections, but not any vestibular input.

These data suggest that, although FL, vPFL and dPFL receive climbing fiber input from distinctly separate regions of the olive, these same structures receive mossy fiber input from similar pontine regions. We hypothesize that the pontine projections to these structures may serve to transmit common gain control/gating signals from the cerebral cortex concurrently to both FL and pFL. *(Supported by DA 2338, NIAAA 2901 and Biological Humanics Foundation).*

PURKINJE CELL ANTIGENIC COMPARTMENTATION AND THE TOPOGRAPHY OF SPINOCEREBELLAR TERMINAL FIELDS.
C. GRAVEL, Lab. Neurobiology, Laval U., Quebec, and R. HAWKES, Dept. Anatomy, U. Calgary, Alberta, Canada.

WGA-HRP injections into the lower thoracic-higher lumbar (LTHL) region of the rat spinal cord reveals parasagittal bands of mossy fiber terminals in the cerebellar cortex. The LTHL terminal fields and the Purkinje cell compartments were compared by immunoperoxidase staining of adjacent sections with anti-zebrin I (mabQ113) and 3D reconstruction. The comparison reveals a complex relationship, including:

- PC compartments subdivided longitudinally by LTHL terminal fields
- some PC compartment boundaries strictly obeyed by the LTHL terminal fields, others not
- differences in terminal field position between the dorsal and ventral surfaces of the same lobule.

One result of the subdivision of PC zones is that anatomical compartment widths are now compatible with the microzones and patches identified electrophysiologically.

AFFERENT ORGANIZATION OF THE LATERAL RETICULAR NUCLEUS OF THE RAT: AN ANTEROGRADE TRACING STUDY. N. Rajakumar*, A.W. Hrycyshyn and B.A. Flumerfelt. (SPON: J.A. Kiernan) Dept. of Anatomy, The University of Western Ontario, London, Canada, N6A 5C1.

The organization of afferent fibres within the lateral reticular nucleus (LRN) of the rat was investigated following placement of HRP-WGA into the red nucleus, fastigial nucleus, various levels of the spinal cord or the sensorimotor area of the cerebral cortex. The pattern of distribution of anterogradely labelled profiles visualised with TMB histochemistry revealed that the caudal three-fourths of the LRN received a large, topographically organized projection from the entire length of the contralateral spinal cord, the lateral part of the rostral half of the LRN received a smaller projection from the contralateral red nucleus, the dorsal part of the middle third of the LRN received a smaller projection from the contralateral fastigial nucleus, and the extreme rostromedial part of the nucleus received a sparse projection from the cerebral cortex. The distribution of afferents from different levels of the spinal cord, red nucleus, and fastigial nucleus overlapped in the middle third of the LRN, whereas the cerebral cortical receiving area of the nucleus was devoid of the other inputs. These data suggest that the middle third of the LRN integrates spinal and supraspinal impulses to the cerebellum, and is involved in a cerebello-rubro-LRN reverberating circuit, while the rostral part provides an additional cerebral cortico-cerebellar pathway. (Supported by M.R.C. Canada).

Development ot Cerebellar Cortical Efferents: An In-vitro Anterograde Tracing Study in Rat Brain Slices. **Leonard M. Eisenman, M.P.A. Schalekamp* and Jan Voogd*. Department of Anatomy, Jefferson Medical College, Philadelphia, PA. 19107, USA., and *Department of Anatomy, Erasmus University, Rotterdam, The Netherlands.**

The anatomical and presumably functional organization of the cerebellum has been demonstrated to be based on a parasagittal schema of afferent and efferent connectivities and biochemical heterogeneities. The manner is which this organization is established during development still eludes us. We were interested in using an in-vitro slice technique to examine the efferents from Purkinje cells to the deep cerebellar and vestibular nuclei to determine their developmental timetable. We iontophoretically injected the nascent cerebellar cortex in embryonic day 18 (E-18) through postnatal day one rats with a 5% solution of horseradish peroxidase (HRP). After six to seven hours of survival in an in-vitro chamber, the slices were removed, placed in fixative and processed histochemically. The results demonstrate that transport from the Purkinje cells can be seen and followed to the region of the cerebellar or vestibular nuclei. In E-18 slices, labeled axons with growth cones could be observed coursing through the white matter and into the cerebellar or vestibular nuclear region. In sections from E-19 through E-20 the labeled axons could be followed into the nuclear regions and seen to ramify among the cell bodies. Terminal swellings, however, were not observed. In E-21 sections the labeled axons could be seen to form terminal swellings over the somas of vestibular neurons. These results demonstrate that the cortico-nuclear and cortico-vestibular projections are forming in late embryonic life and that they appear to begin forming synaptic contacts with their target cells at the latest by day E-21. These findings suggest the possibility that the corticonuclear and corticovestibular projections may be present early enough to serve as the organizing system of cerebellar topography. RE-DEFINING RAT RED NUCLEUS: CYTOARCHITECTURE AND CONNECTIVITYC.L.Tucker*, S.A.Lee* & P.R.Kennedy, Bioengin. Center, Georgia Tech, Atlanta, GA 30332.

Rat red nucleus (RN) is considered to be limited rostrally by the pre-rubral area. We have studied RN cell types and number, distributions and locations in thionin-stained and fluorescently stained sections. Diamidino Yellow (DY) was placed in the dorsolateral funiculus of the spinal cord that contains the rubrospinal tract (RST); Fluoro-Gold (FG) was placed near the inferior olivary nucleus (ION).

Cells corresponded to parvo and magno cell descriptions (Parvo: large central round nucleus, prominent nucleolus, small cytoplasmic/nuclear ratio, rounded outline; Magno: relatively small oval nucleus, eccentrically placed, large cytoplasmic/nuclear ratio, with rectangular or pyramidal cytoplasmic outline.) Parvos were large (30-45u), medium (15-30u) or small (10-15u). Magnos were larger or smaller than 25u. Counts of nucleus-containing cells revealed 3,008 magnos that were situated mainly caudally, as expected, but also extended into and beyond the pre-rubral area. 19,904 parvos extended from the caudal pole through the pre-rubral area and surrounded the fasciculus retroflexus. The magnos tended to be located ventrally, whereas the parvos were located throughout the nucleus.

Labelling the transected RST at C3 with DY in 6 rats produced labelled magnos and parvos. Surprisingly, only 24% of these labelled cells were magnos and 76% were parvos (combined result from 2 rats analyzed in detail). Even though unlabelled (thionin stained) magnos were seen extending into and beyond the pre-rubral area, DY-labelled magnos were only seen caudal to it. DY-labelled large and small parvos were similarly distributed. DY-labelled medium parvos, however, extended from the caudal pole through the pre-rubral area into the para-fascicular region.

In these two rats accurate injections of FG were made in ION producing extensive labelling of RN. 63% of cells labelled with DY from the spinal cord were also labelled with FG from ION. This confirms a similar report of doubly labelled cells using FG and Fast (or True) Blue (Kennedy PR, Neurosci. Abstr., 13(2):852, 1987). 85% of DY-labelled magnos and 55% of DY-labelled parvos also contained FG.

These results suggest that rat RN is more extensive and complex than previously believed. (Support by grant NIH-RO1NS24602-01A2).

164.8

ULTRASTRUCTURAL STUDY OF NORMAL AND HYPERTROPHIC CAT INFERIOR OLIVE. C.I.de Zeeuw*, T.J.H.Ruigrok* J.C.Holstege*, M.P.A.Schalekamp* and J.Voogd* (SPON:S.Gielen). Dept. of Anat., Erasmus Univ. Rotterdam, 3000 DR Rotterdam, The Netherlands.

Several months after cerebellectomy, neurons in the inferior olive (IO) can become hypertrophic. The normal and hypertrophic IO were studied after intracellular labeling with HRP, GABA-immunogold labeling and injection of WGA-HRP in the mesodiencephalon. Compared with the normal, the hypertrophic IO showed 1) larger cellbodies, 2) more and longer somatic spines, which were more often linked by gap junctions, 3) longer distal dendrites, 4) axon collaterals bearing varicosities filled with vesicles, 5) less GABAergic boutons in the neuropil, but an equal percentage apposed to somata, and 6) relatively more mesodiencephalic terminals. The present data show that 1) hypertrophic olivary cells are affected by trophic factors not only at the cellbody but also at the level of somatic spines, dendrites, and axon, 2) the ratio of excitatory to inhibitory terminals is increased in the hypertrophic neuropil, and 3) the electrotonic coupling between hypertrophic olivary cells may be enhanced (Ruigrok et al.,'89, Suppl.Eur.J.Neurosci.) due to a high number of gap junctions between somatic spines.

TEMPORAL EXPRESSION OF CRF IN THE DEVELOPING CEREBELLUM. **S.L. Cummings, J.S. King, and W.S. Young III. Dept. of Anatomy and Neuroscience Program. The Ohio State Univ., Columbus., OH and Lab. Cell Biology, NIMH, Bethesda, MD**

Immunohistochemistry and *in situ* hybridization histochemistry were employed to analyze the ontogeny of corticotropin releasing factor (CRF) in the developing opossum cerebellum. CRF-IR beaded fibers are present by postnatal day (PD) 3. At this time, CRF mRNA is transcribed in the inferior olivary complex, but is not evident in precerebellar nuclei that are sources of CRF-IR mossy fibers in the adult. By PD 18, CRF-IR puncta are within and subjacent to the immature Purkinje cell layer, and paramedian aggregates of CRF-IR puncta which likely are precursors of sagittal bands reported in the adult (Cummings et al., JCN 280:501) are evident in the vermis. By PD 40, CRF-IR climbing fibers are in the mid stage of development, and by PD 76 mature CRF-IR climbing fiber arbors are present in the molecular layer. CRF mRNA hybridization signal is present by PD 18 in brainstem nuclei which are potential mossy fiber sources. CRF-IR terminals with the phenotype of mossy fibers can be differentiated within the internal granule cell layer by PD 40. These data demonstrate that CRF is present in early arriving cerebellar afferents, and suggest that CRF is expressed first in climbing fibers. The role of this peptide in cerebellar development remains to be determined. (NS 08798)

164.10

CORTICOTROPIN RELEASING FACTOR (CRF) POTENTIATES THE ACTIONS OF ASPARTATE AND GLUTAMATE IN THE CAT'S CEREBELLUM. Georgia A. Bishop. Dept. of Anatomy and Neuroscience Program. The Ohio State Univ., Columbus, Ohio 43210

Immunohistochemical studies (Cummings, '89,JCN, In Press) have shown that CRF is present throughout the cat's cerebellum in climbing and mossy fibers as well as a beaded plexus of fibers. In this study, single units in lobules V and VI were isolated extracellularly to determine the effects of CRF, aspartate (ASP) and glutamate (GLU) on the firing frequency of the cell. ASP and GLU increased the firing rate of the unit. When applied alone, CRF had no effect on the firing rate of the cell. However, this peptide enhanced both sub- and suprathreshold effects of ASP in all cases and of GLU in most cases. ASP occasionally induced a rhythmic firing in isolated units. Simultaneous application of CRF abolished this rhythmic pattern of firing. These data suggest that CRF does not function as a classic neurotransmitter in the cerebellar cortex. Rather, it acts as a neuromodulator which potentiates the effects of both ASP and GLU. (Supported by NS 18028).

164.11

SUPPRESSION OF PURKINJE CELL ACTIVITY BY CHEMICALLY CODED EXTRINSIC AFFERENTS. Christopher W. Kerr and Georgia A. Bishop. Department of Anatomy and Neuroscience Program.

Studies from this laboratory have shown that serotonin (5HT) is present in a unique afferent system that is morphologically distinct from classically defined cerebellar afferents (climbing and mossy fibers). 5-HT immunoreactive fibers (IR) and varicosities form a dense plexus within the granule and Purkinje cell layers throughout the cerebellar cortex. A double-label paradigm was used to determine the source of this afferent system. The hemisphere receives 5HT afferents from cells located in the peri-olivary reticular formation. In contrast the anterior vermis receieves its 5HT projection from cells located in the paramedian and lateral reticular nuclei. Serotoninergic fibers in the paramedian lobule and posterior vermis arise from cells located in the lateral reticular nucleus. Although climbing and mossy fibers are excitatory to their target neurons, 5HT appears to suppress activity. Thus the present study provides experimental evidence that an extrinsic afferent system suppresses Purkinje cell activity. (Supported by NS 18028).

164.12

SYNAPTIC DISTRIBUTION OF IDENTIFIED PURKINJE CELL COLLATERALS: ZONE X Yi Fei Chen*, Georgia A. Bishop and James S. King. Dept. of Anatomy and Neuroscience Program, The Ohio State University, Columbus, Ohio

Studies from this laboratory have shown that all Purkinje cells give rise to recurrent collaterals that form a dense plexus within the vicinity of the cell of origin. However, the role of these collaterals in controlling cerebellar output has not been included in most theories of cerebellar function as little is known about their postsynaptic targets. To define the circuits in the area of collateral distribution we have cut serial thin sections through the local axonal plexus of an HRP filled Purkinje cell located in zone x. Targets of the 81 boutons within the ganglionic plexus include the cell bodies and proximal dendrites of basket cells and dendrites of Purkinje cells. Eight boutons contact a single basket cell. Two other basket cells were approximated by single axosomatic boutons. Six boutons contact the proximal dendrites of a single Purkinje cell. Synapses also are formed with the dendrites of interneurons. Thus, recurrent collaterals likely have a differential role in cerebellar function. They may increase Purkinje cell activity via their input to basket cells. They also may decrease cortical output by directly suppressing adjacent Purkinje cells. It is unknown at present if these direct and indirect circuits interact with the same Purkinje cell(s).(NSF 8505971)

164.13

REDUCED CELL SIZE IN THE DEEP CEREBELLAR NUCLEI (DCN) OF GENETICALLY DYSTONIC (*dt*) RATS. J. Lutes & J.F. Lorden. Dept. Psych., UAB, Birmingham, AL 35294.

The movement disorder of the *dt* rat is established by postnatal day 12. Although there are no signs of lesions or degeneration at the light micorscopic level, within 2 wk of the appearance of the movement disorder, increased glucose utilization, decreased muscimol binding, and increased glutamate decarboxylase (GAD) activity can be detected in the DCN of the mutants in comparisons with unaffected littermate controls. Thus, we have looked for morphological effects on the cells of these nuclei. Cross-sectional areas of the somas of 300-600 cells in each nucleus were measured in normal (n=4) and *dt* (n=3) rats at 20 days of age. Cell size in the mutant rats was significantly reduced in the dentate and fastigial nuclei ($p<.005$), but not the interpositus nucleus, the site at which increased GAD activity was detected earliest. Reductions in cell size in the DCN have also been reported in mutant mice in which the Purkinje cells are reduced in number (Roffler-Tarlov & Herrup, 1981). In the *dt* rat, the Purkinje cells are not lost but are reduced in size and show some functional abnormalities. The primary gene defect in the *dt* rat is unknown; however, the alterations in cell size in the DCN may be secondary to changes in the Purkinje cells that terminate in the DCN. (Supported by NS18062 and the Dystonia Med. Res. Fdn.).

164.14

THE GENETICALLY DYSTONIC (*dt*) RAT IS BEHAVIORALLY SENSITIVE TO QUIPAZINE. S.E. Stratton & J.F. Lorden. Dept. Psych., Univ. of Alabama at Birmingham, Birmingham, AL 35294.

The *dt* rat is behaviorally insensitive to harmaline, a drug known to act on the olivo-cerebellar system. In rabbits, quipazine has been shown to have behavioral and electrophysiological effects similar to those of harmaline (Barragan et al., 1985). Quipazine's effects, however, are present at birth while harmaline is ineffective in the rat until 9-10 days of age, the time at which the movement disorder of the *dt* rat first appears. Because quipazine may act on some of the same pathways as harmaline, the behavioral sensitivity of the *dt* rat to quipazine was examined before and after the onset of the motor syndrome. Normal and *dt* rats, 8 and 16-19 days of age, were given quipazine (20, 40 or 60 mg/kg, i.p.). Hyperactivity, forelimb padding, and hindlimb ataxia were seen in normal rats following quipazine. At all ages studied, the effect in *dt* rats was equal to or greater than that in normal rats. In the *dt* rat, harmaline rhythmically activates the inferior olive, but fails to produce rhythmic activation of the cerebellum or a motor tremor. The effectiveness of quipazine suggests that the defect in the CNS of the *dt* rat is independent of the pathway through which quipazine's motor effects are mediated. (Supported by 1FMH09735, NS18062 and the Dystonia Med. Res. Fdn.)

164.15

GLUTAMIC ACID DECARBOXYLASE ACTIVITY IN LATERAL VESTIBULAR AND DEEP CEREBELLAR NUCLEI IN RATS WITH CLIMBING FIBER LESIONS. J.Litwak*, C.Rizzo*, M.Beales*, G.A.Oltmans and J.F.Lorden. Dept. of Pharm. and Mol. Biol., Chicago Med. Sch., N.Chicago, IL 60064 and Dept. of Psych., Univ. of Alabama, Birmingham, AL 35294.

The neurotoxin 3-acetylpyridine (3-AP) selectively destroys climbing fiber afferents to the cerebellar cortex. Following 3-AP administration Purkinje cell activity increases, producing a strong inhibition of the firing rate of neurons in the lateral vestibular (LVN) and the deep cerebellar nuclei (DCN). In parallel with the increased Purkinje cell activity, glutamic acid decarboxylase activity (GAD) in the DCN is increased. The changes in single cell activity of both the Purkinje cells and the LVN and DCN cells changes during the postlesion period. In the current study GAD activity in the specific divisions of the DCN and the LVN was measured at several postlesion intervals to compare biochemical and electrophysiological conditions.

Adult male rats were injected with 75 mg/kg of 3-AP or saline. At 7 and 14 days postlesion the LVN and specific divisions of the DCN were removed using the punch procedure, and GAD activity determined. In the LVN GAD activity was increased greater than 30% at 7 days post-lesion, but then decreased to 15% above control at 14 days postlesion. In contrast, in the DCN GAD activity was increased 12, 24, and 29% (medial, interpositus, lateral divisions, respectively) at 7 days, and then increased to 33, 30, and 40% above control at 14 days. Thus, these results suggest that climbing fiber lesions may have a differential effect on Purkinje cell influences in specific target areas at different postlesion intervals. (Supported in part by the Dystonia Medical Research Found.)

164.16

CHOLINE ACETYLTRANSFERASE ACTIVITY IN CEREBELLAR PROJECTION SITES OF RATS WITH CLIMBING FIBER LESIONS. M.W. O'Brien*, M. Beales*, G.A. Oltmans, and J.F. Lorden (SPON: S. Hoff). Dept. of Pharm. and Mol. Biol., Chicago Med. Sch., N. Chicago, IL 60064 and Dept. of Psych., Univ. of Alabama, Birmingham, AL 35294.

The neurotoxin 3-acetylpyridine (3-AP) has been used to selectively lesion the inferior olive-climbing fiber (CF) input to the cerebellum. This lesion produces increased cerebellar Purkinje cell activity, increased glutamic acid decarboxylase activity in the deep cerebellar nuclei (DCN), and decreased single cell activity in the intrinsic cells of the DCN. To examine the lesion's transsynaptic effects, choline acetyltransferase (ChAT) activity was measured in several motor nuclei including known DCN projection sites.

Adult and juvenile rats were injected with 75 mg/kg 3-AP or saline. At selected post-lesion periods the specific brain nuclei were removed using a micropunch dissection technique, and ChAT activity determined. In young animals there was a significant decrease in ChAT activity in the ventropostero-medial thalamus at 7 days post-lesion. In other areas examined (red nucleus, pontine nucleus, ventral thalamus) no differences were found between lesion and control animals at any of the post-lesion intervals studied (3,7,14 days). (Supported in part by the Dystonia Medical Research Found.)

164.17

AUTORADIOGRAPHIC LOCALIZATION OF AMINO ACID NEUROTRANSMITTER RECEPTORS IN THE CEREBELLAR CORTEX OF PIGEON (COLUMBA LIVIA) AND TURTLE (PSEUDEMYS SCRIPTA). RL Albin, EK Richfield, A Reiner, AB Young, JB Penney. Dept. of Neurology, University of Michigan, Ann Arbor, MI 48109; and Dept. of Anatomy, University of Tennessee, Memphis, TN 38163.

Glutamate and GABA are the main neurotransmitters of cerebellar cortex. We used receptor autoradiography to determine the comparative distribution of GABA and glutamate receptors in the cerebellar cortex of rats, pigeons (Columba livia), and turtles (Pseudemys scripta). Benzodiazepine receptors are found in both granule cell and molecular layers of all three species. GABA-A receptors are densest in the granule cell layer with GABA-B receptors densest in the molecular layer of all three species. In rats and turtles, NMDA receptors are densest in the granule cell layer and quisqualate receptors densest in the molecular layer. In pigeons, quisqualate receptors are densest in the molecular layer with NMDA receptors were densest in the molecular layer. Our results indicate overall conservation of receptor distribution but the NMDA receptor distribution in pigeons suggests divergent organization of the avian cerebellum. Supported by NS19620, NS19613, NS 010300.

TRANSECTION OF THE OLIVO-CEREBELLAR TRACT CAUSES LARGE DECREASES IN N-ACETYLASPARTYLGLUTAMATE, BUT NOT ASPARTATE OR GLUTAMATE IN SELECTED AREAS IN THE RAT CEREBELLUM. M.A.A.Namboodiri, L.Williamson, J.R.Moffett, D.Garrison, #A.C.Murphy, J.H.Neale and +M.Palkovits. Dept. Biology, Georgetown University, Washington, D.C. 20057, #Lab. Cell Biology, NHLBI, NIH, and +Lab. Cell Biology, NIMH, NIH, Bethesda, MD 20892.

The levels of NAAG, aspartate and glutamate were measured in five areas of the cerebellar cortex, the cerebellar nuclei and in the inferior olive of rats ten days after unilateral transection of the olivo-cerebellar tract (OCT). Brain regions were microdissected by the punch technique and NAAG levels were measured using a radioimmunoassay with high specificity (IC50 NAAG = 2.5 nM, NAA = 100 uM) and sensitivity (smallest detectable amount = 1-2 pg/assay), while aspartate and glutamate levels were determined using a Beckman amino acid analyzer. Transections of the OCT immediately lateral to the inferior olive caused substantial decreases in NAAG levels in the ipsilateral cerebellum, as compared to NAAG levels on the contralateral side. Depletions in NAAG levels correlated well with numbers of transected olivo-cerebellar fibers: NAAG levels in the ipsilateral paramedian lobe and vermis (lobules VIII-IX) decreased by 72-94% in rats with total transections of fibers running to these cerebellar areas, while smaller depletions (vermis VIII-IX: 22-24%, vermis IV-V: 44-46%, paraflocculus: 26-44%, paramedian lobe: 31-42%) were measured in rats with partial transections of the OCT. No alterations were observed in the cerebellar nuclei, and a slight elevation in the contralateral inferior olive. Also, no significant alterations in the levels of aspartate or glutamate were detected in any of the above areas. These results indicate that NAAG is present in the olivo-cerebellar tract where it, or glutamate derived from it, may serve as a neurotransmitter. (Supported by NIH Grant DK 37024 MAAN and NIDA grant DA 02297 to JHN).

ACETYLCHOLINE II

165.1

ACETYLCHOLINE-IMMUNOREACTIVE FIBERS IN CEREBRAL AND PERIPHERAL BLOOD VESSELS. T.J-F. Lee, F.J-P. Miao*, T. Okuno*, and K. Kawashima* (SPON: G.N. Pandey). Dept. of Pharmacol. Southern Il. Univ. Sch. of Med. Springfield, IL, and Kyoritsu College of Pharmacy, Tokyo, Japan.

It has been established that cholinergic vasomotor control exists in some vascular beds. The presence of cholinergic vasomotor nerves has been supported by the presence of small agranular vesicle-containing nerve terminals, acetylcholinesterase- and choline acetyltransferase (ChAT)-containing fibers, high ChAT activity and high affinity choline uptake system. ACh-containig fibers in vascular wall, however, has not been demonstrated. In this study, the presence of ACh-immunoreactive (ACh-I) fibers in cerebral and peripheral blood vessels was examined using avidin-biotin complex method. Tissues were fixed in situ by a mixture of allyl alcohol and glutaraldehyde. The results indicate that ACh-I fibers exist in cerebral arteries, pulmonary and mesenteric arteries and veins, and aortae. The distribution patterns of ACh-I fibers are similar to those of ChAT-I fibers. These results, for the first time, provide the most direct evidence for the presence of cholinergic innervation in the vascular wall and further suggest a functional significance of cholinergic innervation in vasomotor control of local blood flow. (Supported by NIH HL 27763, 24683, and SIU School of Medicine)

165.2

NICOTINIC MODULATION OF NEURONAL RESPONSES TO PERIPHERAL STIMULATION IN RAT SOMATIC SENSORY (SI) CORTEX K.M. Jacobs, D. Werner*, and J.P. Donoghue, Center for Neural Science, Brown University, Providence, RI 02912

Iontophoretic application of acetylcholine (ACh) to SI neurons typically enhances discharge evoked by natural sensory stimulation within the cell's receptive field. Less frequently response suppression is observed. The different laminar distributions and suspected locations of muscarinic and nicotinic receptors in SI (Sahin et al, '88) suggests that these receptor subtypes may mediate different effects of ACh.

In the present study we tested the hypothesis that input suppression is mediated by nicotinic receptors and that nicotinic effects are most frequently obtained in mid-cortical layers, where these receptors are most abundant. The sensory responses of 53 single neurons in rat SI cortex were recorded during urethane anesthesia (1.5 g/kg) while the receptive field was stimulated by air puffs or a mechanical stimulator. Responses were recorded before, during, and after the application of cholinergic agonists or antagonists applied iontophoretically through multibarrel glass pipettes. Clear effects of nicotine (NIC) application (H-Tartrate, 0.5M, 10-100 nA) were observed in 39 cells (74%). In 25 cells (64%) the sensory evoked discharge was enhanced by NIC, while it was suppressed in 10 cells (26%). Enhanced cells either returned towards baseline or remained enhanced for minutes after NIC application ended. Enhancement produced during NIC application could be blocked by concurrent application of mecamylamine (MEC). In 4 of 8 cells ACh induced enhancement could not be blocked by MEC. None of the NIC effects showed a preference for the midcortical layers, and similar percentages of enhanced and suppressed cells were found in middle and infragranular layers. All of the NIC-modulated cells located in the supragranular layers (4 of 7) showed enhancement. These results demonstrate that NIC effects can be elicited in all cortical layers and that nicotinic receptor activation can either enhance or suppress sensory responses in SI cortex. Since some cholinergic effects cannot be blocked by NIC antagonists, similar forms of modulation may be produced via muscarinic receptors as well. (Supported by NIH NS22517 and March Of Dimes 5-562)

GALANIN mRNA IN THE PRIMATE NUCLEUS BASALIS OF MEYNERT. L.C. Walker, D.L. Price and W.S. Young III. Neuropathology Lab., The Johns Hopkins Univ. Sch. Med., Baltimore, MD 21205; Lab Cell Biology, NIMH, Bethesda, MD 20892

Immunocytochemical studies of the nucleus basalis of Meynert (nbM) in nonhuman primates indicate that, in addition to a population of smaller galaninergic cells, most large, cholinergic projection neurons also contain the peptide galanin [Melander and Staines, *Neurosci. Lett.* 68:17-22, 1986; Walker et al., *J. Comp. Neurol.* 280: 272-282, 1989]. Studies in humans suggest that galanin occurs in small- or medium-sized neurons (some of which are also cholinergic) but not in the large cholinergic neurons characteristic of the nbM [Chan-Palay, *J. Comp. Neurol.* 273:543-557, 1988]. We used hybridization histochemistry to detect galanin mRNA in the basal forebrain of baboons (*Papio*). Hybridization with a [^{35}S]-labeled synthetic DNA probe to bases 228-271 of rat galanin cDNA [Kaplan et al., *Proc. Natl. Acad. Sci. USA* 85:1065-1069, 1988] disclosed a population of intensely labeled, small-to-medium-sized neurons. These neurons may correspond to the smaller cells showing galanin-like immunoreactivity in the human nbM. Most large, hyperchromic neurons were lightly labeled, and some large cells appeared to be unlabeled. Low levels of galanin mRNA in many large neurons may explain the difficulty in detecting galanin-like immunoreactivity in these cells.

EFFECTS OF GROWTH FACTORS ON REGENERATION OF CHOLINERGIC PROJECTIONS FROM BASAL FOREBRAIN TO MEDIAL CORTEX. T.W. Farris and L.L. Butcher, Lab. of Chemical Neuroanatomy, Dept. of Psychology, UCLA, L.A., CA 90024-1563.

To determine the regenerative effects on cholinergic projection neurons of three putative growth-promoting factors, we administered ganglioside GM1 (30 mg/kg,IP), thyroxine (T4, 2.5 mg/kg, IP) and estradiol benzoate (EB, 10 ug/kg, SC) daily for 14 days to 8 week-old rats with unilateral axotomies of the medial cholinergic pathway arising from the basal nuclear complex and projecting to cingulate, medial and occipital cortices. Brain tissue was processed for acetylcholinesterase (AChE) histochemistry and choline acetyltransferase (CAT) and dopamine beta-hydroxylase (DBH) immunohistochemistry and was analyzed via light microscopy. All measures in all groups demonstrated a build-up of stain proximal to the cortical cut. This effect was greatest for AChE staining and was greatest in GM1-treated rats and least in EB-treated rats. Loss of AChE staining intensity distal to the cut was least in T4-treated rats and was unchanged for GM1 or EB. In all conditions, AChE-positive and DBH-positive fibers immediately adjacent to the cut, which run parallel to the midline on the side contralateral to the cut, turned toward the cut changing course up to 80 degrees to reach the cut. This effect was most pronounced in the GM1-treated rats. Collectively, these data support findings that (1) cholinergic basal nuclear complex (CBNC) neurons are sensitive to thyroid hormones (Gould et al, 1989); (2) GM1 augments the regeneration of injured CBNC neurons; and (3) suggest that medial pathway axotomy is a good model system for studying *in vivo* growth-promoting factors known to exert neuronotrophic effects on cholinergic morphologic and biochemical measures *in vitro*.

CORTICAL CHOLINERGIC FUNCTION AFTER BASAL FOREBRAIN LESION. M. Downen, K. Sugaya*, S.P. Arneric and E. Giacobini. (SPON: R. Becker). Dept. Pharmacology, Southern Ill. Univ. Sch. Med., Springfield, IL 62794

Changes in presynaptic cholinergic function in the cerebral cortex were determined following ibotenic acid lesion of the basal forebrain. K^+-evoked (50 mM) acetylcholine (ACh) release was measured at 2, 4 and 6 weeks following unilateral ibotenic acid injection into the ventromedial portion of the globus pallidus. Release was determined following preincubation with ^{3}H-choline chloride (NEN) in micropunches taken from the fronto-parietal cortex of each hemisphere. Ipsilateral to the lesion, K^+-stimulated release was expressed as percent change from spontaneous release following lesion and compared to evoked release from the contralateral control hemisphere. Potassium-evoked release was significantly decreased in the lesioned hemisphere in all cortical regions sampled at 2 and 4 weeks postlesion ($p < .01$). There was no difference in percent release across cortical regions in both intact and lesioned hemispheres at 2 and 4 weeks after lesion. At six weeks, release was not significantly changed in the lesioned hemisphere as compared to the intact hemisphere. A recovery toward control levels was seen in the rostral punches. However, there was an unexpected reduction of release in the caudal punches from the intact hemisphere. Significant regional differences were seen in percent K^+-evoked release at 6 weeks ($p < .01$). A rostral caudal gradient was observed with the rostrally located punches showing greater release in both hemispheres. Basal forebrain lesion did not alter spontaneous release and there was no regional difference in baseline release at any time point examined. Choline acetyltransferase (ChAT) activity depletion following lesion showed a rostral-caudal gradient. The greatest depletions were seen in the frontal and lateral micropunches. Lesion-induced release effects may be a more sensitive measure of neuronal function than alterations in enzyme activity.

165.6

BUNGAROTOXIN BINDING FOLLOWING NUCLEUS BASALIS LESION. K. Sugaya*, M. Downen and E. Giacobini (SPON: D.M. Caspary). Dept. of Pharmacology, Southern IL Univ. School of Medicine, Springfield, IL, 62794-9230

The nucleus basalis magnocellularis (NBM) represents the major extrinsic source of cortical cholinergic innervation. ^{125}I-alpha-bungarotoxin (alpha-BTX) and ^{125}I-kappa-bungarotoxin (kappa-BTX) specific binding was studied in rat brain at 2, 4, 6 and 12 weeks after ibotenic lesion of the basal forebrain. A unilateral injection of ibotenic acid was made into the NBM. The BTXs specific binding in coronal sections of rat brain was detected by computer-assisted autoradiographic image analysis. There was a significant decrease (32%) of alpha-BTX binding at 2 weeks in sections taken from frontal cortex at 1.5-2.0 mm anterior to Bregma (layers 1 and 2) in the lesioned hemisphere as compared to the contralateral intact hemisphere. The nucleus basalis lesion resulted in a loss of projections from the NBM to the frontal cortex. Our results suggest that BTX binding sites are located on the presynaptic projection from the NBM.

NEUROGENESIS OF THE MAGNOCELLULAR BASAL NUCLEI IN RHESUS MONKEYS. I. Rackauskas*[1], P. Rakic[2], and J.H. Kordower[1], (SPON: M.Fiandaca)[1]Dept. of Anatomy and Cell Biology, Univ. Illinois Sch. Med., Chicago Ill. 60302.[2] Sect. of Neuroanatomy, Yale Sch. Med. New Haven Ct. 06510

The neurogenesis of the magnocellular basal forebrain in Rhesus monkeys was assessed via tritiated thymidine autoradiography. Thirteen neonatal Rhesus monkeys whose mothers were injected with tritiated thymidine between E27 and E50 of gestation served as subjects. Coronal sections from the level of the subcallosal gyrus through the lateral geniculate nucleus were obtained from the archival collection of Rakic (e.g. Rakic, P., *J. Comp. Neurol.* **147:** 523, 1973). These sections were previously processed for autoradiography via standard procedures and counterstained with toluidine blue. The analysis was encompassed the magnocellular neurons within vertical limb of the diagonal band (Ch2) and the four subsectors of the nucleus basalis (Ch4). No autoradiographically labeled neurons were observed at E27 and all neurogenesis within the magnocellular basal nuclei in Rhesus monkeys was complete by E48 Within this developmental window, a bimodal pattern of neurogenesis was observed within the magnocellular basal forebrain. An initial "burst" of neurogenesis was observed at E30 throughout the basal forebrain's rostrocaudal extent. A short quiescent period soon followed that merged into a second wave a neurogenesis which occurred along a general caudal to rostral gradient. The anterior basal forebrain (Ch2, Ch4am, and Ch4al) was generated simultaneously between E36-E45 with peak neurogenesis observed between E40-E43. The intermediate division of Ch4 began its second wave of development at about the same time, but both peaked (E36-E40) and completed its neurogenesis earlier (E43). The posterior division of Ch4 was generated first, generally completing its cell genesis between E33-E36. No neurogenic gradient was observed in a radial direction. These data demonstrate that the magnocellular basal forebrain is generated early in gestation in Rhesus monkeys. This places these neurons in a strategic position to influence their target cells, most of which are generated within the cerebral cortex at a later time. RESPONSES OF CENTRAL CHOLINERGIC NEURONS TO AXONAL INJURY IN NONHUMAN PRIMATES. V.E. Koliatsos, W.C. Mobley*, H.J.W. Nauta and D.L. Price. Neuropathology Lab., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

In monkeys (*Macaca mulatta* and *fascicularis*), we examined responses of basal forebrain cholinergic neurons to axotomy. Under general anesthesia and sterile conditions, animals had complete unilateral transections of the fornix *ca.* 5 mm caudal to commissural decussation. Two weeks later, monkeys were deeply anesthetized with pentobarbital and perfused with paraformaldehyde. Transverse sections through the septum were processed for immunohistochemistry (i.e., choline acetyltransferase [ChAT] and epitopes of phosphorylated neurofilaments) and Nissl stains. Ipsilateral to the lesion, there was a severe reduction in the number of ChAT-immunoreactive medial septal/diagonal band neurons. In Nissl stains, these cells showed reductions in basophilia and cell size. Some loss of neurons was apparent. These results indicate that primate central cholinergic neurons respond to axonal injury in a way similar to rodent cholinergic neurons [Koliatsos et al., *Brain Res.* 482:205-218, 1989]. More recently, we have begun to analyze the effectiveness of nerve growth factor (mouse) delivered intraventricularly in preventing degeneration and in restoring the properties of these basal forebrain cholinergic neurons.

165.9

EXTENDED SURVIVAL OF MEDIAL SEPTAL CHOLINERGIC NEURONS FOLLOWING LESION OF THE FIMBRIA-FORNIX. M.D. Applegate, V.E. Koliatsos and D.L. Price. Neuropathology Lab., The Johns Hopkins Univ. Sch. Med., Baltimore, MD 21205.

It is established that transection of fimbria-fornix axons reduces the number of choline acetyltransferase (ChAT)-immunoreactive neurons in the medial septum. However, it is not clear whether reductions in immunoreactive cells are due to decreased levels of cholinergic markers in viable cells or to degeneration of septal neurons. To clarify this issue, neurons in medial septum were retrogradely labeled by injecting Fluoro-Gold bilaterally into dorsal hippocampus in rats. Seven days later, the dorsal fornix, the rostral tip of the dorsal hippocampus, and the antero-dorsal fimbria were aspirated unilaterally. At 1, 7, and 14 days postlesion, rats were perfused, and the septal region was processed for ChAT-Texas Red immunofluorescence. At days 1 and 7, ChAT immunoreactivity was decreased ipsilateral to the lesion, but there was little change in the number of retrogradely labeled neurons. By day 14, ChAT immunoreactivity was virtually absent, and these cells appeared atrophic; however, the number of retrogradely labeled neurons was only moderately decreased. Further studies will be needed to determine how long these atrophic neurons persist following the lesion and whether NGF treatment can induce them to regain normal size and cholinergic properties.

NUCLEUS BASALIS LESIONING IN THE AGED RAT: NEUROCHEMICAL AND BEHAVIORAL CONSEQUENCES. G.W. Arendash[1], G.J. Sengstock[1]*, K.B. Johnson[1]* and E.M. Meyer[2]. Dept. of Biology, Univ. of South Florida, Tampa, FL 33620[1] and Dept. of Pharmacology, Univ. of Florida, Gainesville, FL 32610[2].

A number of researchers have attempted to mimic the degeneration of nucleus basalis (NB) cholinergic neurons in Alzheimer's Disease (AD) by neurotoxically destroying the analogous NB region in young adult rats. Since the loss of these neurons probably doesn't occur until later in the life of AD patients, NB lesioning in aged rats may approximate more closely the impact that a degeneration of NB cholinergic neurons is having in Alzheimer's-diseased patients. Therefore, 20-21 month old Sprague-Dawley rats were given bilateral NB lesions using ibotenic acid and sacrificed 2.5 or 5 months later. Beginning one month after lesions, animals were tested for cognitive abilities in passive avoidance, active avoidance, and/or Lashley III maze tasks. Compared to sham-lesioned controls, lesioned rats were significantly deficient in the retention of passive avoidance behavior, as well as in the acquisition of 2-way active avoidance behavior. However, no deleterious lesion effect was observed in Lashley III spatial maze learning. A substantial cholinergic hypofunction was found in the neocortex of lesioned animals at both sacrifice time points. These results warrant a continued characterization of the aged, NB-lesioned rat as a useful animal model for the cholinergic hypofunction of AD.

TOPOGRAPHY OF PEDUNCULOPONTINE TEGMENTAL NUCLEUS (PPT) INTERCONNECTIONS WITH THE LATERAL GENICULATE NUCLEUS (LGN) AND N. PREPOSITUS HYPOGLOSSI (PH) IN THE CAT. S. Higo, K. Ito, D. Fuchs, D. Rye, B. Wainer, and R. W. McCarley, Laboratory of Neuroscience, Department of Psychiatry, Harvard Medical School/VAMC, Brockton MA 02401.

Cholinergic PPT neurons modulate excitability of many thalamic and brainstem nuclei, and, in REM sleep, PPT neurons transmit eye movement-gated PGO waves to the dorsal LGN (LGNd). However possible sources of eye-movement related input to PPT, such as PH, have not been investigated.

WGA-HRP injections were made in the rostral, middle and caudal PPT zones, and in each case the resulting anterograde labeling confirmed as cholinergic by subsequent retrograde double labeling studies using WGA-HRP and ChAT immunohistochemistry. LGNd showed an ipsilateral dominance of anterograde labeling from PPT, but no clear topographic differentiation; terminal labeling was dense in layers A, A1, and C, and sparse in layers C1-3 and in the medial interlaminar nucleus. LGNd did not project to PPT. Ventral LGN (LGNv) also had ipsilaterally dominant anterograde labeling from PPT but, in contrast, labeling was topographically organized, with caudal PPT projecting to lateral LGNv and rostral PPT to medial LGNv. Anterograde labeling from all zones of PPT was present bilaterally in medial PH. PH projected to all PPT zones, with main sites of origin ipsilaterally in rostral PH and contralaterally in caudal PH.

These data indicate PPT interconnections with the visual/oculomotor system and suggest a possible anatomical substrate for transfer of eye movement-related information from PH to PPT, and thence to LGNd/v.

DO CHOLINERGIC DIAGONAL BAND NEURONS HAVE INHIBITORY AUTORECEPTORS? R. T. Matthews, Dept. of Anatomy, Texas A&M University, College Station, TX 77843.

Cholinergic neurons of the medial septum/diagonal band area have been electrophysiologically characterized in vitro (Griffith & Matthews, Neurosci. Lett. 71:169, 1986). Extracellular recordings from slices of guinea pig forebrain in vitro can distinguish at least a subpopulation of these cholinergic neurons (Matthews, Neurosci. Abs. 14: 923, 1988). The hypothesis was tested that diagonal band of Broca (DBB) cholinergic neurons have inhibitory autoreceptors which distinguish them from non-cholinergic neurons. Spontaneously active or glutamate-driven DBB neurons were recorded with 5-barrel pipettes and the effects of iontophoresed acetylcholine (ACh), carbachol (CARB) or vehicle were measured. ACh at iontophoretic currents of 2-40 nA (0.2 M, pH 4.0) had variable effects on the firing rates of both presumed cholinergic and non-cholinergic neurons with 17 & 29% excited, 33 & 41% inhibited and 50 & 30% unchanged, respectively. CARB at 1-20 nA (0.2 M, pH 4.0) had variable effects on firing rates of presumed cholinergic neurons with 40% increased, 40% decreased and 20% unchanged, while most non-cholinergic neurons (90%) were potently excited. These data do not support the hypothesis that all cholinergic neurons have an inhibitory autoreceptor which can be used to rapidly distinguish neuron types within the DBB in vitro. ACTIONS OF MUSCARINIC AGONISTS ON CELL TYPES WITHIN GUINEA PIG BASAL FOREBRAIN NUCLEI IN VITRO. W.H.Griffith and J.A.Sim*. Department of Med. Pharmacol. and Toxicol. College of Med. Texas A&M University, College Station, TX 77843.

The present study examined muscarinic agonist-induced changes in membrane potential, input resistance and after-hyperpolarization (AHP) in fast AHP (FAHP), slow AHP (SAHP) and burst-firing neurons in the vertical and horizontal limbs of the nucleus of the diagonal band of Broca (nDBB). Intracellular and single-electrode voltage-clamp techniques were used in an in vitro brain slice preparation from guinea pig. Bath applied muscarine (10uM) or bethanechol (10-30uM) induced small and variable effects across all cell types, which included membrane depolarization (1-5mV) in 49% (n=16), hyperpolarization (1-8mV) in 33% (n=11) or no change in 18% (n=6). Changes in input resistance were not correlated with the direction of membrane response. In only 4 of 16 cells was a membrane depolarization associated with a marked increase in cell firing. The most consistent action of these agonists was a reduction in a long duration AHP (2-3s) that occurred in some cells following a train of action potentials (n=7). Inhibition of the AHP-current was also recorded under voltage-clamp in the presence of TTX. Two other AHP's (<50ms and 200-700ms duration) that followed single spikes in FAHP and SAHP cells, respectively, were not effected (n=5). These results suggest that muscarinic agonists have subtle, yet specific actions on some nDBB neurons. (Supported NS22456, AG07805)

MUSCARINIC RESPONSES IN CULTURED CORTICOCALLOSAL NEURONS MEDIATED BY M_2 RECEPTORS. K. A. Jones and R. W. Baughman, Dept Neurobiology, Harvard Med School, Boston MA 02115.

In the neocortex acetylcholine (ACh), acting through muscarinic receptors, enhances excitability by at least 2 different mechanisms: 1) a slowly activating membrane depolarization, and 2) inhibition of an after hyperpolarization (AHP) that follows repetitive firing. We are interested in the cellular events that are responsible for muscarinic receptor channel coupling in pyramidal neurons, and as a first step have developed a culture preparation to study the receptor pharmacology of cholinergic excitation. Fluorescent latex microspheres were injected into the 1° and 2° visual cortex of 4-5 day-old rat pups. The contralateral visual cortex was enzymatically dissociated 18-24 h later and grown in culture for at least 3 weeks before recording. Whole-cell recordings of membrane potentials or currents were obtained from labelled corticocallosal cells with patch electrodes. In some cases 500 nM TTX, or 5 mM kynurenic acid plus 4 μM bicuculline was added to the medium to inhibit synaptic activity. Following a train of 20-50 spikes most cells displayed a slow component (lasting 3-6 sec) of the AHP, although a few cells produced an after depolarizing potential (ADP) with a similar time course. Currents underlying these potentials were voltage insensitive and reversed near E_K. Brief (1-2 sec) applications of 10-100 μM ACh either abolished the slow AHP or enhanced the ADP, and produced a slow (~1 min) depolarization that resulted from a voltage dependent inward current and a decreased conductance. Atropine (100 nM) abolished these effects. In contrast, the M_1 receptor blocker pirenzepine at low doses (100-500 nM) had either no effect or only slightly blocked the action of ACh. At higher doses (2-10 μM) the block was nearly complete. These results are consistent with the idea that the slow depolarization, slow AHP, and ADP are mediated by M_2 muscarinic receptors. (AFAR and EY03502)

CHOLINERGIC MARKERS IN HUMAN PUTAMEN. A QUANTITATIVE AUTORADIOGRAPHIC STUDY. **C.A. Levesque*, H.R. Brashear, and G.F. Wooten (SPON: C.A. Leslie). Dept. of Neurology, University of Virginia Health Sciences Center, Charlottesville, VA. 22908.**

Investigations of cholinergic neuronal markers in adult human postmortem tissue may add to our understanding of the pathophysiology of neurodegenerative diseases, particularly Alzheimer's Disease; but careful re-validation of assay conditions developed in other species is necessary. We have characterized the binding of [^{3}H]hemicholinium-3 ([^{3}H]HC-3), a presynaptic cholinergic marker by virtue of its selective binding to the sodium-dependent, high affinity, choline uptake site, and [^{3}H]quinuclidinylbenzilate ([^{3}H]QNB), a muscarinic cholinergic receptor ligand and postsynaptic marker. Blocks of human putamen were chosen for these studies because of their high concentration of cholinergic neurons. [^{3}H]QNB association and saturation data revealed that optimal binding occurred with incubation in 1.0 nM [^{3}H]QNB at 24° C for 30 minutes (K_d 0.3 nM and B_{max} 378 fmol/mg tissue wet weight). Higher temperatures and longer incubation times caused tissue degradation. [^{3}H]HC-3 binding was done at 24° C with 20 minute incubation at a concentration of 10 nM (K_d 1-5 nM range determined by an Eadie-Hofstee plot). This concentration provided full saturation with maximal separation between total and nonspecific binding. With both [^{3}H]QNB and [^{3}H]HC-3 binding the human putamen appears homogeneous without evidence of a patch and matrix pattern.

M1 AND M2 MUSCARINIC RECEPTORS MEDIATE ACETYLCHOLINE (ACh) MODULATION OF AUDITORY CORTICAL NEURONS. R. Metherate, J.H. Ashe and N.M. Weinberger Center for the Neurobiology of Learning and Memory, Dept. Psychobiology, University of California, Irvine 92717; Dept. Psychology, University of California, Riverside, CA 92521.

ACh modifies the activity of auditory cortical neurons via muscarinic receptors (Synapse 2:54, 1988). We now report the involvement of M1 and M2 muscarinic receptor subtypes in the effects of ACh.

In barbiturate-anesthetized guinea pigs, iontophoretically-applied ACh modified intensity functions (IFs) at best frequency by facilitating or depressing tone-evoked activity. Facilitation of evoked responses could decrease IF thresholds by over 10 dB. To examine mechanisms underlying multiple ACh effects, we applied the muscarinic receptor antagonists pirenzepine and gallamine to 14 cells whose single tone responses were modified by ACh. ACh-induced facilitation of spontaneous or evoked activity was antagonized more effectively by pirenzepine than by gallamine. However, gallamine effectively blocked ACh depression of activity.

As pirenzepine and gallamine are selective antagonists at M1 and M2 muscarinic receptors, respectively, these initial findings suggest that the modulatory effects of ACh in auditory cortex involve both receptor subtypes.

Supported by ONR (NMW) and NINCDS (RM).

CHOLINE ACETYLTRANSFERASE CONTAINING PROJECTIONS FROM THE FELINE PONTOMESENCEPHALON. Konrad Talbot, Nancy J. Woolf, Jean B. Harrison, Jennifer S. Buchwald, and Larry L. Butcher. Laboratory of Chemical Neuroanatomy, Depts. of Psychology and Physiology, University of California, Los Angeles, CA 90024.

Immunoreactivity for choline acetyltransferase (ChAT) was analyzed in the brains of unoperated cats and in cats in which stereotaxic lesions were made in the pedunculopontine and laterodorsal tegmental nuclei. Moderate to dense ChAT-immunoreactive fiber plexes were observed throughout the forebrain, especially in the lateral geniculate, lateroposterior, intralaminar and midline thalamic nuclei. Relatively discrete lateral and medial cholinergic pathways were traced. Lateral ChAT pathways largely originated in the pedunculopontine nucleus, ascended through the central tegmental fields, compact part of the substantia nigra, zona incerta, intralaminar, reticular and lateroposterior nuclei of the thalamus, and provided afferents to the diencephalon and basal forebrain. Medial cholinergic pathways were traced from ChAT-containing cells in the laterodorsal tegmental nucleus to the periaqueductal gray, dorsal raphe, ventral tegmental area, midline thalamus, hypothalamus, and lateral septal nucleus. ChAT-stained fibers throughout the diencephalon and basal forebrain were markedly reduced in cats with lesions in the pontomesencephalon, whereas ChAT fibers in the cerebral cortex were not altered. CHOLINERGIC INNERVATION OF MONKEY THALAMUS: A CHOLINE ACETYLTRANSFERASE (ChAT)-IMMUNOCYTOCHEMICAL STUDY. C.A. Kitt, A.I. Levey, D.P. Friedman, M.L. Voytko, H.L. Fedor* and D.L. Price. Neuropathology Lab., The Johns Hopkins Univ. Sch. Med., Baltimore, MD 21205.

Distributions of cholinergic elements in monkey thalamus were investigated using immunocytochemistry and a monoclonal ChAT antibody. Two rhesus monkeys were anesthetized, perfused transcardially with 2or3% paraformaldehyde, and tissues sectioned in coronal or sagittal planes. The density of ChAT-immunoreactive processes varied across and within thalamic nuclei. ChAT-positive fibers were conspicuous in the dorsolateral anteroventral nucleus, parvocellular portion of mediodorsal nucleus (lateral region), and the reticular nucleus. Intralaminar nuclei also showed high levels of ChAT-positive fibers. Low levels of ChAT-immunoreactive elements were seen in midline nuclei. A patchy distribution of ChAT-immunoreactive processes was seen in anteromedial and lateral dorsal nuclei as well as within the ventral tier. Medial habenular and anterodorsal nuclei received sparse cholinergic inputs. All layers of the lateral geniculate nucleus contained ChAT fibers with a higher density in layers 1, 5, and 6. Dorsolateral and ventral aspects of the pulvinar complex contain dense levels of ChAT fibers. These results are compared to distributions of muscarinic and nicotinic cholinergic receptors and to patterns of acetylcholinesterase staining in thalamus.

REDUCTION OF [3H]HEMICHOLINIUM BINDING AND IN VIVO ACETYLCHOLINE RELEASE IN RAT STRIATUM BY CORTICAL DEAFFERENTATION: RESTORATION STUDIES WITH CHOLINE AND OXIRACETAM. G. Forloni, D. Amoroso*, N. Angeretti*, A.J.G. Ruiz* and S. Consolo* Dept.Cholinergic Neuropharmacology , "Mario Negri" Institute, 20157 Milan, Italy.

Frontal deafferentation of the rat striatum reduces the tone of striatal cholinergic neurons. This has been established by the measurement of several cholinergic parameters including in vivo acetylcholine (ACh) release by the microdialysis technique and [3H]hemicholinium-3 ([3H]HCh-3) binding to sodium-dependent high-affinity choline uptake (SDHACU) sites by biochemical and autoradiographic techniques. After two weeks, the lesion resulted in a 30-40 % reduction of ACh release and of [3H]HCh-3 binding. Acute i.p. injections of oxiracetam (OXI), 100 mg/kg i.p., induced time-dependent recovery of ACh output from the striata of decorticated rats. Starting 30 min after drug injection, ACh release was already significantly higher in the OXI-treated group than in the saline-treated group and the rate of ACh release continued to rise gradually, with complete recovery by 80 min after drug injection. The full effect lasted at least 100 min longer. A similar effect but with a different time-course was observed with choline chloride (100 mg/kg, i.p.).OXI also normalized SDHACU activity of decorticated rats 2 h after its administration but had no effect in sham-operated rats. The repletion is most likely associated with enhanced ACh formation. These results indicate that the striatum of decorticated rats could constitute a useful model for studying means to restore the deficit in cholinergic neurotransmission. A CHOLINERGIC COMPONENT OF 4-BETA-PHORBOL 12,13-DIBUTYRATE INDUCED DEPOLARIZATION IN THE RAT SUPERIOR CERVICAL GANGLION. C.G. Acosta and J.H.Ashe, Dept. of Psychology, University of California, Riverside, CA 92521.

The sucrose-gap technique was used to record the effect of phorbol esters on the ganglionic potential of the rat superior cervical ganglion. Exposure of ganglia to 4-beta-phorbol 12,13-dibutyrate (ß-PDBu) resulted in ganglionic depolarization (DP) that could be repeatedly elicited by subsequent exposures. Phorbol esters that are ineffective activators of protein kinase C did not produce a ganglionic DP. The amplitude of the ß-PDBu-induced DP was concentration dependent over the range of 0.25 to 2.50nmol. ß-PDBu-induced DP was significantly reduced, but not eliminated, when elicited in the presence of quinuclinidyl benzilate (80 to 150nM), and was increased in amplitude and/or duration when elicited in the presence of eserine (1.5mM).

Transection of the preganglionic nerve, 12 to 14 days before the ganglion was isolated for recording, significantly reduced the amplitude of the ß-PDBu-induced DP relative to contralateral surgical control or non-surgical control ganglia. Depolarizations produced by methacholine (0.6µmol) were not significantly reduced in comparison to responses obtained from intact ganglia.

These results indicate that ß-PDBu-induced ganglionic DP consists of more than one component. The effect of ß-PDBu may involve presynaptic terminals with a subsequent release of acetylcholine, and possibly other neurotransmitters, as well as postsynaptic mechanisms.

MONOAMINES AND BEHAVIOR I

UK-14304 IMPROVES DELAYED RESPONSE PERFORMANCE IN AGED MONKEYS: FURTHER EVIDENCE FOR THE ROLE OF α-2 ADRENERGIC RECEPTORS IN MEMORY ENHANCEMENT. A.F.T. Arnsten and P.S. Goldman-Rakic. Section of Neuroanatomy, Yale Medical School, New Haven, CT 06510.

The α-2 adrenergic agonists clonidine, B-HT920 and guanfacine (GFC) have all been shown to improve the delayed response performance of aged monkeys, and their ability to improve memory has been related to their affinity for the proposed Ri α-2 receptor subtype (J. Neurosci. 8: 4287, 1988). Low doses of the Ri-selective agonist GFC can improve memory without sedative or hypotensive side effects, and a single dose of GFC can have very longlasting, beneficial effects on memory, suggestive of actions through a second messenger system (ibid). In the present study, another α-2 agonist, UK-14304 (UK), which has been shown to enhance adenylate cyclase activity in rodent neocortex (JPET 237:725, 1986), was tested ior effects on memory, blood pressure and sedation in 6 aged monkeys. As with GFC, low doses of UK were able to improve memory without hypotensive or sedative side effects, producing an average of 18.3% improvement with optimal dosage. Longlasting beneficial effects could also be seen after low dose UK administration.The beneficial effects of UK were blocked bythe α-2 antagonist, idazoxan, indicating drug actions at α-2 adrenergic receptors. The separation between UK doses that improved memory (0.000001-0.001 mg/kg) and those that produced hypotension and sedation (0.01-0.05 mg/kg) was not as great as for GFC, consistent with GFC's greater selectivity for the Ri site.

166.2

INDUCTION OF ANXIETY-LIKE BEHAVIORS IN RATS BY OPIATE AND ALPHA-2 ADRENERGIC BLOCK. H. Hsieh*, S. Hendricks, D. Yells*, and B. Graber. Dept. Psychiatry, Creighton Univ. and Dept. Psychology, Univ. of Neb., Omaha, NE 68182.

Naloxone, and opiate receptor blocker and Yohimbine, an alpha-2 noradrenergic receptor blocker, have been shown to induce anxiety and/or panic states in human subjects. Further, these two drugs apparently act synergistically with respect to anxiety induction. The purpose of the present research was to establish an animal model for these effects by determining the behavioral responsiveness of rats to these drugs in several paradigms known to be sensitive to anxiolytic and anxiety inducing manipulations. These behaviors included general activity, open field, and conflict behavior. Rats were tested in these paradigms after administration of varying doses of Yohimbine and Naloxone given separately and in combination. Behavioral effects of the two drugs given separately were in some instances parallel and in other instances, and at specific doses, in opposite directions. When given together these drugs had synergistic effects on some behavior measures. In addition to the behaviors measured it was observed that rats would on occasion suddenly become agitated and difficult to handle following drug treatments. These reactions could possibly be construed as panic. Our findings indicate that rats treated with these drugs may represent a useful model for studying some aspects of the neurochemical substrates of panic and anxiety.

166.3

Alpha-2 Noradrenergic Antagonist (Idazoxan) Decreases Progestin Receptors in the Ventromedial Hypothalamic Nucleus and in the Arcuate Nucleus-Median Eminence. P. A. Vincent and H. H. Feder. Institute of Animal Behavior, Rutgers Univ. Newark, NJ 07102.

Steroid-dependent lordosis behavior in ovariectomized (OVX) guinea pigs is attenuated by alpha-1 and/or alpha-2 noradrenergic (NE) receptor antagonists. Correlated with the decrease in lordosis after alpha-1 NE receptor blockade by prazosin is a decrease in "cytosol" progestin receptors in the ventromedial hypothalamic nucleus (VMN). We examined whether alpha-2 NE receptor blockade with idazoxan (IDA) affects progestin receptors differently than alpha-1 receptor blockade. Ovx female guinea pigs were treated with estradiol benzoate (10ug) at hr 0 and IDA (5 mg/kg; sc) or saline vehicle (VEH) at hr 40 (one hr before assay). A decrease in "cytosol" progestin receptors was found in the arcuate nucleus-median eminence (VEH; 221.9 $\pm$ 17.3 vs. IDA; 161.6 $\pm$ 16.2 fmole/mg protein; $p < 0.05$) and in the VMN (VEH; 40.1 $\pm$ 9.3 vs IDA; 19.3 $\pm$ 3.6 fmole/mg protein; $p = 0.05$). Thus, blockade of either alpha-1 or alpha-2 NE receptor subtype is sufficient to inhibit lordosis and decrease "cytosol" progestin receptors in the VMN. In contrast, blockade of alpha-2 receptor but not of alpha-1 receptor, decreases "cytosol" progestin receptors in the arcuate nucleus-median eminence.

166.4

ANTAGONISM OF DOPAMINE D-2, BUT NOT D-1/D-2, MEDIATED STEREOTYPY BY THE ALPHA-1 ADRENERGIC ANTAGONIST, PRAZOSIN. L.T. Meltzer, T.G. Heffner and J.N. Wiley*. Department of Pharmacology, Parke-Davis Pharmaceutical Research Division, Warner-Lambert Co., Ann Arbor, MI 48105.

Due to the structural similarity of dopamine (DA) and noradrenaline (NA), single compounds can interact with receptors for both systems. We have observed that compounds may have DA agonist as well as NA alpha-1 antagonist actions. To determine the behavioral consequences of this combined activity, we assessed the ability of the NA alpha-1 antagonist, prazosin, to modify the stereotyped behavior in rats produced by either the selective DA D-2 agonist, quinpirole, or the combination of quinpirole plus the selective DA D-1 agonist, SKF 38393.

Prazosin (1, 3 & 10 mg/kg IP) produced a dose-related inhibition of the stereotyped sniffing and licking induced by quinpirole (0.3 & 3.0 mg/kg SC). In contrast, prazosin (10 mg/kg IP) did not antagonize the stereotypy produced by the combination of quinpirole (0.3-3 mg/kg SC) plus SKF 38393 (10 mg/kg SC). These data indicate that compounds that have both DA agonist as well as alpha-1 antagonist actions, may appear selective for the DA autoreceptor.

166.5

CHANGES IN BRAIN MONOAMINES COINCIDENT WITH DEPRESSED BEHAVIOR IN RATS. S. Caldecott-Hazard, K. Moradzadeh*, B. Nguyen*, K. Tachiki*. LBES, UCLA, and Dept. Psychiatry, VAMC, Sepulveda, CA. 91343.

We previously found that a rat model of depressed behavior, withdrawal from chronic amphetamine (AmpWD), produced changes in brain glucose utilization in the dorsal medial prefrontal cortex (DMFC) and habenula (HAB) as compared to controls. In order to further understand the role of these brain areas in depression, levels of dopamine (DA), norepinephrine (NE), serotonin (5HT) and metabolites were assayed during AmpWD. For comparison with previous reports, levels were also assayed in the caudate nucleus (CD). Rats were implanted (s.c.) with osmotic mini pumps containing either amphetamine, 15mg/kg/day, or saline. After 7 days, the pumps were removed and the rats sacrificed 24 hours later. Brains were frozen and brain areas isolated by punch biopsy. Tissue was homogenized, centrifuged, and the supernatant was analysed using a High Performance Liquid Chromatograph. Similar to prior reports (Ellison 1983), DA was decreased and HVA was increased in the CD of AmpWD rats. Also, DA, NE, 5HT, DOPAC, and 5HIAA were decreased in the DMFC of AmpWD rats. Small changes occurred in the HAB, but these data need to be verified. Changes in transmitter levels in DMFC may be indicative of their decreased synthesis and release. Decreased transmitter release may relate to decreased glucose utilization in the DMFC during depression.

166.6

CORRELATION OF NEUROTRANSMITTER RELEASE WITH SEXUAL ACTIVITY IN MALE RATS. E.T. Pleim*, J.A. Matochik, S. Chiang*, J. Mazzone*, R.J. Barfield and S.B. Auerbach. Dept. of Biol. Sci., Rutgers Univ., New Brunswick, NJ, 08903.

In vivo microdialysis of brain tissue allows more direct testing of hypotheses that implicate neurotransmitters in the control of various classes of behavior. The hypothesis that "rewarding" behaviors are accompanied by increases in dopamine release in the nucleus accumbens (N. Acc.) has been supported by studies of ingestive behavior, self administration of drugs, and brain stimulation. We have attempted to extend the DA reward hypothesis to male sexual behavior, using the method of microdialysis of N. Acc. in rats.

Sexually experienced adult Long-Evans male rats were stereotaxically implanted with guide tubes aimed at the posterior nucleus accumbens. On the morning of a test day, a concentric -type microdialysis probe was lowered to the N. Acc. and dialysate samples were collected at 30 minute intervals. Samples were analyzed for DA, DOPAC, HVA, and 5HIAA using an ESA HPLC-EC. After a stable baseline was established, a sexually receptive female was introduced to the test animal's enclosure and measures of male sexual behavior were recorded. After behavioral testing, DA peaks in the dialysate were confirmed using systemic apomorphine administration.

With these methods we are able to detect extracellular DA and metabolites in the N. Acc. of male rats during active copulatory behavior. No significant increase in DA release in the N. Acc. could be detected during or following copulatory activity. Therefore, the current experiment does not provide evidence that male sexual activity is an example of a rewarding behavior that is mediated by an increase in N. Acc. dopamine release.

166.7

TIME SERIES ANALYSIS IN BRAIN DIALYSIS EXPERIMENTS: DETECTING CYCLICITY AND LEAD–LAG RELATIONSHIPS IN BEHAVIOR AND NEUROCHEMISTRY. C.P. Lawler, P.M. Martin, L.L. Devaud, Q.D. Walker*, R.B. Mailman, and M.H. Lewis. Biological Sciences Research Center, Departments of Psychiatry and Pharmacology, Toxicology and Neurobiology Curricula, University of North Carolina, Chapel Hill, NC 27599–7250.

Intracerebral microdialysis allows investigators to examine concurrently, in a single animal, changes in behavioral and neurochemical parameters over time. Time series analysis is a powerful statistical method that can be applied to behavioral/neurochemical temporal patterns and interactions. Time series analysis conducted in the frequency domain (spectral analysis) allows for the detection of periodicities. Parallel neurochemical and behavioral time series can thus be compared to determine the presence of shared cycles, and the lead–lag relationships between the two series. To illustrate the utility of this approach, dialysis probes were implanted in rat caudate nucleus and nucleus accumbens. Dopamine and its acidic metabolites were measured by HPLC–EC every 15 min over a 24 hr period. Concurrent with neurochemical measurements, feeding, drinking, and other behaviors were recorded using a computer–supported observational method. A number of interesting preliminary findings emerged. In addition to a circadian rhythm, ultradian rhythms of 2.5 and 0.75 hr were found for water licking, and for DOPAC in the nucleus accumbens. These periodicities showed considerable shared variance and were phase locked; such coupling was less clear in the caudate nucleus. 166.8

MONOAMINE AND METABOLITE CONTENT IN THE RAT BRAIN FOLLOWING DEFEAT. W. W. Woodmansee, M. Fleshner*, and S. F. Maier. Psych. Dept, Univ. Colo., Boulder, CO 80309.

Inescapable electric shock produces a subsequent shuttlebox escape learning deficit. Monoaminergic alterations, particularly forebrain & hypothalamic norepinephrine (NE) depletion, have been proposed to be responsible for this deficit. Defeat in territorial aggression produces similar behavioral effects (unpublished data). We thus examined the effects of exposure to established aggressive colonies on brain monoamines & metabolites in male rats. Intruders were presented to different colonies for 5 successive 10 minute intervals. Behavioral measurements were obtained for each colony-intruder interaction. Defeated rats were sacrificed immediately following the 5th exposure to a territorially defensive colony & HPLC coupled with serial oxidative-reductive electrochemical detection was employed to measure NE, DA, & 5HT & their respective metabolites (free DHPG, free MHPG, DOPAC, HVA & 5HIAA) in anterior cortex, hypothalamus, & hippocampus. All comparisons were made to two control groups: home cage controls & defeat controls (placed in colonies but separated from residents by a clear Plexiglas barrier). Defeat was not found to alter NE, DA (except hippocampal DA) or 5HT levels in any brain region examined. However, both the defeat & defeat control rats showed significant activation of all three transmitter systems in each brain area. Moreover, NE & DA metabolite levels in cortex & hippocampus were generally more elevated in defeated rats than in defeat controls. Higher MHPG levels in the hippocampus were associated with a rapid & continuous display of submissive postures. 5HIAA was equally elevated in both groups in each brain region examined. These results indicate that NE depletion is thus not a necessary condition for display of the shuttlebox escape learning deficit. Supported by NSF grant BNS 8809527.

166.9

ISOLATION AND in vivo ACTIVITY OF NEUROTRANSMITTERS IN THE AMYGDALA. K.H. Tachiki*, A. Kling, R. Lloyd, K. Moradzadeh,* E. Mirzabeigi* F. Houriani*, O. Ricci* (SPON: R. Ritzmann). Psychiatry Service, UCLA/VA Med. Center, Sepulveda, CA 91343.

The amygdaloid nuclei plays a critical role in the regulation of emotion & social relationships. This diversity of function is paralleled by the presence of steroid receptors and terminals of virtually all neurotransmitters and neuromodulators. We report here on the effects of social isolation in Cebus monkeys on the in vivo levels of various neurotransmitters and/or their metabolites in the amygdala, employing the technique of perfusion by micro-dialysis. There was a marked difference in the basal levels of the biogenic amines and their metabolites from animal to animal (5-HIAA: 15.5 VS 44.0; DOPAC: 2.12 vs 5.06). Following six days of isolation, there was a marked increase in perfusate levels of NE (200%) and 5-HIAA (140%). The DA metabolites, DOPAC & HVA, showed no significant changes with isolation. Effects of isolation appear associated with increased release of NE and serotonin in the amygdala. Research was supported by the Joan B. Kroc Foundation and the Veterans Administration.

166.10

BULBECTOMY ATTENUATES COCAINE-INDUCED INCREASES IN LOCOMOTOR ACTIVITY IN MICE. M.G. Hadfield[1], A.R. Lumia[2*], N.A. Darmani[3*], B.R. Martin[3*], D.I. Schiff[4*] and J.H. Porter[1*]. Depts. [1]Path., [3]Pharmacol. and [4]Psychol., Med. Coll VA/VA Commonwealth Univ., Richmond, VA 23298 and Dept. [2]Psychol., Skidmore College, Saratoga Springs, NY 12866.

Several studies have shown that cocaine increases motor activity in mice. The present study was designed to see if bulbectomy alters this increase.

Adult male albino ICR mice (N=32) were either bulbectomized or sham-operated. One week later, they received 20mg/kg cocaine or saline, i.p. (N=8/group). 20 min. later, they were placed in an Omnitech Digiscan Activity Monitor. This measured horizontal activity (including distance and movements), vertical activity, stereotypies and revolutions.

Cocaine significantly increased every motor measurement except vertical activity. On the other hand, bulbectomy attenuated the cocaine response by decreasing horizontal movements, the distance traveled, the number of stereotypic episodes and the movement time. Rest time was increased. In virtually every instance, bulbectomy normalized the values so they were returned to control levels.

These data indicate that an intact olfactory system is required for cocaine to produce its clinical effects. Severance of monoamine pathways related to prominent limbic structures may be responsible for this effect. Further investigations using this model may yield important information concering cocaine's mechanisms of action. (Supported by NIDA grant #DA-02396)

166.11

HYPERSENSITIVITY TO REWARD-RELATED STIMULI AND TO INTRA-ACCUMBENS D-AMPHETAMINE FOLLOWING SOCIAL DEPRIVATION IN RATS. G.H.Jones*, C.A.Marsden[+] and T.W.Robbins. (SPON: Brain Research Association). Department of Experimental. Psychology, University of Cambridge, Cambridge, CB2 3EB, U.K. and [+] Department of Physiology and Pharmacology, Medical School, Queen's Medical Centre, Nottingham, NG7 2UH, U.K.

Socially deprived rats develop many neurochemical and behavioural alterations consistent with dysfunction of the nucleus accumbens (NACC). For example, isolates show impairments in the acquisition of schedule-induced polydipsia and exhibit a greater anticipatory response to stimuli predictive of reward, both of which are dependent on normal regulation of mesolimbic dopamine.

To investigate the effects of social-isolation on the processing of reward-related stimuli, we used a two lever (CR and no-CR), new response procedure with conditioned reinforcement (CR). This procedure involves the pairing of a neutral stimulus (a light/noise compound) with sucrose reward, which thereby gains reinforcing properties itself (CR). Levers were absent during pairing. Lever pressing for CR (with sucrose no longer available) was tested, both undrugged and following a series of intra-accumbens infusions of d-amphetamine (AMPH; 3,10,20 ug). As previously, (Taylor and Robbins, *Psychopharm.* 84 1984), these infusions selectively enhanced responding on the CR lever, however, this increase was significantly greater in isolated rats when compared to socially-reared controls. Isolates also showed an apparent shift in the dose-response curve to the locomotor stimulating effects of intra-accumbens AMPH (3,10 ug). These results are further evidence for the involvement of dopamine-dependent mechanisms of the NACC in the processing of reward-related stimuli and also suggests disruption of the neural substrates underlying these processes following social isolation.

166.12

TESTS OF THE MONOAMINE HYPOTHESIS OF BEHAVIORAL DEPRESSION BY PRECURSOR LOADING. A.L. Beggs, W.B. Daigle*, S. Hotard*, and T. Hebert*. Dept. of Psychology, Univ. of Southwestern La., Lafayette, LA 70504-3131.

The monoamine hypothesis of depression is supported by reports that the symptoms of depression, such as decreased behavioral output, are alleviated by monoamine agonists while monoamine antagonists bring about, or exacerbate the symptoms. Three experiments were conducted. In the first, learned helplessness (LH) was established and rats were given ip injections of L-phenylalanine, L-tyrosine, L-tryptophan, or saline followed by active avoidance training and passive avoidance trials. Active avoidance data showed that L-phenylalanine rats required fewer trials to criterion. Passive avoidance data indicated L-tryptophan facilititates passive responding, while L-phenylalanine and L-tyrosine impair it. In another experiment, L-trytophan treated rats had longer latencies than other groups. An analysis of trials to criterion revealed differences between all groups with L-tyrosine requiring more trials, followed by L-phenylalanine, saline, then L-tryptophan. The results of these experiments generally support the contention that catecholamine precursor loading produces behavioral activation while serotonergic precursor loading is inhibitory to behavioral output.

166.13

BEHAVIORAL EFFECTS OF ACUTE TRYPTOPHAN DEPLETION IN PSYCHIATRIC PATIENTS AND HEALTHY SUBJECTS. P.L. Delgado, D.S. Charney, L.H. Price, W.K. Goodman, G.K. Aghajanian, G.R. Heninger, Dept. of Psychiatry, Yale University School of Medicine, New Haven, CT 06508

Brain serotonin (5-HT) content is dependent on plasma levels of the essential amino acid, tryptophan (TRP). This study investigates the behavioral effects of acute TRP depletion (ATD) in humans. METHOD: 12 obsessive compulsive (OCD), 43 depressed, and 7 schizophrenic patients (DSM-III-R), and 8 healthy subjects received a 24-hr., 160 mg/day, low-TRP diet followed the next morning by a 16-amino acid drink, in a double-blind, placebo-controlled (ATD and control testing), crossover fashion. On one test the diet and drink were supplemented with L-TRP (control) and on the other test neither the diet nor drink were supplemented (ATD). Behavioral ratings (Hamilton Depression Scale (HDRS), Yale-Brown OCD scale, or Brief Psychiatric Rating Scale) and plasma (for TRP levels) were obtained prior to, during and after testing. RESULTS: Total and free TRP decreased 80 to 90% 5 hrs. after the TRP-free drink (TFD). Drug-free, symptomatic OCD and medicated schizophrenic patients and healthy subjects were behaviorally unchanged by ATD or control testing. OCD symptoms in 5 antidepressant-remitted OCD patients were unchanged by ATD but the 3 OCD patients with previous depression became more depressed (mean 95% increase in HDRS score; 19 ± 7 pre-diet, 34 ± 4 7 hours after the TRP-free drink). 60% of 22 symptomatic, drug-free depressed patients were unchanged during ATD, but became clinically less depressed (40% decrease in HDRS) the day after the ATD while 68% of 21 antidepressant-remitted depressed patients relapsed (300% HDRS increase) during the ATD, with return to remitted state the day after. Implications: Preliminary results indicate that ATD may reverse antidepressant but not anti-OCD or antipsychotic responses in psychiatric patients suggesting that the antidepressant effects may be more dependent on 5HT availability. Behavioral effects of ATD appear restricted to depressed patients.

166.14

THE EFFECTS OF INBRED LEARNED HELPLESSNESS ON BEHAVIOR AND MONOAMINERGIC UPTAKE IN RATS. L.J. Molino, J.M. Caruso,* F.A. Henn and P.M. Whitaker-Azmitia. Dept. of Psychiatry, SUNY Stony Brook, Stony Brook, NY, 11794.

The learned helplessness model established by Maier and Seligman(1975) parallels the human condition of depression Henn et al(unpublished data) have been able to inbreed learned helpless(LH) behavior into rats. We investigated the uptake mechanisms of these inbred LH rats via a developmental model. Rats were trained with random inescapable shock for 40 min. at 0.8mA. 24 hrs. after training, animals were tested for avoidance/escape behavior. Failure to terminate shock within 20 sec. was recorded as a failure. Animals scoring high were grouped into the LH group. Animals scoring low were grouped into the non-learned helpless(NLH) group. Full-sib pairing occurred within each group. On postnatal day 15(D15) and D30, animals were tested for spontaneous alternation and vacillatory behavior. Rats were then sacrificed at D1, D15 and D30 after behavioral testing. Whole brains were removed and homogenized for Mazindol and Paroxetine assay. LH animals displayed significant vacillatory behavior and deficits in spontaneous alternation than NLH animals and controls. Biochemical analysis revealed no changes in uptake for D1. At D15 and D30 there are changes in uptake in LH and NLH animals in comparison to controls. We believe that the behavioral deficits displayed may be related to the changes in the uptake mechanisms.

166.15

STRAIN DIFFERENCES IN CENTRAL AMINES INDUCED BY ACUTE AND CHRONIC STRESSORS. N. Shanks, S. Zalcman*, and H. Anisman. Dept. Psychology, Carleton University, Ottawa, Ontario K1S 5B6, Canada.

A single session of uncontrollable footshock engendered region-specific alterations in the utilization and concentrations of brain norepinephrine (NE), dopamine (DA) and serotonin (5-HT). The magnitude of the amine alterations varied appreciably across six strains of mice, such that reduction of a particular amine was readily engendered in some strains, while in others the stressor was without effect. With a chronic footshock regimen applied over 14 consecutive days, utilization and synthesis was altered such that the amine reductions ordinarily associated with acute shock were absent, and in some cases amine levels exceeded control values. This adaptation, which stemmed from a compensatory increase of synthesis and/or moderation of utilization, was more readily apparent in some brain regions and also varied with the strain of mouse. These data may be relevant to strain-specific behavioral differences associated with acute and chronic stressor regimens.

166.16

CHRONIC STRESS INCREASES BOTH TYROSINE HYDROXYLASE ACTIVITY AND EVOKED NOREPINEPHRINE RELEASE IN LOCUS COERULEUS NEURONS. L.K. Nisenbaum, S.L. Castro, M.J. Zigmond, and E.D. Abercrombie *Department of Behavioral Neuroscience and Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260*

Norepinephrine (NE) turnover is elevated in the central nervous system during stress. Changes in tyrosine hydroxylase (TH) activity have been implicated in this response. We have examined the effects of stress on TH activity in locus coeruleus (LC) neurons and NE release from a terminal projection of the LC, the hippocampus. Three days of chronic cold (4°C) exposure resulted in a 99% increase in TH activity in the LC. After 7 days of cold, TH activity declined to 50% above control in the LC, and was no longer elevated after 14 days of cold exposure. In contrast, enzyme activity in the hippocampus remained unchanged after 3 days of cold exposure. However, 7 days after the onset of cold, TH activity in this structure increased 25% above control and remained elevated for the duration of the experiment (21 days). In order to test the functional significance of the increased TH activity resulting from chronic stress, NE efflux in the hippocampus was measured in awake, behaving rats using in vivo microdialysis. In rats cold-stressed for 21 days, baseline NE efflux did not differ from that of control animals. In contrast, these rats responded to another, acute stressor (30 minutes of intermittent tailshock) with a greater elevation of NE (89% above baseline, n=4) than did rats that had not been stressed previously (41% above baseline, n=5 $p<.01$). Thus, elevated TH activity resulting from chronic stress may contribute to an enhanced noradrenergic response to a subsequent, novel stressor. Correlations Between Peripheral Calcium Parameters and CSF Amine Metabolite Levels in Depression and Mania. C.L. Bowden and M.A. Javors*. Depts. of Psychiatry and Pharmacology, Univ. Texas Health Science Center, San Antonio, TX 78284-7792.

Recent research has suggested that alterations in central serotonergic neuronal function may be associated with behavioral abnormalities like depression, suicide, and alcoholism. The purpose of this study was to examine the relationship of peripheral calcium parameters such as plasma [Ca++], platelet total Ca++ content, platelet membrane CaMgATPase activity, and platelet dense tubular system Ca++ uptake to CSF levels of 5HIAA, HVA, and MHPG, the respective major CNS metabolites of the biogenic amines serotonin, dopamine, and norepinephrine. Positive correlations were found between plasma [Ca++] and CSF 5HIAA in unipolar, bipolar depressed and manic patients. For unipolar patients (n=22), plasma [Ca++] was positively correlated with 5HIAA and HVA, platelet CaMgATPase with MHPG, and platelet Ca++ with 5HIAA. In bipolar depressed patients (n=11), plasma [Ca++] was positively correlated with 5HIAA and MHPG, platelet Ca++ with 5HIAA, and platelet CaMgATPase was inversely correlated with 5HIAA and HVA. In the manic subjects (n=12), plasma [Ca++] correlated positively with 5HIAA and HVA. The most consistent and strong relationships in these three subject groups were observed between Ca++ and 5HIAA. This Ca++-5HIAA relationship warrants further investigation of central Ca++ mechanisms and serotonergic function as potentially important mechanisms in affective disorder, especially bipolar disorder.

166.18

EFFECT OF OLFACTORY BULBECTOMY ON 'OPEN FIELD' BEHAVIOR AND BRAIN CATECHOLAMINES IN RATS. L.J. Petterborg*, P.K. Rudeen and D.B. Bylund. Depts of Anatomy & Pharmacology, Univ Missouri Med Sch, Columbia, MO 65212. (SPON: R.C. McClure)

Rats were either olfactory bulbectomized (OBX) or subjected to sham surgery (SHM). At two wks postop ambulatory and defecation scores were recorded for all rats during 3 min 'open field' behavior tests. At 3 and 6 wks following surgery alpha-2 adrenergic receptor (A2AR) densities were determined in the hypothalamus (MBH), amygdala (AMY) and cortex (CTX). At 4 wks after surgery, CA levels and turnover rates (K) were estimated by HPLC/EC. The OBX group (n=24) had signif-icantly greater mean ambulatory (77 vs 63) and defecation (1.50 vs 0.75) scores than did the SHM group (n=24). A2AR binding was significantly increased in the MBH at 3 wks (7.9 vs 7.0) and AMY at 6 wks (13.1 vs 12.0) in OBX rats. MBH NE (165 vs 207) and EPI (26 vs 38) were lower while DA (144 vs 69) was higher in OBX rats. AMY EPI K (231 vs 16) was increased while DA levels (407 vs 711) and K (-84 vs. 694) were significantly reduced in the OBX animals. These results suggest that alterations in behavior following olfactory bulbectomy may be related to site specific changes in CA metabolism and receptor dynamics.

166.19

PSEUDOCONDITIONING OF AVERSIVE-INDUCED YAWNING FREQUENCY DECREASE IN HY RATS. J. Valencia*, A. Moyaho* and B. Holmgren* (SPON: E. Soto) Dept. de Ciencias Fisiológicas, Instituto de Ciencias, Univ. Autónoma de Puebla, Apartado Postal 406, Puebla, MEXICO.

Conditioning of some inborn motor patterns, such as yawning, scratching and anal licking has been attempted in the past with dubious effects (Konorski, 1967). In a Sprague Dawley subline of high yawning rats (HY), we have tested whether it is possible to condition the yawn-reducing effect of aversive stimulation to the noise of a loud buzzer (80 dB, 5 sec) preceding by 4.5 painful electrical stimulation of the rats' paws (60 Hz, 0.5 sec, 0.6-1.3 mA).

In three initial 30' sessions (one daily) to habituate the animals (n=8) to the experimental setup (transparent glass cages with electrifiable floor), a significant increase in yawning was observed during the 3rd session. Application of the CS-UCS immediately after each yawn during 5 sessions determined a significant reduction (65%) in yawning (Wilcoxon-Wilcox paired test, p 0.02). This decrease did not persist during obervation sessions without any stimulation; on the contrary yawning increased. Retraining during 4 additional sessions showed persistence of the fall in yawning during the 2 initial extinction sessions (CS alone, at fixed intervals). From the 3rd to the 6th extinction sessions yawning increased significantly (p 0.02).

Since in a control experiment (n=7 rats), with randomized application of the buzzer noise/footshock pairing, quite similar results were obtained, we suggest our results are due to sensitization or pseudocondi tioning rather than to true conditioned reduction in yawning.

167.1

CHRONIC DIAZEPAM ADMINISTRATION PRODUCES LONG-LASTING REDUCTIONS IN CORTICAL 5-HT RELEASE
M J Neal, P K Hitchcott* & S E File, Division of Pharmacology, UMDS, St Thomas's and Guy's Hospitals, University of London, London, SE1 7EH, UK

Buspirone, a 5-HT_{1a} agonist, is ineffective as an anxiolytic in patients previously treated with benzodiazepines. We therefore examined whether chronic diazepam treatment produced changes in 5-HT release that could account for this. K-evoked (20mM) release of ^{3}H-5-HT from superfused frontal cortical slices from male hooded Lister rats was measured 30 min after i.p. injection of vehicle or diazepam (4mg/Kg), as appropriate. Compared with controls, there were no significant effects of acute diazepam, but after chronic (5 or 21 days) treatment release was significantly reduced. In rats tested 30h or 7 days after the last of 21 diazepam injections the release was still significantly decreased.

167.2

DIAZEPAM WITHDRAWAL: DECREASED SEIZURE THREASHOLD AND INCREASED ANXIETY REVERSED BY FG 7142 AND FLUMAZENIL.
P.K.Hitchcott*, S.E.File, H.J.Little† and D.J.Nutt†.
(SPON: R.D. Brown)
Psychopharm. Res. Unit., UMDS, Div. Pharmacol., Guy's Hospital, London SE1 9RT & Dept. Pharmacol., University of Bristol, U.K.

Diazepam was administered (4mg/kg/day for 20 days; i.p.) and 36h after the last dose male hooded Lister rats were tested in the social interaction (SI) test of anxiety and then bicuculline infused into the tail vein until the point of tonic convulsion (forepaw extension). Compared with controls (vehicle injections 20 days) the diazepam withdrawal group had decreased SI and had significantly lower seizure threasholds. FG 7142 (5 & 20mg/kg) injected 30 min before testing or flumazenil (4mg/kg; 20min) significantly reversed the decreases in SI and seizure threashold seen during withdrawal. The results from the SI test confirm previous reports with chlordiazepoxide withdrawal (Baldwin & File Brain.Res.Bull.(1987) 20:603-6) and suggest that similar changes in the GABA/benzodiazepine receptor complex also underlie the reduction in seizure threashold to bicuculline.

167.3

LONG-TERM ANXIOLYTIC EFFECTS OF CHRONIC ETHANOL OR CHLORDIAZEPOXIDE TREATMENT IN THE RAT.
S.E. File, P.S. Mabbutt† and P.K. Hitchcott†
(SPON: J.J. Stewart)
Psychopharm. Res. Unit, UMDS, Div. Pharmacol., Guy's Hospital, London SE1 9RT, U.K.

Male hooded Lister rats were used in 2 separate experiments. In experiment 1, rats were fed a liquid diet containing 10% ethanol or control for 5 weeks (mean ethanol intake 12g/kg/day). The liquid diet was then withdrawn and replaced by standard rat feed. In experiment 2, rats were chronically treated with chlordiazepoxide (CDP: 10mg/kg/day i.p.) or control for 4 weeks. Six weeks after withdrawal from ethanol or CDP the rats were tested undrugged in the elevated plus-maze test of anxiety.

Rats that had received chronic ethanol treatment spent a significantly ($p<0.05$) greater percentage of time on the open arms of the plus-maze compared with their controls. The rats previously treated with CDP also spent a significantly ($p<0.05$) greater percentage of time on the open arms of the plus-maze compared with their controls. There were no diferences in total arm entries. Thus there is evidence for anxiolytic effects lasting for considerable time after a period of chronic ethanol or CDP treatment.

167.4

BENZODIAZEPINE RECEPTOR ANTAGONIST ZK 93426, ETHANOL AND SOCIAL BEHAVIOR IN SQUIRREL MONKEYS.
E.M. Weerts* and K.A. Miczek. Dept. Psychology, Tufts University, Medford, MA 02155.

Blockade of the benzodiazepine-GABA-chloride ionophore receptor complex may modify some behavioral and physiological effects of ethanol (ETOH). In dyadic confrontations, animals are prompted to exhibit high levels of agonistic behavior, and this heightened level of activity may be relevant to ETOH effects. Socially housed dominant male squirrel monkeys confronted each other in a specially designed test locale with full visual, olfactory, and auditory access. Dominant males treated with 0.1, 0.3 g/kg ETOH increased aggressive threats and vocalizations, while 1.0, 1.5 g/kg ETOH reduced these behaviors. ZK 93426 (3.0 mg/kg) effectively antagonized the enhancing effects of ETOH, but not the aggression-decreasing effects; the latter effects were actually potentiated by ZK 93426. However, frequency of ETOH-induced staggering was significantly reduced when these animals were pretreated with ZK 93426. ZK 93426 may possess some agonistic properties as is evident by increased duration of sitting. When ZK 93426 was administered with a low dose of ETOH (0.1 g/kg), feeding duration increased 5-fold in the social colony immediately following the dyadic test. In mice tested for sleep-time following ETOH administration, pretreatment with ZK 93426 (10.0 mg/kg) did not fully protect against ETOH's depressant effects, although sleeptime was reduced. These results indicate that under narrow dose and time parameters ZK 93426 does attenuate incoordinating, depressant and aggression-enhancing effects of ETOH, but may also potentiate the aggression-decreasing effects.

167.5

DISCRIMINATION OF THE STIMULUS PROPERTIES OF FLUMAZENIL (Ro 15-1788), A BENZODIAZEPINE ANTAGONIST.
G.A. Rowan and I. Lucki. Department of Psychiatry & Pharmacology, University of Pennsylvania, Philadelphia, PA 19104.

Rats were trained to discriminate the stimulus properties of the benzodiazepine receptor antagonist flumazenil using a conditioned taste aversion procedure. Fluid-restricted rats were injected with flumazenil (33 mg/kg) or saline and then given access to a 0.25% saccharin solution for 30 minutes. When rats (N=15) received a drug trial, saccharin consumption was followed by an injection of LiCl (1.8 mEq/kg i.p.), while on saline trials saccharin consumption was followed by a second saline injection.

Acquisition of the discriminated taste aversion, as measured by the differential effects on saccharin drinking between drug and saline trials, developed after only five pairings of the flumazenil with the LiCl injections. Unconditioned controls (N=9), that received an identical sequence of drug and saline trials, but never received LiCl, did not show differences in saccharin intake. The discrimination was also verified using two-bottle preference measures between saccharin and water.

Flumazenil demonstrated dose-dependent generalization upon varying the training dose. Two other benzodiazepine antagonists of different classes, CGS-8216 and ZK 93426, also demonstrated complete substitution for the flumazenil stimulus. Partial generalization was exhibited with the inverse agonist FG 7142, while PTZ failed to generalize to the flumazenil stimulus. Chlordiazepoxide-dependent rats were also trained to discriminate the flumazenil stimulus using this procedure.

DIAZEPAM, PENTOBARBITAL, METHAQUALONE AND ETHANOL EFFECTS ON SEVERAL BEHAVIORS AND ANTAGONISM BY RO 15-1788.
R. Shukla*, D.J. Mokler and R.H. Rech. Dept. of Pharmacol./Toxicol., Michigan State Univ., East Lansing, MI 48824.

The effects of the benzodiazepine receptor antagonist on a conflict paradigm (condition suppression of drinking, CSD), rotarod performance (RR), motor activity (MA) and body temperature (BT) alone and in combination with diazepam (DZ), pentobarbital sodium (PB), methaqualone (MQ) and ethanol (ET) were studied in rats. DZ, PB, and MQ caused a significant increase in punished responding (shocks) and decrease in unpunished responding (water intake). RO 15-1788 caused a dose-dependent attenuation of the effects of DZ and did not reduce the effect of PB and MQ on either punished or unpunished responding. However, the unpunished responding of PB was significantly potentiated by RO 15-1788. All three agents (DZ, PB and MQ) caused a significant disruption of rotarod performance and motor activity. RO 15-1788 reversed the disruption caused by DZ only; disruption caused by PB and MQ was not modified. DZ, PB, MQ and ET caused a dose-dependent hypothermia. RO 15-1788 significantly blocked the hypothermic effect of DZ and ET, whereas the hypothermia induced by PB and MQ was not altered. It appears that RO 15-1788, being a specific benzodiazepine receptor antagonist, attenuated DZ effects on CSD, RR, MA and BT. ET-induced hypothermia may be reduced by a partial inverse agonistic effect of RO 15-1788. (Supported by grants from the 3M Foundation and a Pradhan Foundation Fellowship [R.S.].)

SEXUALLY DIMORPHIC ASPECTS OF SOCIAL INTERACTION IN ADULT RATS ARE ALTERED BY PRENATAL EXPOSURE TO DIAZEPAM. Renee Primus and Carol K. Kellogg, Dept. of Psychology, University of Rochester, Rochester, N.Y. 14620.

Environment-related social interaction (SI) in the rat was shown to be sexually dimorphic, differentially modulated by diazepam (DZ) as a function of pubertal age, and altered by prenatal exposure to DZ. In male rats, SI was decreased in the unfamiliar environment relative to the familiar environment at 35 and 60 days, whereas in female rats at 60 days, SI was equivalent in the two environments. Acute administration of DZ (0.5 and 1.0 mg/kg) prevented the decrease in SI in the unfamiliar environment in male rats at 60 days only. Prepubertal castration at 19 days completely abolished the differential impact of the two environments on SI and altered the effect of DZ on SI in male rats at 60 days. These effects of prepubertal castration were completely prevented by exposure to testosterone (T), via implanted silastic tubing, over days 30 through 60. Thus, T secretions in male rats influenced the development of environment-related SI and the effects of DZ thereon. Furthermore, induction of precocial puberty in male rats by early chronic exposure to T (days14-35) advanced the development of the anxiolytic action of DZ on SI.

Prenatal exposure to DZ (2.5 mg/kg) during the last week of gestation altered the development of environment-related SI in male and female rats, suggesting that perinatal as well as pubertal influences affect the development of this behavior. Adult male rats prenatally exposed to DZ exhibited an equivalent amount of SI in the two environments, a response similar to SI measured in unmanipulated female rats at 60 days. In contrast, adult female rats prenatally exposed to DZ demonstrated decreased SI in the unfamiliar environment relative to SI in the familiar environment, the typical response measured in unmanipulated adult male rats. Thus, the organization of this sexually dimorphic behavior was altered by prenatal exposure to DZ. Perinatal and pubertal influences appear to interact, perhaps via the BZD-GABA receptor complex, to organize environment-related SI. Sponsored by Grant MH31850.

A RAPID SCREENING METHOD FOR THE ASSESSMENT OF BENZODIAZEPINE RECEPTOR RELATED PHYSICAL DEPENDENCE IN MICE. R.A.Lewis and P.F.VonVoigtlander. The Upjohn Company, Kalamazoo, Michigan 49001.

CF-1 mice were injected subcutaneously with the test compound on a fixed schedule (0800 and 1600 for 3 days, the PM dose = AM dose x 2). If tolerated, a starting dose of 150 mg/kg/day was generally used initially and the dose lowered to 15 and 1.5 mg/kg/day in subsequent assays. Twenty-four hours after the last dose, the mice received an intravenous injection of flumazenil (2.5 mg/kg) and 5 minutes later they were tested for electroshock seizure thresholds by an up-down titration method. Flumazenil precipitated withdrawal was manifested by a lowering of the mA seizure threshold. We have found that compounds with benzodiazepine agonist properties significantly lower these thresholds in a dose related fashion. For example, the following compounds (lowest effective mg/kg/day dose) were active in this regard, chlordiazepoxide (150), diazepam (15), flurazepam (15), alprazolam (15), triazolam (15), midazolam (15), zopiclone (150), Ro 16-6028 (150) and Ro 17-1812 (150). In contrast, zolpidem (150), tracazolate (15) and CL 218872 (15) did not cause physical dependence by this criterion. This rapid and simple screening test may be readily used to predict the physical dependence inducing properties of compounds that act at the benzodiazepine receptor.

INCREASED PERIPHERAL BENZODIAZEPINE BINDING SITES FOLLOWING PORTACAVAL ANASTOMOSIS IN THE RAT. J-F. Giguere[1], E. Hamel[2] and R.F. Butterworth[1], [1]Andre-Viallet Clin. Res. Ctr, Hop. St-Luc (Univ. of Montreal), [2]Montreal Neurological Inst., Montreal, Que., H2X 3J4 CANADA

Recent reports suggest a role for benzodiazepine receptors in the pathogenesis of hepatic encephalopathy. In order to assess this possibility, four weeks after an end-to-side portacaval anastomosis in the rat, central and peripheral-type benzodiazepine receptors were measured using ^{3}H-Ro15-1788 and ^{3}H-PK11195 respectively as specific radioligands. Portacaval anastomosis (PCA) resulted in sustained hyperammonemia, astrocytic alterations and subtle neurological signs of encephalopathy. Affinities and densities of ^{3}H-Ro15-1788 binding sites were unaltered in rats with PCA. On the other hand, ^{3}H-PK11195 binding sites were increased 2 to 3 fold without concomitant changes of binding affinities. Quantitative autoradiographic studies using ^{3}H-PK11195 revealed widespread generalized increases of binding in all brain structures. Increased binding of ^{3}H-PK11195 in these brains probably results from astrocytic abnormalities rather than loss of neuronal structures since activities of neuronal marker enzymes (GAD and CAT) were unchanged following PCA. INCREASED DENSITIES OF PERIPHERAL-TYPE BENZODIAZEPINE RECEPTORS IN AUTOPSIED BRAIN TISSUE FROM ALCOHOLIC CIRRHOTIC PATIENTS WITH HEPATIC ENCEPHALOPATHY. J. Lavoie, G. Pomier Layrargues and R.F. Butterworth, Lab. Neurochem. and Liver Unit, Andre-Viallet Clin. Res. Ctr, Hop. St-Luc (Univ. of Montreal), Montreal, Que. H2X 3J4 CANADA.

It has been proposed that benzodiazepine receptors may be modified in hepatic encephalopathy. In order to evaluate this hypothesis, the integrity of benzodiazepine receptors was evaluated in brain membrane preparations obtained at autopsy from nine alcoholic cirrhotic patients who died in hepatic coma. Histopathological studies revealed the presence of Alzheimer Type II astrocytosis in all cirrhotic brains. Binding to central and peripheral benzodiazepine receptors was evaluated using ^{3}H-Ro15-1788 and ^{3}H-PK11195 respectively. Data from saturation binding assays was analyzed by Scatchard analyses showed no modifications of either affinities (Kd) or densities (Bmax) of central benzodiazepine binding sites. In contrast, densities of ^{3}H-PK11195 binding sites were increased by 64% ($p<0.01$) in frontal cortex and by 31% ($p<0.02$) in caudate nuclei of patients with hepatic encephalopathy. Such changes could play an important role in the pathogenesis of hepatic encephalopathy resulting from chronic liver disease. [Supported by MRC (Canada) and FRSQ (Quebec)]

THE EFFECTS OF ETHANOL SUPERFUSED IN VIVO ON ISOLATED NORADRENERGIC CIRCUITS FROM LOCUS COERULEUS GRAFTS TO CO-GRAFTED BRAIN TISSUE IN OCULO. M.R. Palmer[1] and A-C. Granholm[2]. [1]Dept. of Pharmacology, Univ. of Colorado HSC, Denver, CO, 80262 USA and [2]Dept. of Cell Biology, University of Linköping, S-581 85 Linköping, Sweden

Fetal locus coeruleus (LC) was sequentially grafted with hippocampus CA1 or cortex cerebelli into the anterior eye chambers of adult rats. These brain grafts were allowed to mature and to innervate each other over a period of 4-6 months. Histological, electrophysiological, in vivo voltametric and pharmacological studies indicate that the LC neurons survive and functionally innervate the hippocampal co-grafts. Ethanol, when superfused over the co-grafts in urethane anesthetized animals, caused excitations of hippocampal neuronal activity at doses between 1-30 mM, while applications of 30 mM ethanol and higher depressed the activity of these same neurons. Similar results were observed from cerebellar neurons in LC-cerebellum double grafts except that the cerebellar neurons were more sensitive to the depressant effects of ethanol than were those recorded from hippocampus. The excitations caused by lower ethanol doses in double grafts could be prevented by the co-superfusion of 0.5 - 1.0 μM clonidine with the ethanol. Furthermore, the low-dose excitations were not observed in single grafts of hippocampus in oculo. Our data suggest that the excitations are mediated by changes in the catecholaminergic innervation from the LC grafts. This does not appear to be due to a postsynaptic change in norepinephrine (NE) sensitivity, however, since ethanol did not alter the NE dose-response curves in hippocampal grafts. Thus, the ethanol-induced excitations were probably disinhibitions mediated by an ethanol-induced depression of the inhibitory NE input to target grafts from the LC co-grafts. Indeed, the doses of ethanol which caused excitations in the hippocampal or cerebellar grafts also caused depression of neuronal firing rates in the LC grafts, and the doses of clonidine which prohibited the excitations also inhibited the firing rates in the LC grafts while causing an excitation in the co-grafts. ACUTE AND CHRONIC ETHANOL ALTER INHIBITION OF HIPPOCAMPAL CA3 NEURONS. L.P. Gonzalez, Department of Psychiatry and Behavioral Sciences University of Oklahoma Health Sciences Center, Oklahoma City, OK 73190-3000.

Acute ethanol administration inhibits the spontaneous *in vivo* release of ACh at several sites within the central nervous system. Additional alterations in cholinergic function are observed after chronic ethanol exposure. The study reported here examined ethanol effects on the response of hippocampal CA3 neurons to electrical stimulation of the cholinergic septo-hippocampal projection. Extracellular recordings of hippocampal unit activity were obtained using glass microelectrodes with tip diameters of 1 to 5 microns. Most of these neurons were observed to have firing rates of two to four Hz. Stimulation of the medial septum resulted in a brief increase in single-unit activity, followed by a longer period of reduced activity. Acute ethanol (1.5 g/kg, i.p.) had no effect on the period of increased activity, but it significantly increased the length of the period of inhibition. In rats chronically treated with ethanol, and tested ten hours after withdrawal, ethanol did not alter the period of inhibition. These results show a significant effect of ethanol on the hippocampal response to septal stimulation, and the development of tolerance to this effect with chronic ethanol exposure.

ETHANOL REDUCES THE M-CURRENT IN CA1 HIPPOCAMPAL PYRAMIDAL NEURONS (HPNs) IN VITRO. S.D. Moore*, S.G. Madamba* and G.R. Siggins. (SPON: L. Koda). Research Institute of Scripps Clinic, La Jolla, California 92037

Previous in vivo studies showed that systemic ethanol enhanced HPN responses to iontophoretic acetylcholine (ACh) and somatostatin (SS), with little or no effect on responses to GABA, norepinephrine or 5-HT (Mancillas et al., Science 231:161, 1986). We (Moore et al., Science 239:278, 1988) previously reported that in HPNs SS and ACh in vitro reciprocally regulate the voltage-dependent K^+ current termed the M-current (I_M). Therefore, we tested ethanol superfusion on this current in rat CA1 HPNs in a slice preparation, using single electrode voltage-clamp. At rest, ethanol had little effect on membrane currents. However, at -40 mV holding potentials, ethanol in low concentrations (22 - 44 mM) significantly reduced I_M amplitude in 36 HPNs, by 30 to 42%. Atropine in doses (1 µM) that block muscarinic reduction of I_M did not alter ethanol-induced I_M reduction. Thus, the site of ethanol action is not on ACh release or receptor binding. Neither the anomalous rectifier (Q-current), the A-current, nor the AHP current were reproducibly altered by ethanol. Ethanol 44 mM, but not 22 mM, antagonized I_M augmentation by SS. Ethanol reduction of the M-current may account for the potentiation of ACh responses seen in vivo and provides a mechanism for the excitatory effects of ethanol on some central neurons that possess M-channels. Supported by AA-06420, AA-07456, and MH-44341.

N-METHYL-D-ASPARTATE (NMDA) STIMULATED NEUROTRANSMITTER RELEASE FROM BRAIN SLICES IS INHIBITED BY ETHANOL. R. A. Gonzales and J. J. Woodward. Div. of Pharmacology, Univ. of Texas, Austin, TX 78712.

The effect of ethanol in vitro on the release of [^{3}H]norepinephrine (NE) from rat cortical slices or endogenous dopamine from striatal slices stimulated by NMDA was studied. Cross-chopped (350 µm) slices were prepared from each region and washed for 40 min in oxygenated Krebs-Ringer buffer without magnesium. Cortical slices were loaded with [^{3}H]NE for 30 min followed by 1 hr of additional washing. Tissue was transferred to baskets and transferred (every 1 or 2 min) through a series of vials containing fresh oxygenated buffer with various concentrations of NMDA. NMDA (50 µM-1 mM) stimulated [^{3}H]NE release from cortical slices (up to 5.5% of total [^{3}H] taken up) or DA release from striatal slices (up to 3.1% of total) and this release was completely blocked by 1.2 mM Mg^{2+}. Tetrodotoxin (1.0 µM) attenuated NMDA-stimulated [^{3}H]NE release by >90%. Ethanol significantly reduced 100 µM NMDA-stimulated [^{3}H]NE release from cortical slices in a concentration-dependent manner in a range from 60-200 mM (32-53% inhibition). A similar inhibitory effect (38-70% inhibition) of ethanol (10-200 mM) was observed for 500 µM NMDA-stimulated endogenous DA release from striatal slices. The inhibition of NMDA-stimulated [^{3}H]NE release by 100 mM ethanol was not overcome with increasing concentrations of NMDA up to 1 mM indicating a non-competitive type of inhibition. The effect of 100 mM ethanol could be reversed after a 13 min wash period. Preincubation of the cortical slices with ethanol for 3 min enhanced the attenuating effect of ethanol on NMDA-stimulated [^{3}H]NE release compared to simultaneous addition of NMDA and ethanol. Changes in NMDA receptor function by ethanol may contribute to some of the intoxicating or anesthetic effects of acute ethanol administration. (Supported by NIAAA grants AA07297 and AA08089).

EFFECTS OF CHRONIC ALCOHOL ADMINISTRATION ON VASOPRESSIN- AND OXYTOCIN-CONTAINING NEURONS. JH deSchweinitz* and GP Kozlowski. Department of Physiology, Univiversity of Texas Southwestern Medical Center, Dallas TX, 75235-9040.

Learning and memory is enhanced by vasopressin (VP) and attenuated by oxytocin (OT). Since learning and memory is diminished in alcoholics, we investigated the effects of chronic ethanol (ETOH) administration on these neuropeptides. We previously reported reduced VP neuronal numbers after 5 & 15 da (Soc Neurosci Abstr, 14:196,1988) of ETOH. Here, we extended the treatment period to 30 & 60 da. Animals were administered either: 1. Lab Chow and water ad lib (CCTRL=Chow control), 2. control liquid diet (CTRL) or 3. ethanol liquid diet (ETOH). Male, Long-Evans rats were perfuse-fixed and immunocytochemistry was performed on their serial-sectioned (40 µm) brains using rabbit anti-VP 710 and anti-OT 729. All VP & OT neurons were categorized into major nuclear gps and counted. Means of total numbers of neurons/brain/treatment group for VP (n=5/gp) were: 48 da CCTRL, 3023±180; 30 da CTRL, 2502±214; 30 da ETOH, 1548±87; 60 da CTRL, 2323±125 and 60 da ETOH, 1606±197; whereas, for OT (n=3/gp) means were: 48 da CCTRL, 4754±274; 30 da CTRL, 4044±446 and 30 da ETOH, 4256±231. For VP, significant decreases ($p<.001$) occurred in all nuclear areas except for the anterior commissural nuc. and ant. hypothalamic area (AHA). For OT, there were no significant differences in total neuronal numbers amongst treatment groups but numbers of AHA neurons decreased while those of the paraventricular nucleus increased. Supported by NIAAA AA-06014.

DOES ETHANOL ENHANCE PRE/POSTSYNAPTIC EFFECTS OF BACLOFEN IN VITRO IN RAT HIPPOCAMPAL SLICES? G.D. Frye, L. Taylor*, W.H. Griffith Dept. Medical Pharmacol. & Toxicol., Texas A&M Univ. Col. of Med., College Station, TX 77483

The hypothesis that the CNS actions of ethanol involve changes in GABAergic transmission has recently received support. Ethanol enhances $GABA_A$-gated Cl^- uptake into brain vesicles, an action that is lost after chronic ethanol exposure. Whether acute or chronic ethanol treatment also changes the relative activity of $GABA_B$-mediated events in the CNS was examined in the present studies. The presynaptic effects of the $GABA_B$ agonist, baclofen (BAC), were tested on the CA1 dendritic field excitatory postsynaptic potential (EPSP) in hippocampal slices of rat brain. Bath-applied (-)BAC (1uM) alone reduced the EPSP by 20-30%. However, no further inhibition occurred when (-)BAC was applied with ethanol (10-60mM). Dose-related inhibition of EPSPs by (-)BAC (0.1-10uM) in slices from ethanol-naive or ethanol-dependent rats was not different. During intracellular recording from CA1 cells, the postsynaptic action of BAC was studied using the membrane hyperpolarization (5-10mV) induced by pressure ejection of (±)BAC (100uM). Bath applied ethanol 30mM did not enhance the amplitude of the postsynaptic response to BAC (n = 5). Based on these findings, ethanol does not appear to enhance either pre- or postsynaptic $GABA_B$-mediated inhibition in the hippocampus. (Supported by AA06322, AA00101, NS22456 & AG07805)

URETHANE POTENTIATES THE DEPRESSANT EFFECTS OF ETHANOL ON RAT BRAIN SLICES. W.R. Proctor and T.V. Dunwiddie, Veterans Administration Medical Services and University of Colorado Health Science Center, Denver, CO 80262

Electrophysiological analyses have shown that ethanol application has a generally depressant effect on neuronal activity. Superfusion of *in vitro* hippocampal slices with 80 mM ethanol *increases* the amplitude of the evoked population spike by 15-30 percent during the first 3-6 minutes, followed by a 30-40 percent amplitude decrease. Concurrent intracellular recordings from CA1 pyramidal neurons show minimal changes in a number of measured parameters: 80 mM ethanol usually produced small hyper-polarizations of the resting membrane potential (0.8±0.5 mV, n=18, $p<0.01$) and a small reduction in the calcium-activated potassium conductance (10±3%, n=18, $p<0.01$). However, no significant changes were observed in the input impedance, suprathreshold and subthreshold epsp amplitudes, $GABA_a$ and $GABA_b$ responses or firing thresholds of the sodium spike action potential.

To more closely mimic the *in vivo* recording conditions under which depressions of activity are commonly observed, simultaneous extracellular and intracellular recordings were made from hippocampal slices in 20 mM urethane. The depressant effect on the population spike amplitude was enhanced by 20 to 50 percent compared to the effects of ethanol alone. No additional effects of ethanol on ionic conductances were oberved. Although the mechanisms underlying these interactions are unclear, the present study suggests that at least one common anesthetic may significantly modify the effects of ethanol on neuronal activity. Supported by AA03527 & VA Med. Res. Service.

HIPPOCAMPAL SLICE ELECTROPHYSIOLOGY IS ALTERED BY PRENATAL ALCOHOL EXPOSURE. S.E. Tan*, E.L. Abel, C.S. Zajac, R.M. Yager* & R.F. Berman. Fetal Alcohol Res. Ctr., Depts. Ob/Gyn & Psychology, Wayne State Univ., Detroit, MI 48202.

The effects of prenatal alcohol exposure in rats on hippocampal slice electrophysiology, histology and learning were examined. Pregnant Sprague-Dawley rats consumed ethanol containing liquid diets containing 0%, 17.5% or 35% ethanol derived calories (EDC) from gestation day 8 until parturition. A fourth group was fed standard rat chow as an ad libitum control. Animals prenatally exposed to alcohol had lower birth weights and impaired passive avoidance learning at 17 days of age. At 90 days of age synaptic potentials in area CA1 of the hippocampus were characterized electrophysiologically in in vitro hippocampal slices. Slices from alcohol exposed rats had significantly less paired pulse inhibition compared to 0% EDC and controls. Hippocampal slices from 35% EDC rats also showed less long-term potentiation compared to controls. Litter mates were found to be impaired in radial-arm maze learning. Histological examination of brains from litter mates did not indicate altered number, density or nuclear volumes in area CA1. These data indicate that prenatal ethanol exposure can result in abnormal hippocampal synaptic physiology and suggest that these changes may contribute to the learning impairments observed in rats following such exposure.

Effect of ethanol on neurons in somatosensory (S1) cortex and VPL thalamus in awake, behaving rats. Kosobud, A., Shin, H.-C., and Chapin, J.K. Dept. of Physiology/ Biophysics, Hahnemann University, Philadelphia, PA 19102.

By recording from arrays of chronically implanted microwire electrodes, it is possible to monitor multiple neurons simultaneously in awake, behaving animals. We have used this technique to study the effect of ethanol (EtOH) on higher order sensorimotor processing in the CNS. Microwire electrodes were implanted in S1 cortex and VPL thalamus of 4 adult female rats. In all, recordings from 16 cortical and 3 thalamic cells (4-5 total per rat) were obtained. First, the receptive field properties of each cell were determined. Some cells were selectively sensitive to touch stimuli on the forepaw pads, while others were most responsive to movement of finger or wrist joints. Continuous recordings were obtained from rats locomoting on a timed treadmill (cycle: 10 sec on, 10 sec off) over a 10 minute initial control period, and for 60 minutes following ethanol administration. Drug- and behavior-induced modulation of sensory transmission to these cells was continually tested by repeated mild stimulation (2/sec) through electrodes chronically implanted in the forepaw. In addition, the treadmill included patches of novel surface materials (one very soft, one very irregular). Finally, spike-triggered cross-correlate histograms were constructed to measure direct functional connections between the recorded neurons. A videocamera was used to record motor behavior throughout the experimental session. Overall, EtOH tended to inhibit the sensory responses and activity of cells in both cortex and thalamus, and blunted the distinctions between cell activity under the various conditions. However, selective effects were observed, including a stronger suppression of long versus short latency sensory responses, and a reduction in the inhibitory sensory gating normally observed during movement. Also, the neurons in the forepaw area of S1 cortex showed highly individual activity patterns correlated with movement and sensory stimuli. Responses of individual cells to ethanol were quite variable, with some being virtually unaffected, while neighboring cells showed alterations throughout the recording period. These results are consistent with the notion that EtOH selectively disrupts higher cortical sensorimotor processing. *Supported by PHS grants AA06965, AA00089, and NS26722.*

MULTIPLE WITHDRAWALS FROM CHRONIC ETHANOL TREATMENT "KINDLES" INFERIOR COLLICULAR SEIZURE ACTIVITY. Thomas J. McCown and George R. Breese, University of North Carolina School of Medicine, Chapel Hill, NC 27599-7250

Ballenger and Post proposed that multiple detoxifications from chronic ethanol abuse kindles withdrawal seizures (Brit. J. Psychiat. 133:1,1978). To test this hypothesis in rats, we used a seizure paradigm where seizure activity is electrically elicited from the inferior collicular cortex(IC)(McCown Exp. Neurol. 84:526, 1984). Rats received ethanol liquid diet (ELD) for 5 days and then were withdrawn for 1 day. Seven days after 6 cycles of this regimen, the number of IC stimulations needed to cause seizure generalization was significantly reduced compared to liquid diet controls(8±1 vs. 12±1). After 10 cycles the number of needed IC stimulations was further reduced(6±1), while the same period of continuous ELD reduced the number of IC stimulations to 9±1. Conversely, multiple withdrawals from chronic ELD significantly attenuated amygdala kindling. These findings show that withdrawals from chronic ELD "kindle" the IC, thus increasing ethanol withdrawal seizure sensitivity. (supported by NS-76596)

SEROTONIN III

168.1

MDMA-INDUCED RELEASE OF SEROTONIN (5-HT) AND INHIBITION OF NEURONAL FIRING IN DORSAL RAPHE (DR) BRAIN SLICES: POTENTIATION BY L-TRYPTOPHAN (TRP). J.S. Sprouse, C.W. Bradberry, R.H. Roth and G.K. Aghajanian, Depts. of Psychiatry and Pharmacology, Yale Univ. Sch. of Med., New Haven, CT

Previous work from this laboratory demonstrated that the novel psychedelic MDMA (3,4-methylenedioxymethamphetamine) inhibits the firing of 5-HT-containing DR neurons in midbrain slices. The change in DR neuronal firing is correlated inversely with efflux of 5-HT, suggesting that these inhibitory effects on unit activity could be due to the known 5-HT-releasing properties of MDMA. The present study investigated whether TRP, a 5-HT precursor, affects MDMA-induced changes in DR neuronal firing and 5-HT release.

Extracellular single unit recordings of DR neurons were made in the in vitro rat brain slice; microdialysis probes resting on the slice surface provided a means to estimate 5-HT release from the DR. TRP at 100 μM enhanced both MDMA-induced inhibition of unit activity and 5-HT release; TRP at 500 μM enhanced MDMA-induced 5-HT release and increased basal release to detectable levels. These data suggest that MDMA acts indirectly at the somatodendritic autoreceptor of DR neurons via release of endogenous 5-HT. The question is raised as to what effect TRP may have on the behavioral and neurotoxic actions of MDMA.

168.2

EFFECT OF MDMA ON DOPA ACCUMULATION IN THE STRIATUM AND NUCLEUS ACCUMBENS. J.F. Nash, H.Y. Meltzer and G.A. Gudelsky. Dept. of Psychiatry, Case West. Res. Univ., Cleveland, OH 44106.

The effect of MDMA on the synthesis of DA in the terminals of nigrostriatal and mesolimbic neurons was estimated by measuring the accumulation of DOPA in the striatum and nucleus accumbens 30 min following the administration of the decarboxylase inhibitor, NSD 1015. MDMA produced a dose- and time-dependent increase in DOPA accumulation in the striatum but not in the nucleus accumbens. Although the concentrations of 5-HT and 5-HIAA in both the striatum and nucleus accumbens were reduced 3 hr following an injection of MDMA (20 mg/kg, s.c.), 5-HT and 5-HIAA concentrations were significantly reduced only in the striatum 7 days after administration of MDMA. Pretreatment with the 5-HT_2 antagonist, ketanserin, significantly attenuated the reduction in 5-HT concentration in the striatum 3 hr following MDMA administration and completely blocked 5-HT depletion at 7 days post-administration. Moreover, ketanserin completely blocked MDMA-induced DOPA accumulation in the striatum. These data are supportive of the hypothesis that DA plays a role in MDMA-induced 5-HT depletion.

168.3

MAJOR METABOLITES OF MDA DO NOT MEDIATE ITS TOXIC EFFECT ON SEROTONIN NEURONS IN THE RAT BRAIN. U. D. McCann* and G. A. Ricaurte (SPON: L. Mamounas). Dept. of Behav. Biol., Walter Reed Army Inst. of Res., Bethesda, MD 20307 and Dept. of Neurol., Johns Hopkins Sch. of Med., Baltimore, MD 21224.

3,4-Methylenedioxyamphetamine (MDA) is toxic to serotonin (5HT) neurons in the rat brain (Ricaurte et al., Science 222:986-988, 1985). The major metabolites of MDA in the rat are alpha-methyldopamine (α-MeDA) and 3-O-methyl-α-methyldopamine (3-O-Me-α-MeDA) (Marquardt et al., Biochem. Pharm. 27:1503-1505, 1977). The purpose of this study was to determine if either of these metabolites mediates the toxic effect of MDA on 5HT neurons in the rat brain.

Potential neurotoxic activity of α-MeDA and 3-O-Me-α-MeDA was evaluated in two ways: (1) By systemically administering repeated high doses of their precursors, α-MeDOPA and 3-O-Me-α-MeDOPA, both of which readily cross the blood brain barrier, and (2) By intraventricularly administering various doses of the parent compounds themselves. Two weeks after drug treatment, rats were killed and their brains were analyzed for regional 5HT content. Neither the precursors given systemically nor the parent compounds (α-MeDA and 3-O-Me-α-MeDA) given intraventricularly produced a lasting depletion of serotonin in the rat brain. Furthermore, combined administration of α-MeDOPA and 3-O-Me-α-MeDOPA was also without effect.

These results suggest that neither α-MeDA nor 3-O-Me-α-MeDA, which comprise over 95% of MDA's metabolites (Marquardt et al., 1977), mediate the 5HT toxic effect of MDA, and suggest that either a minor metabolite is involved or that another mechanism is at work.

168.4

REINNERVATION OF CEREBRAL CORTEX BY 5-HT AXONS AFTER DENERVATION BY PSYCHOTROPIC AMPHETAMINE DERIVATIVES. M.E. Molliver, L.A. Mamounas and P. Carr*. *Depts. of Neuroscience and Neurology, The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205*

The drugs 3,4-methylenedioxyamphetamine (MDA) and p-chloroamphetamine (PCA) cause degeneration of 5-HT projections to forebrain, persisting for months. Fine axon terminals in cortex are highly vulnerable, while beaded axons and raphe cell bodies are spared. The long-term cytotoxic effects of these drugs in the rat were analyzed with 5-HT immunocytochemistry. An increased density of 5-HT axons is first detected in frontal cortex, 2 to 4 months after drug treatment. Progressive re-innervation follows a fronto-occipital gradient; partial recovery extends to occipital cortex at 8 months. Straight, longitudinally oriented 5-HT axons extend from rostral to caudal, within layers I and VI, before axon terminals appear in middle cortical layers; this bilaminar pattern of ingrowth simulates perinatal development of 5-HT innervation. The re-innervation reflects sprouting of fine axons, while the beaded axons, which survive drug treatment, do not expand their terminal arborizations. Thus, after drug-induced neurotoxicity, there is regeneration of 5-HT innervation, with sprouting of the axon type that was initially lost. There is no evidence for aberrant re-innervation by beaded axons, yet further studies are needed to determine whether the normal pattern of 5-HT projections is re-established. [Support: DA04431, NS15199].

168.5

MDMA, COCAINE, AND FENFLURAMINE BUT NOT METHAMPHETAMINE PRODUCE NEUROPATHOLOGY OF CULTURED 5-HT NEURONS. E.C. Azmitia, X.P. Hou, P.M. Whitaker-Azmitia, S.A. Hochberg, and R.M. Murphy. Dept. Biology, Chemistry, New York Univ., New York, NY and Dept. Psychiatry, SUNY-Stony Brook, NY.

A variety of drugs of abuse have similar actions on 5-HT neurons -- inhibit ^{3}H-paroxetine binding, inhibit uptake of ^{3}H-5HT and promote release of ^{3}H-5HT. MDMA, cocaine and fenfluramine share these properties while methamphetamine does not. These four drugs were studied for direct effects on fetal serotonergic neurons in cultures. 14 dg rat fetuses were dissected and the raphe area dissociated mechanically. The cells were plated on 96-well plates coated with polylysine. Cells were incubated 24 hours for morphology and three to five days for uptake studies. Drugs were tested from 10^{-3}M to 10^{-10}M applied once, and cultured cells tested for ^{3}H-5HT uptake or after staining with an anti-5HT antibody. MDMA and cocaine produce similar changes in morphology (decrease in the density of 5-HT neurons, decreased fiber length) and MDMA, cocaine, and fenfluramine cause a decrease in uptake development after a single application. Multiple applications of these three drugs significantly potentiated the inhibitory properties. Methamphetamine, at concentrations up to 10^{-4}M, produce no inhibition of 5-HT neurons in culture. Our results indicate fenfluramine > S-MDMA = cocaine > R-MDMA > methamphetamine in neuropathology to 5-HT neurons. Research supported by NIDA 271-87-8144.

THE EFFECTS OF DRUGS OF ABUSE AND SELECTED SEROTONIN AGONISTS ON THE HIGH-AFFINITY SEROTONIN TRANSPORTER; DISPLACEMENT OF [^{3}H]-PAROXETINE. J.C. Poblete, P.M. Whitaker-Azmitia, and E.C. Azmitia. (SPON: J. Martin) Dept. Biology, New York University, Washington Square, New York, NY 10003.

Recently, paroxetine has been shown to be a potent inhibitor of the high affinity 5HT uptake carrier. Using ^{3}H-paroxetine, competitive binding assays were performed to assess the possible interactions of drugs of abuse and selected 5HT receptor agonists. ^{3}H-paroxetine was used at 0.2nM on rat brain membrane preparation, and the incubation time was one hour at room temperature. The drugs of abuse tested were S- and R-MDMA, S-methamphetamine, fenfluramine and cocaine; all of which have been shown to interact with the serotonergic system. The 5HT receptor agonists tested were ipsapirone for the $5HT_{1a}$, TFMPP for the $5HT_{1b}$, and DOI for the $5HT_2$. In addition to these drugs, we also examined the displacement of ^{3}H-paroxetine by fluoxetine, reserpine, Ca^{++} and 5HT. All of the drugs of abuse tested showed displacement of ^{3}H-paroxetine. The rank potency order was fluoxetine (10^{-8}M) > fenfluramine = cocaine = S-MDMA (10^{-6}M) > R-MDMA (10^{-5}M) > S-methamphetamine (10^{-4}M). Interestingly, the specific 5HT receptor ligands tested were also found to displace ^{3}H-paroxetine. The rank potency order of these agonists was fluoxetine (10^{-8}M) > 5HT (10^{-6}M) > TFMPP (high 10^{-6}M) > DOI (10^{-5}M) ipsapirone (10^{-4}M). Reserpine and Ca^{++} do not affect ^{3}H-paroxetine binding. A number of drugs below the concentration producing displacement potentiated ^{3}H-paroxetine binding. (NIDA 271-87-8144)

SEROTONIN NEURONS MAY BE A MAJOR TARGET FOR THE ACTION OF COCAINE: EVIDENCE FROM IN VITRO AND TISSUE CULTURE STUDIES. G.DeGeorge, S.A.Hochberg, R.Murphy, and E.C.Azmitia. Departments of Chem. and Biology, New York University, NY, NY, 10003

It is known that the drug of abuse cocaine exerts its neurochemical effects on dopamine neurons, causing both uptake blockade and release of DA. We have found that cocaine also inhibits the specific high affinity uptake of serotonin in rat brain synaptosomes. Synaptosomes were preincubated with cocaine (1mM-1pM) for 0-20 min, then incubated for 5 min with 50nM ^{3}H-5HT, resulting in a 50% inhibition at 1uM, with maximal at 100uM. This inhibition increased with longer preincubation times. This effect is similiar to that of MDMA on the 5-HT system. Cocaine also promoted the release of 5-HT in preloaded synaptosomes, exhibiting another neurochemical effect of MDMA. Morphometric analysis of cocaine in culture revealed significant neuropathology, with decreases in neuronal density, neurite length, and somal area. Studies in our lab also show cocaine effectively blocks paroxetine binding to the 5-HT transporter at 1uM, Thus it appears that 5-HT neurons are a primary target of cocaine. PSYCHOTROPIC AMPHETAMINES CAUSE A PREFERENTIAL ACUTE RELEASE OF NON-VESICULAR 5-HT. Xi Gu and E.C. Azmitia (SPON: J.F. Hyde) Dept. Biology, New York University, Washington Square East, New York, NY 10003.

Transmitter release can be either vesicular (Ca^{++}-dependent) or non-vesicular (Ca^{++}-independent). It has been previously reported that the MDMA-induced release of ^{3}H-5HT is calcium independent (Nichols et al, 1982; Schmidt, 1987). We have developed a release assay to study the differential effects of fluoxetine on K^+ and MDMA. In addition, we have looked at the dose response of cocaine, MDMA, and fenfluramine on 5-HT release. The release assay used was to preload the synaptosomes with ^{3}H-5HT (5 x 10^{-7}M) at 37°C for 20 min., incubate it with the drugs at 37°C for 10 min., and treat the washed synaptosomes with alcohol which extracted the unreleased ^{3}H-5HT for scintillation counting. Our results provided evidence for two pools of 5-HT for release: an amphetamine induced (non-vesicular and was inhibited by fluoxetine 10^{-7}M) and a K^+(50mM)-induced. In studies of a series of tissue concentration, we noted that fluoxetine can increase the amount of ^{3}H-5HT release in both control and K^+-stimulated systems. This is probably due to its inhibition of reuptake of the released ^{3}H-5HT. In contrast, the release with MDMA (10^{-5}M) was markedly inhibited by fluoxetine by as much as 70%, and this may be due to competitive binding effect of MDMA and fluoxetine for the same 5-HT transporter. Cocaine (10^{-6}M) and fenfluramine (10^{-6}M) were found to be compatible in release potential as MDMA (10^{-5}M). Research supported by NIDA 271-87-8144.

d-METHAMPHETAMINE AND OTHER SUBSTITUTED AMPHETAMINES PRODUCE A SIMILAR PATTERN OF SEROTONERGIC AXON DEGENERATION. Karen J. Axt and Mark E. Molliver. Dept. of Neuroscience, The Johns Hopkins University School of Medicine, Baltimore, MD 21205

It has previously been demonstrated that methylenedioxyamphetamine (MDA), methylenedioxymethamphetamine (MDMA), p-chloroamphetamine (PCA), and fenfluramine (FEN) cause selective ablation of a distinct class of serotonergic (5-HT) axon terminals in the rat brain; fine axons, characterized by small pleomorphic varicosities, are ablated, whereas beaded axons, with large spherical varicosities, are spared. In the present immunocytochemical study, the morphologic pattern of neurotoxicity was examined following administration of d-methamphetamine (d-MA) at doses previously demonstrated to produce neurochemical deficits. Two weeks after various dose regimens of d-MA (including 50 mg/kg b.i.d. x 4 days or 100 mg/kg x 1), selective loss of 5-HT axons was observed throughout the forebrain. Specifically, regions which in control rats are densely innervated by fine axons (e.g., parietal cortex, CA1 of hippocampus, striatum) were relatively devoid of 5-HT-immunoreactive fibers in d-MA-treated rats. Conversely, clusters of beaded fibers (e.g., along the borders of the granule cell layer in the dentate gyrus, layer 3 of lateral entorhinal cortex, and in the glomerular layer of olfactory bulb) exhibited normal 5-HT immunoreactivity. The *acute* effects of 100 mg/kg d-MA were also assessed. Four hours after d-MA, fine fibers were undetected and beaded fibers were intensely stained, suggesting that, like the other substituted amphetamines, d-MA acutely depletes 5-HT from fine axons. Lastly, d-MA was shown to be more neurotoxic than racemic MA. Administration of up to 100 mg/kg (x 4 days) of dl-MA resulted in no long-term change in 5-HT-immunoreactivity. In conclusion, although much larger doses of d-MA are required, this drug produces a pattern of 5-HT axon ablation similar to that reported after PCA, MDA, MDMA and FEN. FINE STRUCTURAL EFFECTS OF AMPHETAMINE AND ITS ANALOGS ON CULTURED NEUROBLASTOMA-GLIOMA CELLS (NG108-15). J. E. Johnson Jr., E. B. De Souza and A. D. Weissman. Neurobiology Laboratory, Neuroscience Branch, NIDA Addiction Research Center, Baltimore, MD 21224.

Amphetamine and several of its analogs, most notably 3,4-methylenedioxyamphetamine (MDA), and 3,4-methylenedioxymethamphetamine (MDMA), have been shown to produce a neurotoxic effect on brain serotonin neurons *in vivo*. To date, very few studies are available describing the effects of these drugs at the fine structural level. Therefore, in the present study, the serotonin-containing neuroblastoma cell line NG108-15 was exposed to 10^{-9} to 10^{-3} M amphetamine, methamphetamine, MDA, MDMA, MDE, and fenfluramine for 3-7 days in culture. Cells were processed according to Johnson and Weissman, 1988 (Brain Research Bulletin, 20, 39-47). By light microscopy, all of the above compounds produced decreases in the number of viable cells at 10^{-3} M, but had little effect on viability or cell morphology at lower doses. However, electron microscopy revealed cell degeneration and ultrastructural changes at pharmacologically relevant drug levels (10^{-6} M). Thus, the present study suggests a neurotoxic effect of the amphetamine class of drugs which goes beyond simple loss of cell monoamine content.

168.11

EFFECTS OF HIGH-DOSE FENFLURAMINE TREATMENT ON STRUCTURAL INTEGRITY OF RAT BRAIN 5HT NEURONS: ASSESSMENT USING QUANTITATIVE AUTORADIOGRAPHY OF ^{3}H-PAROXETINE-LABELED 5HT UPTAKE SITES. N.M. Appel, Wm.M. Mitchell*, J.F. Contrera and E.B. De Souza. NIDA/ARC, Baltimore, MD 21224 and FDA, Rockville, MD 20857.

High-dose fenfluramine treatment in rats causes region-specific decreases in density of serotonin (5HT)-like immunostained axons in brain, appearance of 5HT-like immunostained fibers with morphology characteristic of degenerating axons and long-lasting decreases in brain 5HT, 5-HIAA and 5HT uptake sites. In this study, we used quantitative autoradiography of ^{3}H-paroxetine-labeled 5HT uptake sites, an index of structural integrity of 5HT neurons, to asses regional effects of high-dose fenfluramine treatment on rat brain 5HT neurons. Subacute d,l-fenfluramine HCl treatment (24 mg/kg, s.c., b.i.d., 4 days) in rats significantly decreased the densities of 5HT uptake sites throughout brain at 18 h after cessation of drug treatment. The regional pattern of reduced ^{3}H-paroxetine binding in brain paralleled decreased 5HT-like immunostaining noted following an identical fenfluramine treatment regimen. Specifically, cerebral cortex, striatum, hippocampus, thalamus, and medial hypothalamus were most affected by this treatment; lateral hypothalamus, septum and amygdala were affected to a lesser extent. Preliminary studies suggest that catecholamine uptake sites, assessed by ^{3}H-mazindol autoradiography, were unaffected by this drug treatment. These data suggest that subacute, high-dose fenfluramine treatment causes selective degeneration of 5HT axons in rat brain. Since pharmacokinetic studies show that this dosing regimen exposes rat brain to drug concentrations greater than 600 times those resulting from the therapeutic oral dose, caution must be exercised in extrapolating these data to humans.

168.12

d-FENFLURAMINE PRODUCES LONG-TERM EFFECTS ON CENTRAL SEROTONIN NEURONS IN NONHUMAN PRIMATES. G.A. Ricaurte, M.E. Molliver, J.M. Witkin*, D.C. Molliver, M.A. Wilson, J.L. Katz*. Depts. of Neurol. and Neurosci., Johns Hopkins Univ. Sch. of Med. and NIDA Addiction Research Center, Baltimore, MD 21224.

d-Fenfluramine is prescribed clinically for the treatment of obesity. Recent studies with 3,4-methylenedioxymethamphetamine (MDMA), a congener of *d*-fenfluramine, have renewed concern that fenfluramine may be neurotoxic in humans. As little information is presently available on the neurotoxic potential of *d*-fenfluramine in primates, the present studies assessed the long-term effects of *d*-fenfluramine on serotonin (5HT)-containing neurons in the monkey CNS.

In the first experiment, *d*-fenfluramine was given to 4 monkeys (Saimiri sciureus) subcutaneously at a dose of 5 mg/kg twice daily for 4 days, with 4 control monkeys receiving only saline. Two weeks later, the animals were sacrificed and brains were analyzed neurochemically and histologically. *d*-Fenfluramine produced an 80-90% depletion of 5HT and 5HIAA in all brain regions examined. The depletion was associated with a profound reduction in the density of 5HT-immunoreactive axons in the cortex, and with the presence of markedly swollen axons in more proximal subcortical areas. In a second experiment, monkeys (N=3) received a similar regimen of *d*-fenfluramine at a dose of 1.25 mg/kg, a dose that more closely approximates that used clinically. Regional brain 5HT concentrations in these animals were decreased by 25-35%.

These results show that *d*-fenfluramine produces lasting effects on 5HT neurons in the primate CNS at doses approaching those prescribed to humans. Potential neurotoxicity of *d*-fenfluramine in humans needs to be investigated. [Supported by USPHS Grants DA05707 and DA04431].

SEROTONIN INFLUENCES BARREL FORMATION IN DEVELOPING SOMATOSENSORY CORTEX OF THE RAT. M.E.Blue and M.E. Molliver, Department of Neuroscience, The Johns Hopkins University School of Medicine and The Kennedy Institute, Baltimore, MD 21205

Using serotonin (5-HT) immunocytochemistry, we have previously shown that in early development, 5-HT axons densely innervate sensory areas in cerebral cortex of the rat (D'Amato et al.). Dense patches of 5-HT axons are especially prominent in a part of the somatosensory cortex (SI) containing the cortical representation of the whisker pads, the posteromedial barrel subfield (PMBSF). The present study examines the developmental role of serotonin in barrel formation. Tangential sections through cortex were examined at postnatal days P0, P1, P2, P4, P6 and P30. Dense patches of 5-HT staining are evident in cerebral cortex as early as P0, and by P4 5-HT axons are organized into discrete patches in the PMBSF that form a pattern closely resembling barrels. However, the characteristic cellular configuration of the barrel fields is not evident in adjacent Nissl stained sections until P6. These findings show that 5-HT axons form a barrel-like pattern in SI before there is cytologic evidence of barrel formation. To examine whether serotonin may regulate barrel formation, 5-HT axons were lesioned by administering the selective 5-HT neurotoxin, p-chloroamphetamine (PCA) to neonatal rats. Within the first few days after PCA treatment the 5-HT staining in the barrels diminishes and by one week post-treatment the 5-HT patches are absent. At P6 (3 days after PCA), barrels are not evident in Nissl stained sections of PCA treated rats but are present in controls. By P30, 4 weeks after PCA treatment, 5-HT axons are uniformly distributed in the PMBSF, 5-HT axon density approaches that of controls and the cellular configuration of barrels is evident in adjacent Nissl stained sections. These results indicate that the process of barrel formation is delayed in cortex following neonatal depletion of serotonin. Thus, the 5-HT projection to neocortex may play a trophic role in the development of cortical structures. (Support: HD19920)

SEROTONIN INNERVATION IN VISUAL AREAS OF CEREBRAL CORTEX IN MACAQUE MONKEYS: LAMINAR DISTRIBUTION OF FINE AND BEADED AXONS. M.A. Wilson and M.E. Molliver. *Dept. of Neuroscience, The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205*

Serotonin (5HT) neurons of the midbrain raphe nuclei project widely upon the cerebral cortex in primates, however, there is considerable heterogeneity and specificity in this projection. We have utilized immunohistochemical methods to examine the density, laminar distribution and morphology of 5HT axons in selected visual areas of cerebral cortex. Two species of macaque monkeys were studied, rhesus (*macaca mulatta*) and cynomolgus (*macaca fascicularis*); these species exhibit similar patterns of 5HT innervation.

The density and laminar distribution of 5HT axons vary among different cytoarchitectonic and functional areas of macaque cerebral cortex. In most areas of parietal and temporal neocortex, there is a moderate density of beaded fibers in layer I, and a moderately high density of fine fibers in layers II-VI; few beaded fibers are found below layer II. Primary visual cortex (V1) exhibits a laminar distribution of 5HT axons that is strikingly different. In V1 there is a low density of 5HT axons in layers I-II and a prominent, high density band of both fine and beaded 5HT axons in layer IV. Certain parietal and temporal visual association areas, such as Area 7a and posterior inferior temporal cortex, also have a marked increase in 5HT axon density in layer IV. Thus, in contrast with other areas, V1 and visual association areas are characterized by a prominent density of 5HT axons in layer IV. However, unlike V1, visual association areas exhibit a moderate density of beaded 5HT axons in layer I. These laminar patterns of 5HT innervation may reflect differences in the postsynaptic targets of 5HT axons in functionally distinct areas of primate cerebral cortex. Preliminary retrograde transport experiments indicate that there may also be differences in the location of the raphe neurons which provide 5HT input to visual vs. somatomotor areas. (Support: NIH NS21011, DA04431.)

EFFECTS OF NEONATAL 5,7-DIHYDROXYTRYPTAMINE LESIONS ON SPINAL 5-HT$_1$ RECEPTORS. V. Hlibczuk* and M. R. Pranzatelli (SPON: S. DiMauro). Departments of Neurology and Pediatrics, Columbia University, NY 10032.

To compare effects and routes of injection on recovery in the spinal cord and to delineate the involvement of 5-HT$_{1A}$ receptors in supersensitivity following 5,7-DHT, we injected rat pups intracisternally or intraperitoneally on postnatal day 2 and 5 with 5,7-DHT (100 mg ip, 100 µg ic) or vehicle. Fourteen weeks later, 5-HT$_1$ receptors were measured in saturation radioligand binding assays using [^{3}H]DPAT, [^{3}H]5-HT (with DPAT and mianserin), and [^{3}H]mesulergine to identify 5-HT$_{1A}$, 5-HT$_{1B}$, and 5-HT$_{1C}$ sites and unlabelled 5-HT (10 µM) to define nonspecific binding. Rats with 5,7-DHT lesions exhibited a small reduction (-13%) in B_{max} of spinal 5-HT$_{1A}$ sites and a significant increase (+33%) in 5-HT$_{1C}$ sites ($P=0.02$), with no changes in 5-HT$_{1B}$ sites or in K_ds compared to controls. Route of 5,7-DHT injection did not significantly alter spinal 5-HT$_1$ sites or spinal 5-HT content, which was reduced 81-89%. These data describe novel changes in 5-HT$_{1C}$ receptors in rats with neonatal 5,7-DHT lesions. (Supported by NIH grant NS01158 (CIDA), the Myoclonus Research Fund, the United Cerebral Palsy Research and Education Foundation (R381-88), and the William Randolph Hearst Foundation.)

DEGENERATION IN THE SUPRAEPENDYMAL NEURONAL COMPLEX OF THE THIRD VENTRICLE IN THE HAMSTER FOLLOWING ELECTROLYTIC LESIONING OF THE RAPHE NUCLEI. R. D. Fessler* and J. A. Mitchell. Departments of Anatomy & Cell Biology and Neurosurgery, Wayne State University School of Medicine, Detroit, MI 48201.

Electrolytic lesions of the raphe nuclei (RN) were performed in the golden hamster (Mesocricetus auratus) to ascertain whether the supraependymal neuronal complex (SENC) in the third ventricle receives input from the RN. Golden hamsters (5 males, 10 females, 70-105g) were lesioned to ablate the raphe nuclei. Controls were prepared by stereotaxic placement of the lesioning electrode without passing current. One to five days following RN lesions, animals were anesthetized and perfused via intracardiac puncture with Karnovsky's aldehyde fixative. The third ventricles were prepared for examination by scanning electron microscopy (SEM). The brainstems were sectioned and the extent of RN ablation determined. SEM 24 to 36 hours following RN lesions revealed a marked decline in the number of SENC processes spreading over the tanycytic ependyma of the median eminence. Degeneration of small caliber SENC processes occurred over 24-48 hours. Specimens were nearly devoid of processes and fascicles three to five days after RN ablation. Controls did not exhibit loss of SENC fascicles or individual processes. The results suggest that many of the intraventricular processes associated with the SENC originate in the raphe nuclei.

168.17

SEROTONERGIC INNERVATION OF RAT LOCUS COERULEUS DERIVES FROM NON-RAPHE BRAIN AREAS. V. A. Pieribone, E. J. Van Bockstaele, M.T. Shipley[1] and G. Aston-Jones. Div Behav Neurobiol, Dept Mental Hlth Sci, Hahnemann Univ, Phila., PA 19102; [1]Dept Cell Biol Anat, U Cincinnati, OH 45267

Using standard immunocytochemical methods we examined the morphology and degree of serotonin immunoreactive (5-HT-IR) fibers and terminals in the rat locus coeruleus (LC) and surrounding areas. As previously reported, 5-HT innervation of LC is dense; however, there is no 5-HT-IR fiber pathway from which the innervation appears to derive. Using tract tracing, double labeling and lesions, we have sought to determine the afferent source(s) of 5-HT innervation of LC.

Retrograde transport studies from LC by this laboratory (Science 234:734; Neurosci. Lett. 85:297) revealed no LC afferents in midline raphe groups. Major inputs to LC were found only in the dorsomedial (prepositus hypoglossi; PrH) and ventrolateral medulla (paragigantocellularis; PGi). Interestingly, a lateral division of the B3 5-HT cell group resides in rostromedial PGi. Using iontophoretic injections of the fluorescent retrograde tracer Fluoro-Gold in LC combined with 5-HT immunofluorescence, we have identified 5-HT-IR LC afferents in PGi (B3 cells) and as well as a few in PrH.

Previous studies by others had indicated that dorsal raphe may be a major source of 5-HT in LC. However, in each of three animals 5-HT innervation in LC remained dense despite extensive lesions of dorsal raphe. In addition, injections of the tract tracers WGA-HRP or PHA-L into dorsal raphe failed to produce significant anterograde labeling in LC even though adjacent structures contained dense fiber labeling. These results support those of our previous retrograde experiments indicating that dorsal raphe does not substantially innervate LC.

As described by others, we identified a small collection of 5-HT-IR neurons just near the ventromedial rostral border of LC. Combined tyrosine hydroxylase and 5-HT immunofluorescence revealed 5-HT-IR processes from these neurons that ramify within LC. Experiments using discrete cytotoxic lesions of this area are in progress to determine if these neurons provide substantial 5-HT innervation of LC. INPUT TO SEROTONERGIC NEURONS IN THE DORSAL RAPHE OF THE RAT; COMBINED LABELING OF PRE- AND POSTSYNAPTIC ELEMENTS. M.R. Park and A. Abi-Dargham*, Dept. Anatomy & Neurobiology, Univ. Tennessee, Memphis, The Health Science Center, Memphis, TN 38163.

A major projection to the dorsal raphe nucleus is from an axis of structures lying along the medial forebrain bundle, including lateral hypothalamic (LHA) and ventral tegmental areas (VTA). Confirming physiological findings of excitatory responses to LHA stimulation in putative serotonergic neurons, we present light microscopic evidence that the targets of the LHA and VTA afferents to the dorsal raphe nucleus are neurons that are immunoreactive to serotonin. This is been demonstrated through the use of double labeling protocols that combine anterograde axonal labeling using phaseolus vulgaris leucoagglutinin (PHA-L) and immunohistochemical labeling for serotonin. Varicose PHA-L labeled axons are seen to course along proximal dendrites of serotonin labeled neurons in the dorsal raphe nucleus. The observation of close appositions between possible pre- and postsynaptic elements constitute data that go one step beyond the classical criterion for establishing a pathway by identifying terminal axonal arborizations at the light microscopic level.

Double chromogens to differentiate PHA-L and serotonin labeling were developed in two ways. In one series, diaminobenzidine (DAB) and nickel intensified DAB (brown and blue-black reaction products, respectfully) were used in a modified avidin-biotin complex (ABC) procedure in which the primary and secondary antibody reactions were done sequentially. The second set of procedures used combinations of fluorescent labeled avidin or secondary antibodies and primary antibodies raised in separate species.

Light microscopic observations such as these are useful for observing the pattern of possible connections but do require verification at the ultrastructural level.

QUANTIFIED DISTRIBUTION OF THE SEROTONIN INNERVATION IN ADULT RAT HIPPOCAMPUS. S. Oleskevich and L. Descarries, Centre de recherche en sciences neurologiques (Département de physiologie), Université de Montréal, Montréal, Québec, Canada H3C 3J7.

Serotonin (5-HT) axon terminals (varicosities) were uptake-labeled for light microscope radioautography in horizontal slices of adult rat hippocampus incubated with 1 μM [^{3}H]5-HT. The labeled varicosities, detected as small aggregates of silver grains, were counted with the aid of an image analysis system, in representative sectors of subiculum (SUB), Ammon's horn (CA1, CA3a, CA3b) and dentate gyrus (DG-medial blade, crest and lateral blade) (N rats = 6). After double correction for duration of exposure and section thickness, and measurement of the mean diameter of hippocampal 5-HT varicosities in electron microscope radioautographs, the results were expressed in number of terminals per mm^3 of tissue. The overall density of hippocampal 5-HT innervation was thus evaluated at 2.7 x 10^6 varicosities per mm^3, but appeared significantly higher in SUB (3.6 x 10^6) and Ammon's horn (3.1 x 10^6) than DG (2.2 x 10^6). SUB and DG-crest (2.0 x 10^6) had the highest and lowest regional densities. There were also significant differences in terms of laminar distribution in each region. The stratum moleculare of SUB and CA1, and the stratum oriens of CA3 (5.2 x 10^6 varicosities in CA3-a), had high values in sharp contrast with the low density in the pyramidal cell layer (0.7 x 10^6). Similarly, the granular layer of DG had a much lower density (1.1 x 10^6) than adjacent layers. These quantitative data further document the heterogeneous regional and laminar distribution of the hippocampal 5-HT innervation. They also demonstrate a greater average density of the serotonin than the noradrenaline input to rat hippocampus (Oleskevich et al., *J. Neurosci.*, 1989, in press) and important differences in the regional and laminar distribution of these two monoamine innervations. (Supported by MRC and FRSQ).

SEROTONIN-LIKE IMMUNOREACTIVITY IN THE EARLY EMBRYO OF THE TOBACCO HORNWORM, MANDUCA SEXTA. W.A. Radwan*, N.A. Granger and J.M. Lauder. Dept. of Cell Biology and Anatomy, Univ. of North Carolina, Chapel Hill, NC 27599

The presence of serotonin (5-HT) in the early Manduca embryo was studied immunocytochemically in paraffin sections with a specific 5-HT antiserum. At stage 2 (10% development), when the germ band has formed and separated from the serosa, 5-HT-like immunoreactivity (IR) was detected as fine granules in both the serosa and germ band. Intense 5-HT IR was seen adjacent to these same structures and was also evident as caps on scattered clusters of yolk granules. By stage 4 (20% development), when gastrulation has been completed, 5-HT IR was located in the cells of the dorsal organ (an invagination of serosal cells that may be involved in molting of the first serosal cuticle). Intense 5-HT IR was observed in the first and second serosal cuticles, especially over the dorsal organ. Light staining was seen in the cells of the ectoderm and presumptive endoderm. By stage 7 (35% development), when dorsal fusion of the amniotic folds occurs, several embryonic structures exhibited 5-HT IR, including the ectoderm of the dorsal head region and of the posterior abdominal segments, the developing mouthparts, and the lining of the hindgut. The existence of 5-HT IR in the embryo during major developmental events prior to neurogenesis suggests that 5-HT might act as a morphogenetic stimulus.

SEROTONIN RECEPTORS II

THREE-DIMENSIONAL COMPUTER MODELING OF THE 5-HT$_3$ RECEPTOR PHARMACOPHORE. A.W. SCHMIDT and S.J. PEROUTKA. Department of Neurology, Stanford University Medical Center, Stanford, CA 94305.

Three-dimensional computer-based steric molecular modeling was used to define a "pharmacophore" of the 5-HT$_3$ receptor binding site. Examination of published radioligand binding data revealed 19 different chemical structures with K_i values of less than 10 nM for this site. Of the 19 potent 5-HT$_3$ agents, 10 compounds are derivatives of a common "core" structure (e.g., ICS 205-930, LY 278458, granisetron, DAU 6215). By overlapping the common features of these 19 agents, the following rules were developed:

1. An aromatic ring must be present with a nitrogen atom positioned approximately 6.5 angstroms from the center of the aromatic ring.
2. The nitrogen is embedded in a ring structure whose plane can be placed perpendicular to that of the aromatic ring.
3. No substitutions are present on the side chain to hinder the folding of the non-aromatic ring portion of the molecule back over the aromatic ring.
4. The atom adjacent to the aromatic ring in the molecule along the most direct path to the nitrogen is always trigonal.

This model accurately predicts nanomolar affinity for all known potent 5-HT$_3$ agents and inactivity for drugs such as ergots and 5-HT$_2$ antagonists. This modeling technique also allows for computer-based screening to identify previously unrecognized pharmacological agents that display affinity for the 5-HT$_3$ receptor binding site. Finally, the 5-HT$_3$ "pharmacophore" will be compared to the pharmacophore proposed for the 5-HT$_{1A}$ receptor (Sleight and Peroutka, 1989; this volume).

169.2

[^{3}H]5-METHYL-URAPIDIL BINDING TO SEROTONIN-1A RECEPTORS IN RAT BRAIN. Pingyu Zhong*, Yiwang Chen*, and K.J. Kellar. (SPON: R. L. Verrier). Department of Pharmacology, Georgetown University School of Medicine, Washington, D.C. 20007.

5-Methyl-urapidil (5-MeU) is a derivative of urapidil, a centrally acting antihypertensive drug that lowers blood pressure by an agonist action at 5-HT-1A receptors on the ventral surface of the medulla (Gillis et al., Drugs 35:20, 1988). 5-MeU is 150 times more potent than urapidil in competing for 5-HT-1A binding sites labeled by [^{3}H]8-OH-DPAT. Furthermore, 5-MeU appears to be a full agonist at 5-HT-1A receptors because it and 8-OH-DPAT lower blood pressure in cats to the same extent (Mandal et al., FASEB J. 3:A1013, 1989) and raise prolactin levels equally in rats (Giblin et al., these abstracts). We have measured the binding of [^{3}H]5-MeU to rat brain membranes. [^{3}H]5-MeU (54 Ci/mmol; Byk Gulden, FRG) binds with a K_d of 1 nM. The IC_{50} values of 5-HT (1nM), 8-OH-DPAT (4nM), spiperone (50nM), WB4101 (4nM), and isobim (1nM) in competition studies indicate that [^{3}H]5-MeU binding sites in the cortex represent predominantly 5-HT-1A receptors, but that approximately 10% of the binding sites are alpha-1-adrenoceptors. The number of sites bound appears to be slightly less than that labeled by [^{3}H]8-OH-DPAT; and 5MeU competes for [^{3}H]8-OH-DPAT binding sites with a Hill slope less than 1. Thus, [^{3}H]8-OH-DPAT may label a site in addition to 5-HT-1A receptors also. These data indicate that 5-MeU is a high affinity agonist at 5-HT-1A receptors, and should prove to be useful in studies of these receptors.

169.3

[^{3}H]KETANSERIN BINDS TO A NON-5HT$_2$ SITE IN RABBIT CEREBRAL CORTEX AND NEOSTRIATUM. T.A. Reader, L. Lima* and K.M. Dewar CRSN, Département de physiologie, Université de Montréal, Montréal, (Qué.) Canada and IVIC, Caracas, Venezuela.

A characterization of [^{3}H]ketanserin ([^{3}H]KTS) binding in the rabbit frontal cortex (fCTX) and neostriatum (CPU) was carried out. The association and dissociation kinetics in fCTX could be fitted to two-site models, suggesting that [^{3}H]KTS labels two cortical sites. The saturation curves revealed a single high-affinity site when mianserin was used to define non-specific binding. The curves could be fitted to a two-site model when unlabelled KTS was used for nonspecific counts and the parameters of the high-affinity site were similar to that obtained for one-site in the presence of mianserin. 5-HT$_2$ antagonists inhibited [^{3}H]KTS binding in fCTX at nM concentrations; however, the curves were best fitted to two-site models. In contrast, [^{3}H]KTS binding to CPU membranes could only be inhibited at high (micromolar) concentrations. Micromolar concentrations of monoamine uptake blockers inhibited [^{3}H]KTS binding in both fCTX and CPU. This study demonstrates that [^{3}H]KTS labels a non-serotoninergic recognition site in the rabbit fCTX and CPU that is similar to that found in the neostriatum of the rat, i.e.: probably a monoamine transport site.

SOLUBILIZATION AND CHARACTERIZATION OF MELATONIN RECEPTOR SITES FROM CHICKEN BRAIN. K.C.Chung* and M.L. Dubocovich. Dept. Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611.

The pharmacological characteristics of 2-[^{125}I]-iodomelatonin binding sites was determined in solubilized fractions from whole chicken brain. P_2 membrane fractions were homogenized in 50 mM Tris.HCL buffer (20% glycerol, 1 mM EDTA, 1 mM PMSF, 1mM mercaptoethanol, pH 7.4) and solu-bilized with digitonin (0.5%). Aliquots of the soluble fraction were incubated at 25°C with 2-[^{125}I]-iodomelatonin, and drugs or vehicle. Binding of 2-[^{125}I]-iodomelatonin was time dependent, saturable and increased linearly with protein concentration. Specific binding defined with 10 μM 6-chloromelatonin represented 95% of total binding. Scatchard analysis of 2-[^{125}I]-iodomelatonin (0.025-2.5 nM) reveal binding to two sites with affinities of K_1=0.073 $\pm$ 0.036 nM and K_2=2.17 $\pm$ 1.06 nM (n=3), and $Bmax_1$=4.54 $\pm$ 0.74 fmol/mg protein and $Bmax_2$=40.1 $\pm$ 12.2 fmol/mg protein (n=3), respectively. The relative order of affinities of melatonin analogues for 2-[^{125}I]-iodomelatonin binding sites was: 2-iodomelatonin $\geq$ 6-chloromelatonin > melatonin > N-acetyl-5-hydroxy-tryptamine > N-acetyltryptamine >> 5-methoxy-tryptamine $\geq$ 5-hydroxytryptamine $\geq$ methysergide. We conclude that the solubilized melatonin receptor site retained the binding properties and pharmacological characteristics of the functional ML-1 melatonin receptor (Dubocovich, M.L., FASEB J. 2: 2765, 1988). Supported by grant MH-42922.

169.5

REGION-DEPENDENT HETEROGENEITY OF THE 5-HT$_{1A}$ RECEPTOR SYSTEM IN RAT AND COW BRAIN. Frank Yocca[1], Lawrence Iben[1]*, and Saul Maayani[2], [1]CNS Biology, Bristol-Myers Co., Wallingford, CT 06492-7660 and [2]Dept. of Anesthesiology, Mount Sinai Sch. Med., New York, NY 10029.

Apparent neuronal receptor heterogenity across regions or species may reflect differences in the coupling between the same receptor subtype and different membrane components such as G proteins, resulting in receptor system heterogeneity. To test this hypothesis, the 5-HT$_{1A}$ receptor and its related binding sites were assayed in membrane preparation from the hippocampus (H), cortex (C) and the dorsal raphe (DR) of rat and cow. Functional (inhibition of forskolin stimulated adenylyl cyclase; FSAC) and occupancy (agonist binding) studies were done in parallel. Modulation of occupancy was assessed by 10μM GPPNHP. High level of agonist occupancy (^{3}H-8-OH-DPAT binding) was observed in the DR, H and C of both species, and a marked regional dependence of the IC_{50} values of the GPPNHP effect was found across the brain regions tested (μM) cow: DR (0.8) < H (6.6); rat: H (3.1) < C (5.3). No FSAC could be detected in the DR of both species while the pharmacology of the binding sites was indistinguishable across all regions (See Iben & Yocca). These characteristics reflect differences in regional 5-HT$_{1A}$ receptor systems (i.e. coupling to G protein) and may explain reported differences in relative 5-HT$_{1A}$ agonist efficacy in rat DR and H as measured by electrophysiological methods (Sprouse and Aghajanian, 1987). (Supported in part by USPH GM 34852).

169.6

COMPARISON OF ^{3}H-MESULERGERINE (^{3}H-MES) BINDING TO 5HT$_{1c}$ RECEPTORS IN RAT CORTEX (RC) AND BOVINE CHOROID PLEXUS (BCP). F.P.Bymaster*, L.R.Reid*, R.D.Marsh* and D.T.Wong. Lilly Research Laboratories, Eli Lilly and Company, Lilly Corporate Center, Indianapolis, IN 46285

A unique serotonin (5HT) binding site designated 5HT$_{1c}$ was found in mammals. This study was to determine if ^{3}H-MES, a 5HT$_{1c}$ antagonist, bound to 5HT$_{1c}$ sites in RC and BCP. The incubation mixture for RC contained 30 nM spiperone to mask 5HT$_2$ sites. The inhibition of ^{3}H-MES binding by several drugs is shown in the table. Mianserin, a 5HT$_{1c}$ antagonist, was equipotent as an inhibitor of ^{3}H-MES binding in the brain regions, and the aryl piperazines TFMPP and mCPP exhibit high affinity for the 5HT$_{1c}$ recognition sites in the 2 tissues. Other analogs (LY165163, MK212 and quipazine) were of intermediate activity. Compounds with affinity for other 5HT binding sites were weak inhibitors of ^{3}H-MES binding. We conclude that ^{3}H-MES binding to BCP and RC appears to be the same recognition site and exhibits the characteristics of 5HT$_{1c}$ binding.

Compound	IC_{50}, nM RC	BCP	Compound	IC_{50}, nM RC	BCP
5HT	49	7	8-OH-DPAT	>1000	16000

DOSE RELATED EFFECTS OF THE 5HT$_{1A}$ AGONIST 8-OH-DPAT ON GLUCOSE UTILIZATION IN RAT BRAIN STUDIED WITH 2-DG AUTORADIOGRAPHY. P.M. Grasby*, T Sharp*, P. Kelly* and D.G. Grahame-Smith* (SPON : European Neuroscience Association). M.R.C. Unit and University Department of Clinical Pharmacology, Radcliffe Infirmary, Oxford OX2 6HE . UK..

Selective 5HT$_{1A}$ agonists produce diverse behavioral, neuroendocrine and electrophysiological effects in rats due to stimulation of central pre- or postsynaptic 5HT$_{1A}$ receptors. There is evidence that low doses of 5HT$_{1A}$ agonists, such as 8-OH-DPAT, preferentially stimulate presynaptic 5HT$_{1A}$ somatodendritic autoreceptors, leading to reduced 5HT neurotransmission while higher doses also stimulate postsynaptic 5HT$_{1A}$ receptors leading to an overall increase in 5HT neurotransmission. Here we studied the effect of a low dose (0.05mg kg^{-1} s.c.) and two higher doses (0.25 + 1.0 mg kg^{-1} s.c.) of 8-OH-DPAT in discrete areas of the rat brain, using the 2-DG autoradiographic technique to measure cerebral glucose utilization as an index of functional brain activity. Groups of five male adult rats (250-350 g) received 8-OH-DPAT or saline 5 min before the injection of 40 μCi i.v. of ^{14}C 2-DG. 8-OH-DPAT induced dose dependant reductions (5 - 36%) in glucose utilization in selected brain regions, notably in limbic structures. The highest dose of 8-OH-DPAT (1.0 mg kg^{-1}) increased glucose utilization by 30% in a columnar pattern in the sensorimotor cortex. Our data suggest that the expected decrease or increase in 5HT neurotransmission (caused by a low or higher doses of 8-OH-DPAT, respectively) is not associated with diametrically opposite effects on regional glucose utilization.

169.8

QUANTITATIVE AUTORADIOGRAPHY OF 5-HT-1A SEROTONIN RECEPTORS IN IMINODIPROPIONITRILE (IDPN)-INDUCED DYSKINETIC RATS. S. Przedborski*, M. Wright*, S. Fahn and J.L. Cadet. Columbia University, Department of Neurology, New York, NY 10032.

Injection of IDPN to rats causes persistent motor symptoms such as lateral and vertical twitches and random circling. Increases of 5-HT level in the caudate and in the nucleus accumbens (Cadet J.L. et al., 1988) and changes in 5-HT-2 receptor density in discrete brain regions (Cadet J.L. et al., 1987) have been found in IDPN-treated rats. Activation of 5-HT-1A receptors causes similar behaviors in rats. In the present study, we use in vitro 8-OH[3H]DPAT binding autoradiography to evaluate the effect of IDPN on 5-HT-1A receptor in rat brain.

IDPN-treated rats displayed increases of 8-OH[3H]DPAT binding in the frontal cortex and in the caudate-putamen. In contrast, there were significant decreases in the interpeduncular nucleus, in the pyramidal layer of the CA3 field of hippocampus, in the superior colliculus, and in the pars reticulata of the substantia nigra.

These results provide further evidence for an involvement of the 5-HT system in the development of the IDPN-induced dyskinetic syndrome.

169.9

AUTORADIOGRAPHIC LOCALIZATION OF [^{3}H]BMY 7378, A SEROTONIN$_{1A}$ PARTIAL AGONIST, IS COMPARED TO THE PATTERN OF LABELING OF [^{3}H]8-OH-DPAT IN RAT BRAIN. Sandra L. Moon, Frank Yocca, Raymond C. Lamy*, and Lawrence Iben*. CNS Biology, Bristol-Myers Co., Wallingford, CT 06492.

BMY 7378, a buspirone analog, binds in a uniform manner with high affinity and displays low intrinsic activity at serotonin$_{1A}$ (5HT$_{1A}$) receptors; whereas 8-OH-DPAT, a 5HT$_{1A}$ agonist, apparently binds in a heterogeneous fashion to 5HT$_{1A}$ sites (Yocca et al., Soc. Neurosci. Abstr., 14,#1,551, 1988). In an attempt to investigate whether BMY 7378 and 8-OH-DPAT might have differences in regional localization, their autoradiographic distributions were compared under similar incubation conditions in rat brain.

[^{3}H]BMY 7378 was custom synthesized by New England Nuclear (85Ci/mmol), and an incubation condition was devised that yielded appropriate biochemistry and pharmacology. With the use of this incubation procedure on tissue sections 92% specific binding was achieved.

The binding patterns of the two ligands were virtually identical. Regions of highest binding were the dentate gyrus, hippocampus (CA$_{1\&4}$), lateral septum, entorhinal cortex, interpeduncular nucleus, and dorsal raphe. Labeling of the median raphe and thalamus was sparse. Moderately labeled were the intermediate through deep layers of cortex, nuclei of the hypothalamus and amygdala. Moreover, unlabeled BMY 7378 (0.3nM-0.1μM) added to the [^{3}H]8-OH-DPAT incubation uniformly decreased binding in all brain regions measured.

169.10

AGONIST AND ANTAGONIST PROPERTIES OF BMY 7378, A 5-HT-1A PARTIAL AGONIST, IN 8-OH-DPAT DISCRIMINATION IN PIGEONS. J.A.Stanley*, C.P.VanderMaelen and S.L.Moon (SPON:T.L. Martin). CNS Biology,Bristol-Myers Co.,Wallingford, CT 06492.

BMY 7378 was examined for possible agonist and antagonist activity as indicated by the key chosen during substitution or combination tests in pigeons trained to discriminate the 5-HT-1A agonist 8-OH-DPAT (DPAT) from saline. During training, six pigeons (at 85% weight) were allowed access to food following every 30th peck (FR30) made on the key associated with the pre-session injection. Following discrimination acquisition, test sessions were run during which BMY 7378 was either substituted for or given 15 min prior to the training dose of DPAT. When BMY 7378 (1.0 and 3.0 mg/kg) was substituted for DPAT, 4/6 birds selected the DPAT key suggesting common interoceptive stimulus properties. When these same birds were pretreated with these same doses of BMY 7378 prior to DPAT administration, 3/6 selected the saline key, suggesting an antagonism of the DPAT cue. The three birds who did not demonstrate this apparent antagonism had previously shown nearly complete generalization of the BMY 7378 cue to the DPAT cue, indicating that under either test condition the agonist aspect of BMY 7378 can prevail. These results are consistent with previous data indicating that the partial 5-HT-1A agonist, BMY 7378, can exhibit both agonist and antagonist properties in model systems sensitive to 5-HT-1A agents.

169.11

STRUCTURE-AFFINITY STUDIES: PRELUDE TO THE DESIGN OF 5-HT1D LIGANDS. *R A Glennon* A Ismaiel* M E Pierson* C Chaurasia* Virginia Commonwealth University, Richmond, VA 23298 and K Davis* M Titeler, Albany Medical College, Albany, NY 12208.*

Structure-affinity relationships (SAFIRs) have been developed for the binding of serotonergic and related agents for 5-HT1D sites. Groups of agents examined in search of appropriate structural templates include aminotetralins, phenalkylamines, arylpiperazines, and tryptamines. Most derivatives, with the exception of the tryptamines, display low affinity for 5-HT1D sites. Detailed SAFIR data for 5-HT derivatives reveals that both aromatic rings are necessary for binding, and that O-methylation has little effect on affinity. The following changes decrease affinity: N,N-dimethylation (3- to 5-fold; larger alkyl groups decrease further), α-methylation (50-fold), 2-methylation (300- to 500-fold), removal of 5-OH (10-fold), cyclization of sidechain to β-carboline (> 100-fold). 7-Alkylsubstitution is not well tolerated. 5-Substitution alters affinity.

Using the SAFIR generated with the tryptamines, we were able to increase the affinity of 1-phenylpiperazine (Ki > 1 μM) by more than 5000-fold; e.g. MEP-179, 1-(7-methoxy-1-naphthyl)piperazine, Ki = 2 nM). Continued use of these SAFIR data should allow for the eventual design and synthesis of useful, high-affinity site-selective 5-HT1D ligands. (Supported in part by PHS grant NS23523.)

169.12

^{3}H-NAN-190 AND ^{3}H-BMY-7378: ANTAGONIST RADIOLIGAND PROBES OF THE BRAIN 5HT$_{1A}$ RECEPTOR. L. Fitzgerald* and M. Titeler (1), R.A. Glennon*(2), and F. Yocca (3) (SPON: H. Tedeschi) (1)Dept. Pharmacol.& Toxicol., Albany Med. Coll., Albany, N.Y. 12208; (2) Dept. Med. Chem., Virginia Commonwealth Univ, Richmond, Va. 23298; (3) Div. of Drug Develop., Bristol-Myers, Inc., Wallingford, Ct. 06482

Brain 5HT$_{1A}$ receptors have been extensively studied with agonist radioligands such as ^{3}H-8-OH-DPAT. BMY-7378, a putative partial agonist, and NAN-190, a putative antagonist, were radiolabelled by DU PONT NEN in order to further probe the drug-5HT$_{1A}$ receptor interaction.

The two novel radioligands appear to label a similar site (5HT$_{1A}$ receptor) in homogenates of rat hippocampus and cortex as does ^{3}H-8-OH-DPAT. In rat striatal homogenates only ^{3}H-BMY 7378 and ^{3}H-NAN-190 produced a significant radioligand signal. Drug affinities were different in competition assays using striatal or hippocampal tissues. 5HT demonstrated a K_I values of 10^{-7}M and other 5HT$_{1A}$ drugs demonstrated significantly lower affinities for the striatal binding site compared to the hippocampal and cortical binding site (5HT$_{1A}$ receptors).

The preliminary data indicate that the receptor binding properties of ^{3}H-BMY 7378 and ^{3}H-NAN 190 are significantly different than the receptor binding properties of ^{3}H-8-OH-DPAT. We will present data further exploring the possibility that a novel state of the 5HT$_{1A}$ receptor or a novel 5HT receptor subtype has been labelled with these radioligands. Supported by PHS MH-40716.

^{125}I-DOI: AN HALLUCINOGEN RADIOLIGAND PROBE FOR HUMAN BRAIN 5HT$_2$ RECEPTORS. S.Leonhardt*, M. Titeler (SPON: D.Poulos). Dept. Pharmacol. & Toxicol., Albany Med. Coll., Albany, N.Y. 12208

The phenylisopropylamine hallucinogens appear to exert their effects through stimulation of brain 5HT$_2$ receptors (1). We decided to monitor the hallucinogen-brain interaction with a radioiodonated phenylisopropylamine hallucinogen, ^{125}I-DOI and human cortical tissue homogenates.

Detailed studies in human frontal cortical homogenates indicate that ^{125}I-DOI labels a guanyl nucleotide sensitive state of human brain 5HT$_2$ receptors. The specific binding (defined by 1uM cinanserin) is saturable, with a B_{max} of 0.5 pmol/g wt weight tissue, and a K_D of 0.5nM. The binding site displays the pharmacological properties of a 5HT$_2$ receptor with high affinities for prototypical 5HT$_2$ antagonists. Potent 5HT$_2$ agonists displayed nM affinities for the site. The binding site appears to be identical to the site labelled with ^{3}H-DOB in rat cortical tissue homogenates (2). These data support the hypothesis that hallucinogens act through stimulation of brain 5HT$_2$ receptors. Supported by PHS MH-40716.

CELLULAR LOCALIZATION OF NEOCORTICAL SEROTONIN 1a AND 1b SITES. P.B.Crino, B.A.Vogt, L.Volicer, and R.G.Wiley; Boston Univ. Sch. Med., Boston, MA, 02118; V.A. Hosp., Bedford, MA, 01730, and Nashville, TN, 37203.

Experimental ablations followed by autoradiography with 8-OH-DPAT and ICYP were used to characterize 5-HT1a and 5-HT1b receptor distributions in rat posterior cingulate cortex. Ablations included cortical undercutting, destruction of raphe afferents, cortical ibotenic acid injections, and thalamic injections of the immunotoxin OX7-ss-saporin. Peak 8-OH-DPAT binding was in layer Vb and was not affected by undercut ablations while cortical ibotenic acid injections reduced binding by greater than 50%. Thalamic OX7-ss-saporin injections decreased layer VI binding by 45%. Peak ICYP binding was in layer I. Undercutting decreased grain density by 54% while raphe lesions reduced it by 57%. Ibotenic acid reduced grain density in all layers by 28-47%.

Thus, 5-HT1a sites are located postsynaptically on cortical neurons including cortico-thalamic projection neurons while 5-HT1b sites are located presynaptically on raphe afferents and postsynaptically on cortical neurons. Supported by NIA Grant AG06419 and NINDS 18745.

169.15

CELLULAR LOCALIZATION OF THE SEROTONIN AUTORECEPTOR USING CONCURRENT IMMUNOCYTOCHEMISTRY AND AUTORADIOGRAPHY. H.M. Akbari , P.M. Whitaker-Azmitia, and E.C. Azmitia (SPON: S.M. Feldman) Dept. Biology, New York University, Washington Square East, New York, NY 10003.

The presence of presynaptic autoreceptors on serotonergic neurons has been hypothesized based on electrophysiological and autoradiographic studies. We directly examined the presence or absence of 5-HT_{1a} and 5-HT_{1b} receptors on 5-HT neurons of the midbrain raphe using a combined transmitter immunocytochemistry/receptor autoradiography method. ^{3}H-8-OH-DPAT was used as a selective ligand for the 5-HT_{1a} receptor and ^{125}I-CYP for the 5-HT_{1b} receptor. The effects of fixation on the binding kinetics were assessed on both sections and homogenized tissue. Although the B_{max} was decreased, the K_d was virtually unchanged. Thus, the specificity of the ligands for the receptor was not significantly altered by fixation. Specific binding of 8-OH-DPAT and lack of I-CYP binding on serotonergic neurons indicated that the 5-HT_{1a} receptor and not the 5-HT_{1b} functions as the autoreceptor on the cell bodies of 5-HT neurons. Differential binding densities of 8-OH-DPAT were observed with highest densities in the B8 and B9 cell groups and lowest in B7. We are currently investigating the functional significance of this finding. This work is supported by NSF BNS-8812892 and NINDS NS25391.

CHARACTERIZATION AND USE OF ANTI-IDIOTYPIC ANTIBODIES FOR THE LOCALIZATION OF SEROTONIN RECEPTORS. H. Tamir, K.P. Liu*, P.Y. Yu*, M.D. Gershon, and A.L. Kirchgessner. Div. Neuroscience, N.Y. State Psychiatric Inst. and Dept. Anatomy and Cell Biol. Columbia Univ. P&S N.Y., N.Y. 10032.

In order to locate receptors and other proteins that physiologically bind serotonin (5-HT), an anti-idiotype serum was prepared from affinity purified polyclonal antibodies to 5-HT. The immune serum was purified by affinity chromatography on anti-5-HT-Sepharose or a β-carboline affinity column was used to remove antibodies to 5-HT. Punctate surface immunostaining was demonstrable on fibroblasts transformed with either a cDNA clone encoding the 5-HT_{1C} receptor or a cDNA clone encoding the 5-HT_2 receptor, but not on control fibroblasts that had not been transformed. The anti-idiotypic antibodies also inhibited the binding of ^{3}H-5-HT to membranes obtained from the rat cortex, striatum, and raphe area, but had little effect on the binding of ^{3}H-5-HT to membranes from the cerebellum or hippocampus. In vibratome sections of rat CNS the anti-idiotypic antibodies immunolabeled cells and/or fibers in: the raphe nuclei, substantia nigra, globus pallidus, entopeduncular nucleus, thalamic nuclei, dentate gyrus, cerebral cortex, subfornical organ, supraependymal plexus, lateral hypothalamus, choroid plexus, and anterior horn cells. Simultaneous demonstration of 5-HT immunoreactivity revealed that a subset of neurons in the dorsal raphe nucleus were doubly labeled. The distribution of immunolabeling and regions in which the anti-idiotypic antibodies inhibit the binding of ^{3}H-5-HT are compatible with the conclusion that the antibodies recognize 5-HT_{1C} and 5-HT_2, but not 5-HT_{1A} receptors. Immunolabeled structures in the periphery included neurons in the bowel, Purkinje fibers in the heart, and a subset of cells in the adenohypophysis. Supported by grants MH 37575, NS07062, and NS12969.

DETERMINATION OF 8-HYDROXY-2-(DI-n-PROPYL-AMINO)TETRALIN (8-OH-DPAT) IN RAT BRAIN BY LIQUID CHROMATOGRAPHY WITH ELECTROCHEMICAL DETECTION. K.W. Perry* and R.W. Fuller. Lilly Research Laboratories, Eli Lilly and Co., Lilly Corporate Center, Indianapolis, IN 46285.

Tissue was homogenized in 0.1 M TCA, 8-OH-DPAT was adsorbed by a solid phase extraction column then eluted and injected onto a CN HPLC column and detected by electrochemical oxidation. The method is sensitive to ~5 ng/g. At 30 min. after a 1 mg/kg s.c. dose the concentration in whole brain was ~1 μg/g with no differences observed in six different brain regions. The half-life of 8-OH-DPAT in whole brain was 26 min. with similar half-lives in the hypothalamus, midbrain and hippocampus. Concentrations in whole brain were about 10-fold higher after s.c. than after i.p. doses, consistent with earlier data on 5-HIAA lowering showing 8-OH-DPAT to be more potent s.c. than i.p. Pretreatment with proadifen (SKF 525A), an inhibitor of microsomal drug metabolism, slightly increased brain levels of 8-OH-DPAT. Pindolol, which antagonized the elevation of serum corticosterone caused by 8-OH-DPAT, did not change brain levels of 8-OH-DPAT. This analytical method should be useful in correlating brain levels of 8-OH-DPAT with various neurochemical, behavioral or other functional effects described for this compound.

CATECHOLAMINE RECEPTORS: DOPAMINERGIC (D2)

170.1

VANADATE INHIBITS AGONIST BINDING TO THE D_2 DOPAMINE RECEPTOR. Z. Elazar*, L. Levi* and S. Fuchs. Dept. of Chemical Immunology, The Weizmann Institute of Science, Rehovot 76100, Israel.

Vanadate ions are known to act via different mechanisms; e.g. vanadate is a powerful inhibitor of phosphatases, it inhibits Na^{+}-K^{+}-ATPase, it is known to activate adenylate cyclase coupled to Gs proteins and was recently shown to inhibit the GTPase activity of transducin. We have shown that orthovanadate (in the micromolar range) inhibits the high affinity binding of the D_2 dopamine receptor to specific agonists (apomorphine and N-propylnorapomorphine), while it does not affect the binding to D_2 antagonists (spiperone and haloperidol). These effects of vanadate are similar to those observed with guanine nucleotides or their analogs. However, the effect of vanadate on agonist binding was shown to be additive to that of guanine nucleotides, suggesting that vanadate and guanine nucleotides may exert their effect on the D_2 dopamine receptor via different mechanisms. Indeed, in contradistinction with guanine nucleotides, vanadate did not affect GTPγS binding in striatal membranes, nor did it induce the dissociation of the complex between the D_2 dopamine receptor and its related G proteins. The observed effects of vanadate on the D_2 dopamine receptor system may be explained by either direct modification of the receptor molecule, or alternatively by an indirect effect resulting from inhibition of phosphatase activity.

170.2

LIGAND BINDING CHARACTERISTICS OF THE CLONED RAT DOPAMINE D2 RECEPTOR. J.B. Fischer*[1], K.B. Howie*, J.R. Bunzow*[1], A.C. Server and O. Civelli[1]. Cambridge Neurosci. Res. Inc., Cambridge, MA 02139, and [1]Vollum Inst., OHSU, Portland, OR 97201.

The dopamine D2 receptor was recently cloned from rat brain and expressed in the Ltk⁻ mouse fibroblast cell line (L-RGB2 cells; Bunzow, J.R. et al. Nature 336:783, 1988) where it exhibited the appropriate ligand binding profile. This cloned D2 receptor also is fully functional, i.e., able to mediate the lowering of cAMP levels by dopaminergic agonists (Albert, P.R. et al., Abstr. 71st Ann. Mtg. Endocrine Soc., June 1989). Here we report further ligand binding properties of the cloned D2 receptor and compare them with the rat striatal D2 receptor using a more complete set of ligands. Using [^{3}H]domperidone we confirmed the L-RGB2 receptor density (≅1 pmol/mg protein) previously reported using [^{3}H]spiperone. A single binding site (Kd for [^{3}H]domperidone of 0.4 nM) was found in both L-RGB2 and striatal membranes; identical ligand dissociation rates were also found. A large series of neuroleptic drugs showed very similar IC_{50} values in the L-RGB2 and striatal membranes (correlation r = 0.97). None of the drugs tested suggested that the cloned D2 receptor was a subtype with a unique pharmacological profile. We conclude that this cloned D2 receptor represents the rat brain D2 receptor as measured in striatal tissue.

170.3

CLONING OF THE BOVINE D-2 DOPAMINE RECEPTOR. C.L. Chio*, G.G. Martin* and R.M. Huff* (SPON: I. Abraham). Dept. of Cell Biology, The Upjohn Company, Kalamazoo, MI 49001.

Dopamine D-2 receptors are implicated in the etiology of schizophrenia. Structural analysis and expression of a dopamine D-2 receptor clone will be useful in the search for more effective antipsychotic compounds.

A clone for the rat D-2 receptor was obtained using the polymerase chain reaction technique, with rat whole brain mRNA as the substrate. Oligonucleotides used as primers were based on the published sequence for the rat D-2 dopamine receptor (Bunzow *et al.*, Nature 336:783-787, 1988). The 1479 bp clone, containing the entire coding region (100% identical to the published sequence) was used to screen a bovine caudate cDNA library constructed in Lambda ZapII. One clone of 5 x 10^5 clones screened hybridized with the rat probe at high stringency. The insert cDNA is 2350 bp. Partial sequence analysis of this bovine clone reveals 96% amino acid homology with the rat D-2 clone. cRNA made from this clone is being expressed in *Xenopus laevis* oocytes and cos cells for characterization of the synthesized protein, binding sites and physiological responses.

170.4

IDENTIFICATION OF A D2 RECEPTOR SUBTYPE WHICH ELEVATES INTRACELLULAR CALCIUM. K.L. O'Malley, K.R. Stone* and R.D. Todd. Departments of Anatomy & Psychiatry, Washington University School of Medicine, St. Louis, MO 63110.

Using gene transfer techniques we have isolated a mouse fibroblast cell line (DA10-4) which expresses a novel D2 receptor subtype (Todd et al., Soc. Neurosci. Abst. 14, 411). The expressed receptor has lower affinities for (+) butaclamol, ketanserin and SCH23390 than the D2 site described by Bunzow et al. (Nature 336:783-787). Using the calcium sensitive dye Indo-1 and flow cytometry, we have found that receptor stimulation with D2 selective agonists increases intracellular calcium levels. The changes in calcium levels require extracellular calcium and can be blocked by cobalt or lanthanum. Receptor occupancy is required to maintain elevation of calcium levels and can be reversed by D2 antagonists. No desensitization was observed over 15 minutes.

The DA10-4 D2 sites are the product of a novel D2 gene. Using oligonucleotide primers from the Bunzow et al. D2 sequence (RGB-2) in combination with polymerase chain reaction (PCR) amplification of DNA, we have found that RGB-2 sequences have not been transfected into DA10-4 cells. PCR analysis of reverse transcribed mRNA from DA10-4 cells and rat striatum demonstrates that the homologous mouse RGB-2 gene has not been activated via transfection in DA10-4 cells. Therefore we have identified a novel D2 receptor subtype.

170.5

Behavioral and Neurochemical Effects of Chronic Administration of SKF-38393 in Reserpinized Rats. **J. L. Neisewander, I. Lucki, and P. McGonigle. Departments of Pharmacology and Psychiatry, Univ. of Pennsylvania School of Medicine, Philadelphia, PA.**

We have reported previously that chronic administration of the selective D1 partial agonist SKF-38393 fails to decrease D1 receptor density in the caudate-putamen (CPu), nucleus accumbens (NAc), and substantia nigra (SN). To determine whether intrinsic dopaminergic tone masks SKF-38393 induced down-regulation of receptors, rats were treated with the agonist following depletion of endogenous dopamine by reserpine. Rats were given either reserpine (1 mg/kg, SC; daily for the first 4 days, then every other day) or vehicle on days 1-28. Half of each treatment group were given SKF-38393 (5 mg/kg, SC; twice daily) while the other half received vehicle on days 14-28. Behavior was assessed on day 14 and 28. Rats were sacrificed 24 h after their last treatment and D1 receptor density was measured using quantitative autoradiography of ^{3}H-SCH23390 binding. In control rats, chronic SKF-38393 did not significantly decrease D1 receptor density in the CPu, NAc, or SN. In reserpinized rats, however, chronic SKF-38393 produced a decrease in D1 receptor density in the NAc, but not in the CPu or SN. In control rats, acute administration of SKF-38393 increased grooming and tongue protrusions. Chronic administration of SKF-38393 sensitized the tongue protrusion response but not grooming. In contrast, acute administration of SKF-38393 in reserpinized rats produced stereotyped behavior that did not change following chronic administration of the agonist. Reserpinized rats given vehicle exhibited a spontaneous increase in tongue protrusions that could be blocked by the D2 antagonist spiroperidol. 170.6

HUMAN PITUITARY DOPAMINE D_2 RECEPTORS ARE CODED FOR BY ALTERNATIVELY SPLICED mRNAs. D.K.Grandy, M.M. Marchionni*, H.P.Makam*, L.Reed*, J.R.Bunzow*, M. Litt*, O.Civelli. Vollum Institute, Or. Hlth. Sci. Univ., Portland, OR. 97201.

The receptors which mediate the effects of dopamine are divided into two types, D_1 and D_2, on the basis of their ligand selectivities and coupling with G proteins. The dopamine D_2 receptors have been further differentiated into two subtypes, the post-synaptic and somatodendritic autoreceptors. The nature of this diversity at the molecular level was studied in the human pituitary. A cDNA library was screened using the rat dopamine D_2 receptor cDNA (Bunzow et al., Nature, 336:577, 1988) as probe. The nucleotide sequence of a full-length human clone revealed a strong identity with the rat sequence. One notable exception, however, was the presence of an 87-basepair insertion in the human pituitary RNA. The source of this extra sequence was investigated at the level of the gene. Localized to chromosome 11q22-23, the human gene contains an exon which corresponds to the 87 basepair insertion found in pituitary D_2 receptor mRNA. Currently, studies are underway to demonstrate the function of this extra sequence.

170.7

[^{125}I]EPIDEPRIDE, A HIGH AFFINITY DOPAMINE D2 RECEPTOR LIGAND. A. Janowsky*, R.A. Henningsen*, P.R. Albert*, T. DePaulis*, R. Kessler* and K.A. Neve (SPON: J. Janowsky) VA Medical Ctr. and Depts. of Psychiatry and Pharmacology, Oregon Health Sciences Univ., Portland OR 97207.

We have characterized the in vitro binding of a new radio-iodinated substituted benzamide to DA D2 receptors. At the range of concentrations used in these studies, the binding of (S)-(-)-N-[(1-Ethyl-2-pyrrolidinyl)methyl]-5-iodo-2,3-dimethoxybenzamide approached equilibrium within 1 hr at 30°C. At a ligand concentration of 100 pM, non-specific binding (2 uM (+)-butaclamol) was 5% of total binding to membranes from rat striatum and from GH_4 cells transfected with a D2 receptor cDNA, and 20% of total binding to cortical membranes. The density of binding sites was approximately 1000 fmol/mg protein in striatum and transfected cells, and 20 fmol/mg protein in membranes prepared from medial prefrontal cortex. The K_d values were 15 pM to 30 pM in transfected cells, rat striatum, and cortex. K_d values were constant between 20 and 100 mM NaCl, but increased at lower concentrations to a maximum of approximately 300 pM in the absence of added NaCl. Epidepride inhibited the specific binding of [^{3}H]spiroperidol in GH_4 cells with K_i values of 18 pM and 500 pM in the presence and absence, respectively, of 50 mM NaCl. Because of its high potency, selectivity, and specific radioactivity, epidepride will be useful for in vivo and in vitro studies of dopamine D2 receptors.

170.8

FUNCTIONAL CHARACTERIZATION OF A RAT DOPAMINE D-2 RECEPTOR cDNA EXPRESSED IN A MAMMALIAN CELL LINE. K.A. Neve, R.A. Henningsen*, T.A. Schock*, J.R. Bunzow*, and O. Civelli*. VAMC; Vollum Institute and Depts. of Psychiat. and Pharmacol., Oregon Health Sci. Univ., Portland, OR 97207.

The recent cloning of a complementary DNA for the rat dopamine (DA) D-2 receptor makes it possible to create cell lines expressing this receptor. LZR1 cells (previously described as L-RGB2Zem-1 cells; *Nature* **336**:783-787) were created by transfecting the D-2 cDNA (RGB-2) into mouse fibroblast Ltk$^-$ cells. LZR1 cells express a high density of D-2 receptors, whereas the wild-type cells do not. A number of agonists competitively and stereoselectively inhibited the binding of [^{3}H]spiroperidol to the expressed D-2 receptors. DA was a more potent inhibitor of radioligand binding in the presence of $MgCl_2$ than in the presence of GTP, NaCl, and $MgCl_2$. DA reduced forskolin-stimulated adenylate cyclase activity by 27% in membranes prepared from LZR1 cells. Inhibition of adenylate cyclase by DA was blocked by (+)-butaclamol or prior treatment of intact cells with pertussis toxin. Pertussis toxin-treatment also abolished the high-affinity binding of DA observed in the absence of GTP/NaCl. Treatment of intact cells with 100 μM DA caused a time-dependent loss of [^{3}H]spiroperidol binding, reducing the density of receptors from 1017 fmol/mg protein to approximately 750 fmol/mg after 4-6 hr. These data indicate that the RGB-2 cDNA directs the expression of a DA D-2 receptor capable of interacting with guanine nucleotide-binding proteins and inhibiting adenylate cyclase activity. Furthermore, the density of receptors on LZR1 cells can be regulated by treatment with DA.

170.9

EFFECTS OF CHOLECYSTOKININ OCTAPEPTIDE ON STRIATAL DOPAMINE RECEPTOR BINDING IN THE RAT. M. Nakashima*, S. Kito and R. Miyoshi(SPON:Y.Yamamura). Third Department of Internal Medicine, Hiroshima University School of Medicine, Hiroshima 734, Japan.

The effects of cholecystokinin octapeptide(CCK-8) on dopamine(DA) receptor binding were examined in vitro. Wistar strain male rats were used. P_2 fractions of the striata were prepared and used as the receptor preparation. From DA/^{3}H-SCH23390 competitive binding experiments, competition curves were best fitted to a two-site model. Preincubation of the receptor preparation with CCK-8 caused a partial conversion of high affinity binding sites into low affinity ones. When SK&F 38393, a selective D_1 agonist, was used as a competitor, competition curves were monophasic and a single high affinity state was observed. By preincubating with CCK-8, in addition to high affinity binding sites, low affinity sites appeared. In presence of 120mM NaCl, dopamine binding sites were not altered by CCK-8. Addition of 50μM GTP resulted in a partial conversion of the high affinity sites into low affinity ones which was further advanced by CCK-8. In contrast, CCK-8 had no effect on antagonist binding. Likewise, CCK-8 caused a significant reduction of dopamine D_2 high affinity sites when observed by using ^{3}H-spiperone as a ligand. These results suggest that CCK receptor-stimulation modulates the binding characteristics of dopamine receptors.

170.10

POST-SYNAPTIC DOPAMINE (DA) D-2 RECEPTOR DEPOLARIZES SUPRAOPTIC NEURONES (SON) IN RAT HYPOTHALAMIC EXPLANT. C.R. Yang, C.W. Bourque, L. Renaud. Centre for Research in Neuroscience, Montreal General Hospital and McGill Univ., 1650 Cedar Ave., Montreal, P.Q. Canada H3G 1A4.

A prominent dopaminergic innervation of SON neurosecretory cells has been described (Buijs et al., Brain Res. 326:65-72, 1984) but the cellular mechanisms of DA action are unknown. Current- & voltage-clamp techniques were used to study the actions of DA on SON neurons in superfused rat hypothalamic explants.

Dopamine, administered by bolus injection (final concentration 100-250μM) or bath-application (1-10μM), induced slow depolarization of 3-7mV in 47 of 70 SON cells. This depolarization persisted in the presence of tetrodotoxin (2μM). Furthermore, the action of DA was mimicked by D2 agonist quinpirole (LY171555, 50μM), but not the D1 agonist SKF38393. Under voltage-clamp (V_h= -60mV), DA evoked an inward current (50-100pA, n=5), accompanied by 10-35% increase of steady-state input conductance. The current activated by DA was voltage-independent below resting potential and reversed between -18 and -35mV. The amplitude of the DA response or its reversal potential were not affected by intracellular injection of Cl^-. Thus, post-synaptic DA D2 receptors depolarize SON neurons, presumably via activation of non-selective cationic channels.
(Supported by FCAR, FRSQ, MRC).

170.11

EFFECTS OF ASCORBIC ACID, ISOASCORBIC ACID AND GLUCOASCORBIC ACID ON THE BINDING OF THE D_2 AGONIST ^{3}H-N-0437. L.C. Tolbert, J.J. Spollen*, M.L. Smitherman* and P.E. Morris*. Neuropsychiat. Res. Prog. and Dept. Psychiatry, Univ. of AL at B'ham., B'ham., AL 25294.

Ascorbic acid (AA) is a water-soluble vitamin with multiple known functions in the body. A number of investigators, using in vitro and in vivo techniques, have explored the possibility that AA may have a neuromodulatory role in CNS dopaminergic function. For example, it has been reported to modulate DA agonist binding and cyclic AMP stimulation as well as antagonizing the behavioral and physiological effets of amphetamine and potentiating the effects of haloperidol. The purpose of the present study was to evaluate the specificity of the AA effect on dopaminergic function. Binding studies were utilized as a system uncomplicated by questions of transport etc. [^{3}H] N-0437, (2-(N[2,3n)-^{3}H] propyl-N-(2-thiofuranyl)-2'-ethylamino)-5-hydroxy-1,2,3,4-tetrahydronaphathalene), was chosen as ligand for selectivity, D_2 agonist, and stability. The effects of AA, d-ascorbic acid (isoascorbic acid), and d-glucoascorbic acid on the binding of ^{3}H N-0437 to rat striatal membranes were evaluated. D-glucoascorbic acid was synthesized from published methods. The rationale for the choice of these three compounds was that they have relatively similar redox properties but if the AA effect was a specific receptor mediated phenomena the compounds should have differences in potency. Utilizing 2.5 nM ^{3}H N-0437 and increasing concentrations of the 3 compounds, in micromolor ranges, we confirmed substantial differences in their inhibition curves. The IC_{50}'s calculated from the linear transformed curves were: AA 93.3; isoasc 199.5, and glucoasc 9,549.9 μM. However, utilizing low concentrations, ≤30 nM AA, a significant enhancement in ^{3}H-N0437 binding was observed. In a similar manner, linear transformants of dissociation curves of ^{3}H-N-0437 in the presence of low concentrations, ≤30 nM, AA were inconsistent with effects on a single non-interacting binding site.

170.12

LOCALIZATION OF THE mRNA FOR DOPAMINE D2 RECEPTOR IN THE RAT BRAIN BY in situ HYBRIDIZATION HISTOCHEMISTRY. G. Mengod*, M.I. Martinez-Mir*, M.T. Vilaró*, and J.M. Palacios
Preclinical Research, Sandoz Ltd, Basel 4002, Switzerland

[^{32}P]-labelled oligonucleotides derived from the coding region of the rat dopamine D_2 receptor cDNA have been used as probes to localize in the rat brain the cells containing the mRNA coding for this receptor by using in situ hybridization histochemistry. The highest level of hybridization was found in the intermediate lobe of the pituitary gland. High mRNA content was observed in the anterior lobe of the pituitary gland, nucleus caudate-putamen and accumbens, and the olfactory tubercle. Lower levels were seen in the substantia nigra pars compacta, and ventral tegmental area as well as in the lateral mammilary body. In these areas the distribution was comparable to that of the dopamine D_2 receptor binding sites visualized by autoradiography using [^{3}H]SDZ 205-502 as a ligand. However, in some areas like the olfactory bulb, neocortex, hippocampus, superior collicullus, and cerebellum, D_2 receptors have been visualized but no significant hybridization signal could be observed. The mRNA coding for these receptors in these areas could be contained in cells outside of the brain areas, be different from the one recognized by our probes or be present at levels bellow the detection limits of our procedure. The possibility to visualize and quantify at the microscopic level the mRNA coding for the dopamine D_2 receptors will allow to gain more information about the in vivo regulation of the synthesis of these receptors and their alteration after selective lesions or drug treatments.

170.13

DOPAMINE D_2 RECEPTORS IN THE CEREBRAL CORTEX: DISTRIBUTION AND PHARMACOLOGICAL CHARACTERIZATION WITH [^{3}H]RACLOPRIDE. M.S. Lidow, P.S. Goldman-Rakic, P. Rakic and R.B. Innis, *Section of Neuroanatomy, Yale University, School of Medicine, New Haven, CT 06510*

An involvement of dopamine in the regulation of cognitive functions as well as a widespread dopaminergic innervation of the neocortex have focused attention on the identity of cortical dopamine receptors. However, while the presence and distribution of dopamine D_1 receptors in the neocortex have been well documented a comparable information on cortical D_2 sites is lacking. We report here the results of binding studies in the neocortex and neostriatum of rat and monkey using the D_2 selective antagonist, [^{3}H]raclopride. Tissue homogenates were incubated for 30 min at room temperature with 0.1-6.0 nM of the radioligand in 50 mM Tris-HCl (pH 7.4) containing 120 mM NaCl and 0.1 % ascorbic acid. Nonspecific binding was determined in the presence of 1.0 μM (+)butaclomol. A variety of ligands were used to characterize [^{3}H]raclopride binding in competition studies. In both, neocortex and neostriatum, [^{3}H]raclopride bound in a sodium dependent and saturable manner to a single population of sites with pharmacological profiles of dopamine D_2 receptors with K_d = 2.3±0.3 nM in rat and 1.1±0.3 nM in monkey tissue. D_2 sites were present in all regions of the neocortex, although their density was 50-75 times (rat) and 75-300 times (monkey) lower than in the neostriatum. The density of these sites in monkey and to a lesser extent in rat neocortex displayed a rostral-caudal gradient (B_{max} = 4.3±0.4 fmol/mg protein in rat prefrontal and 2.4±0.46 fmol/mg protein in rat occipital cortex; and B_{max} = 2.4±0.2 fmol/mg protein in monkey prefrontal and 0.6±0.1 fmol/mg protein in monkey occipital cortex). This gradient corresponds to gradient in dopamine concentration within the cortex (Brown, R.M. *et al.*, Brain Res., 168: 133, 1979). Thus, the present study establishes the presence and widespread distribution of dopamine D_2 receptors in the neocortex.

170.14

THE DOPAMINERGIC INNERVATION OF THE PRIMATE FRONTAL CORTEX. S.M. Williams*, M. Geffard and P.S. Goldman-Rakic, (SPON: W.B. Stewart) Sec. of Neuroanatomy, Yale Univ. Sch. of Med., New Haven, CT 06510 and Institut de Biochemie Cellular et Neurochemie du CNRS, Bordeaux, France.

Previous biochemical, radioautographic and tyrosine hydroxylase immunohistochemical studies have indicated that the primate cerebral cortex receives a robust and regionally heterogeneous dopaminergic innervation. So far, however, the dopamine-containing axons of the primate cerebral cortex have not been directly visualized immunohistochemically due to the lack of a dopamine-specific monoclonal antibody. Using such an antibody, we have examined the distribution of dopamine (DA) afferents in several regions of the frontal cortex of the rhesus monkey.

All regions of the frontal cortex that were examined demonstrated an elaborate dopaminergic innervation; however, regional differences were evident in their density and laminar distribution. The density of dopamine-immunoreactive (DA-IR) fibers followed a medial to lateral gradient, with the medial cortical areas receiving the most dense DA innervation. Thus, the medial prefrontal cortex (Walker's areas 25 and medial 9), the anterior cingulate cortex (AC [area 24]) and the supplementary moter cortex (SMA [area 6]) contained a higher concentration of DA-IR axons than the dorsolateral prefrontal cortex (areas 46 and 12) and the lateral primary motor cortex (area 4). In all prefrontal areas examined, analysis revealed a bilaminar distribution pattern of DA-IR processes. Labeled fibers were concentrated in the superficial layers I, II, and IIIa, intermediate in density in the infragranular layers V and VI and lowest in layers IIIb and IV. In SMA, AC and motor cortex, the superficial layers were also densely innervated but the characteristic bilaminar pattern was less prominent. These results corroborate and extend the previous findings indicating the regional and laminar specificity of the DA innervation of the non-human primate frontal cortex. Moreover, the DA innervation observed with this dopamine-specific antibody is consistent with the distribution of DA receptors in frontal cortical areas as demonstrated by *in vitro* receptor autoradiography. Electron microscopic studies are currently in progress to determine the postsynaptic targets of these DA fibers. Supported by MH44866.

PRE AND POSTSYNAPTIC MECHANISMS IN THE DISCRIMINATIVE-STIMULUS EFFECTS OF GBR 12909. K.F. Melia* and R.D. Spealman*. (SPON: P.B. Dews). Harvard Medical School, NERPRC, Southborough, MA 01772

The discriminative-stimulus effects of the dopamine transport inhibitor GBR 12909 (GBR) were studied in squirrel monkeys trained under a two-lever drug discrimination procedure. To investigate presynaptic mechanisms, several inhibitors of monoamine uptake were studied in substitution tests for GBR. Drugs with prominent effects on dopamine transport including cocaine, WIN 35,428, mazindol, bupropion, and methylphenidate occasioned 89-100% GBR-appropriate responding. In contrast, the selective norepinephrine uptake inhibitors desipramine and talsupram and the selective serotonin uptake inhibitor citalopram occasioned no more than 20% GBR-appropriate responding. To investigate postsynaptic mechanisms, D_1 and D_2 dopamine receptor agonists were tested. The D_2 agonists (+)-PHNO and quinpirole occasioned 75 - 85% GBR-appropriate responding, whereas the D_1 partial agonists R-SKF 38393 and SKF 75670 engendered no more than 10% GBR-appropriate responding. The results suggest that the discriminative-stimulus effects of GBR are mediated presynaptically by inhibition of dopamine uptake and postsynaptically by activation of D_2 dopamine receptors. A facilitating role for D_1 receptors cannot be excluded. (Supported by DA00499, DA02658, DA00088, and RR00168).

CHARACTERIZATION AND REGULATION OF D_2 DOPAMINE (DA) RECEPTORS IN RAT ANTERIOR PITUITARY TUMORS. J.Y. Lew and M. Goldstein. Neurochem. Res. Labs. N.Y. Univ. Med. Ctr., New York, NY 10016.

The binding subunits of the D_2 DA receptor in the rat anterior pituitary tumor (7315a) were identified using a photoaffinity probe N-(p-azido-m [^{125}I]iodophenethyl)spiperone (^{125}I-NAPS). The photoaffinity labeled membrane proteins were subjected to SDS-gel electrophoresis and subsequently the autoradiograms were developed. One major peptide with M.W of 32-34 KDa and two minor peptides with M.W of 87-89 KDa and 153-155 KDa were obtained. The labeling of all three peptides was prevented by incubation of membranes with non-radioactive spiperone (Spi) (10 μM) prior to the addition of ^{125}I-NAPS. The low M.W peptide might represent the deglycosylated receptor binding subunit or a proteolytic fragment of the larger peptides.

The effects of chronic treatment with haloperidol (1 mg/kg, s.c. for 4 wks) on the DA receptor density of ^{3}H-Spi binding in the tumor and in the striatum were investigated. Scatchard analysis of the data shows an increase from 94.6 to 351.7 fmole/mg protein in the tumors and an increase from 1185 to 1422 fmole/mg protein in the striata of the haloperidol-treated animals. The treatment with haloperidol did not significantly change the K_d for ^{3}H-Spi binding neither in the tumor no in the striatum. The greater increase of B_{max} for ^{3}H-Spi in the tumor as compared to the striatum might be due to the increased regulation of the D_2 DA receptor in the peripheral tissue or to the absence of D_1 receptors in the tumor. POLYMERASE CHAIN REACTION CLONING OF D2 RECEPTOR SUBTYPES. L.A. Snyder*, J. Brosius , J.L. Roberts and S.C. Sealfon*. Fishberg Research Center in Neurobiology, Mount Sinai Medical Center, New York, N.Y. 10029

The dopamine D2 receptor is an important component of brain circuitry and has been implicated in the pathophysiology of Parkinson's disease and schizophrenia. A rat brain D2 receptor has been cloned by Civelli et al. (Nature336:783). Based on the published sequence, we designed oligonucleotides for PCR cloning.

Oligo(dT) primed cDNA was synthesized from weanling rat brain RNA. When used as a PCR template, with oligos spanning the coding region, at least 2 distinct bands were observed on agarose gels. One band was the expected size of ~1250 bp. An unexpected second band, ~100 bp larger, was also seen. Both bands hybridized to an internal oligonucleotide probe. When estrogen-induced rat prolactinoma cDNA was used as a PCR template for this reaction, a single band was observed corresponding in size to the larger brain product.

Using a second set of oligonucleotides spaced 330 bp apart and spanning the known intron site of the published clone, only one PCR product was found with both brain and prolactinoma cDNA. This suggests that the unexpected larger product is not due to differences in the region immediately surrounding the intron.

Our data suggests that there is more than one D2 receptor mRNA, with tissue specific expression. There may be multiple D2 receptor genes or alternative processing of hnRNA.

CELLULAR LOCALIZATION OF D-2 DOPAMINE RECEPTOR USING CROSSLINKABLE AND PHOTOAFFINITY SPIPERONE ANALOGS, DC Chugani* and ME Phelps. UCLA School of Medicine, Los Angeles, CA 90024

We have proposed that the D-2 receptor ligand spiperone is accumulated in striatum by agonist-mediated receptor internalization (Chugani et al., (1988)J. Cereb. Blood Flow & Metab., 8:291) in order to account for the in vivo kinetics of spiperone and it analogs. This model has been tested by measurement of subcellular distribution of spiperone analogs by subcellular fractionation and immunocytochemistry. Bovine striatal slices (200 μm) were incubated for up to 24h in oxygenated Yamamoto's artificial CSF with the photoaffinity label ^{3}H-azido-methyl-spiperone (AMS) in the presence and absence of (+)butaclamol. As has been found with spiperone in vivo, the uptake of AMS in slices is slow reaching equilibrium at 8-10h. Incubation in the presence of the metabolic inhibitor sodium azide (0.2%) resulted in a large decrease in uptake, indicating an ATP-requiring process, not simply binding, was necessary for uptake. Subcellular fractionation of slices following AMS uptake revealed specific enrichment in both synaptosome and endosome fractions. Polyclonal antibodies have been raised against carboxy-oxime-spiperone (COSP)conjugated to hemocyanin. Rats were administered COSP (1 mg/kg, i.v.) and perfused 4h later with carbodiimide (1%) and glutaraldehyde (0.25%). The brain was postfixed in 4% paraformaldehyde, and vibratome sections (100 μm) were cut. Immunofluorescence revealed numerous labeled processes in striatum, and this labeling was eliminated by pretreatment of the rats with (+)butaclamol. EM studies to determine the subcellular distribution of this labeling are in progress.

EFFICACY AND POTENCY COMPARISONS AMONG APORPHINE ENANTIOMERS: EFFECTS ON SUBSTANTIA NIGRA (SN) DOPAMINE (DA) CELL FIRING. L. Martin*, R.F. Cox and B.L. Waszczak (SPON: R.A. Schatz). Pharmacol. Sect., Northeastern Univ., Boston, MA.

Extracellular single unit recording studies were carried out on male rats to determine responses of SN DA neurons to iv administration of the enantiomers of the aporphine congeners: apomorphine (APO), N-n-propylnorapomorphine (NPA), and 11-hydroxy-N-n-propylnorapomorphine (11-OH NPa). The R-(-)-configuration was found to be the most critical determinant of agonist efficacy and potency. All (-)-aporphines were full agonists able to completely inhibit DA cell firing. The order of their potencies, defined by their ID_{50}'s, was: (-)NPA, 2.0±0.4 nmol/kg>(-)11-OH NPa, 4.7±0.7 nmol/kg> (-)APO, 18.0±4.0 nmol/kg. Thus, potency was improved about 9-fold by replacing the 6N methyl of APO with an n-propyl (ie. NPA). Conversely, the 10-hydroxy was not essential for agonist activity (ie. 11-OH NPa) but could improve potency.

In the (+)-series responses varied. (+)NPA exhibited agonist properties and could fully inhibit DA cells, but its potency was low (ID_{50} 1550 nmol/kg). (+)APO produced only slight but significant decreases in firing at high (8434 nmol/kg) doses, and (+)11-OH NPa was devoid of efficacy in that it caused no significant changes in firing (n=10-17). While efficacy and potency were dramatically reduced or lost, the (+)-enantiomers apparently did retain affinity for DA receptors since they could act as antagonists if given before dose-response curves to (-)APO or NPA.

N-(p-ISOTHIOCYANATOPHENYL)SPIPERONE, A SELECTIVE IRREVERSIBLE ANTAGONIST OF D_2 DOPAMINERGIC RECEPTORS. S.X. Xu,Y. Hatada[1] Ian Creese & D.R. Sibley[1]. Rutgers' Center for Molecular & Behavioral Neuroscience, Newark, NJ 07102, [1]Experimental Therapeutics Branch, NINDS/NIH, Bethesda, MD 20892.

N-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ), an irreversible protein-modifying reagent, has been used extensively in studies involving inactivation of dopaminergic receptor subtypes. This agent is nonselective, however, as it inactivates both the D_1 and D_2 subtypes as well as many other neurotransmitter receptors. Here, we present N-(p-isothiocyanatophenyl)spiperone (NIPS), a novel, highly selective irreversible inactivator of D_2 dopaminergic receptors. In *in vitro* studies, NIPS was found to exhibit a K_i of approximately 20 nM for [^{3}H]methylspiperone binding to D_2 receptors in rat striatal membranes. The affinity of NIPS was dependent on the time of assay, however, as its potency increased with increasing times of incubation. Preincubation of the membranes with NIPS followed by extensive washing resulted in a major reduction of the D_2 receptor maximum binding capacity (B_{max}) as well as a slight decrease in affinity. In *in vivo* administration studies, using [^{3}H]SCH 23390 and [^{3}H]spiperone to assay D_1 and D_2 receptors *in vitro*, we found that 24 hr after injection (s.c) with 5-40 mg/kg of NIPS the D_2 receptor B_{max} was decreased by 58-76%, with no change in D_2 receptor affinity. In contrast, there was no effect on the D_1 receptor B_{max} or affinity. In addition to the reduced D_2 binding capacity, at 20 mg/kg, there was also a small (24%) reduction in frontal cortex 5-HT_2 receptors. However, there was no effect on alpha$_1$, alpha$_2$ adrenergic or muscarinic cholinergic receptors in the frontal cortex, nor on 5-HT_{1A} receptors in the hippocampus. Interestingly, following a single dose (s.c) of either NIPS (20 mg/kg) or EEDQ (10 mg/kg) the D_2 receptor recovery rate was slower following NIPS ($t_{1/2}$ = 169 hr) than following EEDQ ($t_{1/2}$ = 76.7hr). These results suggest that NIPS is a highly selective and irreversible inactivator of D_2 dopaminergic receptors and may prove useful in *in vitro* and *in vivo* functional studies of this receptor subtype. Interactions of Dopaminergic Metabolites at CNS Dopamine D2 Receptors. J.N. Cammack*, E. Michaelis, and R.N. Adams (SPON: A.Oke). Pharmacology Dept., Univ. of Kansas, Lawrence, KS 66046.

In-vitro binding experiments were performed on rat striatal membrane preparations using (^{3}H)spiperone, the potent butyrophenone D2 antagonist. Varying concentrations of the dopamine metabolites 3,4-dihydroxyphenyl acetic acid (DOPAC), homovanillic acid (HVA), and 3-methoxy-tyramine (3-MT) were incubated with the receptor membranes and log-dose inhibition curves were generated. These binding parameters can be compared to the inhibition of spiperone by DA. Several metabolites were as potent, or more so than DA, at blocking specific spiperone binding to this D2 site. The functional implications of these results are far ranging, especially with regard to several neuropathological states known to have a malfunctioning dopaminergic component as possible etiological factors i.e. , Parkinson's disease and schizophrenia. Continuing work in this area should provide answers to the physiological significance of DA metabolites interacting at this D2 locus (for example, whether this interaction is antagonistic or agonistic in nature).

170.22

BIPHASIC DOSE-DEPENDENT EFFECTS OF INTRASTRIATAL QUINPIROLE ON LOCOMOTOR ACTIVITY. C. Van Hartesveldt and G. A. Cottrell. Psychology Department, University of Florida, Gainesville, FL 32611.

Eilam and Szechtman (1988) reported that the D2 agonist quinpirole produced inhibition of forward progression at low doses, and sequential inhibition and excitation at high doses in rats.

We asked whether quinpirole might affect locomotion by acting directly on the dorsal striatum. Castrated male rats received 2 mg/kg or 0.02 mg/kg quinpirole sc, or saline, 20 ug or 40 ug/side quinpirole in 0.5 ul in the dorsal striatum. All rats were placed in activity monitors where activity was recorded for 2 hr.

The low dose of sc and intrastriatal quinpirole significantly decreased activity during the first 15 min but had no effect later. The high dose of sc and intrastriatal quinpirole significantly decreased activity during the first 15 min but significantly increased activity later. Thus both the inhibitory and excitatory effects of quinpirole can be elicited from the dorsal striatum.

170.23

D2 DOPAMINE RECEPTORS MEDIATE THE SUPPRESSION OF CONDITIONED AVOIDANCE RESPONDING INDUCED BY HALOPERIDOL. J.F. McElroy*, J.J. Stimmel* and J.M. O'Donnell* (SPON: D.L. Hjeresen). Life Sciences Division, Univ. of California Los Alamos National Laboratory, Los Alamos, NM 87545.

The relative importance of D1 and D2 dopamine (DA) receptors in mediating the effects of the antipsychotic drug haloperidol (HAL) on conditioned avoidance responding (CAR) in rats has been investigated. Two-way discrete trial CAR was measured in a shuttlebox. Each of 40 daily trials consisted of a 10 sec conditioned stimulus (120 dB tone) followed by a 20 sec unconditioned stimulus (0.9 mA foot shock). Drugs were administered i.p. 30 min before testing to well-trained (> 80% CAR) rats. HAL suppressed CAR in a dose-dependent manner (ED_{50}=0.07 mg/kg), with baseline responding (91% CAR) completely suppressed by 0.1 mg/kg HAL (2% CAR). Acute treatment with the D2 selective agonist quinpirole antagonized the suppressive effect produced by 0.1 mg/kg HAL in a dose-dependent manner (ID_{50}=0.4 mg/kg), with 1.0 mg/kg quinpirole completely preventing the HAL effect (94% CAR). Pretreatment with the D1 selective agonist SKF-38393 (0.1-30 mg/kg) did not antagonize 0.1 mg/kg HAL (< 16% CAR). Apomorphine (0.003-3 mg/kg), an agonist at both DA receptors, partially antagonized HAL (44% CAR). These results demonstrate that D2 receptors predominantly mediate the suppressive effect of HAL on CAR behavior. Moreover, the results with apomorphine are consistent with the existence of a functional interaction between D1 and D2 receptors.

170.24

EFFECT OF I.V. N-n-PROPYLNORAPOMORPINE (NPA) ON SUBSTANTIA NIGRA (SN) DOPAMINE (DA) NEURONS AFTER INTRANIGRAL RECEPTOR INACTIVATION BY EEDQ. R.F. Cox and B.L. Waszczak. Pharmacol. Sect., Northeastern Univ., Boston, MA 02115.

These studies explored a new approach for determining the contribution of somatodendritic autoreceptors in mediating the inhibition of SN DA cell firing caused by i.v. DA agonists. One day before extracellular single unit recording studies, male rats were given unilateral SN injections of the receptor inactivator N-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ; 6 or 12 ug/0.5 ul in 23% Molecusol vehicle, VEH). Neither EEDQ nor VEH injections significantly changed the number of active DA cells or their firing rates. However, in EEDQ-injected rats, dose response curves to i.v. NPA were shifted to the right and maximal responses were depressed relative to curves from VEH-treated rats. Interestingly both the 6 and 12 ug EEDQ injections produced similar 4-fold rightward shifts (ID_{50}'s 1.8 and 1.6 ug/kg, respectively, vs. 0.4 ug/kg in VEH-treated rats) and similar (20%) reductions in the maximal attainable response to NPA. Accordingly, Furchgott analysis showed that both doses of EEDQ inactivated 56% of the total receptors contributing to this response. The fact that both doses caused the same level of inactivation may suggest that SN DA receptors were fully inactivated with both treatments. If quantitative autoradiography (in progress) confirms this is true, it could be concluded that SN DA receptors contribute substantially (~60%), but not exclusively, to the inhibition of DA cell firing by i.v. NPA. (NS 23541)

170.25

INHIBITION OF TYROSINE HYDROXYLASE BY ENANTIOMERIC APORPHINES IN RAT STRIATAL MINCES. R.G. Booth*, N.S. Kula*, J.L. Neumeyer, and R.J. Baldessarini. Mailman Research Center, Harvard Medical School and Medicinal Chemistry Section, Northeastern University, Boston, Mass.

Effects of enantiomeric mono- and dihydroxyaporphines on rat brain tyrosine hydroxylase (TOH) were assessed by measuring formation of $^{14}CO_2$ during the synthesis of dopamine (DA) from ^{14}C-L-tyrosine in striatal minces. Stereoselectivity of presynaptic "autoregulation" of DA synthesis was probed by examining the ability of the R(-) (DA agonist) and S(+) isomers of the noncatechol apomorphine analog 11-hydroxy-N-*n*-propylnoraporphine (11-OH-NPa) and the corresponding catechol-containing congener, 10,11-dihydroxy-N-*n*-propyl-noraporphine (NPA) to inhibit TOH in the presence or absence of the DA receptor antagonist fluphenazine (FLU). R(-) and S(+)11-OH-NPa (EC_{50}=40 and 100 µM, respectively) were about 100-fold less potent than R(-) and S(+)NPA (EC_{50}=0.25 and 1.5 µM) at inhibiting TOH in striatal tissue from normal rats. Furthermore, most of the inhibition of TOH observed with the 11-OH-NPa isomers appeared to be *indirect* and DA-mediated since in reserpinized animals, >50% inhibition of the enzyme could not be achieved even at ≥100 µM aporphine. However, at least part of the inhibition could be attributed to autoreceptor mechanisms since the inhibition observed in tissue of DA-depleted rats was accompanied by an increase in stereoselectivity (2500-fold, R>S) that was fully blocked by FLU. In contrast, the dihydroxyaporphines appeared to inhibit TOH mainly via an autoreceptor mechanism since inhibition could be blocked by FLU in untreated as well as DA-depleted tissue. The stereoselectivity of the NPA enantiomers (6-fold, R>S) was similar in both DA-depleted and nondepleted animals and >90% inhibition of the enzyme was observed with 50 µM R(-)NPA in reserpinized animals (EC_{50}=1.5 µM). These studies demonstrate that synthesis of DA in its nerve terminals can be influenced stereoselectively by aporphine analogs of DA, probably via putative autoreceptor mechanisms. 171.1

IMMUNOCYTOCHEMICAL LOCALIZATION OF DARPP-32, A MARKER OF DOPAMINOCEPTIVE NEURONS, IN THE CEREBRAL CORTEX AND HIPPOCAMPUS OF RHESUS MONKEY. B. Berger, P. Greengard, P.S. Goldman-Rakic INSERM, Paris, France, Section of Neuroanatomy, Yale Univ. Sch. Med., New Haven, CT 06510, Rockefeller Univ., New York, NY.

DARPP-32 (DA-32), a dopamine (DA) and cyclic AMP-regulated neuronal phosphoprotein is specifically enriched in dopaminoceptive neurons containing D1-dopamine receptors. We have localized DA-32 like immunoreactive neurons (LIR) in the cerebral cortex of the neonatal and adult rhesus monkey. Staining was particularly good in the youngest monkeys in whom granular parietal, temporal, occipital and insula areas contained a single row of intensely stained pyramidal cells in layer Va (Vb in area 17). The cells had thick apical dendrites which branched diffusely in layer I. Smaller variably labeled neurons were present in layers IIIa and VI and/or Vb, but never in layer IV. In the prefrontal, motor, and posterior cingulate cortices, a large number of labeled neurons, including Betz cells, populated layers V and VI. In the hippocampal formation, the granule cells of the dentate gyrus and their processes (dendrites, mossy fibers and terminals, in the stratum lucidum of CA3) were intensely labeled. Deep polymorphic neurons were also positive in the subicular complex. In the one adult monkey studied so far, labeled neurons were observed mainly in the entorhinal, temporal, insular and some parietal areas. Labeling of glial cells was more prominent compared with the younger cases. The distribution of DARPP-32 neurons in the infragranular layers of the primate cortex is matched by a high concentration of D1 receptors and dopamine fibers in these layers. (supported by INSERM, Foundation Singer-Polignac and NIMH).

171.2

EFFECT OF SCH 39166, A NOVEL D1 RECEPTOR ANTAGONIST, ON CHOLINERGIC FUNCTION IN THE RAT STRIATUM. C. E. Tedford*, G. Crosby Jr.*, L. C. Iorio and R. E. Chipkin (SPON: A. Barnett).
Schering-Plough Research 60 Orange St., Bloomfield, NJ 07003.

Receptor binding studies in our laboratories have shown that a novel benzonaphthazepine (SCH 39166) displays marked selectivity toward the D1 receptor. To further characterize dopamine receptor selectivity, we utilized modulation of ^{3}H-ACh release in the rat striatum as an index of D2 receptor activity. We investigated the effects of SCH 39166 on electrically stimulated ^{3}H-ACh release from rat striatal slices. Furthermore, comparisons were made between SCH 39166 and either the selective D2 antagonist, S-sulpiride, the selective D1 antagonist, SCH 23390, or the nonselective agonist, apomorphine. Stereoselectivity was also investigated by comparing the effects of SCH 39166 and SCH 23390 on ^{3}H-ACh release with those of SCH 39165 and SCH 23388, their respective stereoisomers.

Results indicated that apomorphine inhibited ^{3}H-ACh release from striatal slices (I.C. $_{50}$ - 0.31 uM). The D2 receptor antagonist, S-sulpiride caused a slight increase in ^{3}H-ACh release alone, and completely reversed the inhibition of ^{3}H-ACh release seen with apomorphine. In contrast, SCH 39166, as well as, SCH 23390 did not reverse the inhibition of ^{3}H-ACh release induced by apomorphine. Interestingly, at high concentrations, both D1 antagonists (SCH 23390 and SCH 39166) inhibited ^{3}H-ACh release. This effect however was not stereoselective and thus probably not related to D1 receptor blockade.

In summary, these studies indicate that the benzonaphthazepine, SCH 39166, represents a novel and selective D1 receptor antagonist.

171.3

EFFECTS OF 6-HYDROXYDOPAMINE LESIONS ON DOPAMINE UPTAKE SITES AND ON DOPAMINERGIC AND MUSCARINIC RECEPTORS IN THE RAT NIGROSTRIATAL SYSTEM. D. Vine*, F.Filloux, J.K. Wamsley, Dept. Psychiat., Univ. Utah Sch. Med., SLC, UT 84132.

Male rats received unilateral 6-hydroxydopamine injections of the medial forebrain bundle or substantia nigra compacta (SNc). Three weeks later, lesion efficacy was demonstrated by circling in response to apomorphine and D-amphetamine. Rats were sacrificed 4 weeks after injection and slide-mounted coronal tissue sections (10μ) were labeled with [^{3}H]BTCP, [^{3}H]SCH 23390 and [^{3}H]QNB to identify dopamine (DA) uptake sites, D1 and muscarinic (AChM) receptors, respectively. There was a marked loss of DA terminals in the ipsilateral caudate-putamen (CPu) of lesioned vs. control rats as indicated by a marked decrease in [^{3}H]BTCP binding of 73% ($p<0.0005$). There were smaller decreases in binding (27-43%, $p<0.05$) in the ipsilateral SNc and substantia nigra reticulata (SNr), indicating partial DAergic denervation of the SNr. Despite this modest DAergic denervation, there was no change in [^{3}H]SCH 23390 (D1) binding in the SNr. This last result could be due to reported D1 "receptor reserve." [^{3}H]QNB binding in the CPu ipsilateral to the lesion was reduced by 12.5% ($p<0.05$). This could derive from loss of posited AChM heteroreceptors on DAergic terminals, or from down-regulation of post-synaptic AChM receptors on GABAergic neurons due to increased ACh release from striatal neurons disinhibited by loss of DAergic input.

171.4

PHARMACOLOGICAL PROFILE OF THE BINDING OF [^{125}I] SCH 23982 IN HUMAN BRAIN. M. Laruelle*, A. Sidhu, M. Casanova*, D.R. Weinberger and J.E. Kleinman. NIMH Neurosciences Center at St. Elizabeths, Washington, D.C. 20032.

The benzazepine [^{3}H]SCH23390 is commonly used to label the D_1 dopaminergic receptor. Recently an iodinated analogue, [^{125}I]-SCH23982, was introduced (Sidhu et al, Eur J Pharmac, 128:213,1986). We studied the binding of this ligand in the human caudate nucleus (CN) and mid frontal gyrus (MFG). In CN, we observed a single saturable site ($K_d = 4.8 \pm 0.92$nM (Means $\pm$ SEM, n = 3), $B_{max} = 276 \pm 22$ fm/mg Protein). Competitive experiments were in accordance with the D_1 pharmacology. In MFG, the K_d was 3.8 ± 0.95nM and the B_{max} was 352 ± 37 fm/mgP. The observed B_{max} in MFG was thus about 13% of the B_{max} in CN. This contrasts with the distribution of the dopaminergic innervation in the human brain but is compatible with an interaction of these ligands with the serotonergic $5HT_2$ receptor. The $5HT_2$ antagonist ketanserin displaced [^{125}I]SCH23982 in a monophasic manner ($K_i = 150$nM) in CN but in a biphasic manner in the MFG ($K_{i_1} = 1.4$nM, 89%, and $K_{i_2} = 656$nM, 11%). Adding ketanserin to the incubation medium (50nM final concentration) induced no changes in the B_{max} in CN but a 82% reduction in MFG. Competition studies with dopamine (DA) and serotonin (5HT) gave the following order of potency: in CN, DA > > 5HT; in MFG 5HT > > DA; in MFG with 50nM ketanserin, DA > 5HT for [^{3}H]SCH23390 and 5HT > DA for [^{125}I]SCH23982. It can be concluded that [^{125}I]SCH23982 labels the D_1 receptor in human CN and the $5HT_2$ receptor in human MFG. As this phenomenon is more marked than with the tritiated ligand, it can be suggested that the iodination decreases the relative D_1 to $5HT_2$ selectivity of this compound.

171.5

STRIATONIGRAL LESIONS AND INTRANIGRAL INJECTION OF RECEPTOR INACTIVATOR EEDQ PREVENT D-1 AGONIST EFFECTS ON SUBSTANTIA NIGRA PARS RETICULATA (SNpr) NEURONS. B.L. Waszczak and L. Martin*. Pharmacol. Sect., Northeastern Univ., Boston, MA.

Previous studies revealed that iontophoretic application of dopamine (DA) or the D-1 agonist SKF 38393 (SKF) causes current-related increases in firing of SNpr neurons. These studies were undertaken to assess whether the excitatory effect of SKF was attributable to activation of D-1 receptors on striatonigral terminals in the SNpr. Extracellular single unit recordings were made in anesthetized male rats which received either: 1) striatal injections of kainic acid (KA; 1 ug/0.5 ul at 2 sites) 1-2 wks prior, or 2) intranigral injections of the receptor inactivator N-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ; 12.5 ug/0.5 ul 22.5% Molecusol) 24 hrs prior to recording. Both treatments prevented the excitatory effects of applied (+)SKF (0.05M) on SNpr cells. In KA-lesioned rats, cells which could not be inhibited by striatal stimulation (indicating their striatal inputs were destroyed) showed only modest (9±5%) increases in firing at 10 nA (+)SKF, whereas cells still sensitive to striatal stimulation (inputs intact) had increases to 73±14% above baseline (n=8-11), like unlesioned rats. After intranigral EEDQ, (+)SKF increased firing only 11±5% above baseline at 8 nA while controls exhibited 61±16% increases at 8 nA (n=11-13). These results suggest that the previously described excitatory effect of DA and SKF on SNpr cells is mediated by activation of D-1 receptors on impinging striatonigral terminals. (Support: NS 23541)

Synthesis of an aldehyde-containing analog of SCH-23390. T.Filtz*, S.Chumpradit*, H.Kung* and P.Molinoff. Departments of Pharmacology and Radiology, Univ. of PA, Philadelphia, PA 19104

SCH-23390 is a high affinity antagonist selective for D_1 dopamine receptors. This antagonist does not contain a functional group that can be conveniently coupled to commercially available resins for affinity chromatography or to photolabile compounds for photoaffinity labelling of receptors. To construct an affinity resin for purification of dopamine D_1 receptors an aldehyde analog of SCH-23390, (RS)-5-(4'-formyl phenyl)-8-chloro-2,3,4,5-tetrahydro-3-methyl-[1H]-3-benzazepin-7-ol (Aldehyde-SCH-23390), was synthesized. 7-Methoxy-4'-bromo-phenyl SCH-23390 was lithiated, formylated and then demethylated to form the aldehyde. NMR and IR analyses were performed to characterize the product. Aldehyde-SCH-23390 displaced ^{125}I-SCH-23982 binding from caudate membranes with a K_i value of 3 nM. The placement of an aldehyde group on the phenyl ring allows for easy coupling of the antagonist to primary amines. Aldehyde-SCH-23390 has been coupled to diaminodipropyl-amine agarose for affinity chromatography. The aldehyde has also been conjugated with biotin-hydrazide for fluorescent labelling of dopamine D_1 receptors. (USPHS NS18591 and NS24538)

Aldehyde-SCH-23390

^{3}H-SCH 39166, A NEW D-1 SPECIFIC RADIOLIGAND: IN VITRO AND IN VIVO BINDING PROPERTIES. R.D. McQuade, G.C.Crosby*, R.A.Duffy * & R.E.Chipkin, Schering-Plough Corp., Bloomfield, NJ 07003

A new radioligand, ^{3}H-SCH 39166 ([-]trans 6,7a,8,9,13b-hexahydro-3-chloro-2-hydroxy-N-(^{3}H)methyl-5H-benzo[d]naphtho-{2,1-b}-azepine, 81 Ci/mmole) has been characterized for its binding to rat striatal membranes. In vitro, ^{3}H-SCH 39166 labels a single class of saturable receptors, with a K_D of 1.7 nM. Competition studies with dopaminergic antagonists demonstrate that binding is D-1 selective and stereospecific. Dopamine yields a biphasic inhibition curve with K_I values of 0.2 and 2.6 uM. The high affinity sites are converted to low affinity by addition of 0.1 mM GPP(NH)P, with all sites exhibiting a single K_I of 2.4 uM.

In vivo, ^{3}H-SCH 39166 labels striatal membranes with optimal binding 1 h after subcutaneous injection. This labeling exhibits both pharmacological specificity (1 umole of SCH 23390 inhibits 90% of the striatal binding) and tissue selectivity (specific cerebellar levels are less than 5% of specific striatal levels).

These data demonstrate that ^{3}H-SCH 39166 is a selective D-1 radioligand, both in vitro and in vivo.

171.8

AGONIST-INDUCED DESENSITIZATION OF D_1 DOPAMINE RECEPTOR-COUPLED ADENYLYL CYCLASE ACTIVITY IN CULTURED NS20Y NEUROBLASTOMA CELLS. Anne C. Barton and David R. Sibley. Experimental Therapeutics Branch, NINDS, NIH, Bethesda, MD 20892.

NS20Y neuroblastoma cells, which express a homogeneous population of D_1-dopamine (DA) receptors, were used in the present study as a model system to demonstrate agonist-induced stimulation and desensitization of D_1 receptor-coupled adenylyl cyclase (AC) activity. Membranes prepared from NS20Y cells showed a dose-dependent increase in cAMP production in response to various dopaminergic agonists. DA exhibited an EC_{50} of 5 μM and a maximal response of 3-4 fold over basal at 100 μM DA which could be antagonized by the active stereoisomers of SCH-23390 and butaclamol. A 1 hr preincubation of NS20Y cells with 100 μM DA induced homologous desensitization of D_1 receptor-coupled AC activity, decreasing DA- but not PGE-, adenosine- or forskolin-stimulated cAMP production. Desensitization was both dose and time dependent. As early as 5 min after preincubation with 100 μM DA, cAMP production was decreased by 45-50% with maximal desensitization (85-90% reduction) occurring by 60 min. Desensitization of D_1 receptor-coupled AC activity decreased the maximal amount of cAMP produced with no decrease in potency for DA-stimulated AC activity. Observed EC_{50} values for control and partially desensitized NS20Y cell membranes were ≈ 5 μM. Examination of [^{3}H]-SCH-23390 binding in control and maximally desensitized NS20Y cell membranes revealed no change in K_D, however, a 65% decrease in receptor number was observed. This decrease in D_1 receptor number does not appear to correlate with the 85-90% decrease in DA-stimulated AC activity after a similar desensitization suggesting a possible functional uncoupling of the D_1 receptor from its effector in addition to receptor downregulation.

171.9

EXPRESSION OF RAT STRIATAL mRNA CODING FOR A D_1 DOPAMINE RECEPTOR COUPLED TO Ca^{2+} MOBILIZATION IN *XENOPUS* OOCYTES. F.J. Monsma, Jr.[1], R.M. Burch[2]*, D.R. Sibley[1], & L.C. Mahan*. Laboratory of Cell Biology, NIMH, [1]Experimental Therapeutics Branch, NINDS/NIH, Bethesda, MD 20892 & [2]Nova Pharmaceutical Corp, Baltimore, MD 21224.

D_1 dopamine (DA) receptors have been classically defined as being coupled to activation of adenylate cyclase activity. We have examined the possibility that additional transduction pathways exist for D_1 receptors by using functional expression assays in *Xenopus* oocytes that have been injected with rat striatal poly (A+) RNA (mRNA). Defolliculated oocytes were assayed electrophysiologically 72 hr after injection with 50 ng of striatal mRNA. Application of 0.1 mM DA induced an inward current (40-100 nA) that was consistent with the activation of the endogenous oocyte Ca^{2+}-dependent Cl^- channels. This current could also be elicited by the addition of the D_1-selective agonist, SKF-38393 but not by the selective D_2 agonist, quinpirole. Prior addition of the DA antagonist cis-piflutixol completely abolished the DA-induced current but had no effect on the serotonin (5HT)-induced current which is also expressed from striatal mRNA. 0.1 mM DA was also found to stimulate $^{45}Ca^{2+}$ efflux by 2-3 fold in striatal mRNA-injected oocytes. This response was mimicked by SKF-38393 and blocked by the D_1-selective antagonist, SCH-23390. No efflux was observed with 0.1 mM quinpirole and the DA response was not blocked with 0.1mM of domperidone, a D_2-selective antagonist. Assay of size-fractionated striatal mRNA using the oocyte/$^{45}Ca^{2+}$ efflux assay revealed a single peak of DA-stimulated activity corresponding to an mRNA size of 2.5-3.0 kb. Oocytes which were injected with the peak mRNA fractions then prelabeled with *myo*[^{3}H]inositol, additionally showed a 4-fold increase in IP_3 production in response to DA. These data suggest the existence of CNS D_1 receptors which are coupled to PI turnover and Ca^{2+} mobilization as well as D_1 receptors which activate adenylate cyclase activity.

THE D1 DOPAMINE (DA) RECEPTOR DOES NOT REGULATE DA SYNTHESIS IN STRIATAL SLICES: ANOMALIES WITH SKF 38393. R.J. Brooderson F.J. White and M.P. Galloway. Depts. Pharmacol. & Psychiat., CCN Program., Wayne St. Univ. Sch. Med., Lafayette Clinic, Detroit, MI 48207.

DA synthesis is controlled, in part, by nerve-terminal D2 autoreceptors. In view of a recent report that D1 receptors may also exist on DA terminals and control membrane excitability (Diana et al. Neuropharmacol. 28, 1989), we sought to determine the existence of synthesis modulating D1 autoreceptors. In a rat striatal slice preparation possessing functional D2 autoreceptors, the D1 selective agonist SKF 38393 produced a concentration dependent (0.3-10 μM) decrease of NSD 1015-induced DOPA accumulation which was neither stereoselective nor blocked by the D1 antagonist SCH 23390. In contrast to SKF, CY-208-243 (0.03-10 μM) a non-catecholic D1 agonist produced only a weak inhibition of DOPA accumulation. This effect was blocked by the D2 antagonist eticlopride (3 μM), but not SCH 23390, suggesting D2 receptor involvement. Since the effects of SKF on DA synthesis do not appear to be D1 receptor-mediated and since catechols, such as SKF, directly inhibit tyrosine hydroxylase (TH), SKF may inhibit TH directly after entry into DA cells. However, nomifensine (3 μM), which blocks the DA transporter, blocked the effects of only the lowest concentration of (-)SKF, suggesting that SKF also enters DA cells through membrane diffusion. Thus, the effects of SKF on DA synthesis in vitro do not appear to be mediated through D1 receptors on striatal DA terminals. Supported by DA-4120, MH-41227 (MPG).

D-1 DOPAMINE STIMULATION OF cAMP ACCUMULATION IN COS-1 AND MOUSE L CELLS. M.E. Steffey*, R.W. Barrett, S.J. Fink, R.R. Bhatt*, E. Gomez* and R.G. MacKenzie. Neuroscience Research Division, Pharmaceutical Discovery, Abbott Laboratories, Abbott Park, Il 60064 and Dept. Neurology, Massachusetts General Hosp., Boston, MA 02114.

We have screened a variety of cell lines for D-1 dopamine responsiveness and report here that the COS-1 and mouse L cell lines have endogenous functional D-1 dopamine receptors as measured by cAMP accumulation. Cells in 24-well plates were washed with EBSS and pre-incubated for 10 min in EBSS containing 0.5mM IBMX. Following the addition of agonist or agonist plus antagonist, the cells were incubated for 15 min and cAMP accumulation was terminated by the addition of 0.1N HCl. The cAMP released from the cells was acetylated and measured by radioimmunoassay. Dopamine stimulates cAMP accumulation 8-fold above basal with an EC_{50} of 0.6μM in COS-1 cells and 3-fold above basal with an EC_{50} of 0.5μM in L cells. Moreover, both cells exhibit a D-1 pharmacologic profile for the stereoisomers of the agonists (-)-apomorphine > (+)-apomorphine and (+)-SKF-38393 > (-)-SKF-38393 and antagonists (+)-SCH-23390 > (-)-SCH-23388 and cis(Z)-flupenthixol > trans(E)-flupenthixol. The COS-1 cell also exhibits a pronounced β-adrenergic stimulation of cAMP accumulation (10-fold above basal, isoproterenol EC_{50} = 12nM) but this is clearly dissociable from the dopamine response by: (1) selective antagonists and (2) desensitization studies in which pre-incubation with dopamine or isoproterenol results in homologous desensitization of the dopamine or β-adrenergic response respectively.

171.12

DOPAMINE RECEPTORS LINKED TO ADENYLATE CYCLASE IN CULTURED ENDOTHELIUM DERIVED FROM HUMAN CEREBRAL MICROVESSELS. F. Bacic*, R.M. McCarron* and M. Spatz, (Sponsor: E. Streicher) Lab. of Neuropathology and Neuroanatomical Sciences, NINDS, NIH, Bethesda, MD 20892

Dopamine as a vasoactive substance can affect both peripheral and cerebral arteries. The contractile activity of dopamine is mediated by α-adrenergic and serotoninergic mechanisms while dilatation of the vessels is associated with D_1-receptors. This report will demonstrate the presence of dopamine D_1-receptors linked to adenylate cyclase (AC) activity in cultured endothelium derived from cerebral microvessels of human brain. A modified technique of Gerhart et al., (Brain Res., 21: 785, 1988) was used for isolation, separation and cultivation of dissociated cerebral microvascular endothelium. The cultured endothelium derived either from capillaries or small (<100 μM) or large (>100 μM) arterioles and venules stained positively for Factor VIII-related antigen and was negative for GFAP. AC activity of endothelium derived from small microvessels exhibited a dose-dependent response to dopamine ($EC=6x10^{-7}M$). All other fractions demonstrated significant but less responses to dopamine ($10^{-5}M$). D_1- but not D_2- antagonists [SCH-23390, RC(+) and sulpiride (S-), respectively] inhibited the dopamine stimulated formation of cAMP in small microvessels. These findings indicate the existence of dopaminergic D_1-receptors linked to AC in human cerebrovascular endothelium.

PHARMACOLOGICAL CHARACTERIZATION OF THE TWO RECEPTORS LABELED BY ^{3}H-SCH-23390 and ^{3}H-MESULERGINE IN HUMAN CHOROID PLEXUS. S.J. Boyson and L. O'Keefe. Depts. of Neurology and Pharmacology, Univ. of Colorado Health Sciences Center, Denver, CO 80262.

^{3}H-SCH-23390 and ^{3}H-mesulergine each label two sites in the choroid plexus of several species. The pharmacological characteristics of these sites were investigated in choroid plexus and in caudate-putamen (as a reference tissue) collected at post-mortem within 36 hours after death. Membranes were prepared and kept at -70°C until use. No patient had had recent exposure to neuroleptics. Membranes were incubated in 2 nM ^{3}H-SCH-23390 with a competing drug for 100 min, washed and collected by filtration. Assays were carried out in triplicate three times. Displacement by virtually all ligands revealed two sites. Drugs which discriminated two sites included D_1/D_2 antagonists (α-flupenthixol, fluphenazine), D_1-selective (NO-756 & SKF-81297), D_1/5-HT_{1c} ((R)-SCH-23390, (S)-SCH-23388, (R)-SKF-83566), 5-HT_{1c} (mesulergine), 5-HT_{1c}/5-HT_2 (ketanserin), and ß-adrenergic (propranolol). Displacement curves obtained by nonlinear regression analysis (PROPHET) revealed that the split of sites with all discriminating drugs was approximately 1:2 in the choroid plexus. The latter site is the 5-HT_{1c} receptor. Binding in the caudate-putamen was also examined. Correlation of the IC_{50} values obtained for the second site in the choroid plexus and the D_1 receptor in the caudate-putamen revealed that the receptor in the choroid plexus was not identical to the D_1 receptor in the caudate-putamen (r^2 = 0.4).

D_1 DOPAMINE AGONIST INDUCES C FOS PROTEIN IN THE STRIATUM OF 6-OHDA-LESIONED RATS. R.A. Mueller, L.M. Grimes, H. Criswell, L.S. Carter*, W.C. McGimsey*, W. Stumpf, and G.R. Breese. Depts. of Anesthesiology, Cell Biology and Anatomy and BSRC, UNC-Chapel Hill, NC 27599.

Induction of the proto-oncogene c fos has been correlated with neural activation in selected brain regions (Science, 1988, 240:1328). The purpose of the present study was to examine the pattern of D_1 agonist induced c fos expression in rats treated as neonates to destroy nigrostriatal dopminergic neurons. Nine rats (3 controls, 6 lesioned) were given injections of SKF-38393 (3 mg/kg). Two hours later, rats were perfused with 4% paraformaldehyde and 0.2% glutaraldehyde. Serial Vibratome sections taken throughout the brain were stained for c fos, and tyrosine hydroxylase (TH). Staining for TH in the mesencephalic dopaminergic system in the lesioned rats revealed that most TH positive cells were absent with only a few cells surviving in the ventral tegmental area (VTA) and dorsal substantia nigra (SN). Expression of c fos was absent in control rats given SKF-38393. In lesioned rats, strong labeling of c fos was noted in the caudate (CP) with a dorsolateral to ventral medial gradient. No expression of c fos was observed in any site with even minimal sparing of TH containing fibers. These results suggest a sensitivity of c fos expression to the D_1 agonist in CP, but other neural systems involved in the behavioral responses do not respond with changes in c fos protein accumulation. (NS 21345 and HD 23042.)

EFFECTS OF BILATERAL ANTEROMEDIAL PREFRONTAL CORTICAL LESIONS ON DOPAMINE AGONIST INDUCED BEHAVIORS IN THE RAT. A.R. Braun, G.E. Jaskiw, R.H. Sexton, K. Vladar* and D.R. Weinberger, CBDB, NIMH Neurosciences Center at St. Elizabeths, Washington, D.C. 20032

The behavioral effects of apomorphine (APO) and of the selective D1 and D2 dopamine receptor agonists SKF 38393 (SKF) and LY 171555 (LY) were evaluated in rats that had received bilateral ibotenic acid lesions of the antero-medial prefrontal cortex (AMPC) (5 g/ 1 AP +3.5, ML +0.7, VD -3.5mm) and sham lesioned controls after a miminum 6 week recovery period. Lesioned (LES) animals treated with SKF 32 mg/kg were more active, expressed a greater variety of behaviors and displayed significantly more vigorous grooming (a behavior specifically elicited by D1 receptor stimulation). LES animals treated with LY 3 mg/kg displayed less non-stereotypic sniffing and grooming and more compulsive sniffing and oral stereotypy. In LES animals treated with the combination of LY and SKF, the frequency of weaker sniffing stereotypies was significantly decreased. These animals expressed more intense compulsive oral stereotypies, as did LES animals treated with 1.25 mg/kg APO. The induction of typical unconditioned behaviors by dopamine agonists does not appear to require the presence of an intact AMPC, but this cortical area may significantly modify the behaviors expressed. Lesions of the AMPC may result in increased sensitivity of D1 receptor associated mechanisms in subcortical areas or other regions of cortex.

171.16

IN VITRO INTERACTION OF L-PROLYL-L-LEUCYL-GLYCINAMIDE WITH DOPAMINE D_1 RECEPTOR AND ITS MODULATION OF D_1 RECEPTOR. S.K. Gupta*, R.L. Johnson*+ and R.K. Mishra. Neuropharmacol. Lab., McMaster Univ., Health Sciences Centre, Hamilton, ON, Can., L8N 3Z5; +Dept. of Medicinal Chem., Univ. of Minnesota, Minneapolis, MN, USA, 55455.

Earlier reports have demonstrated the modulation of CNS dopamine D_2 receptor by PLG and its active analogues. In the present abstract, we report the interaction of PLG with brain dopamine receptor D_1 receptor in vitro. PLG caused an increase in specific binding of [^{3}H]SKF-38393 to bovine striatal membranes in a dose-dependent manner, the maximum effect was observed at 1 µM. Scatchard analysis of [^{3}H]SKF-38393 revealed that there was no change in K_d, however, there was an appreciable increase (B_{max}). The competition curves [^{3}H]SCH-23390/SKF-38393 in the presence of 1 µM PLG displayed an increase in the B_{max} of high-affinity binding sites without an apparent change in K_d. Also, 1 µM PLG protected the high-affinity site even in the presence of 100 µM 5'-guanylylimidodiphosphate. These results demonstrate, in vitro, regulation of the dopamine D_1 receptor by either exposing the unmasked sites of the receptor or by changing the conformation of the receptor (supported by OMHF and NIH).

CHARACTERISATION OF THE DOPAMINE RECEPTOR MEDIATING THE ELECTRICAL RESPONSE OF THE COCKROACH SALIVARY GLAND TO NERVE STIMULATION. A.M.Evans* and K.L.Green*. (SPON: Brain Research Association). Dept. of Pharmacology, Edinburgh University, Edinburgh, EH8 9JZ, U.K.

Stimulation of the nerve supplying the cockroach salivary gland *in vitro* induces secretion, with an associated membrane hyperpolarisation which can be measured using intracellular microelectrodes. Previous studies (House, C.R., *Biol. Rev.*, 55:417, 1980) have shown that dopamine is the transmitter at this synapse. We have used selective dopamine agonists and antagonists to characterise the post-synaptic receptor involved. The effect of nerve stimulation is mimicked by dopamine applied by perfusion (5×10^{-8}M) or locally by pressure ejection from a broken microelectrode. Perfusion with either the DA_1 agonist SK&F38393 ($>10^{-6}$M) or the DA_2 agonist quinpirole, LY171555 ($\geq 10^{-4}$M) also induced a hyperpolarisation. The responses to nerve stimulation and to locally applied dopamine, SK&F38393, and quinpirole were inhibited following perfusion with the DA_1 antagonist (±)SCH23390 (10^{-5} to 10^{-4}M). The DA_2 antagonist (±)sulpiride ($\leq 10^{-4}$M) had no effect on the responsiveness of the preparation. It is concluded that the dopamine receptor mediating the membrane hyperpolarisation of cockroach acinar cells is similar to the DA_1 sub-type found in vertebrates.

THE RESPONSES OF SUBSTANTIA NIGRA PARS RETICULATA NEURONS TO GABA AND SYSTEMIC SKF 38393 IN 6-HYDROXYDOPAMINE-LESIONED RATS ARE REDUCED BY INTERMITTENT BUT NOT CONTINUOUS LEVODOPA ADMINISTRATION. B.G. Weick, T.M. Engber, Z. Susel*, T.N. Chase and J.R Walters. NINDS, Bethesda, MD 20892

The *intermittence* of levodopa (LD) administration has been implicated in the development of motor fluctuations in parkinsonian patients. Behavioral studies have indicated that *intermittent* LD administration but not *continuous* infusion of LD (adjusted to give a similar average daily blood level) abolishes the rotational response to systemic D-1 agonist SKF 38393 administration in rats with 6-hydroxydopamine-induced nigrostriatal dopamine pathway lesions (NSL). Since systemic SKF 38393 administration reduces firing rates of neurons in the substantia nigra pars reticulata (SNpr), a basal ganglia output nucleus, in NSL rats but not in unlesioned rats, we have examined the effects of *continuous* and *intermittent* LD on this response and on the sensitivity of these neurons to iontophoresed GABA. As in the behavioral experiments, we found that *intermittent* but not *continuous* LD abolished the response of SNpr neurons to SKF 38393, 10 mg/kg i.v. (1 ± 14% increase and 54 ± 11% decrease, respectively; no-LD NSL rats, 39 ± 11% decrease, n = 9-11). *Intermittent* but not *continuous* LD also reduced GABA-mediated inhibition in SNpr (30 ± 11% and 62 ± 11%, respectively; no-LD NSL rats, 67 ± 8%; unlesioned controls, 31 ± 9%, n = 9-16). These data support the behavioral observations indicating that the intermittence of LD administration is important in determining the response to dopamine receptor stimulation in this animal model of parkinsonism. The results further suggest that LD treatment schedule affects the tonic activity of GABAergic striatonigral neurons, inducing changes in GABA receptor sensitivity in the SNpr which contribute to the SKF 38393-mediated effects

172.1

BIOCHEMICAL AND ULTRASTRUCTURAL APPROACH OF DOPAMINE RECEPTORS IN THE RAT BRAIN USING ANTI-IDIOTYPIC DOPAMINE ANTIBODIES. N. MONS, M. GEFFARD, P. DUBOURG* and A. CALAS. Neuroimmunology, IBCN-CNRS. and *Neurobiology URA 339 CNRS, Bordeaux, FRANCE.

Alternative immunizations with poly- and monoclonal anti-dopamine (DA) antibodies allowed us to induce a highly anti-idiotypic response in rabbits. In order to remove anti-isotypic and anti-allotypic antibodies, the anti-idiotypic antibodies (Ab2) were affinity-chromatographed on mouse and rabbit non-specific immunoglobulins linked to cyanogen-bromide activated ACA-22 .Using ELISA tests, the capacity of Ab2 to bind to poly- and monoclonal idiotypic sites was evaluated by competition experiments. The Ab2 specifically recognized both poly-clonal and monoclonal anti-DA antibodies. Their ability to recognize DA receptors was demonstrated (1) by (3H)DA displacement and (2) by competition experiments between the Ab2 and different conjugates for the binding to membranes enriched with DA receptors. Our results demonstrate that these Ab2 were the internal images of conjugated DA. The Ab2 were used for ultrastructural preembedding immunocyto-chemistry on vibratome sections with paraformaldehyde fixation and PAP technique. In the striatum, most of the immunoreactive structures were post-synaptic thickenings on dendritic spines and more rarely on dendrites. Presynaptic labellings were very rare. In some cases the same terminal was in contact with two post-synaptic thickenings, only one of them being labelled. These results show that our anti-idiotypic antibodies can specifically recognize DA receptors and offer new perspectives for the structural and biochemical characterization of these receptors.

172.2

SELECTIVE UNILATERAL INACTIVATION OF STRIATAL DOPAMINE (DA) D1 OR D2 RECEPTORS BY N-ETHOXY-CARBONYL-2-ETHOXY-1,2-DIHYDROQUINOLINE (EEDQ): A NOVEL ROTATIONAL MODEL. O. Giorgi and G. Biggio. Dept. of Exp. Biology, Univ. of Cagliari, Italy.

The unilateral intrastriatal infusion of the irreversible DA receptor blocker EEDQ induces a significant decrease in the density of D1 (-48%) and D2 (-45%) DA receptors; in this experimental conditions, the systemic administration to rats of the selective D2 agonist LY 171555 results in ipsilateral rotations (Giorgi and Biggio, Soc. Neurosci. Abs. 14, 453, 1988). The selective D1 agonist SKF 38393 (10 mg/kg i.p.) fails to induce rotations "per se" but potentiates the circling behavior elicited by LY 171555. LY 171555 is unable to induce rotations in EEDQ treated rats following DA depletion by α-methyl-p-tyrosine, whilst the combined administration of LY 171555 and SKF 38393 elicits intense circling behavior in DA depleted rats. Finally, a selective inactivation of striatal D1 or D2 DA receptors can be obtained by the administration of EEDQ plus raclopride or EEDQ plus SCH 23390, respectively. LY 171555 elicits rotations in rats with a selective blockade of D2 DA receptors, but has no effect in animals in which D1 DA receptors have been selectively inactivated. These results support the view that D1 DA receptors play a permissive role in the expression of the motor effects mediated by striatal D2 DA receptors.

172.3

MOLECULAR BIOLOGICAL STUDIES OF D1 AND D2 DOPAMINE RECEPTORS. A.J. MacLennan*, W. Xu*, M. Khrestchatisky*, M.B. Jackson and A.J. Tobin (SPON: C. Sternini). Dept. of Biology, UCLA, Los Angeles, CA 90024

Adult, male Wistar rats were treated with haloperidol for 3 weeks at increasing doses of 2 to 4 mg/kg/day. Poly A RNA was isolated from their frontal cortex and striatum and then injected into Xenopus oocytes. Oocytes injected with striatal RNA responded to 10 uM dopamine (DA) and the D1 DA receptor agonist SKF 38393 (10 uM) when tested with the voltage clamp technique 5 to 8 days after injection. These DA-induced inward currents were significantly reduced by the D1 DA receptor antagonist SCH 23390 (10uM) and significantly increased by the D2 receptor antagonist sulpiride (100 uM). Oocytes injected with RNA transcribed from a cDNA library display "D1" receptor responses. In addition, we have identified three cDNA clones that hybridize at medium stringency to oligonucleotide probes which correspond to a published D2 DA receptor sequence (Nature 336: 783-787, 1988). This work was supported by a grant to AJT from the Scottish Rite Schizophrenia Research Program. AJM was supported in part by a Canadian MRC Fellowship.

172.4

CHARACTERIZATION OF DOPAMINE RECEPTORS IN AN IMMORTALIZED DOPAMINERGIC CELL LINE. M. Wainwright*, B.D. Perry, H.K. Choi, A. Heller, and P.C. Hoffmann. (SPON: J.E.G. Williams) Depts. Psych, Pharmacol/Physiol, Univ Chicago, Chicago, IL 60637

Immortalized dopaminergic (DA) cells were prepared by the fusion of fetal (embryonic day 18) rostral mesencephalic tegmental (RMT) cells with N18 TG2 neuroblastoma cells (Choi et al, Neurosci Abstr. 14, 319, 1988). 125I-SCH 23982 (SCH:D1) and 125I- or 3H-Spiperone (SPIP:D2) were used to label DA receptor binding sites. SCH specific binding, defined by (+)Butaclamol was saturable and reversible. Saturation studies obtained a Kd of 0.5 nM and a Bmax of 35 fmol/mg prot. Drug competition at SCH sites was consistent with that of a D1 receptor with (+)butaclamol > chlorpromazine >> haldol > serotonin. SPIP saturation studies obtained a Kd of 0.35 nM and a Bmax of 3-7 fmol/mg prot. DA stimulated adenylate cyclase (AC) activity was demonstrated and was greater in the presence of haldol suggesting functional coupling of both D1 and D2 sites to AC. These immortalized cells may prove useful for examining aspects of dopamine receptor regulation.

STRIATAL cAMP RELEASE IN-VIVO: EFFECTS OF SKF38393 AND SCH23390 P.H. Hutson and N. Suman-Chauhan. (SPON: E. Wong) MSD, Neuroscience Research Centre, Terlings Park, Harlow, Essex, UK. The technique of intracerebral dialysis has been used to monitor the extracellular concentration of striatal cAMP in response to activation of dopamine receptors by the selective D1 agonist SKF38393. Rats (250-350g) were anaesthetised with chloral hydrate (400mg/kg ip) and implanted with a dialysis probe in the striatum. The probe was perfused continuously at 2µl/min with Krebs Ringer pH 7.4 containing IBMX (1mM) and after 1h, serial 20min samples were collected for determination of cAMP by RIA (Amersham UK) All drugs were dissolved in Ringer containing IBMX and administered via the probe for 20 min (agonists) or 40 min (antagonists). In-vitro recovery of cAMP was 22 ± 5.6% 2µl/min (mean ± SEM, n=4). Basal values for striatal extracellular cAMP concentration in the anaesthetised rat were 16 ± 1 fmol/40µl (mean ± SEM, n = 38) SKF38393 (5, 10, 20, 100µM) dose-dependently increased cAMP. Administration, via the probe, of the selective D1 antagonist SCH 23390 completely prevented the increase of cAMP by SKF38393.

SKF38393	(10µM)	163 ± 11.6
"	" + SCH23390(10µM)	106 ± 15.6
"	" (100µM)	99 ± 6.2

Values are cAMP (means ± SEM as a % of basal, n = 5.)

These data demonstrate the potential for intracerebral dialysis in monitoring the consequences of post-synaptic DA receptor activation in-vivo.

CHARACTERIZATION OF THE GUINEA PIG STRIATAL DOPAMINE AUTORECEPTOR. E.A. Johnson*, C.E. Tsai*, J. Lucci*, A.J. Azzaro. Depts. of Neurology, Pharmacology and Psychiatry, West Virginia University, Health Science Center, Morgantown, WV 26506.

Autoreceptor regulation of dopamine synthesis has been well characterized in rat but not in guinea pig (GP). To further investigate GP as a potential model for human dopaminergic neurofunction, we characterized the GP striatal dopamine (DA) autoreceptor by measurement of the effects of selective DA agonists (D_1, SkF 38393; D_2, RU 24926) and antagonists (D_1, Sch 23390; D_2, Sulpiride) on GP striatal synaptosomal and free tyrosine hydroxylase (TH) activity, and in rat striatal synaptosomes. The D_2 agonist produced a dose-dependent inhibition of TH in both GP (IC_{50}=79 nM) and rat (ED_{50}= 96 nM) synaptosomes. This effect was antagonized by sulpiride. In contrast, the D_1 agonist produced dose-dependent inhibition of TH in both rat (IC_{50}=199 nM) and GP (IC_{50}=99 nM) synaptosomes which could not be blocked by Sch 23390. Inhibition of TH in GP was not due to direct effects on the enzyme, since both agonists were much less potent inhibitors of the free enzyme (RUZ4926, IC_{50}=447 uM; SkF 38393, IC_{50}=36 uM). The potent D_2 agonist-induced/D_2 antagonist-reversed inhibition of TH in GP striatal synaptosomes indicate that the GP DA autoreceptor is of the D_2 receptor subtype. The D_1 agonist results raise a possibility of a 3rd DA receptor subtype.

REGULATION OF DOPAMINE (DA) SYNTHESIS IN VIVO AFTER ACUTE OR CHRONIC AMPHETAMINE (AMPH). C.B.Tyler, M.J. Keegan* and M.P. Galloway, NPRU, Lafayette Clinic, Cell. & Clin. Neurobiol., Wayne State Univ., Psychiatry, SCH. MED.,Detroit, MI 48207

To examine the effects of AMPH on mechanisms regulating DA synthesis, AMPH (3 mg/kg) was administered to male rats at either 45 or 90 min prior to sacrifice. Some animals also received the D1 antagonist, SCH 23390 (0.5 mg/kg), or one of the D2 antagonists sulpiride (20.4 mg/kg) or eticlopride (0.25-5.0 mg/kg). AMPH initially increased DA synthesis in the striatum (ST) and olfactory tubercles (OT) but not in the nucleus accumbens (NA) or prefrontal cortex (PFC). Prior administration of either D1 or D2 antagonists enhanced both the magnitude and duration of the AMPH-induced increase. In the NA, AMPH decreased DA synthesis, an effect which was sensitive to prior treatment with D2 but not D1 antagonists. Neither D1 or D2 antagonists altered AMPH's effects in the PFC. Potential changes in DA autoreceptor (AR) sensitivity after chronic AMPH were examined in female rats treated with escalating doses of AMPH (1-10 mg/kg) for 30 days. Eight days later, the reversal by quinpirole (3-300 ug/kg) of GBL-induced increases in DA synthesis was examined. No differences in basal DA synthesis indicated a lack of neurotoxicity with AMPH treatment. In the posterior ST and NA, but not the anterior ST and OT, the effect of a low dose of quinpirole was enhanced by prior exposure to AMPH, relative to saline controls. Support: DA4120, MH41227, State of Michigan DMH.

D_1 AND D_2 AGONIST ACTIONS ON STRIATAL ADENYLATE CYCLASE ACTIVITY IN ADULT 6-OHDA-LESIONED RATS. H. Jurevics*, H. Criswell, R.A. Mueller and G.R. Breese. Depts. of Anesthesiology, Psychiatry, Pharmacology and the BSRC UNC-Chapel Hill, NC 27599.

Adult rats treated intracisternally with 6-OHDA show greater hyperactivity after systemic administration of quinpirole than after SKF-38393 (JPET 234:447, 1985). The present study examined if striatal adenylate cyclase activity (ACA) to these dopamine agonists is altered in 6-OHDA lesioned rats. Initially, crude homogenates of striatal tissue from control and lesioned rats were incubated with SKF-38393 (100 μM) or quinpirole (100 μM). The ACA to SKF-38393 was not altered by the 6-OHDA treatment. In the presence of 10 μM GTP, quinpirole decreased basal ACA in tissue from control but not 6-OHDA lesioned rats. By combining SKF-38393 and quinpirole, the increase in ACA to SKF-38393 was enhanced (85 $\pm$ 13% from 35 $\pm$ 7%; $p < 0.05$) in unlesioned rats but not in the lesioned rats (42 $\pm$ 5% from 47 $\pm$ 10%: $p < 0.1$). SKF-38393, forskolin (0.5 - 100 μM), NaF (10 mM) and Gpp (NH)p (10 μM) were as effective in increasing ACA in striatum from 6-OHDA lesioned rats as in control rats indicating that adenylate cyclase and G protein coupling to the enzyme are not altered by the lesion. However, these data suggest that coupling of the D_2 receptor to the enzyme complex is impaired after 6-OHDA treatment. (Supported by NS 21345 and HD 23042.)

172.9

DOPAMINE (DA) RECEPTOR SUPERSENSITIVITY AFTER 6-OHDA: GENERATION OF A RECEPTOR RESERVE FOR REGULATION OF STRIATAL CHOLINERGIC ACTIVITY. A. Enz,* M. Goldstein and E. Meller. Preclinical Research, Sandoz, Ltd., Basel, Switzerland and Dept. of Psychiatry, NYU Medical Center, New York, NY 10016.

Unilateral denervation of the nigrostriatal DA pathway with 6-OHDA resulted in a supersensitive response for N-propylnorapomorphine (NPA)-induced elevation of ACh levels, seen as a 4-fold leftward shift in the dose-response curve (ED50: 8.8 and 2.2 ug/kg, intact and denervated sides, respectively), without a change in the maximum response. On the intact side, irreversible DA receptor inactivation with N-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ) depressed the maximal response (to 48% of control maximum), without altering the ED50, while it caused a smaller depression in maximal response (to 76% of corresponding vehicle control), as well as a small rightward shift in ED50, on the denervated side. Response was a linear function of receptor occupancy in the intact striatum, indicating the absence of receptor reserve, whereas it was nonlinear in the denervated striatum; a small receptor reserve of 25-30% was estimated to be present. 6-OHDA-induced supersensitivity appears to reflect the generation of a postsynaptic D2 receptor reserve, which may account for the observation that weak partial agonists elicit response at supersensitive DA receptors but not at normosensitive receptors devoid of spare receptors. The effects of 6-OHDA denervation on response elicited by weak partial DA agonists will also be presented. Supported by NS 23618, NS 08601 and MH 35976.

172.10

POSTMORTEM STABILITY OF MONOAMINES AND NEURORECEPTOR BINDING. M. Al-Tikriti, R. H. Roth, R. B. Innis. Depts. Psychiatry, Pharmacol., & Neuroanatomy, Yale Univ. Sch. of Med., New Haven, CT 06510.

Research on monoamine and receptor binding levels in postmortem human brain tissue depend upon detailed knowledge of the effects of the postmortem interval, tissue preparation, and storage on all outcome measures.

We have used a rat model of the autopsy process, in which rats are sacrificed and the heads cooled following the known temperature curve of the human brain after death. Six animals for each of 7 postmortem timepoints (up to 27 hr) were examined. Samples from multiple brain regions were frozen and later assayed for monoamines (DA, NE, and 5-HT) and neuroreceptors (D1, D2, 5-HT1A, 5-HT2, and CCK).

Preliminary analysis of the data show that both caudate DA and cortical NE levels decrease to approximately 50% within a 3 hr postmortem delay, then further decline to approximately 30% at 9 hr and maintain this concentration until the final 27 hr timepoint. If the frozen samples were thawed even for just a few minutes and then refrozen, DA levels were markedly depleted.

Homogenate receptor binding was performed with 3H-raclopride (D2), 3H-SCH23390 (D1), 3H-8-OH-DPAT (5-HT1A), 3H-ketanserin (5-HT2), and 3H-cholecystokinin (CCK). Except for CCK, receptor binding levels were showed significant postmortem stability, with typically less than 20% decrease at 27 hr postmortem. CCK receptor binding decreased to approximately 50% within 3 hr and maintained this level through the final 27 hr timepoint. The effects of both a single freezing and a thawing/refreezing were insignificant for all five receptors.

These studies support the feasibility of human postmortem neurochemical and receptor binding studies but demonstrate the need for careful tissue handling (not allowing thawing of samples for neurochemical measurements) and for controlling postmortem delay (especially for monoamine measurements and the CCK receptor).

CATECHOLAMINE RECEPTORS: ADRENERGIC

173.1

POSTNATAL DEVELOPMENT OF PRE- AND POSTSYNAPTIC ALPHA$_2$ RECEPTORS IN RAT SPINAL CORD. V.C. Gandhi and D.J. Jones (SPON: L. Bunegin). Dept. of Anesthesiology, UTHSC, San Antonio, TX 78284-7838

The establishment of norepinephrine (NE) - mediated events in synaptic transmission requires concomitant development and maturation of the pre- and postsynaptic elements of noradrenergic terminals. Previous studies have established that in spinal cord alpha$_2$ receptors regulate processes at both sites including the inhibition of NE release and inhibition of NE-stimulated cyclic AMP (cAMP) accumulation. The purpose of the present study was to determine if a correlation exists in the postnatal development of pre- vs postsynaptic alpha$_2$ receptors in rat spinal cord.

K^+-induced [^{3}H]-NE release and [^{3}H]-NE uptake were measured on PND 1 to 60. Significant NE release as well as uptake was observed at birth. NE inhibited [^{3}H]-NE release in a concentration-dependent manner PND 1-60. Maximum inhibition with 1 uM NE of [^{3}H]-NE release occurred at PND 7 (55%) with a subsequent decrease on PND 12 to adult levels (30%). This decrease in sensitivity may be due to a decrease in the number of functional noradrenergic terminals since [^{3}H]-NE uptake also decreased after maximal levels at PND 5.

cAMP accumulation stimulated by NE is a postsynaptic event which is inhibited by alpha$_2$ receptor agonists such as clonidine. Clonidine (1 uM) inhibited NE-stimulated cyclic AMP accumulation 30-40% up to PND 7 with a decrease to 20% at PND 12 and thereafter. The results suggest that the sensitivity of pre- and postsynaptic alpha$_2$ receptors appear to develop in spinal cord in parallel postnatally.

ALPHA 2-BINDING SITES IN THE MEDULLA OBLONGATA OF TREE SHREWS. G. Flügge, S. Schiller* and E. Fuchs. Dept. of Reproductive Biology, German Primate Center, Kellnerweg 4, 3400 Göttingen, FRG.

Alpha 2-adrenoceptors are supposed to be primarily located presynaptically on catecholaminergic fibers (Starke, K., Rev. Physiol. Pharmacol., 107:73-146, 1987) but in the rat brain, they could not be found in all areas revealing PNMT-immunopositive varicosities or cells. We investigated the distribution of ^{3}H-rauwolscine binding sites in the tree shrew medulla oblongata because the anatomy of the medullary adrenergic system of this species resembles that of primates (Mittendorf, A. J. Comp. Neurol., 274:178-189, 1988).

In contrast to the rat, not only the NTS and the nX but also the nXII, part of the n. reticularis parvocellularis, and the area of the adrenergic group C1 were distinctly labeled. Scatchard analysis revealed one type of high affinity binding sites in each nucleus (K_d 0.6 to 1.3 nM) although association/dissociation experiments indicated the existence of high and low affinity binding sites. Competition experiments demonstrated that ^{3}H-RAUW bound to α2-adrenoceptors. In the nXII and the area of C1, ^{3}H-RAUW obviously interacted with dopamine binding structures.

In summary, in the tree shrew medulla oblongata there are α2-receptors with higher affinity for ^{3}H-rauwolscine than in the rat. Furthermore, α2-adrenoceptors in the ventrolateral medulla can be quantified and pharmacologically characterized. In this region, α2-sites have been observed in the human medulla but not in the rat.

173.3

COMPARISON OF THE BINDING CHARACTERISTICS OF α_2-ADRENERGIC RECEPTORS IN RAT BRAIN AND KIDNEY. R. Dawson, Jr. and D.R. Wallace. Dept. of Pharmacodynamics, Univ. of Florida, Gainesville, FL 32610.

The aim of the present study was to examine the binding characteristics of renal versus cerebral cortical α_2-adrenoceptors in the rat. α_2-Adrenoceptor binding was evaluated using either [^{3}H]p-aminoclonidine (PAC), [^{3}H]idazoxan (IDZ) or [^{3}H]rauwolscine (RAU). Crude homogenates or subcellular fractions were used to assess binding in whole kidney or cerebral cortical homogenates from Sprague-Dawley rats. The ratio of specific kidney/brain binding is given below.

Ligand	Crude Homogenate	P_1	P_2
PAC (2nM)	0.32±0.03 (7)	2.0 (2)	0.31±0.06 (7)
IDZ (1nM)	0.30±0.02 (5)	2.0 (2)	0.36 (2)
RAU (2nM)	2.90±0.63 (5)	6.8 (2)	0.97±0.10 (5)

ratio = dpm/mg protein kidney÷dpm/mg protein brain. (n)

Prazosin (1.0μM) displaced 12% of the specific PAC (2nM) binding in brain but 83% of RAU binding. PAC (2nM) binding in kidney was inhibited 60% and RAU was 98% displaced by prazosin (1.0μM). Magnesium stimulation of PAC binding was similar in brain and kidney but GTP inhibition of PAC and IDZ binding was 1.6 times greater in kidney than brain. Amiloride inhibition (IC_{50}) of [^{3}H]RAU binding was comparable in brain (17±5μM) and kidney (10±1μM). Thus, differences exist in brain and renal α_2-adrenoceptors that may be explained by the high numbers of α_2-B subtype in the kidney, whereas the α_2-A subtype is numerous in rat cerebral cortex.

173.4

DEVELOPMENTAL CHARACTERIZATION AND TISSUE DISTRIBUTION OF A RAT ALPHA-2 ADRENERGIC RECEPTOR SUBTYPE. S.K. McCune, D.E. Brenneman and M.M. Voigt, Lab. of Developmental Neurobiology, NICHD and NINDS, NIH, Bethesda, MD 20892.

Alpha-2 adrenergic receptors are involved in numerous physiologic functions. In the brain, a role for norepinephrine has been implied in depression, Parkinson's disease and Alzheimer's disease. Using oligonucleotide probes directed against the third and fourth transmembrane regions of the human platelet α_2 adrenergic receptor, a rat genomic clone encoding an α_2 receptor was isolated and used to study the developmental expression of an α_2 adrenergic receptor subtype. Riboprobe complementary to sequence in the coding region was used to probe Northern blots. A 3.2kb species was present in brain and to a lesser degree in kidney. The message was barely detected in heart but not in liver, lung or pancreas. Using mRNA from embryonic day 15 (E15), embryonic day 18 (E18), newborn, postnatal day 8 and adult rat brains, it was shown that the 3.2kb message is developmentally regulated. It was also shown that a 1.8kb species which strongly cross-hybridizes to the probe was present only in prenatal life, while a 2.5kb species was expressed only postnatally. The cloning and characterization of the two smaller mRNAs are in progress.

173.5

AUTORADIOGRAPHIC, KINETIC, AND EQUILIBRIUM CHARACTERIZATION OF BRAIN ALPHA-2 ADRENERGIC RECEPTORS USING A NEW RADIOLABELED AGONIST, [^{125}I]P-IODOCLONIDINE. B.W. Siegel*, B.M. Baron, J.A. Miller. Merrell Dow Research Institute, Cincinnati Ohio, 45215.

[^{125}I]p-Iodoclonidine ([^{125}I]PIC, a novel ligand generously provided by Dr. R. Garlick of DuPont NEN) binding was measured in well-washed membranes obtained from rat hippocampus + cortex. [^{125}I]PIC bound to a single class of saturable binding sites with Kd = 0.55 nM and Bmax = 230 fmoles/mg protein. Binding was > 90 % specific at 0.6 nM [^{125}I]PIC. IC_{50} values for UK 14,304, epinephrine, BHT 920, phentolamine, and idazoxan were 3, 13, 17, 21, and 21 nM, respectively. [^{125}I]PIC binding was sensitive to guanine nucleotides with rank potency GTPγS > GDPβS > GppNHp ~ GTP ~ GDP > GMP >> ATP. Association was monophasic and complete by 90 min. at 25°C. Dissociation was biphasic with 30 % of the sites dissociating rapidly (K_1 = 0.32 min.$^{-1}$) and the remainder dissociating 50-fold slower (K_2 = 0.0061 min.$^{-1}$).

Quantitative autoradiography was performed in sagittal sections of rat brain and cross sections of spinal cord. The highest levels of binding were found in cortical, hippocampal, hypothalamic, and cerebellar regions. Low levels of binding were found in spinal cord gray matter where cervical, thoracic and lumbar regions demonstrated higher densities than sacral gray matter. Binding in all these regions was heterogeneous and ranged from 1.4 fmol/cm^2 (sacral gray) to 7.42 fmol/cm^2 (cortex).

MOLECULAR MODELLING OF RECEPTOR PROTEINS: G-PROTEIN COUPLED RECEPTORS. V.B.Cockcroft*, B.Brewster*, G.G.Lunt, Molecular Neuroscience Group, Biochemistry Dept., University of Bath, BATH BA2 7AY U.K.

We previously produced a detailed molecular model of the nAChR and proposed some features that may be common to members of the direct ligand-gated superfamily. We now extend our receptor modelling to members of the G-protein coupled superfamily. Aligned sequences in conjunction with published data, were used to construct a model of the human β-1 adrenergic receptor. Helices (TM1 to TM7) were arranged in the membrane with conserved and polar residues facing the binding pocket. It is proposed that receptor activation takes place through a charge relay mechanism: the docking of an agonist's positively charged amine group onto the conserved aspartate of TM2 causes rearrangement of existing through-protein charge interactions. These involve electrostatic interactions between the conserved aspartate of TM2, and a salt bridge between the conserved aspartate of TM3 and the conserved arginine of TM4. This model serves as a good starting point for modelling of other members of the superfamily.

MEASUREMENT OF EXTRACELLULAR cAMP IN THE BRAIN BY MICRODIALYIS: EXTENSION TO UNANESTHETIZED RATS. E.A. Stone and S.M. John*, Dept. Psychiatry, New York University Sch. Med., New York, NY 10016.

We have previously shown that cAMP in the extracellular fluid of the rat brain can be detected by microdialysis sampling with RIA. All experiments so far have utilized anesthetized (urethane) rats only. In the present studies therefore we have applied the technique to nonanesthetized animals. Rats were implanted under pentobarbital anesthesia with 3.5 mm dialysis probes in the prefrontal cortex. Twenty-four hrs later the animals were tested for cAMP recovery at a perfusion rate of 1 ul/min. Baseline cAMP values in the awake animals were found to average 6.0 ± 2.2 (SD) fmol/20 min (n=15) and were relatively stable during 5 hr perfusions between 10-1500 hrs. Several animals showed higher values (15-20 fmol/20 min) which may have resulted from local inflammation near the probe. Inhibition of phosphodiesterase with rolipram produced a dose-dependent rise in cAMP levels. Infusion of norepinephrine (10^{-4} M) to stimulate brain beta adrenoceptors produced 3-10 fold increases in cAMP levels. The response of unanesthetized rats appeared greater than anesthetized animals. The results indicate that the microdialysis-cAMP method can be successfully applied to unanesthetized animals and may be a useful technique to study brain receptor function in vivo during behavioral states. Supported by MH44442 and Air Force grant 89-0208.

173.8

SEROTONERGIC NEURONS ARE NOT NECESSARY FOR AGONIST-INDUCED REGULATION OF β-ADRENOCEPTORS (BARs) WHEN ^{125}I-IODOPINDOLOL (^{125}I-IPIN) IS THE RADIOLIGAND. G.A.Ordway[1]*, C.Gambarana[1], J.Hensler[2], A.Frazer[2]. [1]Case Western Res. Univ, Cleveland, OH; [2]Univ Penn & VAMC, Phila, PA 19104.

Following lesion of serotonergic neurons with 5,7-dihydroxytryptamine (5,7-DHT), chronic administration of desipramine (DMI) to rats does not result in down-regulation of BARs as measured using ^{3}H-dihydroalprenolol (^{3}H-DHA). Our initial saturation experiments indicated that in cortical homogenates ^{3}H-DHA bound specifically to two sites whereas ^{125}I-IPIN bound to a single site. 5,7-DHT treatment did not alter the Bmax or K_d of ^{125}I-IPIN binding. The binding of ^{3}H-DHA was significantly increased in cortical homogenates from 5,7-DHT-treated rats. Chronic administration of DMI produced a significant decrease of comparable magnitude in the density of BARs in cortical homogenates from either sham or 5,7-DHT treated rats when ^{125}I-IPIN was the radioligand. Subtypes of BARs were measured by quantitative autoradiography using ^{125}I-IPIN in experiments done to determine the effect of isoproterenol (ISO; 15μg, icv) in sham and 5,7-DHT treated rats. 5,7-DHT did not significantly alter the ability of ISO to decrease binding of ^{125}I-IPIN to either β_1 or β_2 receptors in any brain region examined. From these data, it may be inferred that the absence of serotonergic neurons does not influence the regulation of BARs when ^{125}I-IPIN is the radioligand. **(Supported by Vet. Adm. & USPH grants MH29094 & MH14654.)**

173.9

DEVELOPMENT OF BETA-ADRENERGIC RECEPTORS: COMPARISON OF ADULT, NEONATAL AND FETAL RAT HEART. A. Torres*, L.E. Crawford*, K.E.J. Dickinson* and D.C. Tucker (SPON:E. Taub). Departments of Psychology and Gastroenterology, University of Alabama at Birmingham, Birmingham, AL 35294.

Beta-adrenergic receptors (β-AR) were studied in fetal, neonatal and adult rat heart. Preliminary studies with iodopindolol detected beta-adrenergic receptors at E-12 and E-13. Receptors were assayed in crude homogenates from ventricles of adult and neonatal rats (<24 hrs old) and from whole hearts of fetuses (E-17) with iodocyanopindolol as the radioligand and alprenolol as the nonspecific displacer. Scatchard analysis indicated similar affinities at all ages with receptor number ordered: newborn > adult > fetal (K_D= 38, 30, 45 pM; B_{max}= 51.1, 36.6, 29.4 fmol/mg protein for newborn, adult, E-17, respectively). Displacement studies with D- and L- propranolol verified that the assay was selective for β-AR. A slight but measureable shift in isoproteronol displacement with the addition of guanosine triphosphate (GTP) was demonstrated at all ages, indicating that the receptors were able to couple to G-proteins and, thus, are likely to be functional. These findings suggest that β-AR number is higher in newborn than in adult heart and that these receptors could respond to circulating catecholamines. How efficiently the receptors mediate changes in beating rate or force of contraction is a subject for future study.

173.10

MOLECULAR CLONING AND EXPRESSION OF THE RAT β_1-ADRENERGIC RECEPTOR GENE. C.A. Machida[1], J. Bunzow[2]*, R.P. Searles[1]*, H. Van Tol[2], P. Teal[1]*, K. Neve[3], and O. Civelli[2]. [1]Division of Neuroscience, Oregon Regional Primate Research Center, Beaverton, OR 97006, [2]Vollum Institute for Advanced Biomedical Research, Oregon Health Sciences University, Portland OR 97201, and [3]Veterans Administration Medical Center, Portland, OR 97201.

The β-adrenergic receptors (β_1- and β_2-ARs) regulate a wide variety of physiological processes through their interactions with catecholamines. To begin analyzing the differential expression of the β-AR subtypes, we cloned the rat β_1-AR gene and expressed these receptors by transfection into β-AR deficient mouse L cells. Nucleotide sequence analyses of the coding region of the rat β_1-AR gene show that it encodes a 463 amino acid protein, with 1 potential Asn-X-Ser(Thr) glycosylation site. The primary amino acid sequence of the rat β_1-AR shows a high degree of similarity with both the human β_1- (88%) and hamster β_2-ARs (43%). A potential 90 bp intron is observed in the 3' nontranslated region of the rat β_1-AR gene. Blot analyses of RNA show high concentrations of β_1-AR mRNA in pineal, heart, and lung, with lower levels in thalamus, amygdala, septum, and hippocampus. Analyses of the transfectant's genomic DNA, mRNA, and β-AR binding characteristics ([^{125}I]-iodocyanopindolol binding and rank order potency of adrenergic agonist displacement) clearly demonstrate expression of the β_1-AR gene and receptor subtype.

SECOND MESSENGERS II

174.1

LITHIUM-SELECTIVE ALTERATION OF BRAIN G_S PROTEIN FUNCTION. S. Avissar,* G. Schreiber,* C.S. Aulakh,* and D.L. Murphy* (SPON: P.A. Newhouse). LCS, National Institute of Mental Health, Bethesda, MD 20892.

We recently demonstrated that lithium inhibits the coupling of both muscarinic cholinergic receptors and ß-adrenergic receptors to pertussis toxin-sensitive and cholera toxin-sensitive G proteins, respectively, thus suggesting lithium alteration of G protein function as the single site for both the antimanic and antidepressant effects of this drug (Nature 331:440-442, 1988). One of the most puzzling aspects of the ability of lithium to ameliorate the manic-depressive condition is its relatively selective action upon the CNS.

In the present study, we show that lithium selectively attenuates the function of G_S proteins in the CNS assessed through isoproterenol-induced increases in GTP binding to these proteins. *In vitro* therapeutic lithium concentrations (1-1.5 mM) inhibit G_S protein function in rat cerebral cortex, while 4- to 6-fold higher concentrations of lithium are required to alter G_S protein function in rat cardiac ventricles. *In vivo* chronic lithium treatment (rat chow containing lithium carbonate) to rats totally abolished isoproterenol effect in the CNS but did not affect peripheral cardiac G_S protein function. Lithium-selective action of CNS G_S protein function may stem from the heterogeneity of the α_S subunit proteins: in the heart, the major species is a 45 kDa molecule, while in the brain, a 52 kDa molecular weight species predominates. The heterogeneity in α_S subunits may thus be the biochemical basis for lithium-selective action on the CNS and for the scarcity of peripheral side effects.

174.2

ANTIDEPRESSANT DRUGS ALTER ß-ADRENERGIC RECEPTOR COUPLING TO G_S PROTEIN G. Schreiber,* S. Avissar,* C.S. Aulakh,* and D.L. Murphy* (SPON: A.M. Mellow). LCS, National Institute of Mental Health, Bethesda, MD 20892.

Our recent findings on the alteration by lithium of brain G protein function coupled to both ß-adrenergic and cholinergic receptors suggest G proteins as a single site for both therapeutic effects of lithium (Nature 331: 440-442, 1988).

In the present study, the effects of chronic treatment with imipramine, clomipramine (tricyclic antidepressants), and clorgyline (a selective MAO type A inhibiting antidepressant) on the coupling of both muscarinic cholinergic receptors and ß-adrenergic receptors to pertussis toxin-sensitive and cholera toxin-sensitive G proteins was investigated. Imipramine (5 mg/kg/day), clomipramine (5 mg/kg/day), clorgyline (1 mg/kg/day), or saline was subcutaneously administered continuously by means of osmotic minipumps to male Wistar rats. Three-week treatment with these antidepressants resulted in ~50% inhibition of isoproterenol-induced increases in GTP binding to rat cerebral cortex G_S protein, without affecting muscarinic receptors coupling to G proteins. Studies are currently in progress to determine whether these findings on the uncoupling of the ß-adrenergic receptor from G_S protein and ß-adrenergic receptor desensitization both induced by antidepressant treatment are independent phenomena.

174.3

Quantitation of GTP-Binding(G-)Protein mRNA In Rat Brain Using InSitu Hybridization: Thomas Akompong*,J.A.Angulo & B.S.McEwen. (SPON.Maureen Gannon) Lab,Neuroendocrinology The Rockefeller University.New York,NY 10021

The G-proteins are universal intermediaries coupled to different receptors and effectors in several signal transduction systems. The distribution of two G-proteins G_i and G_s,were determined using ^{125}I oligonucleotide probes of the α-subunits of these G-proteins by in insitu hybridization. The specificity of the probes was established by competition with 30x excess cold probe. The cortex has more mRNA for G_i and G_s than the striatum. The dentate gyrus and the habenular nucleus have higher G_s and G_i mRNA compared with the cortex and pyramidal cells of CA1-CA3 of the hippocampus, which have equal mRNA for G_i and G_s as compared to the cortex. We also studied the in vivo modulation of the mRNA levels for these G-proteins by estradiol and progesterone in ovariectomized female rats. Preliminary results show that these hormones affect the levels of G_s and G_i in the striatum as well as the hippocampus.

DOPAMINERGIC AND NORADRENERGIC NEURONS EXPRESS MULTIPLE G PROTEIN mRNAs IN THE RAT BRAIN. S.L. Drinnan, B.T. Hope, P.B. Reiner and S.R. Vincent, Kinsmen Laboratory of Neurological Research, Dept. of Psychiatry, Univ. of British Columbia, Vancouver, Canada, V6T 1W5.

The guanine nucleotide binding family of proteins (G proteins) transduce extracellular signals into intracellular events. G_i, G_o and G_s are members of a group of heterotrimeric G proteins found in the brain which affect membrane conductances and second messenger systems. The expression of mRNAs coding for the alpha subunits of these three G proteins was examined in rat brain by *in situ* hybridization using radiolabelled synthetic oligonucleotide probes. Northern blot analysis indicated that the three probes hybridized specifically to mRNA species corresponding in size to those for the alpha subunits of G_i-2, G_o and G_s. The three probes showed widespread and unique distributions throughout the brain. Neurons in various regions known to contain aminergic neurons were labelled. Therefore, dopaminergic substantia nigra neurons and noradrenergic locus ceruleus neurons were identified immunohistochemically and subsequently processed for *in situ* hybridization. The results demonstrate that identified catecholamine neurons in both cell groups express mRNAs coding for all three G-protein alpha subunits investigated. This is consistent with physiological data indicating a role for G proteins in receptor and drug actions in SN and LC neurons.

174.5

DEVELOPMENTAL EXPRESSION OF Go-ALPHA IN PRIMARY NEURONAL CULTURES. J. G. Granneman and G. Kapatos. Laboratories of Biochemical Pharmacology and Neurochemistry, Center for Cell Biology Sinai Res. Inst. and Clin. Cell. Neuroscience Prog., Wayne State Univ., Detroit, MI 48235.

Guanine nucleotide binding proteins (G-proteins) play a central role in the transduction of receptor generated signals. Go is the most abundant G-protein in the central nervous system, where it has been localized in both neurons and in glia. We have characterized the developmental expression of the alpha subunit of Go in neurons by examining mesencephalic (MES) and hypothalamic (HYP) cultures that are essentially free of contaminating glia. Immunoblotting utilizing specific antisera against Go indicates that in neurons from both brain regions, membrane concentrations of Go increase dramatically during the first two weeks in vitro. Thereafter increases in the amount of Go per neuron kept pace with increasing process (axons and dendrites) formation. MES and HYP neurons maintained in culture for 4 days contained multiple molecular forms of Go whereas neurons maintained for two weeks appeared to contain only one form. Finally, increasing neuron density significantly increased membrane levels of Go in MES but not HYP cultures.

GLUCOCORTICOID REGULATION OF ADP-RIBOSYLATION FACTOR (ARF) AND ENDOGENOUS ADP-RIBOSYLATION IN RAT CEREBRAL CORTEX. J.A. Clark, R.Z. Terwilliger*, E.J. Nestler, and R.S. Duman. Laboratory of Molecular Psychiatry, Depts. of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06508.

ADP-ribosylation factor (ARF) is required for cholera toxin-catalyzed ADP-ribosylation of the stimulatory G-protein (Gsα) *in vitro*. While ARF constitutes up to 1% of brain protein, little is known about the regulation or function(s) of this factor *in vivo*. Previously, we reported that Gsα is under hormonal regulation in cerebral cortex (CTX), exhibiting a 30% increase in message and protein following one week exposure to corticosterone (CORT). These findings raised the possibility that ARF may be similarly regulated by hormonal treatment. ARF message in CTX was regulated by CORT, which produced a 50 to 100% increase in mRNA levels. Immunoblot studies are underway to determine the effect of CORT treatment on levels of the protein.

Given that Gsα and ARF are similarly regulated by CORT, we were prompted to look for a possible physiological function for ARF by studying endogenous ADP-ribosylation. ADP-ribosylation assays, performed on CTX homogenates in the absence of cholera toxin, revealed the endogenous ADP-ribosylation of two proteins corresponding to the predominant bands labeled in the presence of cholera toxin, presumably the 45 and 52kD forms of Gsα. This is the first demonstration of endogenous ADP-ribosylation in brain. Furthermore, this endogenous ADP-ribosylation was enhanced 40% by one week of CORT treatment. Together, these findings, in addition to preliminary studies demonstrating a differential regional distribution and developmental expression of this factor in brain, suggest that ARF may play a physiological role in the regulation of signal transduction.

THE GTP-BINDING PROTEIN, G_o, COUPLES MUSCARINIC RECEPTORS TO PHOSPHOLIPASE C IN *XENOPUS* OOCYTES. T.M. Moriarty, E. Padrell*, G. Omri, R. Iyengar* and E.M. Landau. Depts. of Psychiatry and Pharmacology, Mt. Sinai School of Medicine and Dept. of Psychiatry, Bronx V.A. Medical Center, New York, N.Y.

GTP-binding proteins (G-proteins) couple cell surface receptors to cellular effectors. Receptors activate the heterotrimeric G-protein and cause the dissociation of α from βγ subunits. Activated α subunits modulate effector function. Much evidence suggests that G-proteins serve to couple receptors to phospholipase C with resulting release of the second messengers IP_3 and DAG. In this study we sought to identify which of the known G-proteins might couple receptors to phospholipase C. *Xenopus* oocytes have a well characterized electrophysiological response to acetylcholine (ACh): receptor activation stimulates the production of IP_3, mobilization of Ca^{2+} and subsequent activation of Ca^{2+} dependent Cl^- channels. We have shown that the receptor evoked Cl^- current is sensitive to pertussis toxin (PTX) and is also modulated by the βγ subunits of G-proteins. We therefore tested the known PTX sensitive G-proteins, G_o, G_{i1}, G_{i2} and G_{i3}, for potential function in coupling receptors to the IP_3 mediated Cl^- current. G_o reconstituted the response to ACh in cells pretreated with PTX whereas G_{i3} was ineffective. G_o also augmented the response to ACh whereas G_{i1}, G_{i2} and G_{i3} did not. Preliminary experiments using GTPγS activated α subunits suggest that the α subunits of G_o, when directly injected into voltage-clamped oocytes, evoke a Cl^- current as does direct injection of IP_3. These results, in view of the report of a cDNA clone of α_o from *Xenopus* oocytes (Olate *et al.*, *FEBS Letts.* **244**:188-192, 1989), indicate that G_o couples muscarinic receptors to phospholipase C.

174.8

STRUCTURAL AND FUNCTIONAL CHARACTERIZATION OF TWO FORMS OF THE BOVINE BRAIN GTP-BINDING PROTEIN G_o. E. Padrell*, T.M. Moriarty, D.J. Carty*, E.M. Landau and R. Iyengar* (SPON:J. Goldfarb). Depts. of Pharmacology and Psychiatry, Mt. Sinai School of Medicine and Dept. of Psychiatry, Bronx V.A. Medical Center, New York, N.Y.

Heterotrimeric GTP-binding proteins (G-proteins) serve as coupling elements in many signal transduction systems. The most abundant brain G-protein, G_o, has an α subunit of Mr=39000 and is a pertussis toxin substrate. Sequence specific antiserum U-46 identifies recombinant α_o, but not α_{i1}, α_{i2} and α_{i3} protein. The antiserum U-46 recognized two distinct peaks of α_o eluting early and late on Mono Q columns using FPLC. The early peak was termed G_{o2} and the more abundant late peak was called G_{o1}. Both G_{o1} and G_{o2} were uniquely recognized by α_o-specific antiserum U-46 and not by α_i-specific antisera. Both α_{o1} and α_{o2} have similar molecular weights, co-purify with stoichiometric amounts of βγ-subunits and are pertussis toxin substrates. Both forms of α_o migrate distinctly on 9% SDS-polyacrylamide gels containing 4-8 M urea gradients. While α_{o1} and α_{o2} are recognized by an α_o C-terminus sequence specific antiserum, the N-terminus of α_{o2} appears to be different from that α_{o1} or the α_i proteins since the antiserum H-660, which interacts with recombinant α_o, α_{i1}, α_{i2} and α_{i3} does not recognize α_{o2}. Both forms of G_o appear to specifically augment the muscarinic stimulation of phospholipase C in *Xenopus* oocytes. These data indicate the presence of two distinct forms of G_o in bovine brain which couple receptor to phospholipase C.

STIMULATION OF PARTICULATE GUANYLATE CYCLASE (GC) BY BRAIN NATRIURETIC PEPTIDE IN INDIVIDUAL NUCLEI OF RAT BRAIN. A. Israel, M.R. Garrido* and Y. Mathison*. Universidad Central de Venezuela. Caracas-Venezuela.

Brain natriuretic peptide (BNP), a peptide isolated from porcine brain, is present in rat brain neurons. Binding sites for BNP are highly localized in several brain structures such as the subfornical organ (SFO), olfactory bulb (OB) and choroid plexus (CP). In various peripheral tissues BNP increases intracellular cyclic GMP (FEBS 232, 1988).

The presence of functional-coupled to GC binding sites for BNP was examined by measuring the BNP-induced formation of cGMP in several brain areas such as the paraventricular nucleous (PVN), median eminence (ME), pineal gland (PG), SFO, OB and CP. Male S-D rats (220-260 gr) were decapitated and their brains immediately removed. After removal, each area (pool of 10) was homogenized and centrifuged at 105.000 x g for 2 h The supernatant (soluble, S) and the pellet (particulate, P) were assayed for GC activity and cGMP was determined by a radioimmuno assay. In all areas examined, the relative distribution of basal GC activity was 75-80% GC in P whereas it was 20-25% in S fraction. P-GC activity was markedly stimulated by BNP and it had little effect on S-GC. The maximal increase in cGMP concentration by BNP was found to be similar in PVN, PG, CP and OB (97, 77, 115 and 147 %, respectively), while a lower response was observed in SFO and ME (43 and 48 % increase). Vmax values were (in pmol/5min/mg protein, at 500 nM): ME: 56.3 ± 4.7; SFO: 42.9 ± 18; CP: 104 ± 3; OB: 102.6 ± 2.5; PG: 154.1 ± 2; PVN: 208.4 ± 3. Some differences were observed when compared with ANP-stimulated GC activity.

Our results suggest that in the brain, activation of particulate GC and elevation of intracellular levels of cGMP constitute a common mechanism of action for both BNP and ANP (Grants CDCH F-07-10-1928-88).

EXCITATORY AMINO ACID RECEPTORS ACTIVATION INDUCES cGMP FORMATION IN RAT STRIATAL NEURONS IN PRIMARY CULTURE. U. di Porzio and A. Novelli. (SPON: M. Voigt). Lab. of Neurophysiology and Lab. of Mol. Biology, NINDS, NIH, Bethesda, MD 20892,USA.

The development of a responsiveness to excitatory amino acids (EAA) in striatal neurons is of interest for understanding the process of synaptogenesis in the striatum. Second messenger formation consequent to the activation of excitatory amino acid receptors (EAARs) is a reliable index of receptor function.

Here, we present data on the cGMP formation consequent to the activation of EAAR in striatal neurons in primary culture. Primary cultures of striatal neurons were prepared from 15-20 day-old rat embryos, and maintained for more than 20 days in culture (DIC). Intracellular cGMP levels after EAAR stimulation were measured at different DIC. Maximal stimulation (3-4 times over basal levels) was achieved at 13-17 DIC. N-methyl-D-aspartate (NMDA)(10μM) produced a maximal stimulation of cGMP formation in the absence of extracellular Mg^{++}. When Mg^{++}(1mM) was present, 1mM NMDA was required. Maximal stimulation of cGMP formation by glutamate was obtained at 50μM when Mg^{++} was absent, and at 1mM when Mg^{++} was present. In the presence of extracellular magnesium, kainate induced a dose-dependent elevation of cGMP levels, maximal at 100μM. Maximal stimulation of cGMP formation by quisqualate was limited to 1.5-2 times over basal levels and was achieved starting at 5μM. The time course of cGMP formation induced by EAAs reached a maximum from 30 sec. to 2 min., after addition of the agonist, and was dependent upon extracellular calcium. However, it was not mimicked by the calcium ionophore A23187 (10μM).

In conclusion, we have shown that in striatal neurons in primary culture, cGMP formation is coupled to all types of EAAR and develops with time in culture. Since other second messengers, such as arachidonic acid, have been reported to originate from the activation of a selective type of EAAR, cGMP appears to be an independent second messenger possibly mediating the intracellular action of EAA in striatal neurons in primary culture.

ANGIOTENSIN II DECREASES CYCLIC GMP IN NEURONAL CULTURES FROM RAT BRAIN. L.M. Myers* and C. Sumners. Dept. of Physiology, College of Medicine, Univ. Florida, Gainesville, FL 32610.

Angiotensin II (Ang II) has been shown to decrease atrial natriuretic factor-induced increases in cyclic GMP (cGMP) levels in cultured smooth muscle cells (Smith and Lincoln, Am. J. Physiol. 253:C147, 1987). The objective of this study was to determine the effect of Ang II on cGMP levels in neuronal cell cultures prepared from the hypothalamus and brain stem of 1-day-old rats. Experiments were conducted in serum-free medium in the presence of 1.0 mM 3-isobutyl-1-xanthine (IBMX) which was added 2 min prior to treatment. Treatment of neuronal cultures with 1 μM Ang II for 10 min resulted in approximately a 55% decrease in cGMP compared with control values (means ± SE, from 7 experiments, were 44.6 ± 7.7 and 100.7 ± 9.5 pmol cGMP/mg protein in Ang II treated and control cells, respectively). At 10 min, 1 and 10 nM Ang II tended to reduce cGMP levels while concentrations of 100 nM, 1 μM, and 10 μM resulted in percent decreases from control of 26%, 35%, and 46% respectively (control mean was 90.8 ± 10.1 pmol cGMP/mg protein, n=3 experiments). This Ang II effect was blocked by co-treatment with the specific Ang II receptor antagonist Sar^1 Ile^8Ang II (10 μM). In glial cell cultures (>95% astrocytes), cGMP was undetectable using the same radioimmunoassay procedures. Therefore, Ang II-induced decreases in the neuronal culture cGMP content could not be due to effects on the small percentage of glial cells present in neuronal cultures. In summary, we have determined that Ang II acts at specific receptors to decrease cGMP in cultured neurons (supported by PHS grant NS-19441).

THE EFFECTS OF HEPOXILIN A_3-GLUTATHIONE ADDUCT ON MEMBRANE PROPERTIES OF RAT HIPPOCAMPAL CA1 NEURONS. N. Gurevich[1], P.H. Wu*[2], C.R. Pace-Asciak*[2,3], E.J. Corey*[4], W-G. Su*[4] and P.L. Carlen[1]. Playfair Neuroscience Unit, Toronto Western Hosp. and Addiction Res. Fndt.[1]; Dept. Pharmacology[2], Research Institute, Hospital for Sick Children[3], U of Toronto, Canada; and Dept. Chemistry[4], Harvard Univ., Cambridge, MA, USA.

Hepoxilin A_3 (HxA_3), a metabolite of arachidonic acid formed through the 12-lipoxygenase pathway, hyperpolarizes the resting membrane potential (RMP), prolongs the post-spike train after-hyperpolarization (AHP), and enhances the inhibitory postsynaptic potential (IPSP) of rat hippocampal CA1 neurons. A new metabolite, hepoxilin A_3-glutathione (HxA_3-G), formed presumably through the action of glutathione S-transferase, was identified when HxA_3 was incubated with a liver homogenate. In CA1 neurons in vitro, HxA_3-G displayed similar effects to HxA_3 on the RMP, AHP and IPSP, but was more potent than HxA_3, increasing the IPSP up to 7-fold and causing hyperpolarization up to 9 mV at low μM concentrations. These data suggest that HxA_3-G may represent the product of neurobiological interest in the arachidonic acid metabolic pathway. (Support: OMH, MRC, CDA, NIH)

EFFECTS INDUCED BY ARACHIDONATE (AA) ON THE INTRINSIC AND SYNAPTIC PROPERTIES OF CA1 PYRAMIDAL NEURONS. C.Drapeau, L.Pellerin and M. Avoli. MNI, McGill Univ., Montreal, PQ, Canada.

The action exerted by AA, a 20-carbons polyunsaturated fatty acid, was studied in CA1 pyramidal neurons of the rat hippocampal slice maintained "in vitro". AA (50µM) was applied along with indomethacin (50µM), an inhibitor of the cyclo-oxygenase enzyme. The main results can be summarized as follows: (i) Perfusion of AA did not alter membrane resistance. (ii) Action potential amplitude and width increased by 5-8% and 8-14% respectively; the changes in width however did not reach significance. (iii) The threshold for action potential generation increased by 35% ($p<0.05$). (iv) There was a marked decrease in the number of action potentials induced by an intracellular depolarizing pulse. (v) In all neurons, AA induced at least a two-fold increase in the amplitude of the orthodromic EPSP. The increase in excitability was also observed when recording extracellularly. All these changes were not reversed after more than one hour of washing, presumably because of the AA's lipophilicity. Supported by MRC.

174.14

GLUTAMATE SPECIFICALLY INDUCES THE FORMATION OF 12-(S)-HYDROXYEICOSATETRAENOIC ACID IN RAT CEREBRAL CORTEX. L. Pellerin and L.S. Wolfe Experimental Neurochemistry, Montreal Neurological Institute, Montreal, Canada H3A 2B4

Arachidonic acid metabolites, especially those formed by lipoxygenases, have recently become implicated as possible second messengers. Piomelli et al. (PNAS 86: 1721, 1989) demonstrated that metabolites of the 12-lipoxygenase pathway are responsible for mediating the effect of histamine and FMRFamide on electrophysiological responses of Aplysia sensory neurons. As a first step toward a demonstration of a similar mechanism operating in vertebrates, we studied the formation of hydroxyeicosatetraenoic acids (HETEs) following application of various neurotransmitters. HETEs were separated by RP-HPLC and identified by GC-MS. Only glutamate and norepinephrine (100µM) were found to increase specifically 12-HETE by 100%. N-methyl-d-aspartate causes a similar increase while kainate was without effect. However 12-HETE can appear as two enantiomers,(S) or (R), that have quite different origin and properties. To determine which enantiomer(s) is(are) formed in cortex, peak corresponding to 12-HETE in previous experiments was submitted to HPLC chromatography on a DNBPG chiral phase column. It became clear that only the S form is present. These observations further suggest the presence of a specific 12-(S)-lipoxygenase in rat cerebral cortex which activity can be modulated by specific neurotransmitters. Supported by a grant from MRC. L.P is a NSERC scholar.

NEURONAL DEATH: MODELS AND MECHANISMS

175.1

UBIQUITIN MAY BE A CELL DEATH PROTEIN IN THE HAWKMOTH, Manduca sexta. L.M. Schwartz, M. Engelstein* and L.Kosz*. Zool. Dept., U. Mass. Amherst, Mass. 01003.

The death of the intersegmental muscles requires de novo transcription and translation. One of these regulated genes encodes for ubiquitin.

Manduca developmental Northern blots were probed with a Drosophila ubiquitin clone. mRNA levels were very low preceding the muscle's commitment to degenerate. Ubiquitin mRNA levels then greatly increased prior to emergence. When muscles were prevented from degenerating by injection of 20-hydroxyecdysone, ubiquitin mRNA remained at pre-commitment levels. Isolation and sequence analysis verifies that this transcript encodes for authentic Manduca ubiquitin.

Western blots demonstrate that ubiquitin is covalently linked to proteins at all stages. However, the number and intensity of ubiquitinated proteins increases dramatically after commitment.

These data suggest that ubiquitin may participate in the degeneration of the intersegmental muscles. To test this hypothesis, we are injecting ubiquitin anti-sense RNA into Manduca muscle to disrupt translation.

Supported by N.I.H. grant GM40458

MOTONEURON SURVIVAL IN VIVO FOLLOWING TREATMENT WITH EXTRACTS FROM ACTIVE AND INACTIVE MUSCLE. L. Houenou*, D. Prevette* and R. Oppenheim (SPON: T. Troost). Department of Anatomy, Wake Forest University School of Medicine, Winston-Salem, NC 27103.

In most vertebrates approximately 50% of spinal motoneurons die naturally during embryonic or fetal development. Previous studies have shown that chronic paralysis during the cell death period results in the survival of all motoneurons. We previously suggested that this rescue effect is mediated by the activity-dependent regulation of a target-derived trophic factor. Inactive muscle was postulated to produce more trophic factor than normally active muscle. We have now tested this notion and the results do not support our activity model. Motoneuron survival on day 9 following daily treatment of chick embryos in vivo with partially purified muscle extracts from either normally active or from genetically or pharmacologically paralyzed mouse and chick embryos did not differ. Extracts from both active and inactive muscles rescued 25-35% of the motoneurons that normally die. We conclude from these results that activity- blockade prevents motoneuron death in ovo by some means other than increased synthesis or production of a muscle-derived neurotrophic factor. Supported by NIH Grant NS20402 and by IBRO and Philippe Foundation Postdoctoral Fellowships to LH.

OLIVARY CELL COUNTS IN *NERVOUS* AND *LEANER* CEREBELLAR MUTANT MICE. H. Shojaeian, J. Mariani, N. Delhaye-Bouchaud, & K. Herrup. Institute de Neurosciences Univ. Pierre. & Marie Curie, Paris and E.K. Shriver Center, Waltham, MA.

A major factor controlling the extent of histogenic cell death is the size of the postsynaptic target. Quantitative studies suggest that one result of this neuron:target relationship is the numerical matching of pre- and postsynaptic elements. We and others have used neurological mutant animals as model systems as a means of deleting specific populations of neurons. Two such mutants lose Purkinje cells (PCs) postnatally: *leaner* (tg^{la}/tg^{la}) and *nervous* (*nr/nr*). These two mutations are of particular interest because both show regional variation in severity: *leaner* loses more Purkinje cells in anterior than posterior lobules while *nr/nr* loses more Purkinje cells in lateral than medial regions. In *nr/nr*, Purkinje cells are lost progressively from the third to the sixth postnatal week. Counts of inferior olive show that by P24, there is a 23% deficit of neurons and further losses (up to 40%) are observed by P66. In keeping with the pattern of PC loss, the medial accessory olive, which projects mostly to the hemisphere (where PC loss is the greatest), was significantly more affected than the other subnuclei. Unexpectedly, in *leaner* animals, there was no consistent loss of olivary neurons even in animals over one year old (by this age over 80% of the Purkinje cell targets have died. These results suggest either that there is a critical period of sensitivity after which olivary neurons are insensitive to target, or that there are unknown trophic factors in *leaner* that serve to stabilize the olivary cells.

Supported by NS20591 and the FYSSEN foundation.

175.4

QUANTITATIVE STUDY OF PROPORTIONS OF PURKINJE CELLS IN DEVELOPING CHECK CEREBELLUM. S. Zamenhof. Dept. of Microbiology and Immunology, and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024-1747.

The proportions of Purkinje cells to granule cells in cerebella of newly hatched chicks (total 237) were determined using two methods: 1. Counting Purkinje and granule cells on histological sections, and 2. Disintegrating cerebella and counting stained cells in suspension in a hemacytometer. The reliability of the latter method was previously demonstrated also by determinations of cellular DNA (Zamenhof, S., *Wilhelm Roux's Arch.*, 180:1, 1976). The histological method gave proportion 0.3% ± 0.09%, and the suspension method, 0.28% ± 0.04%. Thus, the two methods give comparable results, but the histological method has higher standard deviation, probably because it is subject to regional differences in cerebellum; this makes the suspension method more reliable for the study of effects of extrinsic factors on these proportions. The factors were applied during egg incubation, only in the period of proliferation of Purkinje cells (5E - 7E days). The cerebella of surviving chicks were examined at hatching when these precocial birds already have final cerebellar cell numbers. Using such a method, statistically significant changes in proportions of Purkinje cells were produced by: Higher or lower incubation temperature (Zamenhof, S., *Brain Res.*, 109:392, 1976), excess glucose or excess oxygen (Zamenhof, S., and Klimuszko, D, *Brain Res.*, 128:385, 1977), and antifolate (Zamenhof, S., *Growth*, 49:28, 1985). It is concluded that despite high constancy, the final proportions of Purkinje cells can be changed by appropriate factors applied during an appropriate period of cerebellar development. The possible effect of such changes on functioning of cerebella remains to be studied.

175.5

CONTROL OF NEURONAL SURVIVAL BY ABNORMAL TARGETS IN THE DEVELOPING BRAIN. R. Linden, Instituto de Biofisica da UFRJ, Rio de Janeiro, Brazil.

Neuron death is largely dependent on the availability of targets for developing axon terminals. It has been suggested that mismatching specific motoneuron pools and muscles might further limit neuron survival in the PNS. We have shown that normal numbers of neurons survive in the middle division of the parabigeminal nucleus (PBm) after neonatal ablation of its major target, the contralateral superior colliculus (SC). Here we show that regulation in the PBm is due to its anomalous projection to the lateral posterior nucleus of the thalamus (LP). This projection was identified with the use of radioautographic tracing and histochemical detection of cholinesterase in adult rats that received unilateral SC ablations at birth. We then tested whether the anomalous PBm-LP pathway might sustain the PBm neurons. In rats receiving neonatal ablation of the SC, additional removal of LP prevented the survival of the PBm neurons, while removal of dLGN did not. Thus, interactions of PBm axons with anomalous targets may effectively replace the normal interactions with the SC with regard to the trophic requirements of those central neurons. 175.6

BIRTHDATES OF INFRAORBITAL GANGLION CELLS AND EFFECTS OF NEONATAL NERVE DAMAGE UPON SURVIVAL OF NEURONS BORN ON DIFFERENT GESTATIONAL DAYS. H.L. Enfiejian, P. McCann, N.L. Chiaia, M.W. Miller, G.J. Macdonald and R.W. Rhoades (SPON: A.M. Golub). Depts. of Anatomy, Medical College of Ohio, Toledo, OH 43699 and Robert Wood Johnson Medical School, Piscataway, NJ 08854.

Distinct classes of ganglion cells may be differentially sensitive to neonatal axotomy. Several studies have shown that primary afferent neurons which survive such lesions have larger soma diameters than in normal animals. Since ganglion cell size is correlated with cell birthdate, this suggests that early born ganglion cells may be less sensitive to neonatal axotomy than later-born neurons. We have tested this directly in the V system by combining [^{3}H]-thymidine labelling with neonatal infraorbital nerve (ION) transection and retrograde HRP transport. Fetal rats were labelled with [^{3}H]-thymidine on embryonic days (E-) 9-14 (N ≥4 for each age). On the day of birth, the left ION was transected. Six weeks later, the ION on both sides was labelled with HRP. Tissue was then processed for visualization of both HRP and [^{3}H]-thymidine labelled cells. On the normal side, 5.8% of the ganglion cells that sent axons into the ION were born on E-9; the values for E-10 through E-14 were 21.6%, 16.6%, 21.9%, 30.4%, and 3.8%, respectively. Of the ganglion cells that sent axons into the regenerate ION, 4.9% were born on E-9 and the values for E-10 through E-14 were 17.6%, 15.7%, 27.1%, 28.7%, and 6.0%, respectively. There was a significant difference between the distributions of birthdates for ganglion cells that projected into the normal and regenerate ION's. In the normal ganglia, 56.1% of all ION ganglion cells were born on E-12 through E-14; in the ganglia ipsilateral to the damaged nerve, this value was 61.8% ($t=2.6$, $df=24$, $p<0.02$). Thus, later born V ganglion cells are slightly more likely to survive neonatal axotomy than early born neurons.

POPULATION DEATH CAUSES SURVIVING NEURONS TO PROPORTIONALLY INCREASE CATECHOLAMINE SYNTHESIS. **C.E. Greenwood, N. Seniuk*, W.G. Tatton and F. Biddle*. Departments of Physiology and Nutritional Sciences, University of Toronto, Toronto, Ontario M5S 1A8 and Department of Biochemistry, Univ. of Calgary, Calgary, Alberta, Canada T2N 1N4.**

The total number of substantia nigra compacta (SNc) dopaminergic and locus coeruleus (LC) noradrenergic neurons were determined using tyrosine hydroxylase (TH) immunocytochemistry and Nissl staining for alternate brainstem serial sections from aging (8 weeks-88 weeks) or MPTP-treated (37.5 - 300 mg/kg at 8 weeks of age) isogenic mice (C57BL/6Jbid). The total nuclear counts were combined with target tissue monoamine concentrations (measured by HPLC) for the striatum and cortex to determine mean (μ) levels of dopamine (DA), DOPAC and norepinephrine (NE) per surviving neuron. SNc and LC showed similar graded rates of neuronal death for both aging and MPTP treatment (e.g. μ 68% neuronal loss for 300 mg/kg MPTP and 80% loss at 88 weeks). With aging, μ cortical NE/neuron and μ striatal DOPAC/neuron increased exponentially in relation to cell loss reaching 3.5-5.0 times that at 8 weeks by 88 weeks of age. Striatal DA/neuron increased by only 30-60% for the same range of neuronal loss. At 20 days following MPTP treatment, μ striatal DA/neuron and DOPAC/neuron showed a biphasic relationship to neuronal loss (increasing to 1.5 fold up to 40% SNc neuronal loss and declining thereafter). We suggest that increases in the μ NE terminal content/neuron and μ DA terminal turnover/neuron in the aging animal represents attempts to compensate for the overall decrease in catecholamine innervation caused by the loss of adjacent neurons. The axonal damage caused by MPTP is known to decrease TH levels and thereby catecholamine synthesis. Hence the relative decrease in compensation by the MPTP-treated neurons may result from the additive effects of the response to the loss of adjacent neurons and a decreased TH synthetic response engendered by axonal damage. (Supported by MRC and NSERC of Canada).

TUMOR NECROSIS FACTOR-alpha (TNF-a)-INDUCED CYTOTOXICITY TO NCB20 AND NG-108 NEUROBLASTOMAS. D. Blake*, I. Baker, M. Connolly*, J. Ferkany, and P. Sweetnam. Nova Pharmaceutical Corporation, Baltimore, Maryland 21224-2788.

Tumor necrosis factor-alpha (TNF; cachectin) is believed to be an important mediator of inflammatory responses, cachexia, endotoxic shock, bone resorbtion, pyrogenesis and tumor necrosis. Possible roles for TNF in neurodegenerative disorders such as multiple sclerosis and AIDS have been proposed. The current study evaluated the response of various neuronal and non-neuronal cell lines to TNF.

Cells were grown in flasks, plated (2×10^4) on 6.4 mm wells, cultured for 24 hr. and exposed for an additional 24 hr. to various concentrations of TNF. Viability was determined using colorimetric bioassay (MTT). All cultures contained actinomycin D; control assays were performed in parallel in the absence of TNF or in the presence of the nonspecific cytotoxin A23187.

In sub-nanogram amount TNF induced a dose-dependent necrosis of NCB20, NG-108, and L929 but not IMR-32 cultures. The Ca^{++}-ionophore A23187 was lethal to all cultures. Heat inactivation of TNF eliminated the cytotoxic activity.

The data suggest that some neuronal cell lines are sensitive to the cyotoxic action of TNF. The mechanism by which TNF elicits this activity is being explored.

CELL DEATH DUE TO GDP-INDUCED CALCIUM INFLUX IN XENOPUS OOCYTES. B. Gillo*, S.C. Sealfon* (SPON: B. Cohen). Dept. of Neurology and Fishberg Center in Neurobiology. Mount Sinai Medical School. New York, N.Y. 10029

Xenopus oocytes are an excellent system for studying Ca stores and mobilization. Loading denuded oocytes with nominal 1-2 mM GDP-β-s (Gbs), an undegradable GDP analogue, leads to cell deterioration and death over several hours. We investigated the contribution of Ca influx to cell deterioration. Cell viability was evaluated by measure of membrane potential (Vm) and resistance (Rm). Following 1-2 hr incubation in Ca-containing medium, Vm and Rm were reduced 59% and 85% respectively in voltage-clamped, Gbs-injected cells compared to controls (n=14). In Ca-free medium, the Gbs induced reduction in Vm and Rm was significantly smaller, being 23% and 24%. The Ca-dependent Cl current was used as a monitor of changes in [Ca]i. After 2 hr in Ca-free media, Gbs-injected cells were exposed to 5mM Ca which evoked a current of 356±96nA(n=6); negligible current was elicited in controls (0-15nA, n=6). We suggest that elevations in [GDP]i lead to increased membrane permeability to Ca. This mechanism may contribute to the well known phenomenon of cell death caused by Ca influx.

NEURON SPECIFIC DIFFERENCES IN CALCIUM HOMEOSTATIC CAPACITY. L.R. Mills, P. Dou, and S.B. Kater, Program in Neuronal Growth and Development, and Dept. Anatomy & Neurobiology, Colorado State University, Ft. Collins, CO 80523

We have used the calcium ionophore A23187 to investigate the regulation of intracellular calcium in cultured *Helisoma* neurons. Two identified neurons (B5 and B19), were studied in two different states (growing and non-growing). Our findings demonstrate distinctive neuron-specific, as well as state-specific, responses to intracellular calcium loads. Thus different neurons, as well as the same neuron in different states, have very different calcium homeostatic capacities.

In these experiments, the behavior of neuronal growth cones, and the survival of neurons, were examined during exposure to a range of concentrations of A23187. In parallel experiments changes in intracellular calcium were measured using the calcium indicator fura-2. Under conditions where intracellular calcium levels rose only transiently (e.g., growing B5s, non-growing B5s, and non-growing B-19s), neurons survived and actively growing growth cones continued to elongate. At the other extreme, under conditions where intracellular calcium levels showed a sustained rise (e.g., in growing B19s), neurite degeneration and ultimately cell death occurred. These differences in calcium homeostatic capacity are due, at least in part, to differences in a sodium/calcium exchange mechanism. In the absence of extracellular sodium, neurons normally resistant to the effects of A23187 (e.g., growing B5s, non-growing B5s and non-growing B19s) showed sustained rises in intracellular calcium; these cells also died.

These studies indicate that calcium homeostatic capacities are under dynamic control. (1) They can be differentially expressed in different neurons. (2) They can change in the same neurons depending upon their growth status. Such differences can have profound consequences for the regulation of neurite outgrowth and the susceptibility of neurons to calcium-induced cell death.

ROLE OF CALCIUM CHANNELS IN THE ABILITY OF MEMBRANE DEPOLARIZATION TO PREVENT TROPHIC FACTOR DEPRIVATION INDUCED NEURONAL DEATH: EVIDENCE THAT LEVELS OF INTERNAL CALCIUM DETERMINE TROPHIC FACTOR DEPENDENCE. T.Koike, D.P.Martin and E.M.Johnson, Jr. Dept. of Pharmacology, Washington Univ. School of Medicine, St. Louis, MO 63110.

Sympathetic neurons depend on nerve growth factor (NGF) for their survival both in vivo and in vitro; these cells die upon acute deprivation of NGF. We studied the effects of agents that cause membrane depolarization on neuronal survival after NGF deprivation. High K^+ medium (≥33 mM) prevented cell death; the effect of K^+ was dose-dependent. The high K^+ saving was abolished either by withdrawal of extracellular Ca^{2+} or by preloading the cells with a Ca^{2+} chelator. The Ca^{2+} antagonists nimodipine and nifedipine effectively blocked the survival promoting effect of high K^+. Ca^{2+} agonists Bay K 8644 and (+)-(S) 202 791 did not by themselves save neurons from NGF deprivation, but strongly augmented the effect of high K^+.

Depolarizing agents, choline and carbamylcholine, acting through nicotinic cholinergic receptors, also rescued NGF-deprived neurons. The saving effect by nicotinic agonists was not blocked by withdrawal of extracellular Ca^{2+}, but was counteracted by a chelator of intracellular Ca^{2+}, suggesting the possible involvement of Ca^{2+} release from internal stores. Based on these findings we propose a "Ca^{2+} set point hypothesis" for the degree of trophic factor dependence of sympathetic neurons in vitro.

175.12

INVERSE REGULATION OF Ca^{++} CURRENT DENSITY AND SURVIVAL BY DEPOLARIZATION OF CULTURED RAT MYENTERIC NEURONS. J.L. Franklin* & A.L.Willard (SPON: R. Glasser). Physiology Dept., Univ. of N. Carolina, Chapel Hill, NC 27599.

Chronic depolarization enhances survival of myenteric neurons in culture. It also causes decreased Ca^{++} current density. We have tested the hypothesis that regulation of Ca^{++} currents influences survival.

Myenteric neurons from newborn rats were grown in culture medium containing 5 or 25 mM K^+. The latter concentration causes a sustained 25 mV depolarization. Whole cell patch clamp was performed with 20 mM Ba^{++} as charge carrier. Steps from -90 to 0 mV elicited Ba^{++} currents with transient and sustained components (τ_1=25-60 msec, τ_2>450 msec). By culture day 7, peak densities of transient currents in cells grown in 5 and 25 mM K^+ were 65±27 and 37±17 pA/pF, respectively (p<.007). Densities of sustained components (300 msec after pulses began) were 45±22 and 24±12 pA/pF (p<.01). Cells grown in 25 mM K^+ for 4 days and then switched to 5 mM for 1 day had current densities 60% greater than did cells grown for 5 days in 25 mM K^+. This recovery, to levels equal to 87% of the current density of cells grown 5 days in 5 mM K^+, was prevented by the transcriptional inhibitor DRB.

To test whether excess Ca^{++} influx might account for neuronal death in non-depolarized cultures, the Ca^{++} channel antagonist nifedipine was added to 5 mM K^+ medium. Dose-dependent enhancement of survival occurred; 25 nM nifedipine, which reduces Ca^{++} currents by ≈50% in these neurons, increased survival to 90%, the same as seen in 25 mM K^+. Survival in 5 mM K^+ controls was 61% (p<.01).

These results suggest that return of Ca^{++} current density to control levels after K^+ suppression requires transcription and that chronic depolarization rescues myenteric neurons by preventing excess Ca^{++} influx. Supported by NIH grant NS24362 to ALW.

175.13

Ca^{++}-DEPENDENT EFFECTS OF ACUTE K^+ DEPOLARIZATION ON SURVIVAL OF RAT MYENTERIC NEURONS IN CULTURE. J.C. Thigpen*, J.L. Franklin* & A.L. Willard (SPON: A. Stuart). Physiology Dept., University of North Carolina, Chapel Hill, NC 27599-7545.

Chronic depolarization with elevated K^+ increases survival in cell culture of many types of neurons, including myenteric neurons, whose survival increases 1.5 to 2 fold in medium containing 25 mM K^+ (control is 5 mM K^+). We have asked 2 questions about the effects of K^+: 1. Can acute (brief daily) treatments with elevated K^+ enhance survival? 2. Are the survival-enhancing effects of daily K^+ depolarizations Ca^{++}-dependent? The latter question was asked because depolarization can activate voltage-sensitive Ca^{++} channels in these neurons.

Myenteric neurons from small intestines of newborn rats were plated in medium supplemented with 25 mM K^+. On day 4, plating medium was replaced with fresh medium containing 5 mM K^+. Neurons were counted daily. Survival of neurons grown in 5 mM K^+ from days 4 to 10 increased from 55±9% to 88±5% when the cultures were switched to medium containing 50 mM K^+ for 60 minutes per day. Effects of daily hourly treatment with elevated K^+ were prevented if the high K^+ medium contained 0.2 instead of 2 mM Ca^{++} or if it contained nifedipine (1 μM), which reduces Ca^{++} currents in these neurons by >90%. It was also prevented by a 5 minute pretreatment with 3 μM TMB-8, which is reported to block release of *intracellular* Ca^{++}. To test whether other means of elevating intracellular Ca^{++} could enhance survival, we examined the effects of the Ca^{++} ionophore A23187. Daily 30 second treatments with 10 μM A23187 and 1 μM Ca^{++} increased survival in 5 mM K^+ from 56±12% to 86±11%; 5 minutes of A23187 was lethal.

These results suggest that brief daily elevations of intracellular Ca^{++} significantly enhance survival of myenteric neurons in cell culture, but that excess Ca^{++} influx is fatal. Support: NIH grant NS24362 to ALW.

INTERFERONS CAN PREVENT SYMPATHETIC NEURONAL DEATH INDUCED BY NGF DEPRIVATION. J.Y. Chang*, D.P. Martin and E.M. Johnson Jr. Dept. of Pharmacology, Washington University School of Medicine, St Louis, MO 63110.

We have examined the effects of interferons on survival of cultured rat superior cervical ganglion neurons deprived of nerve growth factor. These cells will die within 48 hours after treatment with antibodies against nerve growth factor. Addition of interferons (IFN-α/β or IFN-γ) concurrently with the anti-NGF antibodies can prevent the cell death in a dose-dependent manner during this period. IFN-γ is much more potent in this respect, with an EC_{50} of approximately 1 unit/ml. In contrast, the EC_{50} of IFN-α/β is approximately 1,000 units/ml. Sympathetic neurons have specific binding sites for IFN-γ on their cell bodies and neurites. Receptor crosslinking results in a major species of protein complex in the region of 100,000 daltons. Further experiments indicate that the IFN can save a majority of cells acutely deprived of NGF for a short period. It can slow down the overall dying process of these neuronal cells over an extended period of NGF-deprivation, but can not prevent the ultimate death. We speculate that IFN may have a role in preventing neuronal cell death during injury, thus minimizing the extent of damage resulting from trauma. 176.1

THE KNEE JOINT OF THE RAT. ANATOMY AND NERVE SUPPLY. C. Hildebrand and E. Lideberg*. Dept. of Cell Biology, Fac. Hlth Sci., Univ. of Linköping, S-581 85 Linköping, Sweden.

Although the rat has been used in several recent papers on experimental arthritis, the gross morphology and nerve supply of the knee joint has not been described in this species. In the present study we examine the knee joint in adult rats. X-ray examination showed persisting tibial and femoral epiphyseal cartilages. The femoral component exhibited a conventional appearance. The proximal end of the tibia showed a deep intercondylar fossa where the cruciate ligaments attached. The thin fibula was fused to a prominent tibial bony shelf. Dissection revealed collateral, cruciate and patellar ligaments as well as menisci, with a conventional morphology. A large cartilaginous formation extended from the proximal border of the patella. Careful examination revealed the presence of a medial (MAN) and a posterior (PAN) articular nerve. The MAN courses as one or two branches from the saphenous nerve to the area surrounding the medial collateral ligament. It contains 10-30 myelinated and 30-100 unmyelinated axons. Behind the knee the PAN leaves the tibial nerve at the level of the gastroenemius muscular branches and courses through the popliteal fat to the capsule. Stimulation of the PAN did not elicit contraction of the popliteus muscle. The PAN is composed of 250-500 axons most of which (70-80 %) are unmyelinated. Neonatal administration of capsaicin has little effect on the proportion of unmyelinated axons in the PAN and MAN.

DIFFERENTIAL RESPONSIVENESS OF CUTANEOUS A-DELTA AND C-FIBER MECHANONOCICEPTORS TO PRURITOGENIC STIMULI IN RAT AND CAT HAIRY SKIN. H.A. Martin and R.P. Tuckett. Dept. Physiol., Univ. Utah Sch. Med., Salt Lake City, UT 84108

Cowhage is a classical itch-producing substance known to induce pruritus in the vast majority of human subjects. Since histamine is implicated as a mediator of pain, as well as itch, it was of interest to compare the responsiveness of cutaneous high threshold mechanonociceptors (HTMs) to these two classes of pruritogens. Saphenous sensory neurons were characterized according to conduction velocity and response to mechanical, thermal and chemical (spicules of cowhage, histamine iontophoresis [1%, 30 sec; 20 μA], hypertonic saline [3.6%, 3 μl, i.d.] and topical glacial acetic acid) stimuli. In rat, from a total of 7 Aδ and 10 C fiber HTMs, 2 C HTMs were activated by both cowhage (CH) and histamine (HI). Two Aδ and 1 C HMTs were activated only by HI. One Aδ HTM responded only to HI; the remainder were unresponsive. In cat, from a total of 5 Aδ and 5 C HTMs, 1 Aδ and 1 C HTM were activated by both CH and HI. One Aδ HTM responded only to HI; the remainder were unresponsive. HTMs that were responsive to HI and/or CH were responsive to heat and hence can be classified as polymodal nociceptors. The data suggest that only a subset of polymodal nonociceptors respond to pruritic stimuli. Hervé Martin is a N.A.T.O. grant recipient (Paris) and has been supported by Philippe Foundation, Inc. (New York). Supported by USPH grant NS15102.

PHYSIOLOGICALLY IDENTIFIED NEURONS IN CAT MEDULLA RESPOND TO IONTOPHORESIS OF ADENOSINE PRECURSORS. J.L. Henry and K.B. Austin*, Depts. Physiology & Psychiatry, McGill University, Montreal, Quebec, H3G 1Y6

Physiologically identified neurons located in the dorsomedial medulla at the level of the obex were recorded extracellularly and tested for their responses to iontophoretic application of ATP and AMP. Recording and iontophoresis was performed in cats which were either chloralose anesthetized (60 mg/Kg I.V.) or decerebrated at the intercollicular level and either spontaneously breathing or paralyzed with pancuronium bromide. Neurons were classified as either 1) somatosensory neurons which responded to tactile stimulation and were located in either the nucleus cuneatus or gracilis, 2) inspiratory neurons which fired in phase with phrenic nerve discharge or with respiration, responded to stimulation of the superior laryngeal and/or vagus nerves, and were located in the solitary tract nuclei. Most of the neurons tested responded to iontophoretic application of ATP. The response during application was an increase in firing rate. In about half the neurons tested a marked decrease in firing rate was observed after the application of ATP was terminated. The majority of cells that responded to AMP exhibited decreased firing rates. The responses to ATP and AMP were similar regardless of type of neuron or animal preparation. These effects of ATP and AMP on medullary neurons are similar to those previously reported for somatosensory nociceptive neurons recorded in the spinal cord (Salter and Henry, Neurosci. 15:815-825, 1985). In light of the fact that inspiratory neurons are a type of viscerosensory neuron, our data indicates that ATP and adenosine may be utilized synaptically in both visceral and somatic sensory systems.

A STUDY OF TYPE I CUTANEOUS MECHANORECEPTOR RESPONSIVENESS IN VITRO. R.P. Tuckett, J.Y. Wei, H.A. Martin, P. Tsai* and K.B. English. Dept. Physiol., Univ. Utah School of Medicine, Salt Lake City, UT 84108.

There is in vivo evidence that type I neurons display chemosensitivity. An in vitro preparation would help to rule out the possibility that such increased responsiveness is due to edema formation secondary to changes in vascular permeability. An in vitro skin preparation has been modified to obtain a higher yield of type I mechanoreceptive neurons than originally reported (P.W. Reeh, Neurosci. Letters, 66: 141-146, 1986). Modifications included dissection under hypothermic conditions and as moving the preparation to a saturated O_2 environment prior to placement in the perfusion system. O_2 loss was minimized by using gas-tight tubing and maintaining a flow of 100% O_2 gas above the surface of the perfusion chamber. Further improvements include placing the skin epidermis side up for precise Haarscheiben localization and improving perfusion underneath the preparation. Type I neurons appear to be relatively more sensitive to hypoxia than other cutaneous receptor populations, perhaps indicating that the Merkel cell/type I complex supports a transmitter mechanism of action potential generation. Supported by USPH grants NS07938 and NS15102.

MECHANICAL AND HEAT RECEPTIVE FIELDS OF CUTANEOUS C-FIBER NOCICEPTORS COINCIDE. **R.-D.Treede*, R.A.Meyer, and J.N.Campbell, Johns Hopkins Univ., Baltimore, MD 21205.**

The receptive fields (RFs) of polymodal nociceptors are usually mapped using mechanical stimuli. These RFs are then typically subjected to heat or chemical stimuli, assuming that the RFs are identical for all modalities. We tested this assumption by comparing the mechanical and heat RFs of 26 C-fiber nociceptors responsive to both mechanical and heat stimuli (CMHs). Standard teased-fiber techniques were used to record from single CMHs that innervated hairy skin of anesthetized monkey. Mechanical thresholds were determined with calibrated von Frey probes, and heat thresholds were determined with a laser thermal stimulator. The borders of the mechanical and heat RFs were mapped with 10 bar and 49°C stimuli. Mechanical thresholds (3.3 ± 1.6 bar, mean ± SD) and heat thresholds (41.1 ± 2.5 °C) of the CMHs were not correlated. Mechanical RF diameters (5.2 ± 1.7 mm) and heat RF diameters (4.3 ± 2.4 mm) were linearly correlated ($p \leq 0.01$) with a slope of one. The centers of the mechanical and heat RFs were within 0.4 ± 0.3 mm. The close match of both size and location of the mechanical and heat RFs suggests one of three possibilities: 1) the transducer for mechanical and heat stimuli is the same; 2) the transducers reside on the same branches; or 3) the distributions of mechanical and heat sensitive branches coincide. (Supported by DFG Tr236/1-1 and NIH NS-14447)

176.6

EVIDENCE THAT BRADYKININ INDUCED CUTANEOUS PAIN IS NOT MEDIATED BY HISTAMINE RELEASE. **S.L.Kozak*, R.A.Meyer, S.N.Raja, D.C. Manning and J.N.Campbell, The Johns Hopkins Univ. School of Medicine, Baltimore, MD 21205.**

Bradykinin (BK) is found in inflamed tissue and is known to cause both acute pain and hyperalgesia in humans. Since BK can degranulate mast cells and release histamine, we wished to determine if the cutaneous pain induced by BK is mediated by histamine. Trained subjects used the technique of magnitude estimation to rate the pain produced by intradermal injections to the volar forearm of BK or histamine phosphate (HIS). Four drug injections (10 nmole in 10 μl) at 10' intervals were administered at the same site. In a given session, one of four sequences was used: (1) BK-BK-BK-HIS; (2) HIS-HIS-HIS-BK; (3) BK-BK-BK-BK; (4) HIS-HIS-HIS-HIS. Pain ratings were recorded every 5s, and the area under the pain-time curve was determined. The pain produced by HIS and BK decreased significantly from 79 ± 20 (mean ± SEM) and 320 ± 26 on the first injection to 12 ± 6 ($p \leq 0.01$) and 10 ± 4 ($p \leq 0.001$) on the third injection, respectively. However, BK injected as the 4th injection after three HIS injections produced a similar level of pain (401 ± 80) as the first BK injection. These results indicate that there is pronounced tachyphylaxis for the pain produced by repeated injections of histamine, whereas there is no crossed tachyphylaxis for bradykinin. It is thus likely that the cutaneous pain produced by bradykinin is not mediated through release of histamine.

176.7

MECHANICALLY-INSENSITIVE NOCICEPTORS IN THE PRIMATE. K.D. Davis, R.A. Meyer, R.H. Cohen and J.N. Campbell, Department of Neurosurgery and Applied Physics Lab., The Johns Hopkins University, Baltimore, Md 21205.

Many psychophysical phenomena cannot be explained by the properties of "typical" mechanically-sensitive nociceptors. In order to study mechanically-insensitive afferents (MIAs), we have developed an electrocutaneous search technique to locate the cutaneous receptive fields of all A- and C-fiber afferents. In barbiturate-anesthetized monkeys, single fiber recordings were made from 34 Aδ- and 79 C-fibers. Cold and warm fibers were excluded from the study. A substantial proportion of the Aδ- (47%) and C- (19%) fibers had either extremely high mechanical thresholds, >10 bars (100 g/mm²), or were unresponsive to mechanical stimuli and were classified as MIAs. Many (13 of 20) of these MIAs did not even respond to intense forceps pinch. MIAs typically had coincident mechanical and electrical receptive fields encompassing a single punctate spot. Heat stimuli (49°C) excited less than half of the Aδ- and none of the C-MIAs. Some of the Aδ-MIAs had moderate heat thresholds (45°C-47°C) and their relatively short utilization times suggest a role in first pain sensation. Intradermal injection of capsaicin or histamine excited some of the Aδ- and C-MIAs not excited by noxious thermal stimuli. These data suggest that MIAs play an important role in pain. (Supported by NIH grant NS-14447 and the Canadian MRC)

176.8

RESINIFERATOXIN IS A POTENT CAPSAICIN-LIKE SENSORY NEUROTOXIN Janet Winter*, Andre Dray, John N.Wood and Stuart J.Bevan* The Sandoz Institute, 5 Gower Place, London WC1.

Resiniferatoxin (RTX), is a potent irritant found in plants of the Euphorbia family. This compound is a diterpene of the daphnane class with a 3-methoxy 4-hydroxy phenylacetic acid conjugated to the 20-OH position. The structurally-related tumour promoting phorbol esters have a free 20-OH function which plays an important functional role in the activation of kinase C. RTX is not a tumour promoter and much of its irritant activity resides in the 3-methoxy 4-hydroxy benzyl side chain which also occurs in the well-characterised sensory neurotoxin capsaicin. An analysis of the effects of RTX on sensory neurons either in culture, or in the isolated neonatal rat spinal cord/tail preparation has shown a potent capsaicin-like action, depolarising a subset of sensory neurons through the long-lasting activation of a specific cation conductance which is permeant to Na^+,Ca^{2+} and K^+. The species and cell type specificity of RTX are identical to capsaicin, but the EC_{50} for most actions is ≤1nM (cf capsaicin EC_{50} 0.1-0.3μM). RTX, like capsaicin, elevates cGMP but not cAMP in neonatal rat neurons from DRG which do not contain neurofilaments. Calcium uptake into mitochondria is dramatically enhanced by RTX . The ion fluxes (^{45}Ca,^{86}Rb and ^{14}C- guanidine) evoked by RTX in cultures of sensory neurons cross -desensitise with those evoked by capsaicin. In the tail cord preparation, application of pmolar RTX desensitised the response to subsequent capsaicin application, without affecting noxious heat or bradykinin-evoked ventral root depolarisations. RTX thus provides a novel potent tool for the investigation of sensory neuron function.

176.9

A PATCH-CLAMP ANALYSIS OF TETRODOTOXIN (TTX) -SENSITIVE AND -RESISTANT Na^+ CURRENTS IN NEURONS ISOLATED FROM SENSORY AND PARASYMPATHETIC GANGLIA OF THE ADULT RAT. **W.C. de Groat, F.F. Weight, G. White*. Section of Electrophysiology, NIAAA, Rockville, MD 20852.**

Using the whole-cell variant of the patch-clamp technique, Na+ currents were studied in neurons which were mechanically and enzymatically isolated from lumbar dorsal root ganglia (DRG) and the major pelvic ganglia (MPG) of adult rats. Under "normal" ionic conditions, neurons exhibited resting membrane potentials (-45 to -60 mV) and action potentials (80 to 110 mV) equivalent to those observed in intact ganglia. Na+ currents were studied under altered external (35 or 75 mM Na+, 0 Ca++, and 115 or 75 mM TEA) and internal (140 mM Cs+ replacing K+) ionic conditions. Both TTX (1μM) -sensitive (TTX_S) and TTX-resistant (TTX_R) Na+ currents were observed in DRG and MPG neurons. DRG neurons that exhibited only a TTX_R current were on the average smaller than neurons with only a TTX_S current (24 μm versus 36 μm). TTX_R currents activated and inactivated on average at more positive potentials than TTX_S currents (activation threshold ≈-43 vs ≈-50 mV and full inactivation ≈-35 vs ≈-46 mV, respectively) in DRG neurons. The existence of TTX_R Na+ currents in parasympathetic ganglia contrasts with the reported absence of such a current in sympathetic ganglia (Pflug. Arch. 411: 481, '88).

176.10

DIFFERENT EFFECTS OF CAPSAICIN ON THE MEMBRANE PROPERTIES OF CULTURED NEONATAL RAT DRG NEURONS M. Alreja*[1], D. Lo[2] and R.H. LaMotte[1] (SPON: L. Marks)
Department of Anesthesiology[1] and Section of Molecular Neurobiology[2], Yale Univ. Sch. of Med., New Haven, CT 06510.

Whole-cell voltage clamp and current clamp recordings were made from 1 day old rat DRG neurons maintained in culture and the membrane effectsof a brief exposure to capsaicin studied.

Under voltage clamp, at a holding potential of -70 mV, bath application of 1uM capsaicin (Sigma, Fluka) produced a transient, inward current accompanied by an apparent decrease in input conductance in 12 out of the 21 neurons tested. Capsaicin (Fluka) invariably produced a higher magnitude current than an equimolar dose of capsaicin (Sigma) irrespective of the order of administration. Preliminary data indicate a reversal potential between -70 and -100 mV for the inward current, suggestive of a potassium conductance since chloride containing electrodes were used. Similarly under current clamp, a transient depolarization associated with an increase in input resistance of the cell was observed.

A transient, inward current associated with an increase in input conductance was seen in 4 neurons. In 2 of the neurons the change in input conductance was prolonged. A reversal potential close to 0 mV has been reported for a similar current recorded by Bevan and Forbes (1988).

In 5 of the 21 neurons tested, 1uM capsaicin did not have any effect on the membrane properties of DRG neurons.

In conclusion, at least 3 populations of neonatal rat DRG neurons can be differentiated on the basis of their response to capsaicin.

ELECTROPHYSIOLOGICAL PROPERTIES AND CHEMOSENSITIVITY OF CULTURED RABBIT TRIGEMINAL GANGLION NEURONS T.K. Baumann and R.H. LaMotte, Dept. of Anesthesiology, Yale University Medical School, New Haven, CT 06510

Adult rabbit trigeminal (primary afferent) neurons in dissociated culture display a variety of electrophysiological properties, e.g. various shapes of action potentials recorded at the soma, differences in accommodation, presence or absence of inward rectification (Baumann and LaMotte, Neurosci. Abstr. 14, 560), thus maintaining some of the differentiated properties of primary afferent neurons observed by others in vivo. Here we have examined the chemosensitivity of trigeminal neurons.

The effects of the irritant capsaicin on cultured newborn and adult rabbit trigeminal neurons were studied using the whole-cell patch-clamp recording technique. When capsaicin (1 or 10 μM) was applied for one minute to the cultures by superfusion (flow rate 1.5 ml/min.), some neurons (two thirds of the newborn, about one third of the adult) responded with an inward current of up to 350 pA. In some neurons the current was transient and faded when capsaicin was washed out of the bath, whereas in other neurons, the current did not return to control values 15 minutes after capsaicin was discontinued. When tested in the same neuron, the higher dose of capsaicin (10 μM) evoked larger transient currents than the lower dose (1 μM). In some neurons capsaicin caused the discharge of action potentials (recorded as currents). The total number of action potentials was greater at the higher dose of capsaicin. An attempt to establish a correlation between electrophysiological properties and chemosensitivity of cultured rabbit trigeminal neurons is in progress.

SYMPATHETIC ACTIVATION INCREASES NOCICEPTOR RESPONSIVENESS AFTER NERVE INJURY. J.Sato* and E.R.Perl Dept. of Physiol., Univ. No. Carolina, Chapel Hill, NC 27599

To test whether nerve injury alters nociceptor reaction to sympathetic activation, under sterile conditions we damaged the great auricular nerve (GAN) of deeply-anesthesized domestic rabbits by stretching, by ligation or by partial division and allowed the animals to recover for 4 to 148 days. Post-operatively, none of the animals exhibited signs of discomfort or skin alterations. Terminally, under deep anesthesia, responses of single C-fiber polymodal nociceptors (CPM) to stereotyped heat stimuli were recorded from fine GAN filaments central to the site of damage and compared to CPM responses in control animals. In controls (n=12), sympathetic trunk stimulation (SS) neither caused CPMs to discharge nor altered heat-evoked activity, but suppressed the usual sensitization to repeated heat stimulation. In sharp contrast, SS substantially (1.5 to 3x) enhanced heat-produced sensitization in 1/2 to 2/3 of CPM units from injured nerves (n=44). SS enhancement of CPM sensitization relative to controls was significant for each type of nerve injury. For some injured nerve CPMs, SS was excitatory by itself and relative to controls increased initial responses to heat. We interpret these results as favoring altered sympathetic effects upon nociceptor terminals after nerve injury as an explanation for some causalgic-like pain syndromes. AN ABNORMALITY OF THE SYMPATHETIC VASOMOTOR INNERVATION IN RATS WITH A PAINFUL PERIPHERAL NEUROPATHY. S.Wakisaka*, K.C.Kajander and G.J.Bennett* (SPON: C. Pechura). NAB, NIDR, NIH, Bethesda, MD 20892.

Painful peripheral neuropathies in humans are sometimes accompanied by an abnormality of cutaneous temperature regulation that is presumed to indicate a dysfunction of sympathetic vasomotor control. The sympathetic dysfunction, in turn, is thought to be causally related to the neuropathic pain sensations. Rats with a painful neuropathy of the sciatic nerve (Pain 33:87-107, 1988) also display temperature abnormalities. As in humans, the incidence is variable, but about one-third of the rats have hind paws that are clearly abnormally hot or cold. As a first step in examining this phenomenon, we examined the effects of the neuropathy on the noradrenergic vasomotor innervation of the affected hind paw.

The plantar artery and vein were excised (from both the nerve-damaged and control sides) and prepared as whole mounts. The glyoxylic acid-induced histofluorescence method was used to visualize norepinephrine (NE). The temperature of the plantar hind paws was measured just prior to sacrifice.

On the control side, NE axons always formed a dense reticulum on the surface of the artery and a sparser web on the vein's surface. Beginning at 5 days post-injury, a few rats had a clear decrease in NE on the nerve damaged side. The NE decrease became increasingly severe and more common through days 5-18; at these times many rats had no detectable NE. By 30 days, NE could not be detected in any of the cases. NE began to reappear by 60 days and was close to normal by 180 days. The expected relationship between the status of the vasculature's NE and skin temperature was not always present. Thus, some abnormally cold paws had no detectable NE and some abnormally hot paws had normal NE.

The data indicate that the experimental neuropathy is associated with an abnormality of sympathetic efferents. The temperature abnormality, however, is not directly related to the sympathetic dysfunction.

DORSAL ROOT GANGLION NEURONS PROJECTING TO THE DORSAL COLUMN NUCLEI OF RATS. R. Giuffrida and A. Rustioni. Cell Biol. & Anat., Univ. N. Carolina, Chapel Hill, NC 27599.

This reinvestigation of dorsal root ganglion (DRG) cells at the origin of the primary afferents to the cuneate nucleus provides a background for a project aimed at identifying neurotransmitters in these neurons. Colloidal gold coupled to WGA-apo-HRP was injected into the cuneate nucleus of rats. After two to three days, rats were perfused with 4% paraformaldehyde and the ipsilateral cervical DRGs were postfixed and embedded in paraffin. The presence of the tracer was revealed by means of silver intensification of the gold particles. In 5 µm-thick sections counterstained with cresylviolet, neurons displaying the nucleolus were considered for quantitative estimates. The percentage of labeled neurons varied in different ganglia depending on the site and size of the injections. Highest percentages, up to 60 -65%, were found as a rule in C5 to C6; at more rostral levels, percentages were regularly lower, in the range of 15% to 25%. The greatest majority of retrogradely labeled neurons were of large size, but medium-size neurons were also labeled. These counts are, on the whole, significantly higher than those reported in previous publications.

176.15

AFFERENT PROJECTIONS AND EFFERENT ORIGINS OF THE VAGUS NERVE IN THE LAMB. J.M. Wild, B.M. Johnston* and P.D. Gluckman*. Depts. of Anatomy and Paediatrics, Univ. of Auckland Sch. of Med., Auckland, New Zealand.

The total sensory projections and motor origins of the vagus were defined in the lamb by injections of cholera toxin B subunit conjugated to horseradish peroxidase into the nodose ganglion (n=17), the cervical vagus (n=6), or the superior laryngeal nerve (n=2). The lambs were perfused after 3 days and brain and spinal cord sections were processed with TMB. Ganglionic injections showed a massive accumulation of reaction product in all ipsilateral and certain contralateral subnuclei of nucleus tractus solitarius (nTS). Other regions receiving descending sensory projections were the area postrema, the dorsal motor nucleus of X (DMNX), the nucleus ambiguus region caudal to the obex, the nucleus of the descending trigeminal tract, and lamina I of the cervical dorsal horn. TS descended to the level of C2 through the neck of the dorsal horn. Ascending projections from the level of entry of TS could be traced by labeled fiber fascicles to distinct dorsomedial and dorsal subnuclei of principal V, and, more rostrolaterally, to caudal regions of the lateral parabrachial nuclear complex. Retrogradely labeled cells were located in DMNX, in nucleus ambiguus, and in the dorsomedial ventral horn and lateral intermediate grey of the upper cervical cord. The last two cell groups had medial dendrites which crossed the midline.

ACTIVITY DEPENDENT LATENCY CHANGES IN SMALL DIAMETER CUTANEOUS AFFERENTS IN RAT SCIATIC NERVE. J.G. Thalhammer, S.A. Raymond, F. Popitz* and G.R. Strichartz. Anesthesia Research Lab., Brigham & Women's Hospital, Harvard Medical School, Boston, MA. 02115.

Each impulse in a series of electrically activated spikes in an axon shows a shift in conduction time (latency) that depends on previous discharges in the fiber (Raymond, J. Physiol. 290:273-303, 1979). Here we have compared these activity-dependent latency changes in functionally characterized cutaneous afferents recorded from rats fully anesthetized with Nembutal.

Forty-one Aβ, 15 Aδ and 10 C-fibers have been characterized according to their response to natural stimulation and studied with electrical stimulation of the nerve trunk. Generally, afferents with slower conduction velocity (CV) show more pronounced latency changes at any given rate, and some C-fibers (CV < 2m/s) show progressive slowing of conduction at stimulation rates below 0.5 Hz. However, among individual units there are large variations in the latency shifts at any one rate. Latencies may double or even triple for certain Aδ units (2< CV <30 m/s) stimulated for several minutes at 5 or 10 Hz, although those identified as cold fibers show no latency increase at 10 Hz, and increase less than 5% even after 20 sec stimulation at 20 Hz. In contrast, Aδ nociceptors with a resting CV (measured at 0.2 Hz) similar to cold fibers show increases as great as 150% in latency during repetitive discharge at 10 Hz, suggesting that the degree of latency shift during activity is correlated more tightly with modality than with diameter (CV).

176.17

SPATIAL FEATURES OF VIBROTACTILE MASKING EFFECTS ON AIRPUFF-ELICITED SENSATIONS IN THE HUMAN HAND A.Pertovaara, J.Kekoni*, I.Tikkala* & H.Hämäläinen Depts.Physiol.&Psychol.,Univ.Helsinki, Finland

The spatial features of vibrotactile masking on airpuff-elicited sensations were determined using a reaction time paradigm in man. The masking decreased monotonically with increasing distance, and identically to longitudinal and transversal directions in dorsal and palmar skin of the hand. The masking was stronger in the glabrous skin, especially in the fingers. In the glabrous skin the spread of high-frequency masking was less extensive than that of low-frequency masking. The mechanical spread of high-frequency vibration was, however, less extensive. A masker applied to the tip of the finger produced stronger masking than a masker in the base of the finger.

Mechanical spread of vibration can only partly explain the masking effects. The stronger afferent inhibition in the glabrous skin of the fingers may explain the superior spatial tactile discrimination properties of the glabrous skin. Peripheral innervation density/size of the cortical representation is of importance in determining the magnitude of masking.

Discharge properties of mechanoreceptive afferents in the cat anterior cruciate ligament. K.J. Cole, D. Pope and R.A. Brand. Depts. of Exercise Science and Orthopaedic Surgery, The University of Iowa, Iowa City, IA 52242.

Proprioceptive information from mechanoreceptors located in the knee's cruciate ligaments has been suggested to contribute to leg motor control. However, the discharge properties of identified cruciate afferents are virtually unknown. The present study was conducted to begin characterizing the discharge properties of cat anterior cruciate ligament (ACL) afferents to mechanical stimulation.

Activity of ACL afferents in the posterior articular nerve was recorded from each of 8 chloralose-anesthetized cats. A small block of the tibia containing the ACL insertions was removed and the leg was disarticulated at the knee. The preparation exposed the ACL and eliminated inadvertant stimulation of joint afferents due to relative tibial-femoral motion that occurs upon loading the ACL in the intact knee.

Afferents were activated upon probing the ACL with a 2 mm dowel using forces as small as 2 grams. Rapidly and slowly adapting afferents were activated. Many of these afferents responded to loads as small as 1.8 grams that stretched the ACL along its long axis; most adapted rapidly There appear to be functional subgroups of ACL afferents; some signal strain or changes in strain, whereas others may signal ACL impingement against the PCL or femoral notch. The correspondence of these signals to joint position or its derivatives must be examined in the intact knee.

THE THEORY OF TEMPORAL SUMMATION PRECLUDES CERTAIN CODES FOR SIGNALING THRESHOLD EVENTS IN THE PACINIAN PSYCHOPHYSICAL CHANNEL. S.J. Bolanowski, Jr. and C. M. Checkosky *. Institute for Sensory Research, Syracuse University, Syracuse, NY 13244 and Dept. Neurosurgery, University of Rochester Medical School, Rochester, NY 14642.

The theory of temporal summation refers to the psychophysical phenomenon in which threshold decreases with increasing stimulus duration. The effect is found in audition and is central. Vibrotactile thresholds mediated by the Pacinian-corpuscle (PC) population (the "P" channel) also exhibit temporal summation. Assuming that the tactile summator is also central, it may be possible to eliminate potential neural codes for signaling threshold in the P channel. Theoretically, temporal summation predicts a decrease in threshold at a rate of -3dB/doubling of duration from 10 to 100 msec. Thus by integrating the response from single fibers for various response criteria, those not having the potential for temporal summation can be rejected as possible coding schemes. PCs isolated from cat mesentery were stimulated with bursts of vibrations (300 Hz) having durations from 10 to 1000 msec, the intensity of the stimuli adjusted for fixed criterion responses of 1,2 and 4 impulses/burst and 1 impulse/cycle. Data were sampled over the entire burst duration, in effect analyzing the response with an ideal summator. The decreases in intensity for increases in duration from 10 to 100 msec were -0.9, -1.2, -2.3 and -0.2 dB/doubling, respectively, with neither the 1 impulse/burst nor the impulse/cycle criteria showing significant summation. The other two criteria show modest summation, indicating that they, but not the others, have the potential for being the neural code for threshold in the P channel. [Work supported by NS23933]

SYNAPTOLOGY OF PHARYNGEAL AFFERENTS IN THE PARATRIGEMINAL ISLANDS OF THE RAT. D.W. Saxon* and D.A. Hopkins. Dept. of Anatomy, Dalhousie University, Halifax, NS B3H 4H7.

The paratrigeminal islands (PTI) in the rat consist of a group of small neurons embedded in the dorsal aspect of the spinal tract of the trigeminal nerve (Chan-Palay, '78). Trigeminal, glossopharyngeal and vagal afferents, some of which derive from the pharynx, terminate in the PTI. WGA-HRP (5%, 3-5 ul) was injected into the pharyngeal musculature and mucosa of male Wistar rats to identify pharyngeal afferent terminations in the PTI. After 3-4 days the medulla oblongata was processed for light and electron microscopy with HRP histochemistry (Mesulam, '78) and ammonium molybdate stabilization (Marfurt et al, '86). Axon terminals in the PTI contained mainly round clear vesicles and formed asymmetric synaptic junctions with neuronal perikarya and dendrites. Terminals with pleomorphic clear vesicles and symmetric contacts were rare. Pharyngeal afferent terminal labeling was found exclusively in axon terminals containing round clear vesicles with occasional dense-cored vesicles. Labeled terminals formed asymmetric synaptic contacts with small diameter dendrites. Pharyngeal afferents projecting to the PTI have a similar synaptic organization to those projecting to the subnucleus interstitialis of the NTS.

CUTANEOUS AND PROPRIOCEPTIVE CONTRIBUTIONS TO TACTUAL DISCRIMINATION OF SOFTNESS. R.H. LaMotte and M. A. Srinivasan* Dept. of Anesthesiology, Yale Univ. Sch. of Med., New Haven, CT. 06510 and Research Lab. of Electronics, MIT, Cambridge, MA 02139.

The capacities of humans to discriminate between objects that varied in softness were measured under conditions that differed as to the relative contributions of cutaneous and proprioceptive cues available to the subject. A series of disks that differed in compliance (slope of displacement vs. force trace obtained by vertical indentations of each disk with a rigid probe) were cast using silicone rubber. Subjects made two-interval forced-choice discriminations using the distal pad of the middle finger. When the maximal force of indentation allowed was low (80g), optimal discrimination was achieved under active touch, wherein both proprioceptive and cutaneous information was available. Under passive touch, when only cutaneous cues were present, discrimination was much poorer and was confounded by alterations in indentation velocity. When the maximal force of indentation was higher (160g) under active touch, and cutaneous cues were eliminated by a local anesthetic, discrimination based on proprioceptive signals alone was not possible. However, without the anesthetic, optimal discrimination was possible under passive conditions based on cutaneous information alone, in spite of variations in indentation velocity. Responses of slowly adapting mechanoreceptive afferent fibers innervating the monkey fingerpad discriminated better the differences in the compliance of the rubber disks at higher forces of indentation. At lower forces, differences in responses to compliances were confounded by variations in the velocity of indentation in accordance with the corresponding psychophysical results. (PHS grant NS15888 and ONR contract N00014-88-K-0604).

NEURONAL DEATH: LESION INDUCED

PROTEIN KINASE C ACTIVITY AND PROTEIN LEVELS FOLLOWING RAT FORNIX-FIMBRIA TRANSECTION. K.L. Leach+ J.F. Tinklenberg,*+ and L.R. Williams. Cell Biology+ and CNS Diseases Research, The Upjohn Co., Kalamazoo, MI 49001.

Protein kinase C (PKC) is a calcium and phospholipid dependent kinase that has been implicated in a variety of cellular processes, including neurite outgrowth, and neurotransmitter release. In the present study, we examined the changes in PKC two weeks after fornix-fimbria (F-F) transection, an injury known to result in the loss of neurons in the medial septum and diagonal band (MS/DB) (PNAS 83:9231, 1986). Microdissections of the MS/DB and whole hippocampus from normal and transected rats were fractionated into cytosol (Cyt) and membrane (Mem) fractions. Western blot analysis using a sheep polyclonal antibody that cross-reacts with the α,β and γ PKC isozymes indicated no significant effect of F-F transection on the amounts of the 82 kDa PKC in either the Cyt or Mem fractions. PKC activity in control MS/DB Cyt and Mem fractions was 2994 and 3718 pmol/min/mg protein (n = 6), respectively. Following F-F transection, MS/DB Cyt and Mem PKC activities increased approximately 40%. Control hippocampal Cyt and Mem PKC activity was 6279 and 6644 pmol/min/mg protein, respectively; Cyt and Mem PKC activity decreased approximately 40% after F-F transection. Our results indicate that alterations in PKC specific activity occur within the affected brain regions, but without detectable changes in PKC protein levels.

DELAYED DEGENERATION IN SEPTAL CHOLINERGIC NEURONS AFTER PRIMARY ISCHEMIC OR IBOTENIC ACID HIPPOCAMPAL INJURY. B.T.Volpe, H. Baker, Dept. of Neurology, Cornell University School of Medicine, The Burke Rehabilitation Center, White Plains, New York 10605.

Animals exposed to transient forebrain ischemia by the method of four vessel occlusion were evaluated to determine whether delayed degeneration of cholinergic cells in the septum occurred. After several days, post ischemic animals reproducibly develop severe neuron loss in the CA1 region of the hippocampus. Animals were exposed to 30 minutes of ischemia or sham operation (n=6), and recovered for one week (n=3) or four months (n=4). Neurons, labelled with monoclonal antibody to choline acetyl transferase (ChAT), were counted in the medial septum, ventral limb and horizontal limb of the diagonal band (MS, VLDB, HLDB). One week after ischemia the number of ChAT positive cells in the MS, VLDB and HLDB was comparable to control values ($p>.05$). However, in animals who survived four months after ischemia, significant loss of ChAT positive cells occurred in the VLDB ($p<.05$). A comparable depression of ChAT positive cells in the septum (MS, VLDB) occurred in animals that survived 4 months after ibotenic acid lesions (n=3) of the anterior dorsal hippocampus (a region of cell loss similar to that in the ischemic animals). These preliminary data suggest that the loss of hippocampal CA1 neurons may provoke delayed degeneration of cholinergic cells in the septum. In view of the importance of the septohippocampal cholinergic system to spatial memory these results may have implications for the behavior of these animals. (Supported by the UPHS, MH40090)

177.3

LOSS OF ChAT LABEL PRECEDES CELL DEATH IN THE AXOTOMIZED RAT FOREBRAIN NUCLEI M.S. Grady and D. Maris* Dept of Neurosurgery University of Washington, Seattle, WA 98195.

The cholinergic neurons of the rat medial septal nucleus (MSN) and vertical diagonal band (VDB) are depleted following unilateral fimbria-fornix axotomy. A number of reports, using acetyl cholinesterase (AChE) or choline acetyl transferase (ChAT) histology suggest rapid neuron death. However, "resuscitation" of these neurons can be achieved using trophic factors even weeks after axotomy. This discrepancy can be resolved by hypothesizing a neuronal metabolic change preventing a positive AChE or ChAT reaction. If this hypothesis is true, then retrograde labelling of the MSN/VDB prior to axotomy should show a persistence of cells.

Sixteen adult rats were prepared with bilateral injections of .1ul of a 4% fluorogold (FG) solution in 2 locations of each hippocampus. Seven days later, a unilateral transection of the fimbria-fornix was performed stereotaxically. Animals were killed at 6, 10, 14, and 28 days after axotomy. Serial 35 micron sections through the MSN/VDB were alternately prepared for analysis using ChAT immunocytochemistry or coverslipped directly and examined for FG labelled cells. Morphometric measurements were performed with the Bioquant image analysis system, comparing the 2 hemispheres.

ChAT positive neurons showed a time dependent loss on the ipsilateral side. Likewise, area and longest dimension decreased slightly within 6 days. FG labelled cells showed a delayed time dependent loss compared to ChAT labelled cells. Nonetheless, significant cell loss and changes in area were seen at 14 and 28 days. These results confirm that neuron death follows fimbria-fornix axotomy, that disappearance of ChAT label precedes cell death, and that neurons shrink both in area and longest dimension.

177.4

LOSS OF BASAL FOREBRAIN CHOLINERGIC MARKERS PRECEDES CELL LOSS AFTER AXOTOMY. C.N. Svendsen*, T.S. O'Brien*, O.Isacson and M.V. Sofroniew. (SPON: H.G.J.M. Kuypers) Department of Anatomy, University of Cambridge, U.K.

Fimbria-fornix (FF) lesions result in an early loss of cholinergic enzyme staining followed by a gradual shrinkage and eventual disappearance of large Nissl-stained neurons from the medial septal nucleus in the basal forebrain. In order to better define the nature and time course of these events, the fluorescent tracer True Blue (T.B.) was injected into multiple sites in the rat hippocampus 7d prior to unilateral FF lesions. Animals were perfused 1-56d after FF-lesion, and medial septal neurons containing T.B. or immunohistochemically stained for choline acetyltransferase (ChAT) or nerve growth factor receptor (NGFr) were counted. Following FF lesions, the principal loss of both ChAT and NGFr staining from septal neurons occured between 6-8d, reaching a maximum by 9d. Prior to this, swollen and darkly stained, retrogradely degenerating, immunoreactive fibers descended along the FF towards the septum and appeared to reach the levels of their parent cell bodies coincidentally with the onset of staining loss. In contrast, no loss of T.B. labelled cells was seen until after 14d, and a loss comparable to that seen for ChAT and NGFr had occured by 28d. From14-28d, morphological changes included shrinkage of T.B. filled cells as well as the appearance of T.B. in the extracellular space and in glial cells, suggesting neuronal pathology, breakdown of membrane integrity or lysis and probable neuronal cell death. These findings suggest that proximal axotomy results in the delayed death of medial septal neurons, and that loss of ChAT and NGFr expression precede cell death. The onset of these events may be triggered by the arrival at the cell body of the retrogradely degenerating axon.

177.5

FATE OF RETROGRADELY LABELED SEPTOHIPPOCAMPAL NEURONS FOLLOWING FIMBRIA-FORNIX TRANSECTION: A TIME COURSE ANALYSIS. G. M. Peterson, G.W. Lanford and E. W. Powell. Dept Anatomy and Cell Biology, East Carolina Univ Sch Med, Greenville, NC 27858.

Marked neuronal loss has been demonstrated in the medial septum-diagonal band complex (MSDB) within two weeks of transection of the fimbria-fornix (FF). In this system, cell death has been documented by the disappearance of neurons stained for Nissl, acetylcholinesterase (AChE) and choline acetyltransferase (ChAT)-immunoreactivity (ir). There is now some evidence that these cells may not actually die following axotomy, but rather may become refractory to histological detection. To further study the effects of axotomy on septohippocampal neurons we have retrogradely labeled neurons in the MSDB prior to FF transection and then compared the number of labeled and histologically stained neurons in adjacent sections at three survival times. Eighteen adult female Sprague-Dawley rats received stereotaxic injections of Fluoro-Gold (FG; 2%, 50 nl) into the hilus of the dentate gyrus at 5 sites along its septotemporal axis. One week later the FF and overlying cortical tissue were bilaterally aspirated in 12 rats; the remaining animals served as time-matched, unlesioned controls. The animals were killed after an additional 3, 6, and 10 weeks and the brains processed for histological analysis. Frozen 40 μm thick sections were cut through the MSDB and hippocampus and 4 sets of adjacent sections were collected: one set was mounted without staining, and used for visualization of FG labeled neurons. The second set of sections was stained with thionin, the third set was histochemically stained for AChE and the fourth set was stained for ChAT-ir. Neurons were counted at three rostrocaudal levels of the MSDB. Compared to unlesioned controls, the number of Nissl-stained neurons and ChAT-ir neurons was greatly reduced at all survival times, as has been previously reported. Marked neuronal shrinkage was noted by 10 weeks, however the number of FG-labeled neurons in the lesioned brains did not differ from the control brains. These data indicate that the septohippocampal neurons do not die following axotomy, but apparently become histologically refractory. *(Supported by ADRDA IIRG-88-059)*

177.6

THE RESPONSE OF PGP 9.5-IMMUNOREACTIVE (IR) NEURONS IN THE RAT BASAL FOREBRAIN TO TRANSECTION OF THE FORNIX-FIMBRIA. M.R.Donald, M.D.Mills*, K.S.Jodelis, and L.R.Williams, CNS Diseases Research, The Upjohn Co., Kalamazoo, MI 49001.

Morphologic evaluation of Nissl-stained basal forebrain neurons indicates the majority of basal forebrain neurons are non-cholinergic neurons that are lost, i.e., uncounted, two weeks after fornix-fimbria (F-F) transection and spared by coincident treatment with NGF (PNAS 83:9231). Positive staining of neurons with a polyclonal antibody to protein gene product (PGP) 9.5, a neuron-specific protein (Brain Res. 278:224), has provided a more objective criteria for determining neuronal presence after F-F transection. The results show consistent, intense staining of neuronal cytoplasm and processes throughout the cortex, caudate-putamen, and basal forebrain. A 28% loss of IR neurons compared to the contralateral side is detected two weeks after a unilateral F-F aspiration in the medial septum of coronal sections representing the rostral third of the basal forebrain. Cholinergic neurons comprise only 10% of the total neuronal population in this region. Magnocellular neurons are lost and many of the surviving neurons on the side of lesion appear atrophied, dystrophic, and have significant reduction in the intensity of reaction product. These results provide greater resolution of the response of basal forebrain neurons to axotomy and indicate a large involvement of non-cholinergic neurons.

177.7

TRANSIENT ISCHEMIA-INDUCED CHANGES IN EXTRACELLULAR GLUTAMATE AND NEURONAL ACTIVITY IN THE IN VIVO MONGOLIAN GERBIL HIPPOCAMPUS. A.Mitani*, H.Imon[1]*, K.Iga[2]* and K.Kataoka* (SPON:N.Ogawa). Dept. of Physiology, [1]Anesthesiology and [2]Orthopedics, Ehime Univ. Sch. of Med., Ehime 791-02, Japan.

Glutamate (Glu) has been implicated as a mediator of ischemic neuronal death. We measured the extracellular concentration of Glu in halothane-anesthetized mongolian gerbil hippocampus by microdialysis technique and recorded spontaneous single neuronal activity (SSNA) in the hippocampal CA1 sector before, during, and for one hour after a 5-min period of transient ischemia which leads to delayed neuronal death in CA1 sector. The Glu was significantly increased during and for a few minutes after the ischemic period. The SSNA disappeared during the same period. It began to reappear about 15 min after recirculation and then returned to preischemic level. Thus, excitotoxicity of Glu was not observed in the above acute phases. We will also present ischemia-induced changes of the hippocampal extracellular glutamate and neuronal activity in chronic experiment.

177.8

THE EFFECTS OF LONG-TERM LOW-PROTEIN DIET ON THE HIPPOCAMPAL MOSSY FIBER SYNAPSES OF ADULT RAT. J.P.Andrade* and M.M.Paula-Barbosa, Dept. of Anatomy, Oporto Medical School, Oporto, Portugal.

We have previously demonstrated that adult rats fed for long periods with a low-protein diet displayed severe cell loss in the cerebellum and hippocampal formation (1).In the latter area the granule and CA3 pyramidal cells were found to be highly vulnerable to this condition with losses up to 40% after 18 months of experiment. Thus,we thought it would be of interest to study the synapse between these two cell types which form one of the major links of the hippocampal trisynaptic circuitry. The neuropil from the stratum lucidum of the undernourished animals presented unespecific axonal and dendritic degenerative changes. The synaptic contacts appeared with normal configuration albeit those formed over dendritic spines which seemed to be reduced. For quantitative purposes the disector method was applied to serial ultrathin sections. The number of synapses per unit volume was found to be significantly reduced after 6 months of treatment and its loss increased with the time of experiment.The fraction of the plasmalemma of mossy fiber endings occupied by active zones was reduced as well. We conclude that long-term undernourishment leads to a decrease in the MF/CA3 synapses. Conversely to what happened after long-term alcohol consumption where a similar synaptic loss was found, no signs of synaptic plasticity was detected. HEAVY METAL INDUCED ALTERATIONS IN THE NERVE GROWTH FACTOR LEVEL IN THE RAT BRAIN. L. Lärkfors*, A. Oskarsson*$, J. Sundberg*$ and T. Ebendal* (SPON: N.G. Carri). Dept. of Dev Biology, Uppsala Univ. and the Nat. Food Ad., Lab. of Tox.$ Uppsala, Sweden.

Nerve growth factor (NGF) has been found to play an important role for the cholinergic neurons in the basal forebrain during development and adulthood. Hypothetically decreasing levels of NGF could cause a degeneration of these cells. Heavy metals have also been suggested to cause neurodegeneration. To determine if heavy metals have any influence on the level of NGF during the first, sensitive postnatal period, we exposed pregnant Sprague Dawley rats with methyl mercury (Hg) in the food (4 mg/kg) or lead chloride (Pb) in the water (200 and 500 mg/l). The pups were also exposed during the first 25 or 50 postnatal days and the NGF levels were analyzed in the cortical areas and in the septum with a sensitive enzyme immunoassay. The pups exposed to Hg exhibited an increase in the hippocampus (60%) on P 25 and 50. In contrast, there was a decrease in the septum (30%) on P 25 and 50. The result from the Pb experiment is now being evaluated. The exact mechanism by which the low levels of heavy metals is affecting the NGF concentration in the developing brain is unknown. This finding might indicate a connection between exposure of heavy metals and neurodegeneration, such as that found in the basal forebrain in Alzheimers disease. Supported by the National Swedish Enviromental Protection Board (5324168-3).

EFFECTS OF NEONATAL AXOTOMY ON DRG NEURONS: AN IMMUNO- AND HISTOCHEMICAL ANALYSIS OF THREE NEURONAL POPULATIONS. B.T. Himes, C. Rogahn* and A.Tessler, Philadelphia VA Medical Center and The Medical College of Pennsylvania, Philadelphia, PA 19129.

Neonatal sciatic nerve lesion has been shown to cause 50% of L5 dorsal root ganglion (DRG) neurons to die. It is not clear if specific subpopulations of DRG neurons survive axotomy. Therefore the right sciatic nerve was cut and ligated in the lower half of the thigh in newborn rats. After a 60 day survival period the right and left L5 DRG were sectioned and every third section was processed for one of three techniques: Calcitonin Gene Related Peptide (CGRP) immunocytochemistry, Thiamine Monophosphatase (TMP) histochemistry or Carbonic Anhydrase (CA) histochemistry. These three markers identify distinct subpopulations of DRG neurons with little overlap. In control and unoperated L5 DRG both CGRP and TMP are found in approximately 40% of the neurons which are mostly small to medium sized. CA is localized in the largest DRG neurons and is present in approximately 15% of the total. Our results show that while the overall number of neurons in the operated L5 DRG is reduced 50% (75% of the axotomized neurons die), the relative proportions of each of the three different populations remains the same. These findings indicate that these subclasses of DRG neurons are equally susceptible to cell death following neonatal axotomy. Supported by the VA Medical Research Service, USAMRDC grant 51930002 and NIH grant 24707.

177.11

[$H]-THYMIDINE LABELLING OF DEGENERATING CELLS IN THE OLFACTORY EPITHELIUM OF BULBECTOMIZED RATS. V.McM. Carr and A.I. Farbman. Dept. Neurobiol. & Physiol., Northwestern Univ., Evanston, IL 60208.

Olfactory receptor neuronal cells(ORCs) of the olfactory epithelium(OE) undergo continual death and replacement throughout a vertebrate's life. Olfactory bulbectomy(OB-X) causes enhanced ORC death in the ipsilateral OE due, iniatially, to transection of ORC axons and, subsequently, to the absence of OB targets for the ORCs produced in reconstitutive processes.

To determine the time from ORC birth to death following OB-X, unilaterally OB-Xd rats were treated with [^{3}H]-TdR (2uCi/gm. b.wt., 3x/24 hrs) at 6 or 8 d. post op., a period of high mitotic activity in the affected OE (Monti Graziadei and Graziadei, 1979) and sacrificed 4-10 days later. Autoradiographs of the OE were examined for the presence of [^{3}H]-labelled (≥4 Ag grains) pycnotic cells. Results show that at 4-6 days post [^{3}H]-TdR exposure 10-20% of the pycnotic cells in the ipsilateral OE were labelled; at 10 days 5-10% were labelled. Most of the labelling occurred in the ORC region of the OE. Occasional labelled pycnotic cells also occurred in the control OE. These times appear insufficient for completion of proliferation, migration, and axonal outgrowth prior to degeneration.

REACTIVE ASTROGLIOSIS IN THE LATERAL GENICULATE NUCLEUS (LGN) OF THE CAT. R.E. Kalil, A.N. Lies and A.L. Shaikh. Center for Neuroscience, Univ. of WI, Madison, WI 53706.

Damage to visual cortex in the cat leads to the retrograde degeneration of neurons in the LGN. This neuronal degeneration is accompanied by the proliferation of glial cells. For example, astrocytes increase both in number and in size, and previous work with the electron microscope (Kalil and Behan, '87) suggests that these cells may sometimes behave abnormally by wrapping their processes around surviving neural elements in the degenerated LGN.

To collect further information on reactive astrogliosis in the LGN, visual cortex was ablated unilaterally in adult cats. Following survival periods that ranged from 1 day to 26 weeks, astrocytes in the LGN were stained with a monoclonal antibody against glial fibrillary acidic protein (GFAP) and prepared for light and electron microscopy. In comparison with normals, an increase in GFAP immunoreactivity (IR) is evident in the degenerating LGN as early as 3 days after a lesion of visual cortex. During the next 11 days GFAP-IR increases markedly, and then appears to decline slightly over the following 6 weeks. Counts of astrocytes in semi-thin sections show an elevation in cell density of more than 30% at 3 days survival and 75% at 2 weeks. These results demonstrate that damage to visual cortex in the adult cat triggers reactive gliosis in the LGN that occurs rapidly and persists for several weeks.

177.13

RETINAL GANGLION CELLS DO NOT SURVIVE TRANSECTION OF THE OPTIC NERVE IN ADULT RATS D.T. Ross and P.Tempesti*. Department of Neurosurgery, University of Pennsylvania, Philadelphia PA.

The identification of treatments which effectively rescue mammalian retinal ganglion cells from retrograde degeneration or enhance axonal regeneration following optic nerve injury has historically been complicated by difficulty in distinguishing different types of ganglion cells from populations of retinal interneurons in the ganglion cell layer. In order to overcome this problem for the present study retinal ganglion cells in adult male Long Evans rats were pre-labelled with the permanent fluorescent retrograde marker DiI (6.0 µl of a 1.5% solution in 100% ethanol) injected bilaterally at the coordinates of the lateral geniculate 2 days prior to unilateral intraorbital optic nerve transection. Fourteen days after optic nerve transection these animals were euthenized, perfused with a 4% paraformaldehyde solution and their retina prepared as wholemounts. Quadrants of these retina were reacted using florescence immunohistochemistry for tyrosine hydroxylase (TH), choline acetyltransferase (ChAT), and aspartate aminotransferase (AAT) with fluoroscein conjugated secondary antisera in order to identify populations of dopaminergic interplexiform cells, cholinergic, and GABAergic amacrine cells, respectively. Normal and experimental retina were examined for the presence of labelled ganglion cells, interneurons, and double labelled cells.

In normal retina extensive populations of large, medium and small neurons are intensely labelled, which appear to correspond to α, β and γ ganglion cells, respectively. Populations of Dopaminergic interplexiform cells, cholinergic and GABAergic amacrine cells are also identifiable in these retina but no DiI labelled cells are double labelled with either TH, ChAT, or AAT. Fourteen days following optic nerve transection no DiI labelled neurons persist in experimental retinae but populations of TH$^+$, ChAT$^+$, and AAT$^+$ neurons were present in normal densities. These results indicate that retinal ganglion cells undergo complete retrograde degeneration within 14 days after optic nerve transection and that the only neurons in the ganglion cell layer which survive are interneurons.

PRELABELING WITH TRUE BLUE IS SUPERIOR TO FLUORO-GOLD IN DEMONSTRATING THE EFFECT OF HINDLIMB AMPUTATION ON DORSAL ROOT GANGLION NEURONS (DRGs). W.T. Garrett*, R.L. McBride, J.K. Williams, Jr.* and E.R. Feringa (SPON: D.S. Feldman). VA Medical Center and Medical College of Georgia, Augusta, GA 30910.

Hindlimb amputation causes loss of dye-labeled neurons from the ipsilateral L-5 DRG. We compared DRGs prelabeled with Fluoro-Gold (FG) or True Blue (TB) to determine if the dyes contributed to neuron loss. We cut the right sciatic nerve 5 mm above the popliteal fossa in 42 adult rats, and soaked the proximal end in 2% FG or 1% TB for 1h. The ends were reapproximated. After 4 days, 10 rats were perfused and 16 rats had rt hindlimb amputation. At 20 weeks the remaining rats were perfused. Comparing 4 day and 20 week controls, no difference in the number of TB labeled cells was found; the number of FG labeled cells was decreased at 20 weeks without an offsetting increase in unlabeled neurons, suggesting FG caused cell death. Labeled, unlabeled and total cells decreased in amputated TB DRGs compared with controls. The FG DRGs showed no additional loss attributable to amputation. Thus FG's toxicity makes it inferior to TB in illustrating the effects of amputation on DRGs. Research supported by the VA.

20 WEEKS AFTER HINDLIMB AMPUTATION, BOTH THE SIZE AND NUMBER OF LOWER MOTOR NEURONS (LMNs) IS DECREASED. J.K. Williams, Jr.*, R.L. McBride, J.L. Hicks* and E. R. Feringa. VA Med Ctr and Medical College of Georgia, Augusta, GA 30910.

We studied the effects of hindlimb amputation on LMNs prelabeled with a retrogradely transported fluorescent dye. LMN somata in 14 rats, 7 weeks old, were labeled by soaking the proximal end of the right sciatic nerve, severed in the popliteal fossa, in 1% True Blue for 1 hour. The nerve was approximated with a sling stitch. Four days later, the right hindlimb was disarticulated at the hip in 7 of the rats. After 20 additional weeks, all rats were perfused with 10% formalin. Labeled neurons were counted on every fifth 30 µm frozen section of the lumbar cord. Control rats had 176±5 ($\bar{x}$±SEM) small (<30 µm greatest diameter), 347±17 large, and 523±16 total LMNs. Compared to controls, amputated rats had more small (230±22, $p \leq 0.05$), fewer large (135±19, $p \leq 0.001$), and fewer total neurons (366±40, $p \leq 0.01$). In control rats, axotomized LMNs had the potential to reinnervate target tissue. In amputated rats, where the target tissue had been removed, there was significant LMN loss and decrease in surviving neuron size. Supported by the VA Medical Research Service.

PRELABELED CLARKE'S COLUMN NEURONS ONE YEAR AFTER T-9 SPINAL CORD TRANSECTION. R.L. McBride and E.R. Feringa. VA Medical Center and Medical College of Georgia, Augusta, GA 30910.

The long-term effects of axotomy were studied in Clarke's column neurons labeled before spinal cord transection with a retrogradely transported fluorescent dye. Ten 8-week-old female rats were anesthetized with ketamine and xylazine and 4 µl of a 2% solution of Fluoro-Gold were injected into the cerebellum. Four days later, the spinal cord of five of the rats was tran-sected at T-9. Forty to 52 weeks after injection the rats were perfused with 10% formaldehyde. Labeled cells were analyzed on 30 µm frozen sections of the T-11 to L-1 lumbar cord. The mean number of labeled Clarke's column neurons per section was 7.5±1.4 ($\bar{x}$±SEM) in control rats and 0.2±0.0 in transected rats ($p<.001$). While only neurons were labeled in control rats, in transected rats unidentified labeled structures were also seen. These were similar to structures noted as early as five weeks after injury in other experiments and presumably are microglia, oligodendroglia or macrophages. If any of these labeled structures are shrunken neurons, even after one year they show no changes indicative of recovery. Supported by the VA Medical Research Service.

DIFFERENTIATION, MORPHOGENESIS AND DEVELOPMENT: FIBER GUIDANCE AND SYNAPTOGENESIS

178.1

INTERCELLULAR INTERACTIONS AMONG INSECT OLFACTORY CELLS IN CULTURE. L.P. Tolbert, L.A. Oland, and G. Or*. ARL Division of Neurobiology, U. of Arizona, Tucson, AZ 85721.

In the olfactory system of the moth, sensory axons induce the formation of large (ca. 60-um diameter) synaptic glomeruli, each surrounded by an envelope of glial cells. Previous observations (see Tolbert & Oland, TINS 12:70) have provided evidence that the development of glomeruli depends upon an interaction between the ingrowing sensory axons and the glial cells of the antennal lobe (AL). The current study is aimed at distinguishing between a passive role for glia and a more active one where glial cells might act as intermediaries in the morphogenetic influence of the afferent axons. In order to test directly whether AL glial cells pre-exposed to antennal cells can substitute for the antennal cells in inducing morphogenetic effects in AL neurons, we have turned to tissue culture (Stengl & Hildebrand, Hayashi & Hildebrand, Neurosci. Abstr. 14:379, 380), where we can readily control interactions between cell populations. Neurons and glial cells are dissociated from ALs at a stage before glomeruli form. In the first experiment, we have examined the effects of antennal cells on mixed cultures of AL neurons and glia and have found that a soluble factor(s) from dissociated antennal cells causes both neurons and glial cells to display morphological features different from control cells. In the second set of experiments, currently in progress, we are testing whether the AL glial cells can mediate these effects. We are exposing glia-enriched cultures to soluble factors from antennal cells and then co-culturing those glia with dissociated AL neurons. We will then determine if these neurons develop morphological features characteristic of the neurons in mixed cultures exposed directly to antennal cells. (Supported by NIH grant #NS20040 to LPT.)

178.2

THE FIRST EVENTS IN THE FORMATION OF INSECT OLFACTORY GLOMERULI INVOLVE SENSORY AXONS AND OLFACTORY-LOBE GLIA BUT NOT OLFACTORY-LOBE NEURONS. L.A. Oland, G. Or*, L.P. Tolbert. ARL Division of Neurobiology, U. of Arizona, Tucson, AZ 85721.

Our previous studies of intercellular interactions during development of the olfactory (antennal) lobe in the moth Manduca sexta have shown that formation of glomeruli requires both sensory axons from the antenna and neuropil-associated glial cells (see Tolbert and Oland, TINS 12:70). Arrival of sensory axons triggers changes in the morphology and distribution of glial cells that are followed by changes in the morphology of antennal-lobe (AL) neurons, suggesting that glial cells may mediate afferent-axon induced changes in AL neurons. To determine how glial cells and the neurons of the system interact during glomerulus formation, we have: 1. filled sensory axons with Lucifer yellow (LY), 2. stained AL neurons using the Golgi method, 3. filled individual AL neurons with LY, and 4. examined the distribution of synapses in regions of developing glomeruli. These studies have revealed that at the earliest stages of glomerulus development, when well defined spheroidal knots of neuropil first become visible, the knots comprise only sensory-axon terminals surrounded by glial cells. The arborizations of AL neurons at these stages are confined to a separate layer of neuropil deep to the axons; synapses are also restricted to this layer. Thus, the initial events in the construction of glomeruli are the creation of knots of terminal branches of sensory axons and the formation of glial envelopes around them. Processes of AL neurons must only secondarily invade the knots to form the synaptic neuropil characteristic of mature glomeruli. (Supported by NIH grant NS20040 to LPT.)

BRAIN MACROPHAGES TRANSIENTLY TARGET CERTAIN AXON TRACTS. C.E.Milligan*, T.J.Cunningham and P.Levitt. Dept. of Anatomy. Medical College of PA., Philadelphia, PA 19129.

The distribution of brain macrophages was mapped in the post-natal rat using immunohistochemical techniques employing a commercially available monoclonal antibody to cells of the rat monocyte/macrophage lineage. Throughout post-natal development the location, density and morphology of these cells change. From P0-P8 stained cells usually have a rounded morphology with no apparent processes and are located primarily within the cellular layers surrounding ventricles and corpus callosum, and lining and within the septum pellucidum. At P8, a substantial increase occurs in forebrain (sub-callosal white matter, internal capsule, fornix, anterior commisure) and cerebellar white matter; many of these cells have processes of varying lengths. From P12-18 the density of stained cells decreases rapidly. This transient tract associated distribution is specific, since many regions containing axon tracts have few or no macrophages throughout post-natal development. During early post-natal development cells with well developed processes also appear in the deep layers of the superior and within the inferior colliculi, where many degenerating profiles are seen. The association of macrophages with certain axon tracts and not simply with ventricles or the septum pellucidum, as well as, their appearance in areas of frank cellular degeneration, suggests that they play an important role in the modelling of these CNS regions during development. 178.4

AFFERENTS FROM SUPERNUMERARY ANTENNAE INNERVATE OPTIC LOBES LACKING A RETINA. William J. Evans and Nicholas J. Strausfeld. ARL Div. Neurobiology, Univ. of Arizona, Tucson, AZ 85721.

Observations of developing antennal and optic lobes suggest that sensory afferents and glial cells play a vital role in determining the subunit organization of target neuropils [Tolbert LP, Oland LA (1989) Trends Neurosci 12:70-75; Fischbach K-F (1983) Dev Biol 95:1-18]. In the absence of ingrowing axons, antennal lobes are aglomerular and optic neuropils lack their normal arrangement of retinotopic columns. We have asked the following questions. 1) Will ectopic afferents invade a sensory neuropil? 2) If so, does cellular organization reflect either identity of the sensory afferents or neurons of the target neuropil? We have attempted to answer this in the moth *Manduca sexta* by obtaining eyeless adults after removing larval stemmata in late fourth or early fifth instar. Supernumerary antennae were grafted onto pupae destined to be eyeless adults. Control animals lacked compound eyes and laminas but possessed reduced optic lobes lacking retinotopic organization. After eclosion, animals having a third antenna in lieu of a compound eye were processed histologically. Bodian and Golgi preparations revealed that 1) in 20% of the experiments antennal afferents invaded glomerulus-like first-order neuropil; 2) projection neurons arising from this neuropil invaded a medulla having a columnar subunit organization; 3) projection neuron dendrites reflected the glomerulus-like organization of receptor endings whereas their terminals were similar to those of normal visual interneurons. The results suggest that antennal afferents can cause glomerular structures in a foreign target neuropil when this neuropil is denied its normal sensory input.

Substrata most suitable for rod photoreceptor cell attachment and process outgrowth in vitro I.J. Kljavin and T.A. Reh, Dept. Med. Physiol. Univ. Calgary, Alberta T2N 4N1 Canada.

In dissociated 3-day rat retinal cultures rods differentiate on top of retinal glial cells by process extension. To identify the molecules that might be involved in this glial-mediated process extension we cultured cells at low density on several ECM components (laminin, fibronectin, collagen I and Matragel). Rods, identified in vitro by a monoclonal antibody to opsin (from R. Molday, U.B.C.), adhered to these substrates but failed to extend processes. The glial mediated diffferentiation of rods appears to be specific to Müller cells in the retina: 90% of the rods on Müller cells showed process outgrowth, while only 23% of those on astrocytes, and less than 1% on 3T3 fibroblasts had processes greater than 2 body lengths. Therefore, Müller cells appear to have a unique capability of promoting differentiation and process outgrowth of rods in culture. Further studies are directed towards identifying the molecules responsible for this Müller rod interaction.

VENTRAL CORD STIMULATION MAY ACTIVATE SYNAPSES IN THE WHITE MATTER OF DEVELOPING SPINAL CORD. L. Ziskind-Conhaim and F. Gigel* (SPON: W. Welker). Dept. of Physiol., and Ctr. for Neurosci., Univ. of Wisconsin, Madison, WI 53706.

Ventral root and cord stimulation via suction electrodes evoked antidromic action potentials that were recorded intracellularly in spinal motoneurons of rat embryos. These action potentials were followed by long-latency (10-150 ms) subthreshold potentials which disappeared when the cord was perfused with solutions that reduce synaptic activation (1 mM-Ca^{2+}/8 mM-Mg^{2+}; 1 mM-Ca^{2+}/0.5 mM Cd^{2+}). The subthreshold potentials could not be generated if 1) the stimulating electrode was located > 0.5 mm away from the cord, and 2) the white matter was destroyed. One possible explanation for these results is that electrical stimulation activates synapses located in white matter (marginal zone).

Electron microscopic observations revealed that at days 16-17 of gestation the number of synapses in the white matter (ventral and lateral funiculus) was at least 3-fold larger than in the intermediate and ventral gray horn. The number of synapses in the gray matter significantly increased by Days 19-20, while synapses in the white matter began to decline near birth, and were absent in the white matter of 2-week-old pups. We conclude that during embryonic development, ventral cord stimulation activates synapses in the white matter. Supported by Research Career Development Award and NIH grant NS 23808.

GENETIC SCREEN FOR MUTANTS AFFECTING NEURONAL CONNECTIVITY IN THE VISUAL SYSTEM OF DROSOPHILA. M.E. Grether*and H. Steller*(SPON: A.D. Lander). Depts. of Biology and Brain and Cognitive Sciences, MIT, Cambridge, MA 02139.

The overall objective of our research is to understand how genes control the assembly of a functional nervous system during embryonic development. To address this issue we use the larval visual system of Drosophila. The gene disconnected is required for the establishment of stable connections between the larval optic nerve and its synaptic partners during embryonic development. We have systematically screened for additional mutations that affect the development of the larval visual system by analysing the projection of the larval optic nerve in embryos homozygous for chromosomal deletions.

We find that a small number of deletions affect the formation of specific neuronal connections in this system. Ectopic position of the target cells due to defective morphogenetic movements does not necessarily prevent "normal" connectivity between the larval optic nerves and their targets. We have also observed axonal outgrowth from the larval photoreceptor cells in the absence of the target cells.

Two of the deficiency stocks, Df(2R)L+48 and Df(3L)w4, ru h e ca/TM6B contain phenotypes of interest to us. In each case, the larval optic nerve projects to an ectopic position in the brain of a basically normal embryo. We are mapping the loci responsible for these phenotypes.

178.8

ANTIGEN PRESENT IN B-PREGANGLIONIC NERVES APPEARS IN B-GANGLION CELLS FOLLOWING SYNAPTOGENESIS. S.L. Van Eyck, J.C. Thigpen* and L.M. Marshall. Dept. of Physiology, Univ. of North Carolina, Chapel Hill, NC 27599.

Lumbar sympathetic ganglia in frog have two main neuronal pathways formed by B- and C-type preganglionic axons which selectively innervate B- and C-type ganglion cells. We investigated the differentiation of the B pathway during development by examining the appearance of an antigenic marker present only in the B-type pre- and postganglionic neurons of adult bullfrogs.

Ninth and tenth paravertebral ganglia from Rana catesbeiana larval stages (XIV-XXV) were examined by immunocytochemistry for recognition by this monoclonal antibody raised against adult frog ganglia. Beginning at about stage XVI, heavily labeled preganglionic axons make synaptic contacts on the yet unlabeled ganglion cells. By the end of metamorphosis many of these innervated ganglion cells express this B-cell marker.

The results indicate that this particular phenotypic marker of the B pathway occurs subsequent to synaptogenesis. This raises the possibility that ganglion cell phenotype may be specified during development through innervation by a particular type of preganglionic axon.

BRAIN METABOLISM AND BLOOD FLOW I

179.1

IMPROVED AUTORADIOGRAPHIC RESOLUTION REVEALS SUBSTANTIAL UNDERESTIMATION BY THE IODOANTIPYRINE METHOD OF BLOOD FLOW IN SOME REGIONS OF RAT BRAIN. T.T. Soncrant, H.W. Holloway*, D.M. Larson*, N.H. Greig*, U. Freo* and S.I. Rapoport. Laboratory of Neurosciences, National Institute on Aging, NIH, 10/6C103, Bethesda, MD 20892.

The autoradiographic [14C]iodoantipyrine (IAP) method (Sakurada et al., Am. J. Physiol. 234:H59, 1978) has been used to measure regional cerebral blood flow (rCBF) in awake animals, yielding values of 40-250 ml/100g/min. The method uses a freely-diffusible tracer, IAP, that accumulates in brain in relation to blood flow during a 45-60 sec i.v. infusion. Regional brain radioactivity is determined by quantitative autoradiography, but resolution is poorer than in deoxyglucose studies. We have found that poor resolution is due in part to post-mortem (and probably pre-mortem) lateral diffusion of tracer in brain and can be improved by rapid freezing, so that distinct cortical layers are apparent. However, some brain regions then have IAP concentrations much higher than previously encountered. For those areas, rCBF calculations based on the IAP model are highly unstable, because failure to maintain a high blood-to-brain IAP concentration gradient leads to a markedly non-linear relation between brain radioactivity and blood flow. Preliminary results with alternate infusion schedules suggest that, in some regions, rCBF is much (possibly twofold) greater than previously recognized, and that coupling between blood flow and metabolism is maintained at a finer anatomic level than heretofore known. Alternate IAP infusion schedules and methods for rapid freezing of the brain that improve resolution and accuracy of rCBF measurements will be presented.

179.2

FREELY DISTRIBUTED IMAGE PROCESSING PACKAGES SIMPLIFY ANALYSIS AND DISPLAY OF FUNCTIONAL METABOLIC ACTIVITY DATA. A.J. Annala. Neural, Informational, and Behavioral Sciences Program, University of Southern California, Los Angeles, CA 90089.

Accurate interpretation of functional metabolic activity data from deoxyglucose autoradiography [2DG-QAR] experiments can be hampered by hardware and software limitations of low cost neurobiological image processing systems. Acquisition of high resolution cameras and development of custom programs for use of nonstandard analysis protocols are beyond the financial capability of all but a few large laboratories. Most of these limitations can be overcome by using image processing packages distributed without charge by investigators in university and government laboratories. These software tools (aips, alv, brlcad, ds, iraf, pbm, touchup, utah rle toolkit, and xim) are designed to be as computer, display device, and data format independent as possible. These packages offer a wide range of image processing functions including: grey scale and color image display, simple image arithmetic, linear and nonlinear filters, fast fourier transforms, geometric transformations, image registration and mosaicing, contour plotting, surface rendering, and volume visualization.

This poster presents a series of 2DG-QAR results generated by these tools including: a very high resolution image (2048H x 2048V pixels) constructed by overlapping frames (384H x 485V pixels) from a low cost video camera; registered pairs of grey scale histological and pseudocolor autoradiographic images of rat and rabbit brains employing a ratio correction for nonuniformities in the underlying light source; typical intensity histograms, surface plots, and automatically generated outlines of stained histological sections. Supported by ONR N00014-88-K-0112, NSF BNS-8718300 and McKnight Foundation grants to R. F. Thompson.

179.3

A SIMULATION MODEL FOR STUDYING INTERREGIONAL CORRELATIONS BETWEEN CEREBRAL METABOLIC RATES. Barry Horwitz, Lab. Neurosciences, National Institute on Aging, National Institutes of Health, Bethesda, MD 20892.

Correlation coefficients between pairs of regional metabolic rates have been used to study patterns of functional associations among brain regions in humans and animals (Horwitz et al., J. Cereb. Blood Flow & Metabol., 1984; Arch. Neurol., 1988). A computer simulation model is presented for the purpose of giving a partial vadidation for correlational analysis. The model generates a set of simulated metabolic data upon which correlational analysis is performed. The model consists of n regions, in which metabolism (or blood flow) in one region is a sigmoidal function of metabolism (or blood flow) in some or all of the other regions. The parameter linking metabolic rates between two regions is called a functional coupling constant. It is shown how the model parameters can be chosen so that simulated and experimental data have values similar to one another. Because the pattern of functional coupling constants in the model is known, these simulations demonstrate that the correlation coefficient between normalized metabolic rates is proportional to the strength of the functional coupling constant, and that correlational analysis yields information on regional involvement in neural systems not evident in the pattern of absolute metabolic values.

179.4

QUANTIFICATION OF THE GLYCOLYTIC AND OXIDATIVE COMPONENTS OF CEREBRAL GLUCOSE METABOLISM IN STIMULATED STRUCTURES. R. F. Ackermann and J.L. Lear*, Divison of Nuclear Medicine and Biophysics, UCLA School of Medicine, Los Angeles, CA 90024; and Division of Nuclear Medicine, U. of Colorado School of Medicine, Denver CO, 80262.

We have used double-label quantitative autoradiography to compare directly the local cerebral metabolic rate for glucose (LCMRG) derived from accumulation of [F-18] fluorodeoxyglucose (FDG), with that derived from the accumulation of [C-14] 6-glucose (GLC). In normal brain, at optimal experimental times, FDG-derived and GLC-derived LCMRG are similar. However, activating the hippocampus with kainic acid, or the optic tectum with flashing light, elevates FDG-derived LCMRG markedly, but leaves the GLC-derived LCMRG at near-normal values. Hypothesizing this discrepancy in stimulated structures to result from induction of aerobic glycolysis, we developed a kinetic model for quantifying the glycolytic and oxidative components of LCMRG. Analysis of the simultaneously obtained FDG and GLC data with this model reveals a significantly elevated glycolytic rate in stimulated structures; the oxidative rate remains relatively unaffected. It is known that Na^+-K^+ ATPase activity largely accounts for brain FDG accumulation, and that Na^+-K^+ ATPase activity can stimulate glycolysis. Thus, the transmembrane ion fluxes that accompany stimulation may trigger glycolysis in affected brain structures via the products of Na^+-K^+ ATPase activity.

PET MEASURED EVOKED CEREBRAL BLOOD FLOW RESPONSE IN AN AWAKE BEHAVING MONKEY. J.S. Perlmutter, L.L. Lich*, and S.Bucholtz*, Washington University School of Medicine, St. Louis, MO 63110.

We have developed a method to measure evoked CBF responses in an awake, behaving monkey using PET and $H_2{}^{15}O$. We trained an animal (operant conditioning, positive reinforcement only) to climb unassistedly into a modified primate chair that was then positioned in the scanner. A 20 gauge catheter was placed in a leg vein to permit $H_2{}^{15}O$ injection. A special headholder and acrylic skullcap permitted precise placement and accurate repositioning. We measured blood flow qualitatively with bolus injection of $H_2{}^{15}O$ and a 40 sec scan. Each session included scans at rest interposed with scans during vibration of a forepaw. Regional CBF responses were identified using subtraction image analysis. After global normalization, the resting image was subtracted on a pixel-by-pixel basis from a comparable image collected during vibration. The region of peak response occurred in the contralateral sensorimotor cortex with a mean magnitude of 10% (± 2.2%) of the gobal mean value for 6 separate experiments, significantly greater than the mean qualitative blood flow change (1.2% ± 2.5%; p=.002) in the same region for rest-rest pairs. This newly developed technique forms the basis for a wide variety of experiments including evaluation of the relationship between evoked blood flow and electrical responses in the brain.

179.6

THE EFFECT OF GENDER ON CEREBRAL METABOLIC RATES FOR GLUCOSE IN HEALTHY HUMANS MEASURED BY POSITRON EMISSION TOMOGRAPHY (PET). S. A. Miura*, B. Horwitz, M. B. Schapiro*, C. L. Grady*, A. Kumar*, E. Wagner*, and S. I. Rapoport, Lab. Neurosciences, National Institute on Aging, National Institutes of Health, Bethesda, MD 20892. (SPON: V. Murphy)

Gender differences have been observed in metabolic studies of the human brain. Using [18-F]-fluorodeoxyglucose and PET (Scanditronix PC1024 with transverse resolution=6mm, axial resolution=10mm) to measure the regional cerebral metabolic rate for glucose (rCMRglc), we studied young (20-40 years), healthy men (N=15) and women (N=9) to see if gender differences in rCMRglc could be detected. A 10 minute transmission scan was obtained prior to each emission scan to correct for attenuation.

Absolute values of the global grey matter metabolic rate for glucose did not differ between groups [men: mean ± SD = (8.67 ± 1.39) mg/100g/min; women: (8.54 ± 1.31) mg/100g/min; p>0.05]. Similarly, absolute values of rCMRglc for 76 individual regions of interest were not different between groups (p>0.05). Ratios of the 76 regional to global values also were compared and yielded gender differences in only 6 regional ratios, a result consistent with chance.

Thus, contrary to the findings of previous studies of resting cerebral metabolism, significant gender differences in absolute metabolic rates were not detected. Differences from previous studies may be due to errors introduced by their use of a calculated rather a transmission derived attenuation correction.

179.7

RESTING BRAIN GLUCOSE METABOLIC PATTERNS CORRELATE WITH SHORT-TERM MEMORY IN OPTIMALLY HEALTHY ELDERLY SUBJECTS. A.Berardi, J.V. Haxby* and S.I. Rapoport, Lab. of Neurosciences, National Institute on Aging, NIA, Bethesda, MD 20892.

Our laboratory has shown that in optimally healthy elderly subjects, right-left parietal brain metabolic asymmetry is correlated with discrepancy in visual-verbal memory performance (Berardi, A., Neurol., 37 (Suppl. 1):160, 1987). The present study attempted to reproduce this finding with independent subjects using a higher resolution scanner, the Scanditronix PC 1024-7B, and [18-F] fluorodeoxyglucose. 10 young (mean age: 30.7±5.4; range=22-39) and 14 elderly (mean age: 69.3±5.6; range 60-81) subjects were studied. All were right-handed and healthy. Visual and verbal short-term (STM) and long-term memory (LTM) measures were derived from continuous recognition memory tests matched for difficulty. Right-left parietal metabolic asymmetry and visual-verbal memory discrepancies were calculated as (R-L)/[(R+L)/2], where R and L represent homologous right and left regional cerebral metabolic rates for glucose (rCMRglc) or visual and verbal memory test scores. Metabolic asymmetry was correlated with short-term, but not long-term visual-verbal memory discrepancy in the healthy old (Pearson r=0.59, p<0.05), but not young subjects. Older subjects with higher left rCMRglc had higher verbal STM test scores and those with higher right rCMRglc had higher nonverbal-visual STM test scores. These results indicate that metabolic asymmetry in the parietal lobe is related to discrepancy between visual and verbal memory in old, but not young healthy adults.

DOES AGING COMPROMISE K^+ TRANSPORT IN HIPPOCAMPAL SLICES? E.L. Roberts, Jr.,* T.J. Sick,* and M. Rosenthal* (SPON: R. Kelley). Dept. of Neurology, University of Miami School of Medicine, Miami, FL 33101

Aging alters brain metabolic activity. For example, aged brain tissue did not augment oxygen consumption as much in response to increased extracellular K^+ activity (K^+_o). Also, following short anoxia, K^+_o homeostasis returned more slowly, and synaptic transmission recovered less completely, in hippocampal slices from aged rats. Hippocampal slices from rats 6-7 mon. and 26-27 mon. of age were studied to determine if aging produced deficits in ion transport in normoxic brain. Slices were placed into an interface chamber in which they were exposed to humidified 95% O_2, 5% CO_2, and were bathed in an artificial cerebrospinal fluid. K^+_o was recorded in stratum pyramidale of slices before, during, and after CA1 pyramidal cells were activated transsynaptically at high frequency (40 Hz) by Schaffer collateral stimulation. Stimulus trains were 2 sec. in duration, and were varied in intensity so that several values for maximum K^+_o during or immediately after a stimulus train were obtained. The rate of K^+_o disappearance after the stimulus train was analyzed by determining the times need for K^+_o to decay to half of its maximum value ($t_{0.5}$) and to its prestimulation baseline ($t_{1.0}$). We found that K^+_o decay times did not increase as brain age increased. Thus, energy for K^+ transport in both age groups may not depend on oxidative metabolism, or aerobic glycolysis in the aged brain may be increased to compensate for reduced oxidative metabolism. We conclude that decreased K^+ transport activity in aged brain tissue following short anoxic insults is not due to deficits in K^+ transport existing prior to anoxia. (Supported in part by a pilot study grant from NIA)

IMPAIRED DECISION-MAKING IN PERSONS AT RISK FOR HUNTINGTON'S DISEASE (AR). W.H. Riege, A.B. Lanto*, J.C. Mazziotta, M.E. Phelps, J.J. Fahl*. V A Med. Center Sepulveda, and Lab. of Nuclear Med., UCLA Sch. of Med., Los Angeles, CA 90024

To determine neuropsychological risk factors in AR persons, we used memory and problem-solving tasks together with evaluation of regional cerebral glucose use (CMRGlc) by positron emission tomography and F-18-fluoro-deoxyglucose. We compared the scores of 58 AR persons and 24 healthy controls on tasks related to decision-making (Abstraction, Progressive Matrices, Time for design reproductions, and Decision bias). AR persons scored low on these, although attention and learning were unimpaired. Even though decision indices were correlated ($p< 0.05$) with CMRGlc ratio of frontal-parietal, of caudate/hem ($r< 0.30$), and of putamen/hem ($r= 0.34$), only a few AR had low regional CMRGlc comparable to those of symptomatic HD persons. With a cutoff of 2 standard deviations below the mean CMRGlc, ten AR persons with basal-ganglia hypometabolism were identified who also scored low ($p<0.01$) in decision and abstraction tasks. Multiple contrasts (with errorwise correction) showed that these 10 AR used twice the time to solve problems, remembered fewer items, and resorted more to guessing than the remaining AR or control persons.

179.10

PET SCAN STUDY OF PATIENTS ON PHENCYCLIDINE. J.C. Wu M.S. Buchsbaum,* W.E. Bunney. Psychiatry Dept, UCI, Irvine, CA 92717.

Introduction: Phencyclidine intoxication is considered one of the best drug models of schizophrenic psychosis. Symptoms of phencyclidine (PCP) intoxication include thought disorders, hallucinations, and delusions. PCP has recently been found to be a noncompetitive antagonist of the NMDA glutamate system. Schizophrenia has been found to have some regional cerebral metabolic abnormalities such as decreased frontal, striatal, and thalamic metabolism on PET scans. If PCP psychosis is similar to schizophrenia, we hypothesize that there will be similar deficits in brain metabolism. Methods:Patients using PCP were recruited. Patients meeting DSM-III-R criteria for PCP abuse and dependence were studied. Patients performed the CPT attention task for 30 minutes after they received 5 mCi of 18F-deoxyglucose. Patients were then scanned in a NEUROECAT scanner (FWHM=7.8mm). Results:A preliminary analysis of 3 patients showed decreased frontal, striatal, and thalamic regional cerebral metabolism compared to a cohort of normal controls. The latest analysis of this study will be presented and discussed.

179.11

SPECT REGIONAL CEREBRAL BLOOD FLOW IN ASYMPTOMATIC HIV + DRUG ABUSERS. S. W. Woods, S. S. O'Malley*, L. H. Price, J. H. Krystal, P. B. Hoffer*, T. R. Kosten*. Dept. of Psychiatry, Yale U. Sch. of Med., New Haven, CT 06508.

An abnormal pattern of relative subcortical hypermetabolism has been reported early in the course of dementia due to human immunodeficiency virus (HIV) infection using positron emission tomography (Rottenberg et al. Ann Neurol 1987;22:700). In that sample, only 1/12 patients (PTS) had intravenous drug abuse (IVDA) as their risk factor for HIV. The present pilot study aimed to extend the previous report in HIV seropositive (HIV+) IVDA PTS not yet manifesting clinical dementia using the more generally available single photon emission computed tomography (SPECT) regional cerebral blood flow (rCBF) technique. METHOD: After giving informed consent, 5 methadone maintained (MM) HIV+ (2M, 3F, mean $\pm$ SD age 33 $\pm$ 10 yrs) and 5 MM HIV- (2M, 3F, 35 $\pm$ 4 yrs) IVDA PTS without clinical dementia underwent: 1) injection of the rCBF tracer Tc-99m HM-PAO (hexamethylpropyleneamine oxime, 20 mCi) followed by SPECT scanning using a neurodedicated multicrystal camera and 2) a comprehensive neuropsychological (NP) test battery. RESULTS: Preliminary analyses by two nuclear medicine physicians blind to HIV status revealed a relatively increased tracer uptake bilaterally in basal ganglia in HIV+ as compared to HIV- PTS (Mann-Whitney U-test, $p<.05$). HIV+ and - PTS showed some impairment on 39 and 25% of NP tasks, respectively. Further image analysis and SPECT/NP correlations will be presented. DISCUSSION: More research is indicated examining the potential role for SPECT rCBF imaging along with NP testing in the monitoring and possible early detection of neuropsychiatric impairment due to HIV infection in the IVDA population.

179.12

SPECT REGIONAL CEREBRAL BLOOD FLOW IN OCD. W.K. Goodman, L.H. Price, C.J. McDougle*, M.A. Riddle*, P.B. Hoffer*, S.W. Woods. Dept. of Psychiatry, Yale U. Sch. of Med., New Haven, CT 06508.

Positron Emission Tomography (PET) studies with ^{18}FDG have consistently shown increased metabolic activity in the orbital frontal cortex (either unilaterally or bilaterally) in Obsessive Compulsive Disorder (OCD) patients (Pts) compared to control subjects (Baxter et al., 1987, 1988; Nordahl et al., 1989; Swedo et al., 1989). Caudate hypermetabolism has been a less consistent finding. A PET study of Pts with Tourette's Syndrome (TS), which may be related to some forms of OCD, showed hypermetabolism of basal ganglia regions (Chase et al., 1984). The present study was designed to extend the PET findings in Pts with OCD (with/without chronic tic history) using the more generally available single photon emission computed tomography (SPECT) regional cerebral blood flow (rCBF) technique. METHODS: After giving informed consent, 11 drug-free, adult Pts with a principal diagnosis of OCD (DSM-III-R) (2F, 9M, mean $\pm$ SD age 33 $\pm$ 15 yrs) underwent injection of the rCBF tracer Tc-99m HM-PAO (hexamethylpropyleneamine oxime, 20 mCi) while lying still with eyes patched in a quiet room. SPECT scanning followed, using a neurodedicated multicrystal camera. After scanning, subjects were assessed regarding their obsessional state at the time of injection. Age- and sex-matched healthy subjects were studied under identical conditions. RESULTS: Data will be presented on the comparison of rCBF in OCD Pts and healthy subjects. The relationship between other clinical variables (e.g., tic history (N=5) & OCD severity) and rCBF will also be analysed. DISCUSSION: SPECT imaging is more widely available and less expensive than PET and seems well-suited to the evaluation of the function of brain regions (i.e., orbital frontal cortex and basal ganglia) reported abnormal in PET studies of OCD.

179.13

METABOLIC EVIDENCE OF BRAIN PLASTICITY IN CHILDREN FOLLOWING LARGE CEREBRAL RESECTIONS. H.T. Chugani*, M.E. Phelps and J.C. Mazziotta (SPON: E. Rubinstein). UCLA School of Medicine, Los Angeles, CA 90024, USA.

Children, unlike adults, can sustain large cerebral resections and yet show remarkably little functional deficit, presumably due to the reorganizational capability of the developing brain. We have used PET with ^{18}FDG in the resting state (eyes open, ears unplugged) to detect metabolic evidence of plasticity in 7 patients who underwent cerebral hemispherectomy as children for the control of intractable epilepsy. In 5 children studied within one year following surgery, PET revealed a typical pattern of hypometabolism in the cerebellar cortex contralateral to the side of hemispherectomy (crossed cerebellar diaschisis). However, in 2 patients studied 6 and 8 years after surgery, crossed cerebellar hypermetabolism was seen instead. Measurements of local cerebral metabolic rates for glucose (lCMRGlc) showed that the magnitudes of increase were 120% and 160% of values in the opposite (normal) cerebellum. In all 5 patients studied within one year of surgery, PET showed no evidence of metabolic activity in the surgically spared striatum and thalamus on the side of hemispherectomy, even though these structures appear normal on CT and MRI. Repeat PET in one of these children 2.5 years following surgery showed that glucose metabolic activity had returned in the largely deafferented caudate. These lCMRGlc changes may reflect altered energy demand in brain regions undergoing anatomic reorganization (e.g. collateral sprouting), such as seen in animal models of hemispherectomy. If such an anatomic-metabolic correlation can be substantiated in animal models, it would provide an intruiging perspective of brain plasticity with PET technology.

179.14

ALTERATIONS OF BRAIN GLUCOSE METABOLISM IN IODINE DEFICIENCY RAT. D.M.Zhang,Z.F.Yang*,D.R.Tian*,W.F Tang*,L.Y.Ma* and Z.P.Chen*(SPON:A.N.Epstein).Department of Anatomy Tianjin Medical College, Tianjin, People's Republic of China.

Iodine deficiency leads to irreversible brain damage during critical period of development. An animal model of iodine deficiency has been produced in rat with a low iodine diet (gestation through 70 days). To identify the distribution of the effect and to localize particulary vunerable regions, the (^{14}C) deoxyglucose method for the measurement of local cerebral glucose utilization was applied to iodine deficient rats at 70 days age. Each rat was injected (IV) with 2-DG 45 min prior to sacrifice. Of 14 brain regions (in 11 animals), all iodine deficiency rats showed reduced glucose utilization. The metabolic rate in the cortical regions was reduced from 29%. The reticular formation and the cerebellum were relatively less affected (4-6%). The auditory system showed the greatest decrease, with a 29% reduction in inferior colliculus and auditory cortex. These results demonstrate that iodine deficiency during development results in a generalized reduction in glucose utilization with the cortical structures and auditory system being particularly vulnerable.

179.15

DIAZEPAM REDUCES REGIONAL CEREBRAL METABOLIC RATE IN NORMAL SUBJECTS. J. T. Metz, H. de Wit*, L. I. Debbold*, S. J. Gatley*, and M. D. Cooper*. University of Chicago, Chicago, IL 60637.

As part of a series of studies with drugs of abuse, we assessed the effects of diazepam (valium) on regional cerebral metabolic rate of glucose (CMRglc), reaction time, and mood.

Eight normal male volunteers (aged 21-29) were studied. Subjects were instructed that they might receive a placebo, a tranquilizer, a stimulant, or alcohol. In each session, on a double-blind basis, they received a capsule containing 0.07 mg/kg diazepam (5 mg for a 70 kg subject), 0.14 mg/kg, or placebo and a citrus flavored beverage. 30 minutes after receiving the drug, they were injected with 6-8 mCi FDG. Subjects performed a visual monitoring task during FDG equilibration to assure that states of alertness were comparable in all subjects and conditions. Subjects also completed a Profile of Mood States before and after each scan. CMRglc was determined by the F-18-2FDG autoradiographic method with a PETT VI scanner. Fourteen ROIs were examined.

Subjects attained average blood levels of diazepam of 60.6 and 119.3 ng/mL at the two doses. Average CMRglc over the whole brain decreased significantly after both doses of diazepam (8.25 mg/100g/min [placebo], 7.36 [5 mg], 7.42 [10 mg]). All regions showed comparable effects. Subjects were less accurate in detecting target light flashes after both doses (96% [placebo] vs 86% [both doses]), but the median time to respond was unaffected (436, 433, and 436 msec at placebo, low dose, and high dose). Mood states were affected only by the higher dose of diazepam: subjects reported decreases in Anxiety and Depression.

This study shows that diazepam decreases overall CMRglc even at doses that do not affect mood or reaction time. These findings can be contrasted to previous findings with ethanol, where effects on CMRglc were correlated with mood.

CHRONIC HYPERAMMONEMIA REDUCES BRAIN GLUCOSE USE J.Jessy*, A.M.Mans, M.R.DeJoseph* & R.A.Hawkins, Dept. of Physiology and Biophysics, University of Health Sciences / The Chicago Medical School, North Chicago, IL 60064.

Ammonia is suspected to be at least partially responsible for the derangement of cerebral metabolism in hepatic encephalopathy. In portacaval shunted rats, a model of liver disease, characteristic changes include: elevated plasma and brain ammonia, increased brain glutamine and neutral amino acids, and increased transport of neutral amino acids across the blood-brain barrier. Most important is a marked decrease in cerebral function, as reflected by brain glucose and oxygen consumption. It is known that ammonia can alter blood-brain barrier transport and brain amino acid content, but whether hyperammonemia alone is responsible for diminished cerebral function has not been established. To answer this question rats were made hyperammonemic by intraperitoneal injections of urease. Glucose use and tryptophan transport were measured simultaneously in 5 min using a single injection, dual-label technique. After 48 h of urease treatment plasma ammonia was elevated (con. 0.15, exptl. 1.03 μmol/ml) as was brain glutamine (con. 5.4, exptl. 17.8 μmol/g) comparable to values observed in shunted animals. Hyperammonemia enhanced tryptophan transport by 177% and increased brain tryptophan content by 77% although plasma total tryptophan was unchanged. These changes were correlated with plasma ammonia and brain glutamine levels. Cerebral energy metabolism, as reflected by glucose use, was depressed and this depression was inversely correlated with brain glutamine content. These results show that some important metabolic derangements found in hepatic encephalopathy can be reproduced by hyperammonemia alone in otherwise healthy animals. Supported by NS 16389 and NS16737.

BRAIN FUNCTION, TRYPTOPHAN TRANSPORT, AND METABOLITES AFTER 6 HOURS OF PORTACAVAL SHUNTING. A.M. Mans, M.R. DeJoseph*, J.F. Giguere* and R.A. Hawkins, Dept. of Physiology, The Chicago Medical School, North Chicago, IL

Portacaval shunting in rats leads to decreased brain function (as indicated by lower glucose consumption), alterations in blood-brain barrier transport, and abnormal concentrations of many metabolites. We found previously that several of the most characteristic abnormalities were present as soon as 1 or 2 days after shunting. Because these factors may be etiological in hepatic encephalopathy, it is important to establish how early the changes occur, and which are correlated with decreased function. We repeated our measurements 6 hours after portacaval shunting or sham-operation. Brain glucose use showed a slight decrease ($p=0.052$) suggesting that brain energy metabolism and function was already affected. Tryptophan transport and brain content were increased. Plasma ammonia and glutamine were raised. Many plasma amino acids were elevated; branched chain amino acids were not decreased, as they are at later times after shunting. Therefore, changes in brain amino acids and transport were not dependent on decreased neutral amino acid competition effects, as has been suggested. Supported by NIH grants NS16389, NS16837.

EARLY, REVERSIBLE DECREASES OF α-KETOGLUTARATE DEHYDROGENASE ACTIVITY IN THE BRAINS OF THIAMINE-DEFICIENT RATS. M. Heroux* and R.F. Butterworth, Lab. Neurochem., Andre-Viallet Clin. Res. Ctr, Hop. St-Luc (Univ. of Montreal), Montreal, Que. H2X 3J4.

Administration of the central thiamine antagonist pyrithiamine (PT) to the rat results in neurological symptoms including nystagmus and loss of righting reflex which are promptly reversed by administration of thiamine. Measurement of thiamine-dependent enzymes in brain tissue of symptomatic PT-treated rats reveals early selective decreases of α-ketoglutarate dehydrogenase (αKGDH) in cerebral cortex (by 25%, $p<0.01$), cerebellum (by 30%,$p<0.01$), thalamus (by 56%, $p<0.01$) and pons (by 45%, $p<0.01$). Decreased αKGDH is accompanied by decreased concentrations of aspartate, glutamate and GABA and concomitantly increased alanine suggesting decreased entry of glucose carbon into the TCA cycle. αKGDH decreases precede the appearance of neurological symptoms by 2-4 days in all regions of brain. Activities of pyruvate dehydrogenase (PDH) were unaltered in all brain regions. Following thiamine rehabilitation of symptomatic animals, αKGDH activities returned to normal. These results suggest that the reversible oculomotor and cerebellar symptoms of thiamine deficiency result from selective decreases of αKGDH rather than PDH in brain. [Funded by MRC]

MK801 EFFECT ON QUANTITATIVE REGIONAL CEREBRAL GLUCOSE METABOLISM S. Kuo*, J. Dale*, H. Kaneda*, N. Kaneda*, T.N. Chase, C.A. Tamminga, Maryland Psychiatric Research Center, University of Maryland, Baltimore, MD 21228; NINDS, NIH, Bethesda, MD.

MK801 is a potent and selective PCP agonist. Its action in mammalian brain could help to clarify the behavioral and biochemical actions of selective PCP receptor stimulation. Regional cerebral glucose metabolism (RCGM) was assessed using 14C-2-deoxyglucose and autoradiography as described by Sokoloff. MK801 was administered intravenously 10 minutes prior to the 2DG at doses of 0.1 and 1.0 mg/kg. The semi-restrained animals demonstrated mild sterotypies and body weaving at the higher dose, but no apparant motor hyperactivity as seen with PCP. Regional analysis of glucose metabolism suggested two major findings: 1) MK801 significantly increases RCGM in the limbic regions, eg. hippocamous, subiculum, mediodorsal thalamus and cingulate cortex; and 2) MK801 decreases RCGM in sensory-processing brain areas, eg. auditory cortex; sensorimotor cortex; inf. colliculus, and lateral lemniscus. This pattern of alterations contrasts with PCP-induced metabolism changes cheifly by a lack of MK801-induced RCGM changes in extrapyramidal areas. These data suggest that PCP receptor stimulation enhances glucose metabolism in limbic structures and that this change may correlate with motor and mental sequelae of MK801.

QUANTITATIVE MODIFICATIONS OF THE DOUBLE-LABEL 2-DEOXYGLUCOSE AUTORADIOGRAPHIC METHOD ELIMINATE THE CONTRIBUTION OF THE FIRST TRACER TO THE SECOND FUNCTIONAL CONDITION. H.L. Loats, H.H. Holcomb, G.E. Alexander and M.R. DeLong. Johns Hopkins Medical Institutes, Dept. of Neurology; U. MD Psych. Res. Ctr.; Baltimore, MD; and Loats Associates, Westminster, MD.

Using [14C]- and [3H]-2-deoxyglucose we have improved the double-label autoradiographic method for measuring serial state changes in local glucose utilization rates (Friedman et al., J. Exp. Neurol., 1987) by removing the first injected tracer's contribution to the second functional condition. Using rats, we have applied the same or different vibrissae stimulation during two serial injections of radiolabeled 2-deoxyglucose (2DG). Vibrissae stimulation is initiated prior to injection of 120 microCuries/kg [14C]-2DG. A routine plasma sampling protocol is followed for 30 minutes; the rat is stimulated for 25 minutes. At the end of this first functional phase, [3H] 2DG, 7.2 milliCuries/kg, is rapidly injected and plasma samples are again taken in a conventional schedule. The second functional state either repeats or changes from the first as dictated by the experiment. At the conclusion of 60 minutes, the brain is removed and processed in a standard manner. Tissue defatting is accomplished with hexane prior to imaging. Each 20 micron section is autoradiographed twice, once with a filter to eliminate [3H] radiation and once without the filter. Plasma activity curves characterizing each tracer's history are used to calculate the first tracer's contribution to the first condition, the first tracer's contribution to the second condition and the second tracer's contribution to the second condition. Because the first tracer's rate during the second condition is the same as the second tracer's rate during the second condition, an image representing that utilization is generated and subtracted from the first tracer's combined utilization in both conditions.

TEMPORAL PARAMETERS FOR OPTIMAL SEPARATION OF EXPERIMENTAL CONDITIONS IN THE DOUBLE-LABEL 2DG METHOD. H.R. Friedman, C.J. Bruce, and P.S. Goldman-Rakic, Sec. of Neuroanatomy, Yale Univ. Sch. of Med., New Haven, CT 06510.

Double-label modifications of the 2DG technique using ^{3}H and ^{14}C-2DG greatly increase its range of application by permitting brain metabolism to be mapped under 2 separate experimental conditions in the same animal. However, the essential assumption - that the uptake of each label reflects primarily the condition that follows has been questioned by assertions that the 1st isotope labels both conditions in comparable amounts (McEachron et al., Soc Neurosci Abstr, 1988). We addressed this issue quantitatively by estimating the percentage uptake of the 1st label in the 2nd condition directly in a double-label paradigm in which ^{14}C-2DG was given 1st and the 2 conditions were 35 and 10 min long, respectively. During each condition, different vibrissae were manually stroked in awake rats. The cortical columns obtained for each label were commensurate with the whisker stimulated: no indication of the 2nd condition's whisker column was visible in the X-ray image of ^{14}C activity. Formulae derived to assess percentage-uptake of the 1st label in the 2nd condition were applied to radioactivity measurements taken across the cortical barrel fields in digitized ^{14}C and ^{3}H images. The data show that approximately 10% of the ^{14}C uptake was reflected in the 2nd condition. Our previous double-label 2DG studies used 30 min intervals for both the 1st and 2nd conditions (Friedman et al. EBR, 1987), and when we applied these formulae we found that 25 - 30% of the ^{14}C uptake was reflected in the 2nd condition. Lengthening the entire duration of the experiment (from 45 to 60 min) especially by lengthening the 2nd condition therefore appears to worsen the 1st label contamination of the 2nd condition perhaps via rephosphorylation. Indeed, McEachron et al. reported substantial labeling of their 2nd stimulation condition in a single-label 2DG experiment of 90 min duration. However, given optimal temporal intervals, double-label 2DG remains a valid and useful technique for obtaining fine dissociations of brain activity across 2 behavioral conditions in the same animal. Supported by PHS grants MH38546, MH 00298 & EY04740.

EFFECT OF STIMULATION OF AREA POSTREMA ON BLOOD FLOW TO CHOROID PLEXUS, BRAIN, AND EXTRACRANIAL TISSUES. J.L. Williams and D.D. Heistad. Univ. of Iowa and VA Med. Ctr., Iowa City, IA 52242.

The area postrema (AP) is involved in cardiovascular and volume regulation. We examined effects of stimulation of AP on blood flow to choroid plexus (CP), which produces cerebrospinal fluid (CSF), and on distribution of blood flow to brain and other tissues. AP was stimulated electrically in 11 rabbits and 7 dogs, and blood flow was measured with microspheres. Arterial pressure was maintained constant during AP stimulation. AP stimulation (25 μa) decreased blood flow (ml/min/100 g) to CP of the lateral ventricles from 321±43 (mean±SE) to 174±35 in rabbits and from 554±73 to 291±58 in dogs (P<0.05). In contrast, stimulation of AP had no significant effect on blood flow to cerebral cortex, thalamus, caudate, cerebellum, or brainstem in either species. Stimulation of adjacent medullary regions had no effect on blood flow to CP. In dogs, AP stimulation decreased blood flow to the kidney 34±8%, but had no effect on renal blood flow in rabbits. AP stimulation decreased blood flow to duodenum 55±5% and 46±5% in dogs and rabbits, respectively. Blood flow to masseter muscle did not change in either species.

In summary, stimulation of AP produces large changes in blood flow to CP. We speculate that AP may play an important role in the regulation of CSF production and perhaps in volume regulation in the brain.

179.23

ELECTRICAL STIMULATION OF THE SPHENOPALATINE GANGLION INCREASES REGIONAL CEREBRAL BLOOD FLOW INDEPENDENT OF GLUCOSE UTILIZATION IN THE CAT P.J. Goadsby Department of Neurology, The Prince Henry and Prince of Wales Hospitals, Little Bay NSW 2036 AUSTRALIA.

Recently physiological studies have demonstrated a neurogenic vasodilator innervation of the cerebral vessels from the facial nerve (Goadsby, *Am J Physiol*, in press, 1989). Anatomical studies, including investigations employing tracer studies have suggested that the facial nerve vasodilator fibers distribute through the sphenopalatine and otic ganglia. This study determined if the sphenopalatine ganglion exerted an influence over the cerebral circulation by directly stimulating it and measuring cerebral blood flow. Regional cerebral blood flow was determined using the tracer [^{14}C]-iodoantipyrine and regional brain dissection, and regional cerebral glucose utilization determined using the 2-deoxyglucose method, in the α-chloralose anesthetized cat to evaluate the effect of electrical stimulation of the sphenopalatine (pterygopalatine) ganglion. Unilateral stimulation resulted in increases in blood flow in the ipsilateral cerebral cortex of up to 45% (parietal cortex) with, in addition, increased flow in the white matter of the corpus callosum (42%). Flow was not altered in either the brainstem or basal ganglia (caudate nucleus). In contrast to these changes in cerebral blood flow no changes in cerebral glucose utilization were seen in any of the brain areas studied and in particular there were no changes in the areas in which blood flow increased. These data provide clear evidence that the innervation of the cerebral vasculature from the main parasympathetic ganglion can alter cerebral blood flow independent of cerebral metabolism.

179.24

INCREASE IN SPINAL CORD BLOOD FLOW ELICITED FROM DORSAL MEDULLARY RETICULAR FORMATION IN RAT. P.M. Lacombe*, C. Iadecola, K. Chida*, M.D. Underwood and D.J. Reis, Div. of Neurobiology, Cornell Univ. Med. Coll., NY, N.Y. 10021. (SPON: D. Labar)

Stimulation in the dorsal medullary reticular formation (DMRF) in rat increases cerebral blood flow (CBF) and glucose utilization globally. The increases are, in part, mediated by epinephrine released from the adrenals (*Am. J. Physiol.* 252:H1183, 1987). We examined whether stimulation of the DMRF also elevates spinal cord blood flow (SCBF) and, if so, whether the increases are dependent upon adrenal catecholamines. Rats were anesthetized (chloralose), paralyzed (tubocurarine) and artificially ventilated. The DMRF was stimulated electrically (40-75μA, 50 Hz, 1 sec on/1 sec off) and the elevations in arterial pressure were controlled. Local CBF (lCBF) and local SCBF (lSCBF) were measured autoradiographically using the ^{14}C-iodoantipyrine technique. In controls (n=5) lSCBF ranged from 19±3 ml/100g/min in the white matter (WM) of the thoracic lateral funiculus to 83±4 in laminae VI and VII of the lumbar gray matter (GM). As before, DMRF stimulation (n=6) increased lCBF in all regions (p<0.01). Stimulation also increased lSCBF in all segments bilaterally and symmetrically (p>0.05; paired t-test), averaging 206±7% of control (p<0.05). The elevations were greater in WM (280±15% in cervical ventral funiculus) than in GM (200±9% in cervical dorsal horn). Acute bilateral adrenalectomy (n=5) did not change resting lCBF (p>0.05; n=5), but reduced lSCBF increases from DMRF stimulation by 40-50% (p<0.05; n=5) in all spinal segments, the residual elevations averaging 160±5% (p<0.05). We conclude that stimulation of the DMRF produces a global elevation in SCBF which is, in part, dependent on adrenal catecholamines. Thus the DMRF is capable of powerfully driving the metabolism and blood flow of the entire neuraxis.

AN ANTEROGRADE PHA-L STUDY OF THE EFFERENT PROJECTIONS OF THE DORSAL RAPHE NUCLEUS IN THE RAT. Robert P. Vertes. Mercer University, School of Medicine, Macon, GA 31207

The PHA-L technique was used to trace the ascending and descending projections from the dorsal raphe (DR) nucleus. DR fibers terminated heavily in the following structures: nucleus incertus, laterodorsal tegmental nucleus, mesencephalic central gray, pedunculopontine tegmental nucleus, midbrain dopamine-containing cell groups (retrorubral nucleus, VTA and the SN-pars compacta), the central and rostral linear nuclei, the lateral hypothalamic area, the supramammillary nucleus, parafascicular, central medial, mediodorsal and reuniens nuclei of the thalamus, lateral preoptic area, substantia innominata, lateral septal nucleus, the caudate-putamen and the frontal cortex. The following structures were moderately innervated: dorsal hypothalamus, paracentral and central lateral nuclei of thalamus, amygdala, nucleus accumbens, hippocampus and the entorhinal cortex.

The DR was found to project strongly to DA-containing cell groups of the midbrain as well as their major sites of innervation (e.g., mediodorsal thalamic nucleus, the medial basal forebrain, the lateral septum, caudate-putamen and the frontal cortex). This system of projections is consistent with the recent demonstration that DA-containing neurons of the DR are destroyed by MPTP (Unguez and Schneider, Neurosci. Lett. 94:218, 1988) as well as earlier work showing that DR neurons are destroyed in Parkinson's disease.

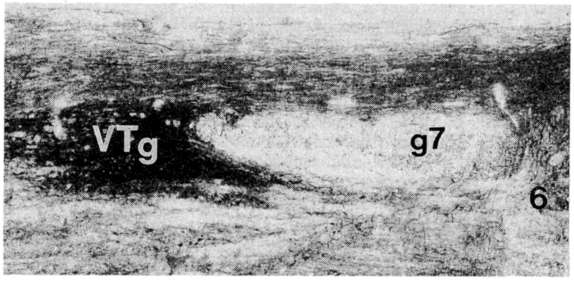
PROJECTIONS OF CENTRAL TRIGEMINAL NUCLEI TO THALAMUS, CEREBELLAR CORTEX, AND SUPERIOR COLLICULUS OF THE RAT. G.W. Patrick, T. Hodgini*, A. Travis* and J.A. Stanek*, Dept. of Anatomy, Kirksville College of Osteopathic Med., Kirksville, MO 63501



To further determine trigeminal projections, retrograde tracers were injected into anesthesized rats placed in a Kopf stereotaxic frame. Flurogold (FG) was injected into the ventrobasal thalamus (VBT), Fast Blue (FB) into superior colliculus (SC) and Diamidino Yellow (DY) into paramedian lobule (PML) of the cerebellar cortex. After a 24 hr. survival period, the animals were perfused with 10% neutral formalin. Sections were taken and analyzed by reflected light fluorescence with UV excitation. The main sensory nucleus (MSN), subnucleus interpolaris (Vi), and caudalis (Vc) contained single FG labelled cells projecting to contralateral VBT. Single labelled FB containing trigeminotectal neurons were seen in contralateral MSN, Vi and Vc. DY only containing trigeminocerebellar neurons were located in MSN and Vi. Double-labelled FG and DY containing cells were found in MSN and Vi, indicating individual neurons projecting to the VBT and PML. FG and FB double labelled neurons, trigemino-thalamic and -tectal, were present in MSN, Vi and Vc. Trigeminal neurons with collateral axons suggests a high degree of complexity of incoming signals and serve as a basis for understanding functional mechanisms.

THE HUMAN VENTRAL TEGMENTAL NUCLEUS. George Paxinos, Xu-Feng Huang* and Istvan Törk*. Schools of Psychology and Anatomy, University of New South Wales, Kensington, NSW 2033, Sydney, Australia.

In 1884 Gudden observed that in the rabbit the majority of the fibers in the mammillotegmental tract terminated in a distinct nucleus of the pontine tegmentum which he named after himself - das Guddensche Ganglion. This nucleus is now known as the ventral tegmental nucleus (VTg) and has been identified in all species studied except the human, where no trace of it has yet been detected, despite specific searches conducted by Gudden and others (see Petrovicky, Acta Anat. 80: 276, 1973). On the basis of acetylcholinesterase (AChE) reactivity, we now report that the VTg exists in humans as a densely AChE reactive nucleus rostral to the abducens nucleus (6) and the genu of the facial nerve (g7) as shown in the accompanying photograph of a sagittal section.

DISTRIBUTION OF NEUROPEPTIDE IMMUNOREACTIVITY WITHIN THE SUBNUCLEI OF THE NUCLEUS OF THE SOLITARY TRACT-DORSAL MOTOR NUCLEUS OF THE VAGUS IN THE PIGEON. **M.L. Berk and H.J. Karten. Dept. of Anat., Marshall Univ. Sch. of Med., Huntington, WV 25704 and Dept. of Neurosci., Sch. of Med., Univ. of Calif., San Diego, La Jolla, CA 92093.**

An immunocytochemical study was undertaken to localize substance P (SP), leu-enkephalin (LE), cholecystokinin (CCK), neurotensin (NT), and vasoactive intestinal polypeptide (VIP) within the nucleus of the solitary tract (NTS)-dorsal motor nucleus of vagus (DMN). Subnuclei of NTS: Many immunoreactive fibers are present in medial and lateral NTS subnuclei for all five peptides with some notable exceptions. Subnuclei medialis dorsalis pars anterior centralis and medialis dorsalis, pars intereminentialis contain few VIP, LE, and NT fibers, moderately dense SP fibers, and very dense CCK fibers. The lateral parasolitary subnucleus has few, if any, immunoreactive fibers for all peptides. Subnuclei of DMN: Numerous immunoreactive fibers are present in various DMN subnuclei. However, few VIP and CCK fibers are present within subnuclei anterior dorsalis parvocellularis, anterior dorsalis mediocellularis and post. intermedius mediocellularis. Subnucleus post. dorsalis magnacellularis contains a moderate number of SP fibers but few fibers of the other peptides. The relationships of the distribution of the peptides to their potential influence on organ function will be discussed.

PROJECTIONS FROM THE MEDULLARY C1 AREA ONTO BRAINSTEM MONOAMINERGIC NEURONS. A.P. Nicholas* and M.B. Hancock. Department of Anatomy and Neurosciences, University of Texas Medical Branch, Galveston, Texas, 77550.

Phaseolus vulgaris-leucoagglutinin (PHA-L) was iontophoretically deposited in the rostral ventrolateral medulla of anesthetized Sprague-Dawley rats. Following survival times of 7-10 days,the rats were anesthetized and perfused with 4% paraformaldehyde. The brainstem was removed and sectioned (30 µm) with a Vibratome. PHA-L-immunoreactive (PHA-LI) elements were immunostained black with the PAP technique and nickel-intensified diaminobenzidine (Ni/DAB), while phenylethanolamine N-methyl transferase-immunoreactive (PNMTI), tyrosine hydroxylase-immunoreactive (THI) or serotonin-immunoreactive (5HTI) neurons were stained amber with the PAP technique and DAB alone. Black-stained PHA-LI cells were present at the deposition site among amber-stained PNMTI cells of the C1 cell group. PHA-LI varicosities were observed in contiguity with THI neurons of the A1, A2 and A5 cell groups, 5HTI neurons of the B1, B2 and B3 cell groups, and PNMTI neurons of the C1, C2 and C3 cell groups. Projections to adrenergic and noradrenergic cell groups from the C1 region were extensive, both ipsilaterally and contralaterally. This study demonstrates that the C1 area, a known vasopressor region, has widespead projections to local monoaminergic brainstem cell groups.

THE DISTRIBUTION OF BULBOSPINAL SEROTONINERGIC NEURONS THAT CO-CONTAIN ENKEPHALIN OR SUBSTANCE-P IN THE NORTH AMERICAN OPOSSUM. V.K. Reddy*, P.C. Cassini*, R.H. Ho and G.F. Martin. Dept. of Anatomy and Neuroscience Program, The Ohio State University, Columbus, OH 43210.

Our earlier studies have shown that many serotonin (5-HT), enkephalin (ENK) and substance-P (SP) immunoreactive neurons in the raphe nuclei and reticular formation project to the spinal cord in the opossum. In the rat and cat some of the 5-HT neurons in these nuclei contain ENK and SP. We attempted to localize spinally projecting neurons that co-contain 5-HT and ENK or 5-HT and SP in the opossum. In anaesthetized opossums, True Blue was injected unilaterally into the second or third cervical segment. Following an appropriate survival period, colchicine was injected into the brainstem 24 hrs prior to perfusion. Frozen (coronal) sections of the brainstem were cut and processed by the method of Wessendorf and Elde (J. Histochem. Cytochem., 33, 984, 1985) to demonstrate two antigens on the same section. 5-HT neurons that contain ENK or SP were present in several brainstem nuclei. The spinally projecting neurons that contain 5-HT and ENK were limited to the nuclei raphae magnus and obscurus and the nucleus reticularis gigantocellularis, pars ventralis. Spinally projecting neurons that contain 5-HT and SP were found in the same areas and in the nucleus raphae pallidus. Further studies are in progress to identify these neurosubstances in bulbospinal terminals in the opossum. (Supported by NIH 25095)

ENKEPHALIN-IMMUNOREACTIVITY AND MESSENGER RNA ARE EXPRESSED IN A DISCRETE PROJECTION FROM THE NUCLEUS OF THE SOLITARY TRACT TO THE NUCLEUS AMBIGUUS IN THE RAT. E.T. Cunningham Jr.†, D.M. Simmons, L.W. Swanson and P.E. Sawchenko, The Salk Institute, La Jolla, CA 92037, & †The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

We have described a circumscribed, partly somatostatinergic, projection from the nucleus of the solitary tract (NTS) to the rostral, or compact, part of the nucleus ambiguus (NA) in the rat. Complementary studies of the central sensory and motor representation of the esophagus support the notion that this pathway subserves reflex control of esophageal motility. Here, axonal transport, immunohistochemical and *in situ* hybridization techniques were used to determine if enkephalin (ENK), a peptide commonly coexpressed with somatostatin in medullary cell groups, is contained in the NTS-to-rostral NA projection. The results may be summarized as follows: (1). Cells immunoreactive (IR) for proenkephalin-derived peptides were found in the central, or esophageal-sensory, portion of the NTS in colchicine treated animals. (2). Preproenkephalin mRNA signal was found over the central part of the NTS, and appeared more abundant than that for preprosomatostatin. Combined retrograde transport-hybridization histochemical studies identified cells in the central NTS that project to the NA and contain either mRNA species. (3). Fibers labeled in the compact NA following deposits of the anterograde tracer PHA-L in the central NTS displayed a distribution similar to that of endogenous ENK-IR, with many also displaying ENK-IR. (4). Unilateral electrolytic lesions that included the central NTS virtually eliminated ENK-IR in the ipsilateral compact NA. Together, these studies suggest that ENK is prominently expressed in a putative interneuronal pathway from the central part of the NTS to the rostral NA that subserves reflex control of esophageal peristalsis.

MIDBRAIN RETICULAR NEURONES IN VITRO ARE SENSITIVE TO AMINES AND OPIATES. A. Khateb*, M. Serafin* and M. Mühlethaler. Dept. de Physiologie, CMU, 1211 Genève 4 , Switzerland.

Midbrain reticular neurones are known to play a major role in a network controlling sleep and arousal. Since they receive a variety of inputs implicated in the sleep/waking cycle, it is important to understand their sensitivity to different putative neurotransmitters. Using an isolated and perfused preparation as well as brainstem slices we have in particular investigated their sensitivity to amines and opiates. Compounds were bath-applied on cells that were characterized by the presence of a broad action potential, slow repetitive firing and an A current, and thus presumed to be cholinergic (Leonard and Llinas, Soc. Neurosci. Abst.: 14, 197,1988). Opiates inhibited these cells through a direct effect on receptors of the Mu type. The amines were also found to have mainly inhibitory effects with the exception of histamine which always had a direct excitatory effect. These data support the view of an interaction of opiates and amines with neurones of the ascending reticular formation. A balance in between excitatory and inhibitory amines impinging upon these cells could contribute to the control of behavioral states. (Swiss NSF grant no 3.288-0.85).

THALAMIC-PROJECTING NEURONS IN BRAINSTEM CHOLINERGIC NUCLEI INCREASE THEIR FIRING RATES ONE MINUTE IN ADVANCE OF EEG DESYNCHRONIZATION ASSOCIATED WITH REM SLEEP.
S. Datta, D. Paré, G. Oakson* and M. Steriade. Lab. of Neurophysiol., Laval Univ. School of Med., Québec, Canada.

Brainstem reticular neurons were recorded from PPT and LDT cholinergic nuclei during transition from slow wave sleep (S) to REM sleep in behaving cats. Neurons were localized within PPT/LDT limits on sections stained for NADPH-diaphorase and were antidromically invaded from reticular, LG, PUL-LP, intralaminar and medial thalamic nuclei. About 20% of tonically discharging brainstem-thalamic neurons increased their spontaneous discharges 1 min before EEG desynchronization with shift from S to REM sleep. Firing rates were 250-300% higher during REM sleep (median around 35 Hz) than during S. Because PGO waves occurred during the transitional S-to-REM (or pre-REM) epoch and some of these PPT/LDT neurons were also PGO-on (see Steriade et al., this meeting), we performed separate analyses and determined that the tonically increased firing rate preceded the first thalamic PGO wave by about 40 sec. This correlative evidence indicates that brainstem cholinergic neurons with identified thalamic projections are the best candidates for inducing disruption of synchronized spindling rhythmicity, one of the major aspects of EEG synchronization. Supported by MRC grant MT-3689.

DIFFERENT CLASSES OF PGO-ON NEURONS IN PEDUNCULOPONTINE AND LATERODORSAL TEGMENTAL BRAINSTEM CHOLINERGIC NUCLEI.
M. Steriade, D. Paré, S. Datta, G. Oakson* and R. Curro Dossi*. Lab. of Neurophysiol., Laval Univ. School of Med., Québec, Canada.

It is known that brainstem peribrachial neurons discharge short spike bursts 15-25 msec before the thalamic PGO wave and are otherwise silent. We now report that, in addition to a very low percentage (<5%) of such PGO-on bursting (130-170 Hz) cells, a great diversity of PGO-related neurons exists in brainstem cholinergic nuclei. We recorded PPT and LDT neurons with antidromically identified thalamic projections during REM-sleep of behaving cats. (a) A class of neurons discharged high-frequency (500-600 Hz) spike bursts 30-40 msec before the thalamic PGO wave, upon a background of tonically increased firing rates during REM sleep. This raises the possibility that such events are generated at a depolarized level, contrary to what is expected for a low-threshold rebound burst. (b) Other neurons discharged trains of tonic repetitive spikes preceding the thalamic PGO wave by 150-300 msec. (d) Still another population was REM-on, but PGO-off, suggesting that such neurons may belong to the category of GABAergic neurons recently described in the LDT nucleus and that their PGO-related silence may disinhibit neurons with tonic PGO-on discharges. Supported by MRC grant MT-3689.

AFFERENT CONNECTIONS OF THE PEDUNCULOPONTINE TEGMENTAL NUCLEUS IN THE RAT.
T.L. Steininger, D.B. Rye, and B.H. Wainer. Dept. of Pharm. and Phys. Science, Univ. of Chicago, Chicago IL 60637.

The cholinergic neurons of the pedunculopontine tegmental nucleus (PPTn) are a major source of ascending cholinergic fibers from the brainstem, and may modulate cortical activity through efferents to the thalamus and basal forebrain. Other evidence suggests that the PPTn is involved in the production of pontine-geniculate-occipital (PGO) waves that accompany the onset of rapid-eye-movement (REM) sleep. Knowlege of the afferents will provide additional insight to the function of this nucleus.

The retrograde tracer wheatgerm agglutinin-conjugated horseradish peroxidase (WGA-HRP) was pressure injected (5 to 15 nl) into the area of the PPTn. Retrogradely labeled neurons were consistently found in the posterior lateral hypothalamus, the paraventricular nucleus of the hypothalamus, zona incerta, sub-parafascicular nucleus of the thalamus, and the laterodorsal tegmental nucleus. Less heavily labeled areas included the midbrain central gray, pontine and medullary reticular formation, and the somatosensory relay nuclei in the medulla.

These anatomical data are consistent with previous studies that demonstrate that the PPTn is not involved in motor functions, and suggest that this cholinergic nucleus integrates visceral, sensory and behavioral state information. (NS 17661 and GM 07839)

PONTINE TEGMENTUM MECHANISMS IN THE GENERATION OF HIPPOCAMPAL THETA RHYTHM.
A. Nuñez*, I. de Andrés, C. Barrenechea* and E. García-Austt*. Dept. Morfología. F. Medicina. UAM and Dept. Investigación. H. Ramón y Cajal . Madrid. Spain.

Electrical stimulation of oral pontine tegmentum (PnO) elicits hippocampal theta rhythm (θ) (Vertes 1982). This report describes the findings of a study of the unitary activity of PnO neurons during θ and the effect of carbachol microinjections in PnO. Transmembrane potential propierties of medial septal (SEP) and diagonal band (DB) neurons were also examined through intracelullar "in vivo" records. Experiments were performed in urethane anesthetized and curarized rats. During θ evoked by sensory stimulation,the firing rate in 53% of PnO neurons increased and decreased in 18%. Rhythmical firing was not observed in PnO neurons, however, spikes were phase-locked with hippocampal θ in 28%. Microinjections of carbachol (1-4 %, 20-40nl) in contralateral PnO elicited θ (4-6 Hz) and firing rates similar to those described above. These effects were abolished by atropine injections in PnO. Electric stimulation of PnO (300 Hz, 100-200 μA) evoked θ, as well as, a depolarization of SEP neurons together with an increase of the rhythmical burst rate of DB neurons. We may conclude that the activity of PnO neurons contributes to hippocampal θ generation through a cholinergic system, modifying transmembrane potential of SEP and DB neurons. PnO neurons seems to act -through excitatory and inhibitory mechanisms- providing a tonic, non-rhythmic outflow to SEP and DB neurons. Finally, the presence of PnO neurons which spikes are phase-locked with θ suggests the existence of septal and/or hippocampal θ feedback .

NEUROPHYSIOLOGICAL EVIDENCE FOR THE GATING OF HIPPOCAMPAL AUDITORY RESPONSES BY PONTINE RETICULAR FORMATION NEURONS.
P.C. Bickford-Wimer and R. Freedman, Departments of Pharmacology and Psychiatry, Univ. Colorado Health Sci. Ctr. and Veterans Admin. Med Ctr, Denver, CO. 80262

Rat hippocampal CA3 neurons show diminished response to the second of paired auditory stimuli, at interpair intervals up to several seconds. Both intrinsic inhibitory mechanisms and extrinsic inputs have been proposed to alter or "gate" the response of the hippocampus to sensory afferents. We found that pontine reticular formation neurons also exhibit a diminished response to paired auditory stimuli. Their initial response occurs at 20 msec, about 20 msec before the hippocampal response. Electrical stimulation of this brainstem area, followed by auditory stimulation, results in a diminished auditory response in the hippocampus, similar to the decrement seen when two auditory stimuli are paired. Primary auditory relay nuclei did not show diminished response to paired auditory stimuli, and their electrical stimulation did not decrease the response to subsequent auditory stimuli. The pontine reticular formatiom may thus participate in auditory sensory gating in the hippocampus.

BURST FIRING OF MEDIAL VESTIBULAR NUCLEI NEURONES IN VITRO.
M. Serafin*, P.P. Vidal, C. de Waele*, A. Khateb* and M. Mühlethaler, Dept. de Physiologie, CMU,1211 Genève 4 , Switzerland; *Laboratoire de Physiologie Neurosensorielle, CNRS, Paris, France.

The vestibulo-ocular reflex (VOR) generates a distinct pattern of eye movements in response to a differential input from the semicircular canals, consisting of slow and quick phases. During the quick phase of the vestibular nystagmus, type I medial vestibular neurones (MVN), located in the vestibular nucleus contralaterally to the side of head rotation, respond to a brisk disinhibition by a burst of spikes. Using guinea pig brainstem slices we found 3 main cell types: Type A displayed a single afterhyperpolarization and a presumed A current, type B had a double afterhyperpolarization and sodium and calcium plateau potentials. Type C neurones, which represented only a small minority, were the only ones whose intrinsic membrane properties could be at the origin of burst responses. These neurones, which in some respects had similar properties to type B neurones, usually discharged in a tonic manner at rest but responded with a burst when fired from a hyperpolarized level. When the sodium conductances were blocked by TTX (10-6 M) an underlying low threshold spike (LTS) was revealed. This LTS, very similar to the one described in thalamic neurones, was due to a calcium conductance as it was completely eliminated in presence of cadmium (2-3 mM). It is therefore tempting to speculate that, an LTS could play a role in the genesis of the bursting activity of MVN neurones during the quick phases of vestibular nystagmus in vivo. (Supported by a Swiss NSF grant no. 3.288-0.85).

VAGAL EFFERENT DISCHARGE IN RESPONSE TO A PERIPHERAL EMETIC STIMULUS IN THE FERRET. J.S. Davison*, R. Egizii, K.A. Sharkey* and G.E. Lucier. University of Calgary, Dept. of Medical Physiology, Calgary, Alberta T2N 4N1 Canada.

Intragastric administration of 1.5M NaCl is an effective emetic stimulus in the halothane anaesthetized ferret. At levels of halothane greater than 0.8 vol%, this stimulus does not elicit vomiting but the prodromal signs are still present. We have investigated vagal efferent discharge in response to intragastric 1.5M NaCl under these conditions. Single unit efferent activity was recorded in nerve strands dissected from the cervical vagus of ferrets anaesthetized with halothane (0.8-1.5 vol%), paralyzed with gallamine and artificially ventilated. All units were spontaneously active and responded to either gastric distention or chemical stimulation with 1.5M NaCl. The majority of units responded to gastric distention; 50% responded to chemical stimulation including those that were not mechanosensitive. The response to chemical stimulation was characterized by high frequency and prolonged discharge continuing after removal of the stimulus and was most evident at the lower anaesthetic levels. The ability of this emetic stimulus to activate vagal efferent discharge does not depend on activation of the full emetic episode. This modulation of vagal efferent activity may account for certain visceral prodromata elicited by emetic stimuli.

EPILEPSY: KINDLING I

181.1

ONTOGENY OF THE SENSITIVITY OF GABAERGIC INHIBITION IN VARIOUS EPILEPTIC CONDITIONS. H.B. Michelson, J. Kapur, and E.W. Lothman, Department of Neurology, University of Virginia, Charlottesville, VA 22908.

Using methods previously developed in our laboratory (J. Neurophys. 61:417, 1989) we examined the effects of a single seizure, of a model of recurrent triggered seizures and of a model of status epilepticus on hippocampal paired pulse (GABAergic) inhibition at various postnatal (PN) ages. Under urethane-anesthesia, population spikes were recorded in the stratum pyramidale of one CA1 region in response to stimulation of the contralateral CA3. The stimulus intensity and interpulse interval of paired stimuli were varied to systematically characterize the potency of paired pulse inhibition (PPI). The three seizure models were elicited with 20 Hz, 10 second trains, delivered at different rates. PPI was quantified 30 and 60 minutes after an isolated seizure, and hourly up to 4 hours after recurrent seizures and status epilepticus. The findings were that: 1) a single seizure caused a transient reduction of PPI, which lasted longer in younger animals; 2) after recurrent triggered seizures and with spontaneous seizures there were larger and longer lasting reductions of PPI than after a single seizure; 3) the changes associated with recurrent triggered seizures were smaller than those with status epilepticus; 4) profound losses of PPI were often, but not always, accompanied by spontaneous seizures. We conclude that GABA-mediated inhibition in the hippocampus at all postnatal ages is sensitive to post-seizure reductions in its potency and that this sensitivity is greater in young animals. This may be related to the propensity of the young brain for seizures. However, a diminution of GABAergic inhibition cannot be the sole mechanisms accounting for this propensity.

181.2

DEVELOPMENTAL PROFILE FOR THE ABILITY OF THE HIPPOCAMPUS TO SUPPORT ELECTROGRAPHIC KINDLING AND STATUS EPILEPTICUS. E.W. Lothman, H.B. Michelson, and J. Kapur, Dept. Neurology, University of Virginia, Charlottesville, VA 22908.

The pattern of seizures triggered by 10 second stimulus trains to the hippocampus differs markedly as a function of the time between trains. In urethane-anesthetized adult rats, when such trains are delivered every few minutes, successive afterdischarges lengthen in a fashion like that seen during kindling in awake animals. When the stimuli are spaced closely, producing a nearly "continuous hippocampal stimulation" (CHS), cyclical seizures appear during the course of CHS. Following CHS, spontaneous epileptic activity appears after a delay of 2 hours. The present experiments examined how these responses varied as a function of postnatal (PN) age. A microelectrode was positioned in the stratum pyramidale of one CA1 region. 10 sec, 20 Hz stimuli of 1 msec pulses at twice afterdischarge threshold were given to the contralateral CA3 region every 5 minutes (RRHS protocol) or continuously (CHS protocol). All ages showed an increase in afterdischarge durations during the RRHS protocol. The degree of lengthening was not different among the various ages examined (PN7, PN14, PN18, PN21, PN28 days of age, adults). During and after CHS, PN28 animals responded like adults. Some, but not all, of the PN18 animals showed adult-like cycling of seizures during CHS. However, none of these animals developed delayed, spontaneous seizures after CHS. At PN7, seizures were seen at the outset of CHS, but subsequent cycling of seizures did not occur and no delayed spontaneous seizures appeared after completion of CHS. These findings indicate that the processes which allow kindling of electrographic seizures in the hippocampus are present by PN7 whereas those which support status epilepticus mature later.

181.3

ELECTROPHYSIOLOGIC MARKER FOR THE KINDLED STATE: MAXIMAL DENTATE GYRUS ACTIVATION. J.L. Stringer and E.W.Lothman. Dept. of Neurology, Univ. Virginia Med. Ctr., Charlottesville, VA 22908.

Maximal dentate gyrus activation (MDA) consists of bursts of large amplitude (20-40 mV) population spikes that have been shown to be critical for the production of an afterdischarge in the hippocampus of rats. Electrophysiologic characteristics of MDA in fully kindled rats were compared to those in age-matched surgical control rats. Animals were anesthetized with urethane and trains of 20 Hz stimuli administered to the left CA3 region while recording in the right dentate gyrus. By systematically increasing the stimulus intensity, the thresholds for MDA and for afterdischarges were determined. In surgical control animals, the afterdischarge threshold was 6 times the threshold for MDA. In kindled animals these thresholds were equal; i.e. at the stimulus intensity threshold for elicitation of MDA an afterdischarge was produced. Once activated, the duration of MDA in kindled animals was significantly longer than in the surgical control animals ($p<0.01$, grouped t-test). These data suggest that kindling causes alterations in the processes which control the initiation and termination of MDA. The MDA parameters identified here provide a practical means to investigate basic mechanisms of kindling.

181.4

INTRAVENOUS PHENYTOIN BLOCKS AMYGDALOID KINDLED SEIZURES C. Shin, L. C. Rigsbee*, L. S. Butler* & J. O. McNamara, VA and Duke Univ. Med. Ctrs., Durham, N. C. 27705.

The efficacy of anticonvulsant drugs is one prerequisite for the validity of an animal model of epilepsy. Kindling is a model of human partial and 2^{o} generalized seizures (SZ). A strong correlation exists among drugs effective against SZ in humans and in kindling with one striking exception, i.e., phenytoin (PHT). PHT is an effective anticonvulsant in humans, but was found ineffective against kindled SZ by previous reports using intraperitoneal (IP) or oral administration. We reexamined its efficacy against amygdala-kindled SZ in rats using intravenous (IV) route to insure reliable access of PHT to the bloodstream.

IV PHT suppressed kindled SZ 60 min after injection in a dose-dependent manner: Motor SZ, by 50% at 12.5 mg/kg and 100% at 25 and 50 mg/kg; electrographic SZ, by 44% at 12.5 mg/kg and >90% at higher doses. No overt toxicity was observed at the time of testing. IV PHT produced a linear increase in serum concentration with increasing doses. At 50 mg/kg, serum levels were 48.7 $\pm$ 2.1 ug/ml after IV compared to 9.8 $\pm$ 8.4 after IP administration (mean $\pm$ SD).

Previous findings of inefficacy of IP PHT are most likely due to low and variable serum levels achieved. PHT powerfully suppresses kindled SZ, when adequate serum levels are reached. Thus the excellent correlation among drugs effective against SZs in humans and in the kindling model strengthens the validity of this model.

181.5

NMDA Receptor Plasticity in Kindling: Increased Number of Glycine Receptors and Glycine-Stimulated TCP Binding in Hippocampal Membranes. G.C. Yeh*, D.W. Bonhaus, J.V. Nadler and J.O. McNamara. Duke and V.A. Med. Ctr. Durham NC. 27705

Electrophysiologic studies indicate that kindling is associated with increased NMDA receptor-mediated synaptic transmission. Biochemical studies indicate that, while a change intrinsic to post-synaptic sites likely contributes to the electrophysiologic findings, there is no increase in the number of NMDA binding sites. Therefore, we tested whether an alteration in a second component of the NMDA receptor/channel complex, namely the glycine binding site, may account for the electrophysiologic findings. We measured glycine receptors (using [3H]glycine) and glycine activation of the NMDA channel (using [3H] TCP binding). Kindling was found to increase the density of glycine receptors by 41%, when assayed one month after the last evoked seizure ($p<.05$). At the same time the ability of glycine to activate the NMDA receptor-gated ion channel was increased by 29% ($p<.05$). No alterations in glycine binding or glycine-stimulated TCP binding were detected in animals sacrificed 24 hours after the last seizure. This is the first demonstration of plasticity of the glycine receptor. Up-regulation of the glycine recognition site on the NMDA receptor-channel complex may be one molecular mechanism that maintains the longlasting hyperexcitability in the hippocampus of kindled animals.

181.6

MORPHOLOGICAL EVIDENCE FOR SYNAPTIC REORGANIZATION INDUCED BY KINDLING IN THE STRATUM MOLECULARE OF THE CA1/SUBICULUM TRANSITIONAL REGION OF THE RAT HIPPOCAMPAL FORMATION Jose E. Cavazos and Thomas P. Sutula. Depts. of Neurology, Anatomy and Neuroscience Training Program. University of Wisconsin-Madison.

In the rat hippocampal formation studied with the Timm method there are two areas of punctate staining: 1) the terminal zone of the well-known mossy fiber pathway, and 2) the stratum moleculare of the ventral CA1/subiculum transitional region (Haug, Adv Anat Embr Cell Biol 48(1): 1-84, 1973). Synaptic reorganization is induced in the mossy fiber terminal zone by kindling, as demonstrated by development of mossy fiber terminals in the supragranular region of dentate gyrus (Science 239: 1147, 1988). To consider the possibility that kindling might induce synaptic reorganization in other brain areas, the stratum moleculare of CA1/subiculum was also examined after kindling. After 50 class V seizures evoked by olfactory bulb, amygdala or angular bundle stimulation, there was a dense band of Timm granules in the stratum moleculare of the CA1/subiculum, which was not present in implanted unstimulated controls or normal rats. Timm granules were also increased in CA1/subiculum at earlier stages of kindling. The results demonstrated that kindling induces morphological alterations in CA1/subiculum in addition to the mossy fiber pathway, and suggest that kindling may also induce synaptic reorganization in other pathways.

181.7

REGIONAL VARIATION IN THE DISTRIBUTION OF MOSSY FIBER SYNAPTIC REORGANIZATION INDUCED BY KINDLING: EVIDENCE FOR A RELATIONSHIP OF SYNAPTIC REORGANIZATION TO PATTERNS OF NEURAL ACTIVITY. Thomas P. Sutula and Jose E. Cavazos. Depts. of Neurology, Anatomy and Neuroscience Training Program. University of Wisconsin-Madison.

The factors that influence formation and maintenance of neural connections in developing and adult animals are uncertain. In adult animals kindling reorganizes connections of the mossy fiber pathway, as indicated by the development of mossy fiber terminals in the supragranular area of dentate gyrus. If synaptic reorganization in the dentate gyrus is a consequence of neural activity, the distribution of synaptic reorganization along the septotemporal axis should reflect patterns of activity in afferent pathways. To investigate this hypothesis, the distribution of mossy fiber synaptic reorganization after amygdala and perforant path kindling was studied with the Timm method at three different levels of the septotemporal axis. After perforant path kindling the increases of supragranular Timm granules were more prominent in septal than temporal dentate gyrus ($p<0.001$), in contrast to a more even distribution along the septotemporal axis after amygdala kindling. The results demonstrated regional variation in the distribution of synaptic reorganization that depends on kindling site, and suggest that mossy fiber synaptic reorganization is a consequence of patterns of neural activity during kindling.

STIMULATION-INDUCED STATUS EPILEPTICUS RELIABLY PROVOKES HIPPOCAMPAL MOSSY FIBER SPROUTING. M.M. Okazaki and J.V. Nadler. Depts. Pharmacology and Neurobiology, Duke Univ. Med. Ctr., Durham, NC 27710.

Degeneration of hippocampal CA4 neurons is a consistent feature of complex partial epilepsy in humans. Histochemical evidence suggests that, when a sufficient percentage of CA4 neurons is destroyed, mossy fibers sprout axon collaterals that grow into the molecular layer of the fascia dentata. These fibers appear to form a recurrent excitatory circuit that is not normally present. Detailed study of this aberrant circuit requires a reliable means of destroying enough CA4 neurons to provoke robust mossy fiber sprouting. The present study was undertaken to determine whether stimulation-induced status epilepticus (SISE) would serve this purpose.

Adult male rats were chronically implanted with a bipolar stimulating electrode in the angular bundle and a recording electrode in area CA3 of the ipsilateral dorsal hippocampus. At least a week later, the animals were electrically stimulated with pulse trains of 10 s duration (monophasic rectangular pulses, 0.2 ms, 20 Hz, current supramaximal for synaptic response) delivered every 40 s while they were unanesthetized and unrestrained. This procedure eventually resulted in continuous seizure activity that persisted after the stimulator was turned off. Two weeks later brain sections were prepared and stained for heavy metals by the Timm's sulfide silver method.

Heavy metal staining suggested the presence of robust recurrent mossy fiber sprouting in 8 of 9 rats that experienced at least 4.5 h of SISE. The sprouting was largely confined to the caudal third of the hippocampal formation, where the CA4 lesion was most extensive. In two animals stimulated for a comparable period with a current insufficient to induce SISE, there was little evidence of mossy fiber sprouting. Therefore SISE can serve as a useful tool for studying the role of axon sprouting in epilepsy. (Supported by NIH grant NS 17771.)

INTRACELLULAR CORRELATES OF THE KINDLING OF SYNCHRONIZED BURSTS IN RAT HIPPOCAMPAL SLICES. S.M. Bawin, M.D. Mahoney* and W.R. Adey. Departments of Physiology and Neurosurgery, Loma Linda University and Veterans Administration Medical Center, Loma Linda, CA 92357.

We previously demonstrated kindling of synchronized bursts by repeated sinewave stimulation (SW, 2-5 s, 60 Hz, 20-50 μA) in the CA2/3 area of rat hippocampal slices. The synchronized bursts involved the NMDA receptor system. Here we report the behavior of individual CA2/3 neurons during and following SW.

Intra- and extracellular responses were recorded concurrently. Test pulses (100 μs, 50-150 μA, 0.1 Hz) and SWs (every 5 min) were applied via bipolar electrodes in the stratum radiatum. Intracellular depolarizing steps (10-100 ms, 0.5-2 nA, 0.1 Hz) alternated with test pulses. Hyperpolarizing steps measured the membrane resistance.

Small depolarizations (5-10 mV) occurring during the first SWs were potentiated (20-25 mV) during repeated stimulation. Single action potentials (APs) then occurred at the beginning of SW, while bursts of APs, riding on small depolarizing waves, occurred later. Following these changes during SW, intra- and extracellular responses to test pulses started to exhibit delayed bursts or late EPSPs. There was no change in resting membrane potential, resistance, or responses to intracellular depolarizing steps. The early responses (fast EPSP or AP and population spike) were not potentiated.

Thus, SW selectively kindled late responses in CA2/3 pyramidal neurons. Activation of the NMDA receptors and associated calcium currents during SW may lead to long-lasting changes in the CA2/3 network of recurrent excitation.

CONTINUOUS HIPPOCAMPAL STIMULATION DECREASES CALCIUM CALMODULIN-DEPENDENT PROTEIN KINASE II ACTIVITY. J.B. Perlin, S.B. Churn*, E.W. Lothman[2], W.C. Taft and R.J. DeLorenzo. Dept. of Neurology and Dept. of Pharmacology and Toxicology, Medical College of Virginia-VCU, Richmond VA 23298 and [2]Dept. of Neurology, Univ. of Virginia School of Medicine, Charlottesville VA 22908.

Septal kindling leads to a permanent decrease in calcium-calmodulin-dependent protein kinase (CKII) activity (Brain Res. 377,47,1986). Recently, Lothman et al. (Epilepsy Res. 3,107,1989) demonstrated that 90 min continuous hippocampal stimulation (CHS) leads to progressively enhanced seizure activity which can become self sustaining (SSS). We investigated whether CKII is also decreased in this novel model of epilepsy.

Five male Sprague-Dawley rats (250-270g) and 5 paired surgical controls were stereotactically implanted with bipolar hippocampal electrodes. Test animals received a stimulus consisting of 10 sec trains of 50 Hz, 1 msec biphasic square wave pulses every 11 sec for 90 min. Animals were sacrificed following CHS but prior to SSS to eliminate effects of subsequent seizures on enzyme activity. CKII activity was measured in hippocampal homogenates by in vitro phosphorylation, SDS-PAGE, and autoradiography. CHS reduced hippocampal CKII activity by an average of 37 ± 14% ($p<0.0125$; Students Paired t-test). CKII activity was decreased in the stimulated animal from all 5 pairs (range 5 - 85% decrease). The decrement of activity among pairs was directly related to the intensity of the epileptiform discharges observed during monitoring intervals. In the same animals, no differences in cerebellar CKII activity were noted, but a trend toward decreasing activity in the cortex was observed. In summary, as with conventional kindling, CHS produces a decrease in CKII activity.

DYSREGULATION OF MEMBRANE SYSTEMS FOR PHOSPHORYLATION-DEPHOSPHORYLATION IN THE KINDLING MODEL OF EPILEPSY. J.T. Slevin, T.C.Vanaman*, and G.N. Barnes*. Veterans Administration and Univ of Kentucky, Lexington, KY 40536.

Phosphorylation-dephosphorylation events in hippocampal membranes may play a central role in learning, memory, and epilepsy.We have shown that rat hippocampal phosphoprotein phosphatase 2Ao (pp2Ao) apparently redistributes from cytosol to synaptic plasma membranes (SPM) by 2 min and that membrane protein kinase C (PKC) maximally decreases 4 min after electroshock (ECS); both return to control values by 10 min post-ECS. We report here that a similar but earlier decrease of SPM PKC occured after an ECS given to rats which had been kindled to Stage V by entorhinal stimulation 1 month earlier. Furthermore, there was an attenuation of the post-ECS redistribution of pp2Ao in the same kindled rats. Using an in vitro hippocampal slice preparation, similar effects on PKC and pp2Ao were seen in control and kindled hippocampi exposed to 5 min of Ca^{+2}-dependent, K^{+} depolarization. These data suggest that following epileptic discharge: 1) there may be a more rapid PKC activation/deactivation cycle in the hippocampus of kindled than control animals; and 2) neurotransmitter-induced activation of pp2Ao is altered in kindled animals. Since cAMP and Ca^{+2}/Cam dependent kinases are in vitro substrates for pp2Ao (Barnes etal, SocNeurosciAbstr, 1989), the above data suggest that cAMP and Ca^{+2}-regulated kinase activities may be permanently altered in SPM of kindled animals. KINDLING INDUCES GREATER PROTEIN KINASE C ACTIVATION THAN LONG TERM POTENTIATION. L. J. Burdette, M. E. Gilbert & J. P. O'Callaghan. Graduate Hospital, NSI & U.S. Environmental Protection Agency, Philadelphia, PA & Research Triangle Park, NC

Based upon evidence that translocation of protein kinase C (PKC) from cytosol to membrane may be implicated in long term potentiation (LTP), synaptic potentiation and PKC activity were measured following kindling and LTP stimulation. Male Long Evans rats were implanted with electrodes in the perforant path and dentate granular cell layer. Initial input/output (I/O) curves were generated for a kindling, an LTP and a control group. The kindling group was stimulated daily until generalized seizures were elicited. The next day I/O curves were generated for all groups. LTP stimulation then was delivered to kindling and LTP groups and a third I/O curve was obtained 90 minutes later. Synaptic potentiation was determined by the difference in the population spike amplitude between initial, pre- and post-LTP I/O curves. Rats were sacrificed and hippocampal cytosol and membrane fractions were prepared. PKC activity was measured as the difference in activity with and without phosphatidylserine. Kindling potentiated baseline responses by 150%; further enhancement by LTP stimulation was minimal. At these same intensities, LTP rats showed 35-65% enhancement. The percentage of total PKC activity present in membrane was 68%, 50% and 32% in kindled, LTP, and control rats, respectively. These results suggest that differences in synaptic potentiation elicited by LTP and kindling stimulation reflect differences in PKC activation. In addition, the observation that membrane PKC activity was elevated in the contralateral hippocampus of kindled rats indicates that PKC translocation results from seizure propagation. CHRONIC, NON-OSMOTIC PLASMA VASOPRESSIN AND VASOPRESSIN mRNA INCREASES FOLLOWING AMYGDALA KINDLING R.S. Greenwood, R.B. Meeker, and J.N. Hayward, Dept of Neurol. and Neurobiology Curriculum, UNC Sch. of Med., Chapel Hill, NC 27599

In the present study we sought to determine if amygdala kindling influences physiologic responses through synaptic interactions by measuring plasma vasopressin (VP) release and VP mRNA in magnocellular neuroendocrine cells.

Plasma VP levels, hematocrit and osmolality were measured in blood from amygdala kindled and non-kindled, adult male Sprague Dawley rats sampled through a chronic indwelling venous catheter. These blood samples were drawn before and after an amygdala stimulus both prior to beginning kindling and after kindling. In addition, five rats that had received kindling four months earlier and three control rats were processed for in situ hybridization. An [^{125}I]dCTP-labeled oligomer specific for VP mRNA (VP mRNA) was hybridized to 20 um cryostat sections followed by processing for high resolution autoradiography.

As previously reported (Greenwood et al, 1986), amygdala stimulation evoked an immediate but variable increase in plasma VP. Moreover, the resting plasma VP in kindled rats was significantly higher than plasma VP from rats before kindling (before kindling VP- 2.1+0.3 pg/ml vs kindled VP- 3.0+0.3 pg/ml $p<0.05$). No significant changes occurred in hematocrit or plasma osmolality. Quantification of the autoradiographs with a Bioquant Image Analysis System demonstrated a 300% increase in labeling in the supraoptic nucleus of rats that had received the kindling stimulus.

These results are consistent with a permanent alteration in genomic expression resulting from synaptic activation and enhanced mRNA translation. Supported in part by Javits Award NS-14311.

INCREASE OF PROSOMATOSTATIN mRNA FOLLOWING AMYGDALOID KINDLING VS. A SINGLE ELECTRICAL STIMULATION. H.Shinoda, J.P.Schwartz and N.S. Nadi[1]. Clinical Neuroscience and [1]Medical Neurology Branches, NINDS, NIH, Bethesda MD 20892

We have reported that prosomatostatin(SS) mRNA and SS were increased 3 days after the last stimulation in the cortex and striatum of amygdaloid-kindled rats (Mol.Brain Res., 1989). In order to investigate the potential role of neuropeptides in the kindled state, SS and proenkephalin (PE) mRNA were measured 1 day, 3 days, 1 week and 6 weeks after the last stimulation. In both kindled and single stimulated rats (200 uA, 1 msec, without seizure activity), SS mRNA increased in frontal cortex (44 and 34%), in temporal cortex (41 and 43%), and in hippocampus (34 and 37%) respectively 1 day after the stimulation and had returned to basal level by 1 wk.In striatum, SS mRNA increased slightly at 1 day, reached a peak of 70% increase by 3 days and returned to basal by 1 wk. PE mRNA did not change in these brain regions. These data show that SS mRNA is increased by a single electrical stimulation: the increase in SS thus cannot be directly relevant to the induction of kindling.

VISUAL SYSTEM: DEVELOPMENT AND PLASTICITY II

182.1

MORPHOLOGY OF RAT RETINAL GANGLION CELLS (RGCs) DURING FETAL AND POSTNATAL DEVELOPMENT. E.N. Yamasaki*, M.S. Rocha*, A.S. Ramoa. Lab. Mol. Pharmacol. II, Fed. Univ. Rio de Janeiro, Brazil 20540.

The retina of the adult rat contains α, δ and γ-like types of RGCs analogous to those found in the cat. We have examined how the adult form is achieved during development. We also asked which cells project to topographically incorrect portions of the superior colliculus (SC) and whether these errors affect development of RGC dendritic trees. Retinae were dissected from rats between embryonic day 20 (E20) and postnatal day 30 (P30) and maintained alive in a tissue-slice chamber. RGSs were identified by retrograde transport of rhodamine labeled microspheres injected into the SC and their fine morphology revealed by intracellular injections of Lucifer Yellow. At E20, RGCs were morphologically immature, with a few relatively simple, unbranched dentrites. A more elaborate pattern of dentritic branching was present in the neonatal retina and a few α, δ and γ-like cells could be distinguished by P5. Morphological features not present in the adult included a large number of dentritic spines and more highly branched dentrites. The axons often gave rise to collaterals or short side branches. These transient features reached a peak in number around P10 and declined during the following 2 weeks. Therefore, rat RGCs undergo extensive dendritic and axonal remodelling during development, as occurs in cat (Ramoa et al., J. Neurosci. 8:4238, 1988). Moreover, up to P5, RGCs terminating in topographically appropriate and inappropriate regions of the SC were morphologically indistinguishable, suggesting that initially a few cells of all RGC classes make projection errors. By P10, however, only a few γ-like cells remained from this population with inappropriate connections. Thus, mechanisms for elimination of targeting errors may differentially affect each RGC class. SPIKING PROPERTIES OF DISSOCIATED GANGLION CELLS IN DEVELOPING CAT RETINA. I. Skaliora*, L.M. Chalupa, A.J. Gabor and R.P. Scobey. Depts. of Psychology, Neurology, and the Physiology and Neurobiology Graduate Groups, Univ. of California, Davis CA 95616.

We are investigating action potential patterns of retinal ganglion cells in postnatal and adult cats. Cells are dissociated using light papain treatment for 10 minutes and kept in culture at 10°C for up to 30 hours after removal from the eye. Intracellular recordings from isolated ganglion cells are obtained using the whole cell variation of the patch-clamp technique. Ganglion cells are identified by retrograde labeling with rhodamine beads previously injected into the superior colliculus and lateral geniculate nucleus.

After a giga-seal is obtained, voltage recordings are made (current clamp mode) followed by current recordings (voltage clamp mode). In response to depolarizing steps of current (1-80pA), two spiking patterns have been observed. Some cells show a sustained pattern of discharge lasting the duration of current application, while others show a transient pattern with rapid adaptation during the stimulating current. To date, both sustained and transient responses have been observed in different ganglion cells of the same retina as early as P5. This approach is being used to investigate the development of membrane conductances in the three main classes of ganglion cells of the cat retina.

182.3

EXPRESSION OF A HIGH AFFINITY LAMININ RECEPTOR IN THE RAT NEURAL RETINA. G.Yang*, P.J.Douville*, and S.Carbonetto. (Spon:S.David) Center for Neurosciences Reseach, McGill University, Montreal General Hospital, 1650 Cedar, Montreal, Canada.

We and others have reported the presence of a high affinity (K_d=1nM) laminin receptor (LR) in neural cells. With polyclonal antisera to a synthetic peptide derived from the cDNA sequence of the LR (Yow et al, PNAS, 85:6394-6398,1988) we investigated immunocytochemically its developmental expression in rat neural retinas. LR immunoreactivity was not detected until postnatal day 6 (P6), when strong reactivity appeared in the ganglion cell layer (GCL), and much weaker immunoreactivity in the inner nuclear layer (INL) and some horizontal cells. By P14, LR immunoreactivity persisted in GCL but diminished in INL and horizontal cells. In the adult, immunoreactivity was exclusively localized in the GCL. The onset of LR expression coincided with differentiation of the inner plexiform layer (IPL) and correlated with immunostaining for neural adhesion molecule (NCAM) in the IPL. The timing and localization of LR immunoreactivity as well as its persistance in adult retina suggests that the antigen(s) identified by the antiserum may be involved in the establishment and maintenance of structural integrity of the GCL.

182.4

A POSITIONAL MARKER FOR THE DORSAL EMBRYONIC RETINA IS AN OPEN CONFIGURATION OF THE SO-CALLED 68KD-LAMININ RECEPTOR. U.C.Dräger, P.McCaffery*, S.A.Rabacchi, L.A.Kobierski*, H.-M.Chu*, R.L.Neve. Harvard Med. Sch., Boston, MA 02115.

In a search for determinants of positional information in the eye we made three monoclonal antibodies (MAb's) which label the dorsal part of the undifferentiated embryonic retina; two of the MAb's show a very strong dorso-ventral (D-V) difference, the third MAb labels the entire retina with only a slight dorsal preference. Through biochemical and molecular analysis we identified the antigen as a protein previously cloned as the 68kD-laminin receptor. A fourth MAb, which also strongly recognizes this laminin receptor in Western blots, shows immunohistochemically no preference at all for the dorsal retina. In order to understand the nature of the D-V difference seen by some but not all MAb's, we tested embryonic eyes bisected into dorsal and ventral halves: neither RNA blots nor Western blots reveal a D-V difference, indicating that the protein is present, but some of its epitopes are inaccessible in ventral retina. Tests for a biochemical correlate of the immunohistochemical D-V difference-- Western blots of D-V halves run on non-denaturing gels, of trypsin-digestion series and of formalin-fixed eyes-- have so far been negative, but we can demonstrate in Western blots much higher MAb-binding to fixed dorsal retina. Conversely, an immunohistochemical correlate of the biochemically even distribution of the antigen is seen in sections of formalin-fixed eyes treated with the denaturing reagents SDS or urea, which partially unmask the antigen in ventral retina; and in embryos fixed with ethylene glycol*bis*(succinimidylsuccinate), a homobifunctional cross-linker with very long spacer arm (16Å), which makes the antigen evenly accessible throughout the eye for all MAb's. These observations indicate that the D-V difference in the antigen is a non-covalently determined difference in conformation, probably a masking of epitopes in ventral retina by tighter coiling of the protein or by association with additional molecules. Supported by NIH grant EY01938.

182.5

NEUROPEPTIDE SYSTEMS IN THE DEVELOPING RAT RETINA. D.Zhang and H.H.Yeh. Dept. Neurobiology and Anatomy, Univ. Rochester School of Medicine, Rochester, NY 14642

Do different neuropeptide systems in the mammalian retina follow a similar pattern of development? We have previously described the development of corticotropin releasing factor (CRF)-like immunoreactive (-LI) amacrine cells in the rat retina. Here, we examined the ontogeny of other neuropeptide systems, including vasoactive intestinal polypeptide (VIP), substance P (SP) using a combination of immunohistochemistry and [3H]-thymidine autoradiography. Emphasis was placed on comparing their developmental patterns with that of the retinal CRF system. In the adult rat retina, these neuropeptide systems display distinctly different cellular morphology and patterns of fiber distribution.

During development, immunoreactivity to these neuropeptide systems were first detected at different times; CRF-LI appeared first, followed by SP- and VIP-LI. Eye opening coincided temporally with some changes in all these neuropeptide systems. Whereas CRF-LI cells already were adult-like by eye opening, VIP- and SP-LI cells have yet to complete their development. A center-to-periphery gradient was found in the CRF and SP systems but not in the VIP system. In addition, CRF and SP systems displayed a differential distribution; the immunoreativity was more prominent in the superior (S) and temporal (T) regions than in the inferior (I) and nasal (N) regions of the retina. Furthermore, quantitative determinations revealed that these peptide systems developed differently in terms of parameters such as changes in cell number and density. Preliminary results of our birthdating study suggest that, unlike CRF-LI cells which cease mitotic activity prenatally, VIP cells were still being generated postnatally.

Overall, our results indicate that different neuropeptide systems may correlate with different subpopulations of retinal cells and that they follow different programs in development.

DIFFERENTIAL GABA- AND GAD- IMMUNOREACTIVITY IN THE CHICK RETINA DURING DEVELOPMENT. J.N. Hokoç; A.L.M.Ventura*; P.F. Gardino* and F.G. de Mello*. Instituto de Biofisica Carlos Chagas Filho, UFRJ, Rio de Janeiro. BRAZIL.

In early stages of retina development, GABA may be synthesized from putrescine. This synthetic pathway decreases in later stages, as glutamate decarboxylase (GAD) activity increases several fold (de Mello et al., '76). In this study, aldehyde-fixed chick retina sections from several stages of development were used to localize GABA and GAD-immunoreactivity (IR) in an attempt to discriminate GABA synthetic pathways. In mature retinas, GABA-IR cell bodies were localized in the distal and proximal inner nuclear (INL) and ganglion cell layers (GCL). Processes arborized in both outer (OPL) and inner plexiform layers (IPL). GAD-IR cells were seen in the innermost row of the INL and in the GCL, with processes arborizing in the IPL. During the development GABA was clearly detected in retina cell bodies as early as E8. However, GAD-IR neurons were not observed in retinas of embryos younger than E12. Thus, our data provide the first morphological evidence that GABA-IR in E8 may be accounted for an alternative GABA synthetic pathway.

THE EFFECT OF GABA ON RETINAL MATURATION AND SYNAPTOGENESIS IN VIVO. E.Messersmith*,V.Blanchard* & D.Redburn. Dept. Neurobio. & Anat., UT Med.Sch.,Houston,TX 77225.

Previous work suggest that Type A horizontal cells may be pioneering elements for the outer synaptic layer of the rabbit retina, providing structural and/or chemical substrates necessary for appropriate synaptic connections between the three major cell types. During a critical period, lasting approximately one week after birth, Type A horizontal cells transiently express GABAergic properties. In order to examine the possible role of GABA during this critical period, GABA-A receptor antagonists, bicucculline and picrotoxin, were injected intraocularly at birth. Retinal development was significantly altered during the 5 days following treatment. Lamination of neuronal processes into inner and outer plexiform layers was disrupted. The normal complement of cells within the inner retina was reduced with a concomitant increase in photoreceptors cells and rosette formation. Bicucculine was more potent and gave more consistent effects than did picrotoxin. An injection of the GABA-B receptor antagonist, phaclophen, had little effect on retinal development. We suggest that GABA-A receptors and the transient expression of GABA by Type A horizontal cells may play an important role in normal synaptic development. Supported by NEI grant 1566-12.

182.8

ALTERATIONS IN THE TIMING OF RETINAL DEVELOPMENT DURING THE PROTRACTED DEVELOPMENT OF THE CALIFORNIA MOUSE. D.R. Sengelaub, M.A. Bimler*, J.A. Burke*, and A.R. Cover*. Program in Neural Science, Dept. of Psycholgy, Indiana University, Bloomington, IN 47405.

The Syrian hamster (Mesocricetus auratus) and the California mouse (Peromyscus californicus) are closely related cricetid rodents. While the hamster is three times larger in body size, their eye size and weight, total retinal cell number and distribution, retinal ganglion cell number, and overall brain size are quite similar. This similarity is interesting in that both the length and rate of development, two factors hypothesized to be important in producing species differences in retinal organization, are strikingly different between hamsters and California mice. Gestation (16 days in hamster vs. 33 in mice), the closed eye period (CEP= 30 days in hamster vs. 47 in mice), age of sexual maturity, and attainment of adult body size are significantly longer or delayed in the mouse. We have studied the protracted development of the California mouse to determine how formative events in retinogenesis have been orchestrated in the production of its hamster-like eye.

Generation of the ganglion cell layer of hamsters and mice has a similar timing and duration, with cells beginning to withdraw from the cell cycle at approximately 37% of the CEP. However, peak cell number and the onset of cell death in the retinal ganglion cell layer occur at approximately 67% of the CEP in the hamster, but are delayed in the mouse, occurring at about 80% of the CEP. Growth of the eye is remarkably similar in duration and rate between the two species, but again occurs throughout a later portion of development in the California mouse. It appears that the protracted development of the California mouse is accompanied by a delay in post-generational events in retinal development, resulting in a retinal topography and eye conformation similar to that of the hamster.

182.9

TERMINAL CELL BIRTH IN THE CAT RETINA D. H. Rapaport and A. J. Vietri* Department of Anatomy, University of Sydney, Sydney NSW 2006, AUSTRALIA.

Two zones of cell division have been recognized in the retina of the cat. To determine the identity of cells generated by them kittens received an injection of ^{3}H-thymidine, and the retinas were sectioned thinly and processed for autoradiography.

At P5 cell birth is occurring at the edge of the retina at high density. On average, 125 labelled cells are found within the peripheral 1mm of linear extent. The density of cell birth decreases rapidly to only 2 per linear 100µm at P21. The cells generated during this period are rods (RPR), bipolar (BP), and Müller (Mü) cells in approximate constant proportions of 3.7:4.7:1.9, respectively. The density of label in central retina is very low postnatally, ranging from .09-.52/linear mm within 5.7mm centered on the area centralis. At P5 most central labelled cells are BP (65%), 25% are PR, and 7% are Mü. By P11 there is a strong shift from BP cell birth (now 33%) to RPR's (55%) while Mü's remain approximately the same (10%). This trend continues to P21 where the proportions are now 75%-RPR, 20%-BP, and 5%-Mü.

Postnatally cell birth is mainly confined to peripheral retina and stops between P10-P15. There is no obvious sequence of birth. A sparse population of mitoses persists centrally, and with increasing age tends to generate mostly RPR's. Perhaps the persistence of RPR birth maintains their density during ocular growth in the cat, as apparently in goldfish (Johns, '82, J. Neurosci. 2: 179-198).

182.10

ACTIVITY AND THE MODULATION OF AXON LOSS IN THE CAT'S OPTIC NERVE. A.J. Scheetz, M.W. Dubin, University of Colorado at Boulder, and R.W. Williams, Yale University

In the cat, 100,000 retinal ganglion cells die during the first two postnatal months (Williams *et al.*, 1986). To determine the role of action potential activity in this ganglion cell death, we injected the action potential blocker tetrodotoxin (TTX), monocularly, from birth through day 60. Animals were perfused at the end of this continuous blockade, on day 60, and optic nerves prepared for electron microscopy. The size of the remaining ganglion cell population was estimated by counting axons in the optic nerves.

The axon population in the nerves of the TTX-treated eyes was 160,000 ± 1000 (n=3). This is precisely the same number as in normal cats, 6 weeks of age or older. Thus, neither activity nor the injection procedure itself affects the magnitude or timecourse of naturally-occurring cell death on the injected side. In marked contrast, the axon population on the uninjected side was significantly higher than normal, 182,000 ± 1000 (n=3). This reduced incidence of cell and axon loss is comparable to that seen in the remaining eye after early monocular enucleation, even though the normal number of axons from the treated eye remains in the TTX-injected case. There is a hypertrophy of layers of the lateral geniculate nucleus that receive input from the untreated eye (Dubin, personal observations). Active ganglion cells are probably at a competitive advantage and their axons are able to sprout into territories that are only loosely held by silent axons from the other eye. This increase in territory preserves active ganglion cells that would otherwise have died.

182.11

EVOLUTIONARY PLASTICITY IN THE FELINE RETINO-GENICULATE SYSTEM. Robert W. Williams, Yale University, Carmen Cavada and Fernando Reinoso-Suárez, Universidad Autónoma de Madrid.

The Spanish wildcat, *Felis silvestris tartessia*, is a relict of a once widespread species from which domestic cats descended (Kurtén, '65). Our aim is to evaluate evolutionary change in the visual system associated with a 40-50% reduction in body size that has taken place in this cat lineage over the past 25,000 years. To do this we compared neurons and fibers in the retina, optic nerve, and lateral geniculate nucleus (LGNs) of wildcats and domestic cats using quantitative EM methods, retrograde HRP labeling, and direct 3-D counting.

The decline in body size has been accompanied by a decrease in brain mass from ~34 g to 27 g. Correlated with this change there are 35% fewer ganglion cells in domestic cats than in wildcats—160,000 vs. 240,000. However, the size of the retina remains the same. Therefore, ganglion cells are more widely spaced in the domestic cat retina. There are also 35% fewer neurons in the domestic cat LGN—550,000 vs. ~880,000. Unlike the retina, this decline is matched by an equivalent decline in the size of the LGN—from ~39 to 26 mm^3. Therefore, the density of LGN neurons is similar in both species.

We conclude that the brains of domestic cats are smaller than those of wildcats because they contain fewer—not smaller—neurons. The stable 1-to-3.5 ratio between ganglion cells and LGN neurons in both species probably results from well conserved trophic interactions between neuron populations during development. Whether the rapid evolutionary change in brain structure has been achieved by variation in rates of neuron proliferation or cell death remains an open and intriguing question.

This work was supported by ICONA (Spain) and the NIH.

182.12

LOCALIZATION OF TAURINE-LIKE IMMUNOREACTIVITY (TLI) IN RAT OPTIC NERVE. Norma Lake, Luisa De Marte* and Carole Verdone-Smith*, Depts. of Physiology and Ophthalmology, McGill University, Montreal, Canada, H3G 1Y6.

The role of taurine in the vertebrate retina or optic nerve is unknown, however our recent EM morphometric studies have indicated that in addition to retinal cell degeneration taurine deficiency causes shrinkage of optic nerve axons, decreases in myelin thickness and frank loss of nerve fibres [Vis. Res. 128: 1071-76; Neurosci. Abs. 14: 358 (1988)]. We have developed an antibody to taurine, useful for immunocytochemistry by raising antisera in rabbits immunized with taurine as a hapten conjugated to a carrier protein. During early postnatal development TLI is very prominent in bundles of ganglion cell axons within the retina. In the adult optic nerve about 2mm behind the eye, the most prominent TLI occurs within glial cells. Preliminary studies show co-localization with glial fibrillary acidic protein (GFA) in some of these structures suggesting that some of the cells containing TLI may be astrocytes. One can speculate that the effects of taurine deficiency on the optic nerve may be secondary to glial cell dysfunction, in addition to the other etiologies we have proposed.

THE MORHOLOGY OF ABERRANT MAMMALIAN RETINAL GANGLION CELLS. R.J.T. Wingate*, and I.D. Thompson* (SPON: Brain Research Association). University Laboratory of Physiology, Parks Road, Oxford OX1 3PT, Great Britain.

We have compared the detailed morphology of those hamster retinal ganglion cells which have an aberrant uncrossed projection from the nasal retina with those of the normal uncrossed and crossed populations. Populations are identified by the pattern of retinal decussation seen following a unilateral injection of rhodamine-latex microspheres into the optic pathways. Retrogradely labelled cell bodies are then located in an in vitro retina preparation and selectively impaled with glass micropipettes under a compound microscope and epifluorescent illumination. Detailed dendritic morphology is revealed by intracellular injection of Lucifer Yellow. Cells with an aberrant uncrossed projection to the mid-brain are found to have an abnormally sparse dendritic arbor with a significantly lower branching density. Such arbors are not seen in cells with appropriate decussation patterns. After monocular enucleation at birth, the increased nasal uncrossed population shows a more variable distribution of dendritic morphologies.

THE DISTANCE OF AXOTOMY FROM THE NEURONAL CELL BODY INFLUENCES RATE OF RETROGRADE DEGENERATION BUT NOT LONG-TERM SURVIVAL OF RETINAL GANGLION CELLS (RGCs). M.P. Villegas-Pérez*, M. Vidal-Sanz*, G.M. Bray, and A.J. Aguayo. Montreal General Hospital and McGill University, Montréal, Québec, H3G 1A4, Canada.

In the mammalian CNS, axotomy close to the cell body causes retrograde degeneration and death of many neurons. For example, more than 90% of RGCs die soon after optic nerve (ON) transection near the eye (Villegas-Pérez et al., J. Neurosci. 8:265, 1988). However, with axotomy further away from the cell body, RGC survival increases with the distance of ON transection (Villegas-Pérez et al., Soc. Neurosci. Abstr. 14:673, 1988). To study the effects of distance of axotomy on long-term RGC survival, we prelabeled RGC with diI and then transected the ON at 0.5, 3, 8, or 10 mm from the eye in adult Sprague-Dawley rats. The densities of surviving RGCs were assessed by counting diI-labeled neurons in 12 standard areas of each experimental retina in groups of animals examined at 1, 3, 6, 9, and 12 months after axotomy.

After 6 months, the number of surviving RGCs had fallen to approximately 5-10% of the normal RGC population in all of these retinas. Thus, the distance of ON transection from the eye appeared to influence the rate of RGC degeneration but not the long-term survival of these cells.

182.15

SYNAPSE FORMATION BY REGENERATING RETINAL GANGLION CELL AXONS DIRECTED INTO AN INAPPROPRIATE TARGET (THE CEREBELLAR CORTEX) IN ADULT HAMSTERS. T.J. ZWIMPFER*, A.J. AGUAYO, G.M. BRAY and D.G. LAWRENCE. Montreal General Hospital and McGill Univeristy, Montréal, Québec, Canada, H3G 1A4.

Regenerating retinal ganglion cell (RGC) axons of the adult hamster form synapses when guided to one of their appropriate targets, the superior colliculus (Carter D.A. et. al., Soc. Neurosci. Abstr. 14:654, 1988). To investigate the selectivity of regenerative synaptogenesis by adult mammalian CNS axons, regrowing RGC axons were guided into an inappropriate target, the cerebellar cortex, via a bridging peripheral nerve graft. Regenerating RGC axons penetrated the cerebellar cortex for distances up to 650 μm and arborized within the granule cell and Purkinje cell layers. Retino-cerebellar synapses were observed within the granule cell layer from 2 to 5 months after graft insertion. The morphology of the retino-cerebellar axon terminals and synapses was similar to that of both control and regenerated retino-collicular axons, although the mean area of retino-cerebellar axon terminals was larger.

These results indicate that in the absence of an appropriate target, regenerating CNS axons in adult mammals can form differentiated and persistent synapses with inappropriate target neurons.

MODELING THE COMPUTATIONAL ORIGIN OF ROTATIONAL OPTIC FLOW DETECTORS FOR VISUAL PROPRIOCEPTION. G. C. Belmont* and J. I. Simpson, (SPON: H. Cohen). Dept. Physiol. & Biophys., NYU Med. Ctr., New York, NY 10016.

A computational model is being developed to account for the response properties of neurons of a visual proprioception system subserving compensatory eye movements and related behaviors. This system, which originates in the accessory optic system (AOS), detects global retinal image movement associated with self-motion, and its neurons have been characterized in the rabbit. They are speed and direction selective and the spatial organization of their direction selectivity is suited to detection of rotational optic flow about particular axes. This type of receptive field first appears in the AOS and is elaborated at the level of the visual tegmental relay zone, to which the AOS projects. At later synaptic levels rotation selective receptive fields underlie the visually-modulated complex and simple spike activity of cerebellar flocculus Purkinje cells, which can be divided into three classes on the basis of the orientation of the best-response axis of the climbing fibers. These axes are located close to the best-response axes of the semicircular canals and the rotation axes of the extraocular muscles. A previous model showed how the basic AOS response properties can be derived from those of on, direction-selective retinal ganglion cells. The current model seeks to describe how the AOS response properties are spatially combined to produce rotational optic flow detectors. Modulation of these detectors shows a near cosine relation with the angle between the best-response axis and the stimulus rotation axis and it is to this relation that the model is fit while incorporating data on the speed selectivity and retinal distribution of ganglion cells and the spatial distribution of direction selectivity within the receptive fields of neurons to which the AOS projects.

183.2

THE SYNAPTIC ORGANIZATION OF GABAERGIC AND NONGABAERGIC NEURONS IN THE PRETECTUM AND THE ACCESSORY OPTIC SYSTEM IN THE RABBIT: RETROGRADE TRACING COMBINED WITH GABA IMMUNOCYTOCHEMISTRY. J.J.L. Van der Want and J.J. Nunes Cardozo. Dept.of Morphology, The Netherlands Ophthalmic Res. Inst. P.O.Box 12141,1100AC Amsterdam, The Netherlands. (SPON: ENA)

Neurons in the pretectum and the accessory optic system (AOS) have been investigated ultrastructurally after retrograde labeling with WGA-HRP injected in the inferior olive and postembedding GABA-immunocytochemistry. The large number of GABA-positive neurons in the pretectum and the AOS suggests that some GABAergic neurons could be projection neurons. However, following injections of WGA-HRP in the inferior olive all retrogradely labeled neurons were GABA-negative. These projection neurons have large to medium sized cell bodies and are strongly contacted by GABA-positive terminals. In contrast to the GABA-negative cell bodies the GABA-positive cell bodies are surrounded by glial processes and receive few terminals. The GABA-positive terminals exhibit distinct morphological features: F-terminals, of axonal origin making axosomatic contacts and P-terminals, presumably of dendritic origin terminating mainly in the neuropil. GABA-negative terminals comprise F and P terminals and R terminals that are of retinal origin. The retrogradely labeled neurons showed striking similarities with respect to their ultrastructure and terminal organization, irrespective the localization in different nuclear areas.

183.3

PROJECTIONS OF THE LATERAL TERMINAL ACCESSORY OPTIC NUCLEUS (LTN) OF THE MARMOSET. R.H.I. Blanks, R.J. Clarke*, Y. Torigoe, S. Pham*, R.A. Giolli, Department of Anatomy and Neurobiol., Univ. Calif. Irvine, Irvine, CA 92717 and Departamento de Fisiologia e Farmacologia, Univ. Federale de Pernambuco, Cidade Universitaria, Recife, Brazile.

The projections of the largest of the monkey accessory optic (AOS) terminal nuclei, the LTN, have been studied using ^{3}H-leucine autoradiography (6 animals) and retrograde HRP techniques (10 animals). The largest projections are to the ipsilateral nucleus of the optic tract (NOT) and dorsal terminal nucleus (DTN). There is a small, contralateral projection to the olivary pretectal nucleus and LTN provided by axons crossing in the posterior commissure. A second, moderate projection is to the interstitial nucleus of the superior fasciculus (posterior fibers) (IN-SF$_p$) that ends abruptly in the marmoset midway between the LTN and ventral, medial terminal nucleus (MTN$_v$). A third, large projection is to a part of the ventral tegmental area termed the "visual tegmental relay zone" (VTRZ). This bundle also provides a large input to the mesencephalic and pontine reticular formations (PRF) and small fields to the dorsal MTN (MTN$_d$), MTNv and interstitial nucleus of Cajal. It crosses and provides some terminals to the contralateral VTRZ. A fourth major projection targets the supraoculomotor periaqueductal gray above the oculomotor nucleus; the IV and VI nuclei are unlabeled in all experiments. Lastly, there are two long-descending bundles: i) one courses within the medial longitudinal fasciculus to terminate within the dorsal cap of the inferior olive, ipsilaterally, ii) another travels ventral to the brachium conjunctivum and provides a moderate projection to the superior and medial vestibular nucleus, ipsilaterally. Retrograde HRP studies are incomplete, but all connections above have be confirmed except those to the vestibular nucleus and PRF. The present findings are in general agreement with the well-documented connections of the AOS nuclei of other mammals, and further support the general conclusion that the LTN provides a major relay of visual information to important oculomotor centers. (Supported in part by NSF grant BNS-8612919-02)

183.4

RESPONSES OF PRETECTAL NEURONS OF THE BEHAVING MONKEY U. J. ILG* (SPON: K. Behrend) Allg. Zoologie und Neurobiologie, University of Bochum, P.O. Box 10 21 48, D-4630 Bochum, F.R.G.

The pretectal region of vertebrates has been shown to contain neurons which do respond directionally selective to movements of large stimuli with ipsiversive preferred direction. These neurons can be localized in the Nucleus of the Optic Tract NOT (Hoffmann et al. 1988 Exp. Brain Res. 69: 635-644)

Single unit activity and eye movements were recorded from the NOT of awake and behaving monkey (M. fascicularis).

The recorded pretectal units are directionally selective with ipsiversive preferred directions for velocities up to 400 deg/sec of random dot pattern independent of luminance (0.1 to 14 cd/m*m tested). The latency of the response to the onset of movement in preferred direction varies betweem 80 and 100 ms. During OKN the activity of these neurons can be interpreted as a function of slip direction and velocity. During pursuit these neurons respond to target and background induced slip with contrary preferred directions.

183.5

RECIPROCAL CONNECTIONS BETWEEN ACCESSORY OPTIC SYSTEM AND PRETECTUM IN MONKEY (MACACA FASCICULARIS). M. Magnin*, C. Baleydier* and H. Cooper* (SPON: J. Bullier). Unité 94 I.N.S.E.R.M., 16 avenue Doyen Lépine, 69500 Bron, FRANCE.

Organization of the accessory optic system (AOS) and its connections with the pretectum are described in macaque monkey. Monocular intravitreal injections of tritiated amino acids confirm the existence of the three AOS nuclei as classically recognized in non primate species. Retinal AOS projecting cells, labeled by retrograde tracer injected in the lateral terminal nucleus (LTN) are distributed mainly within the foveal region of the contralateral eye.

Injections of tritiated amino acids in the pretectum demonstrate a major contralateral projection to the lateral and the medial terminal nuclei of the AOS (LTN and MTN) and a sparser projection to the ipsilateral LTN. From experiments of retrograde tracers (fluorescent dye or HRP) injected in the LTN, it appears that the contralateral projection originates from the pretectal olivary nucleus (OPN). Besides this crossed OPN-AOS connection which seems specific to primates, the classical projection from the nucleus of the optic tract (NOT) to the ipsilateral LTN was also found.

HRP injection in the pretectum reveals a bilateral, although mainly ipsilateral, reciprocal projection from the LTN to the pretectum

The direct connection between LTN and OPN suggests a possible role of the AOS in the control of the pupillary light reflex, supported by previous descriptions of numerous luminance responsive cells in the AOS.

183.6

Somatostatin Immunoreactivity within the Pretectal Complex of the Cat. J.T. Weber, L. Meyer*, A. Arimura and I-li Chen*. Tulane University Medical School, New Orleans, LA 70112.

Immunocytochemistry was used to identify the cellular components within the pretectal complex of the cat that presumably contain the neuropeptide, somatostatin (SOM). The anterior pretectal nucleus (APN), nucleus of the optic (NOT), and pretectal olivary nucleus (ON) contain the largest numbers of SOM-positive neurons; the posterior pretectal nucleus (PPN) contains relatively few SOM-positive neurons. Only one SOM-positive neuron was seen within the medial pretectal nucleus (MPN). SOM-positive fibers and terminals are found within all pretectal nuclei but are most numerous within ON and MPN. Comparisons of cell body areas reveal that in the NTO and ON the mean size of SOM-positive neurons are significantly larger than the mean size of Nissl stained neurons. For example, a sample of SOM-positive neurons within the NTO has a mean somal area of 352.6 u^2 (SD = 161.8) while a sample of Nissl stained neurons, in adjacent sections, has a mean somal area of 221.2 u^2 (SD = 103.7). No size difference between SOM-positive and Nissl stained neurons is apparent within the APN and PPN. These preliminary data suggest that a population of pretectal projection neurons contains SOM. This hypothesis is currently being tested with the combined use of immunocytochemistry and retrograde transport methods. Supported by NIH grant EY03731.

183.7

Ultrastructural Analysis of Retinal and Cortical Terminals within the Cat Olivary Pretectal Nucleus. B.Hutchins, and J.T.Weber. Baylor College of Dentistry, Dallas, Tx. 75246 and Tulane Medical School, New Orleans, La. 70112.

The cat olivary pretectal nucleus (ON) receives a rich supply of retinal projections within the head and tail regions (Hutchins and Weber, Br.Res., 331('85)150-154) as well as projections from the extrastriate cortex (Hutchins et al., Anat. Rec., 205('83)88). To test the hypothesis that retinal and cortical terminals may synapse on the same ON cell, the optic nerve was sectioned on the left side six days prior to sacrifice and HRP was placed throughout the extrastriate cortex on the right side in the same animal. Ultrastructural analysis of retinal projections within the ON head revealed primarily extraglomerular terminals which were in contact with medium to large diameter dendrites. Glomerular retinal terminals appeared to be in contact with small to medium diameter dendrites and all of the retinal terminals were of the RLP type. Cortical terminals were primarily of the RSD type although there were a few labelled RLD terminals. Retinal and labelled cortical terminals typically synapsed in close proximity along small diameter dendrites. In a few cases, degenerating retinal profiles were identified terminating on small HRP labelled cortical terminals. Thus, these data suggest retinal and cortical information can influence the same ON cell and there is direct modulation of cortical projections by retinal terminals. Supported by NIH grants EY06977 (BH) and EY03731 (JTW).

183.8

Transmitter and Peptide Content of the Isthmo-Optic Nucleus in the Pigeon (*Columba livia*) : A study of non-tectal afferents. W.Woodson*, T. Shimizu, and H.J. Karten, Dept.Neurosciences, Univ. California, San Diego.92093.

The only documented afferent to the isthmo-optic nucleus (ION) originates from the optic tectum (McGill et al ., *J. Anat. (Lond)*.100: 5,1966a,b). The cells of origin are found in layers 9 and 10 of the stratum griseum et fibrosum superficiale. Some of the neurons in this layer express γ-aminobutyric acid (Cuenod and Streit., *The Neurosciences: Fourth Study Program*. 989,1974). However, transmitter survey of the ION reveals that although we have not identified a neurotransmitter expressed by ION neurons, the neuropil contains not only large quantities of glutamic acid decarboxylase terminals but also moderate amounts of serotonin and tyrosine hydroxylase immunoreactivity. In addition, a survey of peptides indicates ION cells to be negative for all neuropeptides thus far tested, though the neuropil contains occasional processes immunoreactive for substance P, enkephalin, oxytocin, neuropeptide Y, and cholecystokinin octapeptide.

Injections of Phaseolus Vulgaris Leucoagglutinin (PHA-L) into the ION and/or surrounding tegmentum resulted in numerous terminals within the contralateral and ipsilateral ION. Also, following injections into either the raphe nucleus or hyperstriatum accessorium, fibers and terminal endings could be observed within the ION.

These results indicate that the centrifugal system upon the retina is not only modulated by the optic tectum but also by afferents from diverse areas in the central nervous system. (Supported by the Ford Foundation and NEI Grant EY06076-02).

183.9

ION-TYPE RETINOPETAL SYSTEM IN TELEOSTS AND BIRDS. H. Uchiyama and R.B. Barlow, Jr., Institute for Sensory Ressearch, Syracuse University., Syracuse, NY 13244

Centrifugal (efferent) pathways to the retina have been found in most vertebrates. Their morphological diversity (location of somata of retinopetal neurons in the brain, fiber connections, manner of intraretinal termination, etc.) indicates functional variety. However, some retinopetal systems share common features, such as a tectal input. A good example is the isthmo-optic nucleus (ION) which has been extensively investigated in birds. Therefore, we term these systems "ION-type" retinopetal systems. In addition to birds, these systems have been found in the cyclostomes, advanced teleosts and reptiles.

Here we present a study of the properties of the ION-type retinopetal systems of teleosts and birds, with particular emphasis on their central connections. In advanced teleosts (Acanthopterygians), retinopetal neurons are found in the diencephalon, while in birds retinopetal neurons are in the caudal-most mesencephalon (isthmic region). In both systems the retinopetal neurons receive a major input from the optic tectum. In a teleost (filefish) and a bird (Japanese quail), tectal neurons projecting to the retinopetal nucleus were labeled by HRP injections to the nuclei. Their dendritic patterns suggest that the tectal neurons integrate retinal and non-retinal inputs. Thus, the ION-type retinopetal system could be regarded as a tectal output to the retina. The function of the ION-type retinopetal system seems to be closely related to the visuomotor function of the tectum. (Supported by NIH EY-00667 and NSF 8709059)

183.10

BINOCULAR INTERACTIONS IN THE ACCESSORY OPTIC SYSTEM (AOS) OF THE PIGEON. D.R. Wylie and B.J. Frost. Dept. of Psychology, Queen's Univ., Kingston, Ont., Canada, K7L 3N6.

Several studies have demonstrated that the AOS is a self-motion analyser involved in processing visual information for compensatory head and eye movements. The nucleus of the basal optic root (nBOR), a component of the avian AOS, receives direct input from the displaced ganglion cells of the contralateral retina. The nBOR also receives input from the contralateral nBOR, thus providing an indirect route from the ipsilateral retina. In the pigeon, electrophysiological studies have shown that neurons in nBOR respond best to slow-moving wholefield visual stimuli moving in dorsal, ventral or temporal directions in the contralateral visual field. In this study we have demonstrated that some nBOR neurons respond to wholefield stimulation of the ipsilateral eye. In most cases the modulation by wholefield stimulation of the ipsilateral eye is much less than that of the contralateral eye, however, in some cases the response to stimulation of the ipsilateral eye is equal to or greater than that of the contralateral eye. These binocular neurons prefer either approximately the same direction in both eyes, or motion in opposite directions in the two eyes. Thus, it is suggested that some nBOR neurons specify a translation motion while others encode a rotation of the head. This research was supported by MRC grant #MA 7244 to B.J.F.

183.11

VISUAL RESPONESE PROPERTIES OF NUCLEUS ROTUNDUS CELLS IN THE PIGEON. S-Y Jiang*, Y-C Wang* and B.J. Frost. Departments of Psychology and Physiology, Queen's University, Kingston, Ontario, Canada, K7L 3N6.

The avian tectofugal pathway, which is similar to the mammalian colliculo-pulvinar-MT pathway, consists of the optic tectum (OT), nucleus rotundus (RT), and ectostriatum. Anatomical studies have shown that discrete zones within RT receive inputs from different tectal laminae, and in turn project to subregions of ectostriatum. Standard extracellular recordings were made with tungsten microelectrodes from Ketamine/Rompun-anaesthetized pigeons. Computer-generated stimuli were back-projected onto a tangent screen, and visual landmarks and receptive field boundaries were plotted. Based on recordings from 144 single units, several different classes were identified. (1) Luminance units: These units, which comprised 19% of the sample, had large receptive fields (RFs) and either systematically increased (11%), or decreased (8%) their firing to increases in luminance of the whole screen. (2) Looming units: These units (16%) also had large RFs, and responded to moving objects, but gave their largest response to expanding light or dark disks. They exhibited no X-Y directional preference and gave no "ON" or "OFF" responses. (3) Directional cells: These units gave standard directionally specific responses to Kinematograms. Some of these cells responded specifically to leading edge occlusion (Frost et al., 1989) with either excitation or inhibition. (4) Movement cells: These cells were similar to class (3) but exhibited no direction preference. Supported by NSERC of Canada.

183.12

VISUAL DEPRIVATION CHANGES DIRECTIONAL PREFERENCE OF ACCESSORY OPTIC SYSTEM (AOS) NEURONS IN CHICKENS. C.L. Natal*, J.C. Letelier*, X. Rojas* and J. Wallman. Biology Dept., City College, CUNY, New York, NY 10031.

The AOS appears to be a major input for non-horizontal optokinetic nystagmus (OKN). In month-old chickens, there is a strict division of the principal AOS nucleus into regions with upward and downward sensitvity. This segregation has been confirmed by 2-deoxyglucose autoradiography. Previous work found this anatomical parcellation much less evident in newly hatched birds, and that visual deprivation had effects on OKN and the pattern of 2-DG labelling, suggesting that the directional specificity of nBOR neurons is shaped by visual experience. To test this hypothesis, single unit recordings were made in normal and visually deprived chickens.

In normal chickens, we have recorded to date 21 "up" units and no units with nasalward sensitivity. In visually deprived chickens, only 7 units responded best to upward motion, but 23 were excited by nasalward motion. Even after 3 weeks of subsequent visual experience, fewer "up" units were found and the nasalward population was still conspicuous. These results argue that visual experience during a critical period either causes a shift of the directional sensitivity of AOS neurons in the upward direction, or that it prevents the shift from upward to horizontal sensitivity that occurs in the absence of vision. Supported by CNPq and NSF grants.

Retinal application of bicuculline eliminates direction sensitivity in the turtle's basal optic nucleus *in vitro*. A. F. Rosenberg and M. Ariel. Dept. of Behavioral Neuroscience, Univ. of Pittsburgh, Pittsburgh, PA 15260.

Direction sensitive (DS) retinal ganglion cells (RGC's) may converge onto cells in the mesencephalic basal optic nucleus (BON) to encode retinal slip, thereby providing a neural signal to drive optokinetic nystagmus (OKN). Direction sensitivity in the retina is mediated by GABA since it can be blocked by picrotoxin or Cl^- free ringers (Ariel & Adolph, 1985). In addition, GABAergic mechanisms play a role in the retinal processing required for OKN. Intravitreal injection of GABA antagonists have been reported to elicit a spontaneous nystagmus (Ariel et al., 1988). Therefore, DS-RGC's may be the primary input to the BON which in turn is involved in OKN.

We use a pharmacological approach to elucidate the connections occurring between the retina and the BON. The visual response properties of BON cells were characterized in an *in vitro* whole-brain, eyes-attached, telencephalon-removed preparation. All cells recorded were DS over a broad velocity range, had large receptive fields and responded best to moving large, textured visual stimuli presented to the contralateral eye. In general, these cells had little if any spontaneous activity and exhibited a poor response to light onset or offset. Application of 25-100 uM bicuculline, a $GABA_a$ receptor antagonist, via superfusion or bolus injection resulted in the elimination of directional sensitivity in BON cells. The cells became movement sensitive to any direction in addition to becoming much more responsive to onsets and offsets of light.

We conclude, therefore, that the directional information found in the BON is processed at the retina and is GABA mediated. Therefore, antidromic activation from the BON can become a useful marker for identifying DS-RGC's in the eyecup for anatomical or physiological studies.

183.14

A VISUAL LAMINA IN THE MEDULLA OBLONGATA OF THE FROG. M.T.Wallace and E.R.Gruberg. Dept. of Biology, Temple University, Philadelphia, PA. 19122

Using single unit extracellular recording we have discovered a lamina of visually responsive units in the medulla oblongata of the frog, Rana pipiens. The lamina extends the entire rostrocaudal length of the medulla, and is confined to the medial medulla. The lamina is restricted to the neuropil of the rhombencephalic reticular formation. Most units within the lamina can be driven binocularly, and have very large receptive fields (greater than 90°). In addition, units in the rostral medulla tend to be unimodal (solely visual), while units in the caudal medulla are generally bimodal (visual and somatosensory). Unlike the visual centers in the midbrain and thalamus, this region does not appear to be organized along retinotopic lines. Unilateral ablation of the optic tectum and posterior thalamus abolishes visual responses in the medulla elicited by stimulation of the contralateral eye, suggesting that much of the visual activity in the medulla is mediated by the tectum and/or posterior thalamus. To determine the inputs to the visual medulla we have been using HRP histochemistry. The optic tectum, torus semicircularis, mesencephalic tegmentum, and the anterior and posterior thalamic nuclei project to the medulla oblongata.

PREY CATCHING IS SPARED AFTER HEMISECTION OF THE OPTIC CHIASM IN THE FROG. R.F.Waldeck and E.R.Gruberg. Dept. of Biology, Temple University, Philadelphia,PA 19122.

We made hemisections of the optic chiasm and studied subsequent visual behavior and the distribution of retinotectal fibers. After cutting either the posterior or the anterior half of the optic chiasm frogs still respond to prey in the entire ground level visual field. However, they are unresponsive to visually presented threat stimuli in the entire visual field. The distribution of optic fibers in the tectum was determined using ^{3}H-proline autoradiography and horseradish peroxidase histochemistry. Animals with the posterior half of the chiasm severed have the dorsomedial and ventrolateral tectum labeled, while animals with the anterior half of the chiasm severed have complementary labelling. Although HRP labelling in posterior chiasm lesions is limited to the dorsomedial and ventrolateral area visually driven units can still be recorded throughout the contralateral tectum.

It was earlier shown that removal of the optic tectum leads to the loss of visually guided prey catching behavior in the contralateral monocular field. In our current work, it appears animals can respond to prey without direct retinal input to the optic tectum. Another retinorecipient area, such as the posterior thalamus, may play a mediating role in frog prey catching.

THE NATURE OF ELECTRICAL TRANSIENTS RECORDED IN FROG TECTAL NEUROPIL. A.C. Grant* and J.Y. Lettvin* (SPON: L.S. Frishkopf). Research Laboratory of Electronics, MIT, Cambridge, MA 02139.

In this study we have reexamined the properties of those transients evoked in the tectal neuropil of the frog, Rana pipiens, by excitation of RGC types 1 and 2. Both visual stimulation and electrical stimulation in the optic nerve and n. isthmi were used to generate responses in the tectum. First, unlike single unit RFs which are circular, tectal multiunit receptive fields (MURFs) are distinctly oval. The MURFs are oriented in space so as to define a visual "pole" which lies at or near the optic axis. Second, in addition to the common triphasic units, diphasic (first phase positive) and negative monophasic units are also present in the neuropil. Within a MURF the RFs of each unit type are distinct and always lie in the same order with respect to the visual "pole". Third, there is often a coincident firing of adjacent elements in the neuropil resulting in spikes with more than three phases. Fourth, excitation of two different tectal afferent fibers can produce the same transient. It is concluded that single units in the dorsal neuropil are not, as is generally assumed, generated presynaptically by an afferent axon's terminal arbors. Instead, they are generated by electrically active dendritic structures which have a marked anatomical anisotropy. Rapid-Golgi impregnations support this conclusion.

183.17

ANTEROGRADE AND RETROGRADE LABELING IN THE VISUAL SYSTEM WITH HERPES SIMPLEX VIRUS (HSV): VARIABLES INFLUENCING TRANSPORT. R. B. Norgren, H. C. Bubel*, A. Wander* and M. N. Lehman. Depts. Anat. & Cell Biol., Microbiol. and Ophthal., Univ. Cincinnati Med. Coll., Cincinnati, OH 456267

HSV has great potential in elucidating the structure and function of the visual system due to its transneuronal transport and complete filling of neurons with immunoreaction product. Factors influencing the transport of HSV in both the anterograde and retrograde direction were examined in the current study. Three strains of purified HSV were used: McIntyre and Shealey (type 1) and strain G (type 2). HSV was injected either into the vitreous body or into the superior colliculus (SC) of golden hamsters. Tissue was processed as previously reported (Norgren & Lehman, Brain Res. 479:374, 1989). After intraocular injection of the three strains HSV we found significant differences in the amount of labeling. Labeling in retinorecipient nuclei was most prominent with strain G, followed by the Shealey strain; the least amount was observed with McIntyre strain. No labeling of neurons was observed after intraocular injection of UV irradiated virus confirming that immunolabeling was detecting active replication of virus within retinorecipient neurons. After injection of McIntyre strain into the superior colliculus, labeled neurons afferent to the SC in brain and the retina were observed. In contrast, we were rarely able to demonstrate labeled neurons in either the brain or the retina of animals that received injections of Shealey strain into the SC. [Supported by NIH grant NS 24292 (MNL)]

183.18

PRIOR UNILATERAL OPTIC NERVE TRANSECTION ABOLISHES CAPSAICIN-INDUCED DEGENERATION IN DIENCEPHALIC AND PRETECTAL VISUAL STRUCTURES. S. Ritter and T. Dinh*. Department of VCAPP, Washington State University, Pullman, WA 99164-6520

Capsaicin is a neurotoxin capable of causing degeneration in discrete areas throughout the neuroaxis (Ritter and Dinh, JCN 271: 79). After neonatal capsaicin treatment, affected sites include the suprachiasmatic nucleus (SCh), the ventrolateral geniculate nucleus (VLG) and the medial and olivary pretectal nuclei (MPT and OPT). In adults, capsaicin-sensitivity is greatly attenuated or absent in the OPT and VLG, although still present in the SCh and MPT. In this experiment, we tested the hypothesis that capsaicin-induced terminal degeneration in the SCh, VLG, MPT and OPT results from destruction of retinal ganglion cell projections to these sites. The optic tract was transected unilaterally in anesthetized 15-16 day old Sprague-Dawley rat pups. At 20 days, 30 days, 3 or 6 mo of age, lesioned rats and controls were anesthetized and injected systemically with capsaicin or the vehicle solution. They were sacrificed 6 or 18 hr later and tissues processed using a cupric-silver stain for labelling degenerating neurons. In rats injected with capsaicin at 20 and 30 days of age, prior unilateral optic nerve transection eliminated capsaicin-induced degeneration in all four nuclei on the contralateral (denervated) side, but not on the ipsilateral side. Likewise, in lesioned adults, capsaicin-induced degeneration was present only in the ipsilateral SCh and MPT. These results suggest that capsaicin causes degeneration in the SCh, VLG, MPT and OPT by selective destruction of ganglion cell projections to these sites.

IMMUNOHISTOCHEMICAL STUDY OF ASTROGLIAL REACTION TO DEAFFERENTATION IN VISUAL NUCLEI OF RAT. R.Schmidt-Kastner*, K.Wietasch*, D.Meller*, U.Eysel (SPON: European Neuroscience Association). Dept. of Neurophysiology, Ruhr-Universität Bochum, D-4630 Bochum, F.R.Germany.

Astrocytes play an important role in deafferentation and plasticity (Gage et al., Exp.Neurol.102:2-12,1988). This study focusses upon astrocytic reaction to deafferentation in subcortical visual nuclei of rat where side comparisons are possible due to the almost complete crossing of retinal fibers. Deafferentation was produced in pentobarbital-anesthetized rats by unilateral optic nerve section (n=30) or by unilateral ischemic destruction of the retina using photochemically-induced vascular thrombosis (n=16). Brains from controls (n=20) and experimental animals surviving 1,2,4,6,7 or 21 days were studied with immunohistochemistry using antibodies against glial fibrillary acidic protein (GFAP) and vimentin (VIM). Antibodies against neurofilament peptides served to study damage of retinal axons and the Fink-Heimer technique to reveal terminal degeneration. In normal brains GFAP-staining in astrocytes was dense in the pretectal olivary nucleus, moderate in the dorsal lateral geniculate nucleus (dLGN) and low in the superior colliculus (SC). Degenerative changes of neurofilament staining and positive Fink-Heimer reaction first occurred at day 2. A subtle increase in GFAP-staining began to manifest in contralateral SC already 1 day after lesion. From day 2 on glial reactions were also seen in dLGN and pretectal area contralateral to lesion which persisted up to day 21. VIM-staining occurred in the affected optic tract and in glial processes of the deafferentated SC and dLGN. In conclusion, astrocytes in the subcortical visual system of rat react rapidly and with high spatial precision to deafferentation.

DISTRIBUTION OF GABA-A RECEPTORS IN SUBCORTICAL VISUAL NUCLEI OF MAMMALS. K. K. Glendenning, B. N. Baker*, S. L. Cochran* and R. B. Masterton. Dept. Psychology, Florida State Univ., Tallahassee, FL 32306.

Previously we have shown a systematic increase in the density of GABA-A receptors both in DGL and in LP through early mammals to prosimian primates. To explore the possibility this increase might be accompanied by related changes in other visual structures as well, we extended the study to include the major subdivisions of the superior colliculus, pretectum, VGL, DGL, and LP in 6 species.

The results suggest that the muscimol labeling totaled over the 4 major terminal nuclei of the optic nerve is more closely related with an animal's diurnal cycle than with any other behavioral, visual, structural, or other biochemical adaptation, while the heavy labeling in the superficial layer of superior colliculus alone is most closely related to the proportion of retinal cones.

The close relationship (r=.937, p<.006) between the density of GABA-A receptors in the dorsal lateral geniculate and in the lateral posterior nucleus is not reliably related to either behavioral or structural variation nor, among mammals alone, to phyletic grade. Therefore, it is possible that their parallel in GABA-receptor density may be due instead to their unique interdependence on cortex and a commonality of demands placed on thalamocortical input.

CIRCADIAN RHYTHM IN THE PERIOD PROTEIN OF DROSOPHILA. K.K. Siwicki*, D.M. Zerr* and J.C. Hall, Biology Department, Brandeis University, Waltham, MA 02254

The protein encoded by the period (per) locus of Drosophila, which influences the fly's behavioral circadian rhythms, is itself subject to daily oscillations in immunoreactive staining. Neurons, photoreceptors, and glial cells in the fly's head are strongly labelled by our anti-per antibody at "lights on", but are not detectably stained at "lights off" (in a 12 hour light: 12 hour dark cycle). The daily rhythm in the staining of the per protein continues in constant darkness for at least four days, with a period of about 24 hours in wild-type flies, and about 19 hours in mutant per-short flies. These results indicate that the period of the free-running circadian rhythm in the per protein is influenced by the per mutations.

The per protein is not detectable at any time of day in flies exposed to constant light, a treatment that renders flies arrhythmic in behavioral assays. In various light: dark regimes, we found a good correlation between per protein staining and behavioral circadian rhythms. Nonetheless, the distribution and daily cycling of the per protein appeared to be normal in several visual system mutants (norpA-P24, ninaE-oll7, and disco). Thus, the effects of light on the staining of the per protein may be mediated by extra-retinal photoreceptors.

DROSOPHILA DUSKY (DY) MUTATIONS ALTER CIRCADIAN RHYTHMS. F. R. Jackson, L.M. Newby, and S.M. DiBartolomeis. Neurobiology Division, Worcester Fndn. Exptl. Biol., Shrewsbury, MA 01545.

The *Drosophila andante* (*and*) mutation lengthens freerunning periods for circadian and ultradian (courtship song) rhythms (Smith, R.J., Ph.D. Thesis, Cal. Tech., 1982; Kyriacou, C.P., pers. comm.). It maps to region 10E2-3 of the X chromosome, an interval that includes the *miniature-dusky* (*m-dy*) locus. Because the *and* allele is associated with a dusky-like phenotype (small and dark wings), we have examined the relationship between the two types of mutations.

Four new γ ray-induced *dusky* mutations (dy^{n1}, dy^{n2}, dy^{n3}, dy^{n4}) were isolated on the basis of wing size. Each of the four mutations fails to complement an existing *dy* mutation; i.e., they are alleles of the *dy* locus. Importantly, three of the new *dy* mutations affect circadian rhythms of eclosion and locomotor activity. Like *and* mutants, dy^{n1}, dy^{n3}, and dy^{n4} flies exhibit abnormally long circadian periods (eg., for locomotor activity, dy^{n1} = 25.7 ± 0.3 h, dy^{n3} = 25.2 ± 0.3 h, and dy^{n4} = 25.2 ± 0.1 h, whereas *and* = 25.4 ± 0.1 h and the wild type = 24.0 ± 0.2 h). The morphological and behavioral phenotypes associated with *andante* and *dy* mutations suggest they are alleles of a single locus.

To initiate molecular studies of these mutants, we have cloned approximately 100 kb of DNA encompassing the *m-dy* locus. Existing chromosomal rearrangements and RNA transcripts are currently being mapped within the cloned interval to delineate the physical limits of the locus.

ROLES FOR cAMP AND INTRACELLULAR CALCIUM IN THE GENERATION OF CIRCADIAN RHYTHMS IN BULLA. M.R. Ralph, S.B.S.Khalsa and G.D.Block. Dept. of Biology, University of Virginia, Charlottesville, VA 22901.

Cyclic nucleotides and calcium are thought to be components of biochemical pathways that mediate phase shifts of circadian rhythms in Aplysia (Eskin et al., 1982,1984) and Bulla (Khalsa & Block, 1988). We have investigated the involvement of these cellular components in the generation of rhythms in Bulla gouldiana. We have found that the cAMP analog, 8-Br-cAMP (2mM) produces phase shifts of the freerunning rhythm of compound action potential (CAP) frequency. Acute effects of the agent on CAP frequency and the phase response curve (PRC) are similar to hyperpolarization. Phase shifts induced by forskolin were similar in magnitude and direction.

However, the phase response curve for the phosphodiesterase inhibitor, caffeine, was different from cAMP in that large advances (+2 hr) were induced immediately prior to subj. dawn and large delays (-3 hr) directly following dawn. This feature of the caffeine PRC was closely mimicked by Thapsigargin, an agent that is reported to cause the release of Ca^{2+} from IP_3-sensitive stores. Since caffeine may also cause Ca^{2+} release from stores, these results suggest that two mechanisms may underlie the phase shifting effects of caffeine. One may be a cAMP-dependent process that may result in hyperpolarization of pacemaker cells. A second mechanism may involve the release and subsequent re-uptake of intracellular Ca^{2+}. The abrupt change from phase advances to delays at subjective dawn suggests that a spontaneous release of intracellular Ca^{2+} at dawn may be a normal component of the rhythm generation mechanism.

CHLORIDE CONTRIBUTES TO PERIOD REGULATION IN THE BULLA OCULAR CIRCADIAN PACEMAKER. S.B.S.Khalsa, M.R.Ralph & G.D.Block. Biology Dept., University of Virginia, Charlottesville, VA 22901.

The eye of the mollusc Bulla contains a circadian pacemaker whose cells express a rhythm in membrane potential and in compound action potential frequency. In examining the contributing ionic conductances we have found that inhibiting chloride flux significantly shortens the period of the rhythm.

Replacement of extracellular Cl^- with sulfate, in a solution osmotically balanced with sucrose, shortens period in a Cl^- concentration dependent manner. Complete Cl^- replacement (100%) shortens period relative to control eyes by 2.6 hr. per cycle ($\Delta\tau$=-2.6, N=5); at 90% $\Delta\tau$=-1.5 hr. (N=3), at 80% $\Delta\tau$=-0.8 hr. (N=2), and at 75% no period shortening is apparent. This effect is not dependent upon the divalent sulfate ion, since similar period shortening was observed in solutions with the Cl^- replacing monovalent anions isethionate ($\Delta\tau$=-1.1 hr., N=4) and glutamate ($\Delta\tau$=-1.2 hr., N=4).

The Cl^- channel blocker 9-Anthracene Carboxylic Acid also shortened period in a concentration dependent manner; at 1 mM $\Delta\tau$=-1.8 hr. (N=3), at 500 μM $\Delta\tau$=-1.0 hr. (N=3) and at 100 μM $\Delta\tau$=-0.2 hr. (N=2). The Cl^- transport inhibitors Furosemide (500 μM, $\Delta\tau$=-0.5 hr., N=4) and Piretanide (100 μM, $\Delta\tau$=-0.3 hr., N=2) also shortened period. However, the more specific Cl^- channel blocker Diphenylamine Carboxylic Acid was ineffective.

Since the Cl^- transport inhibitors are known to affect Cl^- channels as well, it is not possible to discern the relative contribution of Cl^- conductance and Cl^- transport with our preliminary data, although a conductance mechanism seems most likely. However, a constant Cl^- conductance, and therefore a constant depolarization in its absence, is inconsistent with the previously observed period lengthening with depolarizing high K^+; Cl^- conductance may therefore be regulated in a circadian cycle.

TEMPORALLY VARYING ANTIGENS IN THE EYE OF BULLA GOULDIANA. M.H. Roberts, Y. Chen*, and V. Bedian, Dept. of Biology, Clarkson University, Potsdam, NY 13676.

The eye of the marine snail Bulla gouldiana expresses a circadian rhythm generated by the rhythmic depolarizations of a population of electrically coupled neurons located at the retinal base, the basal retinal neurons (BRNs). BRN axons project down the optic nerve to the central ganglia where they modulate locomotor activity.

In order to identify: 1) components of the eye responsible for generating the rhythm, and 2) markers for the BRN axons within the brain, we raised monoclonal antibodies (MAbs) to the eye of Bulla. Following immunohistochemical screening, we performed immunoblot analysis of separated eye homogenates, in order to determine the molecular weights of the antigens recognized by our MAbs.

We have identified antigens specific to regions of the eye. Several antibodies recognize antigens specific to groups of neurons in the brain. Of particular interest is the antigen recognized by MAb B4D3.E3. This antibody, which stains the basal retinal region of the eye, as well as fibers along the periphery of the retina, displays a day/night variation in staining. The staining in eyes is high just after dusk and is low at dawn. This variation is also seen following "Western" transfer as a sharp band at approximately 10kD. We are currently investigating if the variation continues in constant conditions.

A SECOND CIRCADIAN RHYTHM IN THE BULLA EYE. Michael Geusz* and Terry Page, Dept. of Biol., Vanderbilt University, Nashville, TN, 37235.

The eye of the mollusk Bulla gouldiana is a useful preparation for the study of the cellular basis of circadian rhythms. One group of cells in the eye, the basal retinal neurons, generates a circadian rhythm in compound action potentials (CAPs) in the optic nerve (Block et al., 1984, J. Comp. Physiol. A 155: 365-378). Recently, we discovered a circadian rhythm in small (10-40 uvolt) impulses in the optic nerve from a second population of cells in isolated eyes maintained in artificial seawater and darkness at 15°C. The frequency of these units, continuously recorded for 5-7 days, varied with a circadian rhythm that was approximately 12 hours out-of-phase with the rhythm in CAPs and damped out after 3-5 cycles. The activity reached a peak during the subjective night, when CAPs are absent, declined prior to the onset of CAP activity, and typically fell to a minimum within an hour of the peak CAP frequency. The phase of the rhythm was dependent on the prior light cycle. The amplitude of the rhythm was less stable and damped more rapidly than the CAP rhythm. Other results suggest that the small-impulses may be inhibited by light.

AN APLYSIA EYE PROTEIN ASSOCIATED WITH CIRCADIAN PACEMAKER NEURONS AND RELATED TO THE PERIOD-PROTEIN OF DROSOPHILA. **S. Strack* and J.W. Jacklet, Neurobiology Research Center and Dept. of Biology, SUNY Albany, Albany, NY 12222**

We have reported staining of gastropod circadian pacemaker neurons with an antibody against the period (per) protein, which is known to control rhythms in Drosophila (Soc.Neurosc.Abst.1988,190.10). The putative per-like antigens were characterized by immunoblot analysis using the same antibody that was used for immunocytochemistry. We found a strongly immunoreactive 48 kD protein exclusively localized to Aplysia eyes, where immunocytochemistry shows specific staining in pacemaker cell bodies and their processes. Preliminary protein-fractionation experiments show this 48 kD protein is associated with membranes. The level of the per protein in Drosophila varies with the circadian rhythm (Siwicki et al., in preparation). By quantifying immunoblot-staining of the 48 kD Aplysia eye antigen from animals dissected at different times during the light-dark cycle, levels of the putative per-homolog were found to oscillate with the same phase as Drosophila per. Levels were minimal prior to lights-off (CT 11) and reached a three-fold higher peak before lights-on (CT 23). When Aplysia were kept in constant darkness, oscillations in protein amount continued for one to two cycles before plateauing at the peak level. These results suggest the per-like protein may function in the light entrainment pathway. The localization of the 48 kD per-related antigen to Aplysia pacemaker neurons and oscillations in abundance that mirror cycling of Drosophila per suggests to us that the clocks of these species share fundamental protein components. CIRCADIAN RHYTHM PHASE SHIFTED BY REVERSIBLE TRANSCRIPTION INHIBITOR. S. Ramasubban* and A. Eskin. Dept. of Biochem. and Biophys. Sci., Univ. of Houston, TX 77204.

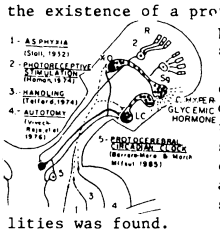
The role of protein synthesis in circadian mechanisms has been studied extensively using translation inhibitors, which phase shift and change the period of circadian rhythms. Transcription inhibitors, Actinomycin D and Aflatoxin B, have been shown to abolish rhythms (Karakashian and Hastings, 1962; Rothman and Strumwasser, 1977), but the interpretation of their effects is difficult due to the irreversible nature of these transcription inhibitors. We have begun an investigation of the role of transcription in the circadian rhythm of the isolated eye of Aplysia using a reversible transcription inhibitor, 5,6- dichloro-1-ß-d-ribobenzimidazole (DRB). DRB inhibits the synthesis of heterogenous nuclear RNA at the level of initiation (Tamm & Sehgal, 1978).



^{3}H-uridine incorporation into TCA precipitable material of the isolated Aplysia eye was inhibited about 85% by 0.1 mM DRB. Recovery after 3 h DRB treatments appeared complete following a 20 min wash; ^{3}H-uridine incorporation was measured for the 3 h following the wash. DRB appeared to have no effect on translation as measured by ^{3}H-leucine incorporation during a 2 h DRB treatment. DRB (2 h, 0.1mM) produced large phase shifts in the circadian rhythm at some phases (3.7 h delay, CT 6-8 , N=3) and no phase shifts at some other phases. Preliminarily, the DRB sensitive phases of the rhythm appear to be from CT 01 to CT 12. DRB had variable effects on the frequency of nerve impulses, producing at times a small inhibition. However, the effect of DRB on spiking did not correlate the effect of DRB on the rhythm.

Our results indicate that transcription is an important process in the circadian system and, moreover, that DRB will be a valuable tool for exploring the specific role of transcription in the circadian oscillator.

STRESSING AND CIRCADIAN GLYCEMIC RESPONSE IN CRAYFISH. B. Barrera-Mera and S. March Mifsut*. Depto. de Fisiología, Facultad de Medicina, U.N.A.M. Apdo. Postal No. 70-250, 04510 México, D.F. México.

The effect of autotomy, CO_2, and asphyxia used as hyperglycemic stimuli were tested in intact crayfish and in crayfish with damaged central nervous systems, in which the existence of a protocerebral control by a circadian pacemaker for visual activity and sugar regulation was also tested.

In contrast with the potent control of light-adapting response of retinal shielding pigments, in those preparations in which the surgical isolation of the protocerebrum was performed, a clear absense of hyperglycemic response to severe stimulation of sensory modalities was found.

As judged by the amplitude of the hyperglycemic response, these findings suggest that the amount of hyperglycemic hormone released from crayfish sinus gland would directly result from a heavy bombardment of afferent neural signals to the sinus gland coming both from peripheral and visceral sensory receptors, as it is illustrated in Fig. 1 in which exogenous and endogenous glycemic agencies are represented.

184.10

ROLE OF THE SINUS GLAND IN THE SYNCHRONIZATION OF THE ERG CIRCADIAN RHYTHM IN CRAYFISH. B. Fuentes-Pardo, J.A. Prieto-Sagredo*, E. Moreno-Sáenz† and J. Hernández-Falcón*. Depto. Fisiología, Fac. Medicina, UNAM. Apdo. Postal 70250, México, 04510 D.F.

Electroretinogram (ERG) of the crayfish depicts a circadian rhythm susceptible to be synchronized by photoperiods. To get insight on the role of the neuroendocrine system (NS) in this process, we recorded the ERG rhythm from both, intact (In) and to sinus gland-deprived (SGD) crayfish submitted to 12:12 photoperiods. Group 1 animals received the photoperiod in only one eye; group 2 an L:D photoperiod in one eye and D:L in the other. The results were: a) in the In animals, application of one photoperiod on one eye imposes its phase on the rhythm of non-stimulated eye; b) in the SGD animals the stimulated eye follows the imposed photoperiod, the other one shows an unclear circadian rhythm c) in the In animals the simultaneous application of the L:D to one eye and D:L to the other evokes phase shifts in both eyes but showing tendencies to interact; d) in SGD animals the L:D to one eye and D:L to the other causes a 180° phase shift between the activity of the eyes. We concluded that: a) in SGD animals, the overt rhythm is associated to a passive following of the light changes by photoreceptors; b) the phase relation between the ERG rhythms is maintained by the activity of the NS; c) the synchronization of the ERG rhythm by photoperiods reflects maximal phasing of the oscillators underlying the ERG rhythm and requires periodic activity of the sinus gland.

LEARNING AND MEMORY–PHARMACOLOGY NMDA

185.1

LONG-LASTING, APV-SENSITIVE, INCREASE IN FIELD EPSPs BY OXIRACETAM IN RAT HIPPOCAMPAL SLICES. R. Corradetti*, A.M. Pugliese*, L. Ballerini* and G. Pepeu (SPON: M. Raiteri). Dept. Preclin. and Clin. Pharmacol., Univ. Firenze, Italy.

The effect of the nootropic drug oxiracetam (Oxi) on field EPSPs was investigated in the CA1 region of rat hippocampal slices, obtained as previously described (Corradetti et al., J. Neurochem. 41, 1518, 1983), and superfused, in a submerged chamber, with oxygenated aCSF. Stimulation of the stratum radiatum, at 0.1 Hz, evoked field dendritic EPSPs, whose initial slope was measured. Bath applied Oxi (0.1-100 uM) increased the slope of EPSPs. This effect was antagonized by the NMDA antagonist D-(2)-aminophosphonovalerate (APV, 50 uM, n=7). The effect of Oxi on EPSP slope was maximal at 1 uM (+70± 11%, n=12). A 45±12 % increase persisted after 45 min wash, and subsequent high frequency stimulation (100 Hz, 0.4 s, x2) induced a moderate long-term potentiation (LTP). However, the total increase in slope (105%) was as in control LTP (99%), showing lack of additivity to Oxi effect. Consistently, after LTP, 1 uM Oxi slightly, yet reversibly, increased the EPSP. The enduring effect of Oxi, which also mimicked LTP for the need of NMDA-receptor activation, may be relevant for Oxi nootropic action. (Supported by CNR: 87.01425.04).

185.2

NMDA RECEPTORS AND MEMORY: PARALLELS BETWEEN THEIR ROLE IN LEARNING AND SYNAPTIC PLASTICITY. S.P.Butcher*, R.Hendry*, and R.G.M.Morris* (SPON: Brain Research Association) Dept. Pharmacol, Univ.Edinburgh, Edinburgh EH8 9JZ, Scotland.

The selective NMDA antagonist AP5 is known to block the induction of hippocampal LTP but have no effect upon its expression or maintenance. We have therefore studied whether AP5 impairs new spatial learning without affecting the recall of old information.

Rats were first trained in a water-maze to search for a fixed hidden platform (ending with 4 trials at 1 trial per day). They were then implanted with osmotic minipumps for i.c.v. drug administration (aCSF or 30mM D-AP5). For 18 rats, the platform was moved to the opposite location in the pool (eg from NE to SW) while for 12 it remained in the same place. During 8 retraining trials (1 trial/day), rats given D-AP5 were only impaired in the sub-group required to learn a new platform location. Furthermore, all rats were equally biased towards the former training quadrant on the 1st trial of retraining, measured as the distribution of time spent swimming around the pool. Hippocampal tissue levels of AP5 measured using HPLC were 0.23 ± 0.04 nmol/mg wet wt. (range 0.09 - 0.71), similar to values previously shown to cause spatial learning impairments.

These results cannot be explained in terms of a drug induced sensorimotor impairment and support the hypothesis that the underlying mechanisms of LTP have to be activated in spatial learning although not in recall.

185.3

EFFECTS OF PCP AND SIGMA RECEPTOR LIGANDS ON ACQUISITION OF A PASSIVE AVOIDANCE RESPONSE IN RATS. K. W. Jones*, L. M. Bauerle*, and V. J. DeNoble. (SPON: W. K. Schmidt) E. I. DuPont Medical Products Dept., P.O. Box 80400, Wilmington, DE 19880-0400.

Drugs with a strong binding affinity for the PCP receptor, such as PCP and MK-801, are known to disrupt learning and memory whereas the amnestic effects of compounds with a mixed PCP/sigma affinity are not as well delineated. Rats received s.c. doses of MK-801, PCP, ketamine, (+)-SKF 10,047, (+)-pentazocine, (+)-3-PPP, or DTG 30 min before passive avoidance (PA) acquisition training. PA acquisition consisted of placing male CD rats in the illuminated side of a two compartment apparatus. When they went into the dark side, they received two 3-sec 1.0 mA footshocks. Retention testing occured 24 hr later. The rat was placed in the illuminated side and the latency (≤ 300 sec) for entering the dark compartment was recorded. Drugs with a high PCP receptor affinity [MK-801 (0.1-0.3 mg/kg), PCP (0.54-1.7 mg/kg), and ketamine (5.4-17 mg/kg)], produced significant dose-dependent amnesia. The mixed PCP/sigma agonist (+)-SKF 10,047 (5.4-10 mg/kg) also produced amnesia. (+)-Pentazocine interefered with memory, but at a significantly higher dose (54 mg/kg). In contrast, drugs with a high sigma receptor affinity [(+)-3-PPP (1-17 mg/kg) and DTG (0.17-3 mg/kg)] had no effect on PA acqusition. These results suggest that the effects of mixed PCP/sigma agonists on PA acqusition are due to their effects on PCP receptor activity.

185.4

QUISQUALATE RECEPTOR BINDING IN HIPPOCAMPUS FOLLOWING CLASSICAL CONDITIONING OF THE RABBIT NICTITATING MEMBRANE. G. Tocco*, N. Uenishi*, J.K. Thompson*, C. Weiss, M Baudry@, R.F. Thompson (SPON: W. Boyar) USC, Dept. Psych., L.A., CA 90089-1061, @CLNM, UC Irvine,CA 92717.

Hippocampal pyramidal neurons exhibit a rapid within-trial increase in firing frequency during classical conditioning of the rabbit eyelid response. Another model for learning and memory in the hippocampus is Long Term Potentiation (LTP). Different types of glutamate receptors have been shown to be involved hippocampal LTP. While NMDA receptor activation triggers LTP, changes in quisqualate receptors might be responsible for the maintenance of LTP. We have therefore investigated the binding of different glutamate analogs to hippocampi of rabbits that were classically conditioned.

Both quantitative autoradiography in tissue sections and ligand binding to membrane preparations were used to evaluate changes in tritiated AMPA binding to quisqualate receptors following classical conditioning. Both hippocampi of conditioned and unpaired control rabbits were analyzed.

The results indicate that learning of the conditioned response is accompanied by an increase in tritiated AMPA binding in hippocampus suggesting that a modification in properties of quisqualate receptors is involved in the mechanisms of associative learning.

185.5

EFFECTS OF A NOVEL NMDA ANTAGONIST ON LONG-TERM POTENTIATION AND MEMORY. D.L. WALKER* and P.E. GOLD. Neuroscience Program & Department of Psychology, Univ. Virginia, Charlottesville VA 22903.

N-methyl-D-aspartate (NMDA) receptor activation may be important for the establishment of long-term potentiation (LTP) and for learning and memory. A recently developed drug, NPC 12626, is a competitive NMDA receptor antagonist which crosses the blood-brain barrier. We examined the effects of this drug on perforant path - dentate gyrus LTP and on inhibitory avoidance and spontaneous alternation tests.

Rats injected with NPC 12626 (100 mg/kg) 150 min prior to high-frequency stimulation showed no signs of LTP for up to 60 min after tetanus whereas the population spike of control animals increased by 150%. In rats treated 90 min beforehand, LTP was blocked during the first 10 min but increased to control levels within 60 min. NPC 12626 did not itself affect the baseline response nor did it affect LTP when injected after tetanization.

Mice injected with NPC 12626 (35 mg/kg) 35 min prior to inhibitory avoidance training had significantly impaired retention performance (median latencies = 23 sec vs 202 sec for controls). Mice treated with NPC 12626 before spontaneous alternation testing exhibited significantly fewer alternations than did control animals (62±2.7% vs 74±3%).

These results support the view that NMDA receptor activation contributes to LTP and to learning and memory. (Supported by MH 31141 and ONR N0001489-J-1216; NPC 12626 was generously provided by NOVA Pharmaceuticals).

185.6

A COMPARISON OF THE MEMORY MODULATING EFFECTS OF MK-801 AND NALOXONE IN A NOVEL TEST OF PAVLOVIAN FEAR-CONDITIONING. G.A. Cicala*, L.B. Estall*, J.L. Azorlosa*, and S.J. Grant, Dept. Psychology and Program in Neuroscience, Univ. Delaware, Newark, DE. 19716

Compounds that act at NMDA and opiate receptors are known to modulate memory consolidation and retention. We have tested the effects of the non-competitive NMDA antagonist MK-801and the prototypical opiate antagonist naloxone on second-order Pavlovian fear conditioning in rats. This paradigm has the advantage of eliminating possible confounds of drug-induced pain enhancement and state-dependency since nociceptive stimuli are not present when the drug is administered during the second order conditioning session. This permits direct assessment of drug effects on associative processes.

Naloxone (1-4 mg/kg) produced significantly enhanced second-order conditiong. This was probably due to antagonism of endogenous opiates. MK-801 (0.25 mg/kg) blocked the second-order associations, but the endogenous pathways involved in this action are unknown. Test on the interaction between MK-801 and naloxone are in progress.

185.7

METHYLENEDIOXYAMPHETAMINE (MDA): EFFECTS ON CLASSICAL CONDITIONING. N.M. Bormann*, A.G. Romano & J.A. Harvey (SPON:V. Aloyo). Med. Coll. of PA/EPPI, Phil. PA 19129.

Acquisition and extinction of the rabbit's nictitating membrane response was used to examine the effects of MDA on learning. Doses of 1, 3 and 10 umol/kg were injected, s.c., 30 min before each of 4 training sessions consisting of 60 pairings of a tone CS and corneal air puff US. MDA produced a dose-dependent enhancement in acquisition which was significant at the lowest dose tested (1 umol/kg or 0.179 mg/kg). Four days later, subjects were tested for retention of CRs during 4 daily extinction sessions but no drug was injected. There were no differences between subjects previously given MDA or vehicle in the retention or subsequent extinction of CRs, suggesting the absence of state dependent learning under MDA. As a control for any nonassociative effects of MDA, separate groups were given vehicle or MDA (10 umol/kg), 30 min prior to each of 4 daily sessions consisting of unpaired presentations of CS and US. MDA had no effect on baseline responding, responding to the tone CS or on the amplitude of the UR elicited by the US. In previously trained animals, there was also no effect of MDA (10 umol/kg) on tone intensity thresholds for elicitation of CRs. In summary, MDA appears to have enhanced CR acquisition through an effect on associative learning without producing any detectable changes in the response evoking properties of the CS or US. Supported by NIDA Grant DA04944.

INTRAVENTRICULAR ADMINISTRATION OF THE NMDA ANTAGONIST APV DISRUPTS LEARNING OF AN ODOR AVERSION THAT IS POTENTIATED BY TASTE. G.B. Crooks, Jr., G.S. Robinson, Jr.*, T.J. Hatfield*, P. W. Graham* and M. Gallagher. Department of Psychology, University of North Carolina, Chapel Hill, NC 27599.

Previous research has shown that systemic administration of the non-competitive NMDA antagonist MK-801 impairs taste potentiated learning of an odor aversion (TPOA) at a dose that does not alter learning when either a taste or odor alone is paired with an effective unconditioned stimulus. In this study intraventricular administration of APV (2.5 µg. bilateral) was given prior to training under one of three conditions; during a 5 min drinking session rats were exposed to either a taste alone (0.1% saccharin), an odor alone (30 µl almond extract) or the compound taste/odor. Thirty min after the session malaise was induced (0.3M LiCl 190 mg/kg, i.g.). Aversions to the odor and taste were then tested separately. Administration of d-APV selectively impaired TPOA. Identical doses of l-APV were ineffective. Drug treated animals, however, acquired robust taste aversions. In a subsequent experiment NMDA-induced lesions of the amygdala basolateral nucleus (ABL) were likewise found to selectively impair TPOA. Further studies will examine whether intact NMDA function in the ABL is necessary for TPOA. Because ABL receives multimodal sensory inputs and exhibits LTP (Chapman, P.F., & Brown, T.H., Soc. Neurosci. Abstr., 14, 566, 1988), a NMDA mechanism at this site may be used to store information in this task. Supported by a NSF Predoctoral Fellowship to GC, a NIMH Research Scientist Award to MG (KO2-MH00406), and NIMH grant MH35554.

185.9

NMDA ANTAGONIST MK801 IMPAIRS ACQUISITION BUT NOT PERFORMANCE OF SPATIAL WORKING AND REFERENCE MEMORY. M.L. Shapiro and Z. Caramanos*. Department of Psychology, McGill University, Montreal, Quebec H3A 1B1.

NMDA receptor activation is necessary for inducing, but not for maintaining or expressing glutamate-dependent LTP in hippocampus. MK801 blocks NMDA receptors and LTP induction. If the same mechanisms enable both spatial memory and LTP, then blocking NMDA receptors with MK801 should impair the acquisition, but not the performance of memory tasks. To assess the effects of MK801 on memory, 2 groups of 8 SD rats were compared. An MK group was injected i.p. with .06 mg/kg MK801, and a SAL group with normal saline, 30 min. before behavior testing. Spatial working (WM) and reference (RM) memory were tested on an 8 arm radial maze. For each rat the same 4 arms of the maze were baited once per trial, while the other 4 arms were never baited. Re-entering baited arms during one trial defined WM errors, whereas entering unbaited arms defined RM errors.

After 45 days of testing, the SAL group performed near perfectly, while the MK group was severely impaired on both RM and WM tasks. Giving the well-trained, SAL group MK801 (.025, .06, .075, .10 mg/kg) affected neither WM nor RM. Higher doses (.12 & .15 mg/kg) produced slight ataxia and both WM and RM deficits. Thus, functioning NMDA receptors are necessary for acquiring both spatial WM and RM, but not for performing either WM or RM after training. The results suggest that spatial memory acquisition and LTP induction may share some common mechanisms.

185.10

EFFECTS OF NMDA ANTAGONISTS ON IMPAIRMENT OF THE PASSIVE AVOIDANCE RESPONSE IN MICE. M.J.Benvenga, A.V.Wing*, and R.A.DelVecchio.* Anaquest/BOC Health Care, Murray Hill, New Jersey, 07974.

Memory impairment is a phenomenon that has been linked to the density of N-methyl-D-aspartate (NMDA) binding sites in the hippocampus and other brain regions (Geddes, et.al., Brain Res, 1986). Consistent with this, 2-amino-5-phosphonovalerate (APV), a competetive NMDA antagonist, has recently been shown to impair memory retention in rats (Danysz, et.al., Neuropharm, 1988). The present study investigated the effects of 3(2-carboxypiperazin-4-yl)-propyl-1-phosphonic acid (CPP) and CGS 19755, isosteric antagonists of NMDA receptors, and PCP, an allosteric antagonist, on passive avoidance behavior in mice.

Male Swiss-Webster mice (25-30g) were injected either 30 minutes prior to or immediately following one-trial passive avoidance training (N=8/group). Groups were treated with CPP (0 [vehicle = distilled water], 1.0, 3.0, 5.0, 7.0, 10.0, 15.0 or 20.0 mg/kg), CGS 19755 (0, 1.0, 2.0, 4.0, 6.0, 10.0, 15.0 or 20.0 mg/kg) or PCP (0, 0.5, 0.75, 1.0, 2.0 or 5.0 mg/kg). All mice were tested 24 hours after initial exposure to the apparatus and the latency to respond on the second day was recorded. Median group latencies were compared by Mann Whitney U-tests.

The results indicated that both CPP and CGS 19755, competetive NMDA antagonists, produced a memory deficit similar to that produced by PCP, when administered prior to the training trial. Both CPP and CGS 19755 were approximately one-fifth as potent as PCP. When assessing the effect of posttrial administration, compared to PCP, much higher doses of CPP and CGS 19755 were necessary to disrupt the passive avoidance response. This suggests that isosteric antagonists affect memory acquisition differently than memory consolidation.

185.11

THE EFFECTS OF L-GLUTAMIC ACID DIETHYL ESTER ON DISCRIMINATION LEARNING IN RATS. R.Lalonde. Hôtel-Dieu Hospital, Neurology Service, Montreal, Quebec, Canada H2W 1T8.

Cortico-cortical and corticofugal pathways use excitatory amino acids as neurotransmitters. High levels of quisqualate receptors are found in the cortex, the striatum and the limbic system. For these reasons, it may be predicted that quisqualate receptor antagonists cause learning impairments. As a first test of this hypothesis, the effects of L-Glutamic Acid Diethyl Ester (LGDE) on a visuotactile simultaneous discrimination learning task were evaluated.

Male Sprague-Dawley rats (n=7) were injected with LGDE at 0,120,240 or 360 mg/kg while learning a discrimination in a T-maze between an arm covered with aluminum foil and an uncovered arm. It was found that rats at the two highest doses learned the task more slowly and committed more errors than at the two lowest doses.

These results indicate a role for quisqualate receptors in discrimination learning. It may be possible to dissociate between discrimination learning and other processes such as recognition memory (Mishkin, Malamut and Bachevalier, 1984, In:Neurobiology of learning and memory G Lynch et al. eds, pp. 65-77) by comparing LGDE with other antagonists.

185.12

NMDA ANTAGONISTS PRODUCE IMPAIRMENT OF SPONTANEOUS ALTERNATION BEHAVIOUR IN MICE. J. Parada-Turska‡, C. Ikonomidou‡ and W.A. Turski. Department of Pharmacology, Medical School, Jaczewskiego 8, PL-20090 Lublin, Poland.

The role of N-methyl-D-aspartate (NMDA) receptors in memory processes was examined using Y-maze and passive avoidance task. In the Y-maze, the total number of arm entries which represents locomotor activity, and alternation behaviour, thought to reflect working memory, were measured. All drugs were injected i.p. in adult male Swiss S mice 30 min prior to the test. Vehicle-treated animals performed 32.7 arm-entries and 59.4% alternations during an 8 min session. The competitive NMDA antagonist, CGS 19755 (cis-4-phosphonomethyl-2-piperidine-carboxylate), at doses of 1 and 2 mg/kg, influenced neither locomotion nor alternation behaviour. CGS 19755, at the dose of 4 mg/kg, lowered total number of arm-entries and alternations. Similarly, CPP (3-((+)-2-carboxypiperazin-4-yl)-propyl-1-phosphate), another competitive NMDA antagonist, reduced locomotor activity at doses of 2.5 and 5 mg/kg and attenuated alternation ability only at the highest dose of 5 mg/kg. On the contrary, the non-competitive NMDA antagonist MK 801 ((+)-5-methyl-10,11-dihydro-5H-dibenzo(a,d)cycloheptan-5,10-imine maleate), at doses of 0.1 and 0.2 mg/kg, dramatically enhanced total number of arm entries and reduced alternation behaviour. NMDA, at doses of 10, 25 and 50 mg/kg, showed no effect on locomotor activity and alternations in mice. NMDA, at the dose of 50 mg/kg, blocked both CGS-19755 and CPP-induced reduction of locomotor activity and alternation behaviour. NMDA had no effect on MK 801-induced enhancement of locomotor activity and reduction of alternation ability. These results suggest that blockade of excitatory transmission at NMDA receptors with antagonist-doses which do not affect locomotor activity does not impair working memory. In the passive avoidance task, mice were trained to avoid dark compartment entry (2 s, 0.6 mA, unscrambled DC current; 24 h before retention test). CPP, at doses of 1 and 2.5 mg/kg (30 min before training; i.p.), did not affect retention but impaired performance during the retention test at the dose of 5 mg/kg. MK-801, at doses of 0.02 and 0.05 mg/kg (30 min before training; i.p.), had no effect on retention and reduced retention at doses of 0.1 and 0.2 mg/kg. CGS-19755, 1 and 2 mg/kg, did not impair the performance during the retention test and reduced retention at the dose of 4 mg/kg. NMDA, 50 mg/kg, antagonized the effect of CPP, 5 mg/kg, CGS-19755, 4 mg/kg, and MK-801, 0.2 mg/kg. CPP, 5 mg/kg, and MK-801, 0.2 mg/kg, did not affect retention when administered immediately after training or 30 min before the test session. The results suggest that NMDA receptor antagonists decrease acquisition (learning) but do not impair retention (memory). Supported by the Polish Academy of Sciences.

LEARNING AND MEMORY–PHARMACOLOGY: MONOAMINES

186.1

ABILITY OF SEROTONERGIC RECEPTOR AGONISTS AND ANTAGONISTS TO ATTENUATE NBM LESION-INDUCED DEFICITS IN ONE-TRIAL INHIBITORY AVOIDANCE RETENTION. H.J. Altman[1], D.J. Jenden[2] and H.J. Normile[1], [1]Department of Psychiatry, Wayne State University School of Medicine, Detroit, MI 48207; [2]Department of Pharmacology, U.C.L.A. School of Medicine, Los Angeles, CA 90024.

A substantial body of evidence appears to suggest that the cholinergic and serotonergic nervous systems play an important and possibly interactive role in the mediation of the processes underlying learning and memory. The purpose of the present series of experiments was to determine whether the retention deficit normally exhibited by NBM-lesioned rats trained in a one-trial inhibitory avoidance task could be ameliorated by the administration of selective serotonergic receptor agonists and/or antagonists immediately following training. NBM lesions were produced by infusing ibotenic acid (bilaterally) into the NBM two weeks prior to behavioral assessment. Retention testing occurred 24 hours following training under extinction conditions. The results of this series of experiments appear to suggest that the retention deficit normally exhibited by NBM-lesioned rats is significantly attenuated by immediate post-train administration of the 5-HT1 agonist TFMPP, but not by the 5-HT2 antagonist ketanserin, in spite of the observation that both agents appear to significantly facilitate retention in non-lesioned animals. (Supported in part by NIA grant #AG07069 and ADRDA grant #RG87087).

186.2

THE EFFECTS OF SEROTONERGIC INTRAHIPPOCAMPAL NEONATAL GRAFTS ON LEARNING AND MEMORY IN RATS TRAINED IN THE STONE 14-UNIT T-MAZE. T.M. Ramirez[1]*, H.J. Altman[2], H.J. Normile[2], D.M.Kuhn[2], and E.C. Azmitia[1] (SPON: I.N. Montgomery). [1]Department of Biology, New York University, New York, N.Y. 10003, [2]Department of Psychiatry, Wayne State University School of Medicine, Detroit, MI 48207.

An increasing body of evidence appears to suggest that serotonin plays an important role in the mediation of the processes underlying learning and memory. An area of the brain which is known to be a major target area for serotonergic afferents emanating from the midbrain raphe nuclei is the hippocampus - an area of the brain that has long been suspected to be essential to the processing of information by the brain. The purpose of the present study was to determine the effects of intrahippocampal serotonergic neuronal grafts on learning and memory. The behavioral task used was the Stone 14-unit T-maze (a complex, positively-reinforced spatial discrimination task). Consistent with previous reports from a number of other laboratories on the effects of acute stimulation of the serotonergic nervous system on learning and memory, implantation of raphe-derived intrahippocampal neonatal grafts significantly impaired learning in rats trained in the Stone maze. The results of the present study confirm and extend previous reports which appear to suggest that augmentation or stimulation of serotonergic neurotransmission may interfere with new learning.

186.3

EFFECTS OF COMBINED SEROTONIN DEPLETION AND LESIONS OF THE NUCLEUS BASALIS MAGNOCELLULARIS ON ACQUISITION OF A COMPLEX SPATIAL DISCRIMINATION TASK. H.J. Normile[1], D.J. Jenden[2], D.M. Kuhn[1], W.A. Wolf[1]* and H.J. Altman[1]. [1]Department of Psychiatry, Wayne State University Sch. of Med., Detroit MI 48207; [2]Department of Pharmacology, UCLA Sch. of Med., Los Angeles, CA 90024.

Recent data suggest that the cholinergic and serotonergic neurotransmitter systems interact in the mediation of many physiological processes, including learning and memory. The purpose of the present study was to examine the effects of destruction of cholinergic neurons projecting from the nucleus basalis magnocellularis (NBM), alone or in combination with global serotonin (5-HT) depletion, on learning in rats trained in the Stone 14-unit T-maze - a complex, positively-reinforced spatial discrimination task. Destruction of cholinergic neurons within the NBM was accomplished by the infusion (bilateral) of ibotenic acid. Global 5-HT depletion was accomplished by the systemic administration of p-chloroamphetamine (PCA). The results show that PCA-induced 5-HT depletion enhanced acquisition. This effect was completely antagonized by NBM lesions, despite the fact NBM lesions alone did not produce a deficit in this task. The results further support the view that the cholinergic and serotonergic systems interact in learning and memory processes. (Supported by NIA grant #AG07069).

PLASMA GLUCOSE LEVELS PREDICT THE ATTENUATION OF EPINEPHRINE-INDUCED MEMORY ENHANCEMENT BY ADRENERGIC BLOCKADE. J.L. Hall & P.E. Gold. Dept. Psychology, University of Virginia, Charlottesville, VA 22903.

Posttraining epinephrine release or administration enhances memory. The effects of epinephrine on memory are blocked by pretreatment with alpha- or beta-adrenergic antagonists. Recent evidence indicates that epinephrine-induced elevations in blood glucose (BG) levels may contribute to the hormone's effects on memory. The present experiment determined whether adrenergic antagonists alter the BG response to epinephrine, thereby blocking epinephrine effects on memory.

BG levels were assessed in rats before and at several times after injections of phenoxybenzamine (an alpha-adrenergic antagonist; 2 mg/kg) or propranolol (a beta-adrenergic antagonist; 0.5 mg/kg) followed in some animals by epinephrine injections (0.1 mg/kg) 30 min later. At these doses, epinephrine enhances memory and the antagonists block the epinephrine-induced memory enhancement. Epinephrine resulted in maximal BG increases of 30 mg/kg within 30 min of injection. Neither antagonist itself significantly altered BG levels. However, phenoxybenzamine potentiated and propranolol attenuated the hyperglycemia resulting from epinephrine injection.

These findings suggest that aberrations in BG responses to epinephrine injection contribute to the disruption of memory enhancement after adrenergic blockade. Further, the opposite direction of effects of the two classes of antagonists (alpha- and beta-) on epinephrine-induced hyperglycemia suggests that the blockers' effects are mediated by different mechanisms. PD 122655: A NOVEL ALPHA-2 ANTAGONIST WITH COGNITION ACTIVATING PROPERTIES. R.E. Davis, L.L. Coughenour*, W.H. Moos, T.A. Pugsley, R.D. Schwarz, A.J. Thomas. Parke-Davis Pharmaceutical Research, Warner-Lambert Co., Ann Arbor, Mi. 48105.

Alpha-$_2$ antagonists are known to increase central noradrenergic function via presynaptic autoinhibition. Through this action these agents may be therapeutically useful in reversing the noradrenergic and cognitive decline accompanying aging and dementia. This led us to initiate an effort to discover, novel alpha-$_2$ antagonists with cognition activating properties. This effort yielded a series of chemically novel arylaminopyridnes with alpha-$_2$ antagonists properties typified by PD 122655, N-(3-chlorophenyl)-4- pyridinamine. PD 122655 binds with nM affinity at alpha-$_2$ sites and uM affinity at alpha-$_1$ sites with little or no affinity for other receptors (alpha-$_1$/alpha-$_2$ = 56). It possesses alpha-$_2$ antagonist properties in several peripheral systems and dose dependently enhances the synthesis of norepineprhine in discrete brain regions. PD 122655 also improves water-maze acquisition of hippocampally deficient mice, decreases scopolamine-induced and spontaneous swimming activity in rats and reverses clonidine-induced cognitive impairments in aged- rhesus monkeys. Based on this evidence PD 122655 appears to be an orally active alpha-$_2$ antagonist with cognition activating properties.

186.6

NEONATAL DSP4 REDUCES ENVIRONMENTAL INFLUENCES ON BRAIN NEUROCHEMISTRY AND OLFACTORY LEARNING IN DEVELOPING RATS. C.A. Cornwell-Jones, M.W. Decker, T. Gianulli*, E.L. Wright* and J.L. McGaugh. Dept. of Psychology, Syracuse Univ., Syracuse, NY, 13244, Center for the Neurobiology of Learning & Memory, and Dept. of Psychobilogy Univ. of Calif., Irvine, CA 92717.

Neonatal rats were injected with either DSP4 or 6-OHDOPA to determine whether these produce impairment in postweaning olfactory adaptation comparable to that produced by 6-OHDOPA (Cornwell -Jones et al., Behav. Neural Biol., 25:217, 1982). Controls housed in a new odor for 10 days after weaning with either 6-OHDOPA injected rats or other controls showed normal tolerance for the odor. In contrast, the odor was aversive to controls housed in the odor with DSP4-treated siblings. Drug-treated rats showed no effects of either olfactory or social experience. Housing controls with DSP4-treated rats depressed hippocampal NE and serotonin (5-HT) by 57% and 62%, and elevated olfactory cortex NE and 5-hydroxy-indole acetic acid (5-HIAA) by 32% and 174%. Controls' DSP4 treated cagemates showed parallel changes in regional 5-HT and 5-HIAA, but not NE levels. Experience-induced changes in NE may modulate environmental effects on brain and behavior.

186.7

INTERACTION BETWEEN DSP4 AND NALOXONE (NAL) IN AN ACTIVE AVOIDANCE TASK. R. Kunstmann[1], M.C. Bennett[2] and F.J. Hock[1]. (SPON: A. Frostholm) [1]HOECHST AG, P.O.B. 80 03 20, D-6230 Frankfurt/M. 80, FRG; [2]University of Colorado Health Sciences Center Dept. of Pharmacology, Denver, CO 80262

Male NMRI mice were given injections of the noradrenergic neurotoxin, DSP4 (25 mg/kg, iv) or a comparable volume of the vehicle 24-74 hr prior to behavioral testing. Animals were given 2 days of training on an active avoidance task. NAL was given (1, 3, or 10 mg/kg, ip) prior to training on day 1 and day 2, or prior to training on day 1 only. There was a dose-dependent impairment of acquisition by NAL in the vehicle-pretreated groups. NAL also modulated retention (day 2) performance of the active avoidance task. For the vehicle-pretreated groups, 1 mg/kg NAL facilitated and 10 mg/kg NAL impaired performance on day 2. DSP4 alone impaired acquisition but not retention of this task. NAL produced somewhat different effects in the DSP-4-pretreated mice than in the vehicle-pretreated mice. NAL (1 mg/kg) ameliorated the DSP4-induced impairment of acquisition; 10 mg/kg NAL did not significantly alter the acquisition; 10 mg/kg NAL did not significantly alter the acquisition of this group. For the DSP4-pretreated mice that received NAL before training on both days, the dose-response characteristics for retention scores were similar to those of vehicle-pretreated mice. However, for DSP4-pretreated mice that received NAL before training on day 1 only, the effective facilitating dose was shifted to the right.

186.8

DIFFERENTIAL EFFECTS OF PRETRAINING AND POSTTRAINING INTRA-AMYGDALA ADMINISTRATION OF APOMORPHINE ON LEARNING AND MEMORY. K.Vu*, J.B.Introini-Collison and J.L.McGaugh (SPON: B.J.Vasquez).Center for the Neurobiology of Learning and Memory and Department of Psychobiology, University of California, Irvine, CA 92717.

The present experiments examined the effects of intra-amygdally injected apomorphine on learning and memory processes as evaluated in inhibitory avoidance and the Morris water maze tasks. Apomorphine (0.1-3.0 µg) significantly impaired retention of the inhibitory avoidance when given immediately posttraining. Similarly, apomorphine (0.3 µg; 5 min pre-training) significantly impaired retention in the water maze. This latter effect was more manifest on the first trial of each day and was also observed when apomorphine was given immediately posttraining, suggesting a facilitatory effect of apomorphine on acquisition and an impairing effect on retention. This conclusion was corroborated when the most effective dose of apomorphine (0.3 µg) was given in the amygdala 5 minutes prior to training using multitrial training procedures.

These findings indicate that intra-amygdala injections of apomorphine impair retention in water maze as well as in inhibitory avoidance tasks. However, the findings that in both tasks apomorphine enhances acquisition, indicate that apomorphine has differential effects on learning and retention.

186.9

CONDITIONING OF A DOPAMINERGIC DRUG-STATE. E.N Damianopoulos* and R.J. Carey (SPON: M.R. Lynch). Department of Psychiatry, SUNY and VA Medical Center, Syracuse, NY 13210

Two groups of rats received 2.0 mg/kg apomorphine (S.C.) either 10 min prior to placement in a drug conditioning box (paired group) or 30 min. after (unpaired group) in 10 consecutive one trial per day sessions. Two-weeks later, all animals were tested without drug or vehicle injection in the conditioning box. Paired but not unpaired animals exhibited hypermotility and inhibition of dopamine metabolites which characterized the behavioral and biochemical effects of the dopamine agonist apomorphine treatment. Conditioning effects were also observed for animals treated with haloperidol (1 mg/kg I.P.). These findings are consistent with the concept of a conditioned central drug state.

186.10

PAVLOVIAN CONDITIONING OF L-DOPA INDUCED ANTI-PARKINSONIAN MOVEMENTS. R.J. Carey. Department of Psychiatry, SUNY and VA Medical Center, Syracuse, NY 13210

In rats with unilateral 6-hydroxydopamine (6-OHDA) lesions of the substantia nigra, L-DOPA induced antiparkinsonian effects occur as contralateral rotational movements. In this study, drug-naive rats with unilateral 6-OHDA lesions were given 5 L-DOPA-carbidopa treatments (10 or 20 mg/kg L-DOPA with 1 or 2 mg/kg carbidopa). Some of the animals were exposed to a test environment for a 10 min. period during the L-DOPA treatment phase whereas other animals which received the identical L-DOPA treatment were exposed to the same environment but unpaired with the drug treatment. Two weeks after the final L-DOPA treatment, the animals were placed in the same environment without drug or vehicle treatment for a 10 min. test period. Animals which had received the environment-L-DOPA pairings exhibited contralateral rotation identical to that exhibited for L-DOPA whereas animals in the environment-L-DOPA unpaired treatment group exhibited the spontaneously occuring ipsilateral rotation.

186.11

EFFECT OF D-AMPHETAMINE ON SPINAL FIXATION IN RATS. M. J. Bartelt*, A. G. Hutchins*, and M.M. Patterson (SPON: D. Johnson). Dept. of Psychology and College of Osteopathic Medicine, Ohio Univ. Athens Ohio, 45701

It has been demonstrated that lasting hind limb flexion (spinal fixation) may be induced by external stimulation to the upper right hind limb in spinalized rats (Steinmetz 1981). The goal of the present study was to clarify earlier conflicting reports on the effect of d-amphetamine on spinal fixation. Palmer (1969) found d-amphetamine to decrease the time required for spinal fixation while F. Mouravieff-Lesuisse (1970), using the same dose of d-amphetamine (2mg/kg i.p.), reported no decrease in fixation time.

In the present study, 14 rats were anesthetized with Nembutal (50 mg/kg i.p.) and randomly assigned to either the d-amphetamine (2mg/kg i.p.) or saline/control group. The animals were administred the appropriate substance and then spinalized at T7. Immediatly following 20 minutes (normally a time too short to demonstrate reliable fixation) of upper hind limb stimulation (2-4mA, 100-pps, 7msec, repetitive dc pulses), fixation was measured by the amount of weight needed to remove the hind limb asymmetry.

At the 20 minute stimulation time we found a significantly greater amount of fixation in the d-amphetamine (mean wgt=8.4 gms) as compared to the saline/control group (mean wgt=1.9) at p<.01. These results, which support Palmer's (1969) work, suggest that catacholamines may be involved in the fixation of spinal reflexes.

186.12

MEMORY FOR APPETITIVE AND AVERSIVE EVENTS IMPROVED BY POST-TRAINING INJECTION OF DOPAMINE AUTORECEPTOR AGONISTS Mark G. Packard and Norman M. White, Department of Psychology, McGill University, 1205 Dr. Penfield Ave., Montreal, Quebec Canada H3A 1B1

Previous work has shown that post-training injection of the dopamine (DA) D2 receptor agonist, LY171555, improves memory, while a D1 agonist, SKF38393, does not. In the first experiment, a post-training SC injection of 0.06mg/Kg of apomorphine, a mixed DA receptor agonist, improved retention of a conditioned emotional response; lower and higher doses (0.01-1.2mg/Kg) had no effect. The low effective dose suggests that the observed memory improvement may result from activation of a DA autoreceptor. We tested this hypothesis using an appetitive task in a radial maze: a light cue signalled the location of food in 4 different arms on each trial; rats were required to visit each lit arm twice within a trial. All rats were given 1 trial per day for 10 days and were injected following trial 5. Apomorphine, LY171555 and BH-T920, a specific DA autoreceptor agonist, all improved acquisition of the task at 0.05mg/Kg relative to saline and delayed drug injection controls. These findings suggest that the memory improving action of DA agonists is effective for both aversive and appetitive tasks, and that the effect may be mediated by an event involving the autoreceptor. In view of the many reports that post-training amphetamine (which promotes DA release) improves retention, this event is unlikely to be simply the reduction in DA release caused by autoreceptor activation.

186.13

DOPAMINE AND MEMORY: EFFECT OF ACUTE SCOPOLAMINE TREATMENT ON DOPAMINE METABOLISM IN RAT HIPPOCAMPUS AND FRONTAL CORTEX. C. Missale, P. Liberini*, S. Sigala*, M. Pizzi*, M. Memo, P.F. Spano. Inst Pharmacol Exp Ther, Sch Med, Univ Brescia, Italy.

The aim of the present study was to investigate some neurochemical correlates of the transient memory disruption induced in rats by scopolamine. After the acquisition of the passive avoidance response, male Sprague Dawley rats were divided into groups of 10 and trated with various doses of scopolamine or saline. Two hours later animals were tested for retention of the acquired response. Rats were killed by decapitation and the contents of DA and its metabolites (DOPAC and HVA) were determined in the frontal cortex and dorsal hippocapmus by HPLC.

The results indicate that scopolamine induced a selective decrease in the content of DA metabolites in the hippocampus (- 46 % DOPAC and - 38 % for HVA) and frontal cortex (- 50 % for both DOPAC and HVA). This phenomenon paralleled, in term of time- and dose-dependence the drug-elicited amnesic effects, as measured by the passive avoidance test, thus supporting the idea of a role of DA in learning and memory.

186.14

p-CHLOROAMPHETAMINE BLOCKS THE MEMORY ENHANCING EFFECT OF PHYSOSTIGMINE IN RATS WITH N. BASALIS OF MEYNERT LESIONS. A.C. Santucci, V. Haroutunian, P.J. Knott, P.D.Kanof* and K.L. Davis*. Dept. of Psychiatry, Mount Sinai School of Medicine, New York, NY 10029.

The present study examined the effect of p-chloroamphetamine (PCA), a purported serotonergic releasing agent, on memory in rats with N. basalis of Meynert (nbM) lesions. Sham and nbM operated rats were trained on a passive avoidance task one month postoperatively. Thirty min prior to training subjects were injected with either PCA (2.5 mg/kg) or saline. Immediately after training subjects received injections of either physostigmine (0.06 mg/kg) or saline. All animals were tested 72 hr after training. Results indicated that 1) nbM lesions produced memory impairments, 2) posttraining physostigmine reversed these impairments, 3) pretraining PCA blocked the memory enhancing effect of physostigmine and 4) PCA alone impaired retention in both sham and nbM animals. In a parallel study 2.5 mg/kg of PCA decreased 5-HT and 5-HIAA levels in the frontal cortex of rats 60 and 120 min postinjection. These data indicate that the serotonergic and cholinergic systems interact on a functional level.

186.15

SYSTEMIC BUT NOT INTRA-AMYGDALA ADMINISTRATION OF FLUOXETINE FACILITATES MEMORY. S.To*, I.B.Introini-Collison and J.L.McGaugh (SPON: G.D.Novack). Center for the Neurobiology of Learning and Memory and Department of Psychobiology, University of California, Irvine, CA 92717.

In previous studies we have found that retention is influenced by treatments affecting several neuromodulatory systems within the amygdaloid complex. These experiments examined the role of the serotonergic system. Flood and Cherkin (Psychopharmacol. 93:36, 1987) reported that either pre- or posttraining systemic or icv injections of the serotonin uptake blocker fluoxetine enhanced retention in mice trained in a shock motivated T-maze task. The present experiments examined the effects of fluoxetine on retention of an inhibitory avoidance task and the Morris water maze in rats. Male Sprague Dawley rats were trained in a step-through inhibitory avoidance task and given fluoxetine (15 mg/kg; ip) posttraining. On the retention test 1 week later, the performance of fluoxetine-injected rats was significantly better than that of the saline controls. Similarly, fluoxetine (15 mg/kg; ip) administered 15 min pretraining significantly enhanced the rate of learning of the platform location in the Morris task. However, intra-amygdala fluoxetine (1.0, 3.0 or 10.0 µg) did not significantly modify retention in either task. These findings indicate that the serotonergic system in the amygdala is not involved in the modulatory influence of fluoxetine on memory.

CAN SEROTONERGIC DEPLETION INFLUENCE BEHAVIOR FOLLOWING NBM LESIONS? A.L.Markowska, G.L.Wenk, and D.S.Olton. Department of Psychology, The Johns Hopkins University, Baltimore, MD 21218.

The present study investigated the effects of serotonergic depletion upon the performance of rats with lesions of the nucleus basalis magnocellularis in a nonspatial memory task. Lesions were made by injecting ibotenic acid into the NBM. Serotonin was depleted by systemic injection of p-chloroamphetamine (PCA). After four weeks of testing, the choice accuracy of PCA rats was not different from that of control rats (CON), while the choice accuracy of NBM rats and rats with combined treatment (NBM+PCA) was significantly lower and not different from each other. With prolonged testing (28 weeks), performance improved in CON rats and NBM rats, but not in PCA rats and NBM+PCA rats. These results show that damage to the serotonergic system did not produce an initial behavioral impairment, but did disrupt the recovery following NBM lesions. Pharmacological challenges to the cholinergic (scopolamine, physostigmine) and serotonergic (methysergide) systems describe further interactions between the two systems. Overall, these findings suggest an influence of both the NBM and the serotonergic system in processing nonspatial information. (Supported by NSF BNS 88-07010).

GENE EXPRESSION IN SPINAL CORD FOLLOWING BRIEF SENSORY STIMULATION. S. Williams*, W. Wisden* and S.P. Hunt* (SPON: D. Bousfield). M.R.C. Molecular Neurobiology Unit, Cambridge CB2 2QH, U.K.

Brief sensory stimulation can lead to rapid induction of the "immediate-early" onset gene, c-*fos* in spinal cord neurons (Hunt *et al.*, *Nature* 328:632, 1987). We have extended these observations to include other members of this gene 'family' and to map the appearance of gene product up to 24h after the initial stimulation. Rats were anaesthetised with Equithesin and the hind-paw stimulated by immersion in a water-bath for 20s at 52°C. mRNA for c-*fos*, NGF-IA, NGF-IB and c-*jun* A was detected at 5-15 min in the superficial dorsal horn and remained high for over 2h. By 4h, deeper-lying neurons were labelled but the superficial signal was greatly attenuated. Fos protein was seen to increase again from 4-16h bilaterally in a population of neurons in intermediate laminae. Local anaesthetic blockade of the ipsilateral sciatic nerve 1h after stimulation did not diminish this "second wave" of c-*fos* positive cells, implying independence from ongoing primary afferent discharge, and suggesting that the initial brief stimulation had triggered a long-term change in neuronal activity within the CNS.

187.2

FORMALIN INCREASES DORSAL HORN SUBSTANCE P CONTENT. K.E. McCarson and B.D. Goldstein. Department of Pharmacology and Toxicology, Medical College of Georgia, Augusta, GA 30912-2300.

Substance P (SP) found in primary afferent terminals has been proposed as a mediator of nociception in the dorsal horn of the spinal cord. The release of SP from these small diameter afferent neurons can be stimulated by a number of noxious stimuli. Formalin, a known nociceptive stimulus, has been shown to produce a biphasic effect with early (0-10 min) and late (20-60 min) increases in dorsal horn SP in immunohistochemical studies. This study was undertaken to determine if formalin affects the total dorsal horn content of SP. The right hindpaws of anesthetized rats received either an injection of 5% formalin or noxious mechanical stimulation (pinch) as a positive control. Saline injected and naive animals served as negative controls. After various time intervals the dorsal horns of the lumbar enlargement were assayed for SP using radioimmunoassay. Formalin produced a 262% increase in SP in the ipsilateral dorsal horn 10 minutes following hindpaw injection which decreased to baseline levels by 60 minutes. Hindpaw pinch increased SP in the ipsilateral dorsal horn by an average of 174% during the entire 60 minute period following the stimulus. Saline injection produced no significant effect. Contralateral dorsal horn SP levels were unchanged by any of the hindpaw treatments. The increases in SP produced by these nociceptive stimuli may be due either to increased release into the dorsal horn or increased cleavage of SP precursors in the primary afferent terminal. Supported by NS18664.

187.3

LACK OF CORRELATION BETWEEN THE LEVELS OF SUBSTANCE P (SP) IN THE DORSAL HORN (DH) AND PAIN-RELATED BEHAVIOR FOLLOWING FORMALIN. L.N. Holland and B.D. Goldstein. Department of Pharmacology and Toxicology, Medical College of Georgia, Augusta, GA 30912-2300.

The injection of dilute formalin into the hindpaw has been shown to increase SP in the rat DH as measured immunohistochemically. These SP levels have a time-course which is similar to the biphasic change observed in pain-related behaviors in the formalin test. Systemic morphine produces a decrease in this behavior, but causes a further increase in SP levels. Systemic morphine or lidocaine injected into the hindpaw without formalin will increase SP levels. We, therefore, measured the effect of lidocaine on pain-related behavior due to formalin, and determined SP changes which may be associated with lidocaine pretreatment.

The pain-related behavior due to formalin was measured by the Digiscan (Omnitech Electronics, OH) as duration of stereotypy for 60 minutes following a 5% formalin injection. The levels of the SP were quantified using immunohistochemistry at 60 minutes. An injection of 2% lidocaine with epinephrine into the hindpaw reduced the formalin-induced stereotypy time but resulted in a further increase in the levels of SP in the DH.

These data suggest that SP changes in the DH as a result of lidocaine pretreatment do not correlate with the reduction of pain-related behavior following formalin. Supported by NS-18664.

PREPRODYNORPHIN AND PREPROENKEPHALIN mRNAs IN THE SPINAL CORD DURING A MODEL OF NEUROPATHY, NERVE INJURIES AND PERIPHERAL INFLAMMATION. G. Draisci, K.C. Kajander, G.J. Bennett, M.J. Iadarola and R. Dubner. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892.

Previous studies have shown an increase in dynorphin gene expression during inflammation of the hind paw. In the present study, we analyze a model of neuropathic pain (caused by loose ligatures around the sciatic nerve which induces a partial deafferentation) and compare it to nerve crush, nerve transection and peripheral inflammation for alterations in spinal cord preprodynorphin (PPD) and preproenkephalin (PPE) mRNA levels.

Total lumbar spinal cord RNA was extracted at 2, 5, 10 and 20 days after sciatic nerve ligation and RNA blots were prepared. Blots were hybridized with ^{32}P-labeled probes for rat PPD (from J. Douglass and O. Civelli), rat PPE (from S. Sabol), and rat B-actin (from U. Nudel). Blot analysis was conducted at 2 days after sciatic nerve crush, transection and carrageenan inflammation of the hind paw.

A 2-fold increase in preprodynorphin mRNA occurred two days after ligation, reached a peak by 5 days (4-fold) and declined to 50% over control by 20 days. In addition to the ligation model, only inflammation produced an increase (4-fold) in dynorphin mRNA. No alterations were found at 2 days for transection or crush compared to sham operated rats. Only relatively small changes of preproenkephalin mRNA were found after inflammation (50% over control) and no changes were found with the other manipulations.

Our results show that in the sciatic nerve ligation model of neuropathic pain a rapid and sustained activation of dynorphin gene expression occurs. Thus, an increase in dynorphin mRNA occurs with both peripheral inflammation and peripheral neuropathy. This suggests that afferent input from small fibers and an intact connection with the periphery are important for dynorphin gene activation since these two features are common to both models.

PROLONGED ELEVATION OF MULTIPLE FOS IMMUNOREACTIVE PROTEINS IN RAT SPINAL CORD: WESTERN BLOT AND IMMUNOCYTOCHEMICAL ANALYSIS. M.J. Iadarola, C.L. Yeung*, G. Draisci and M.A. Ruda. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892.

We have recently found a rapid and transient increase in c-fos mRNA in lumbar spinal cord following carrageenan-induced inflammation of the hindpaw. In addition to the c-fos proto-oncogene, which codes for a nuclear transcription factor, other genes exist which code for Fos-immunoreactive proteins (Fos-related antigen or FRAs). In order to study the protein product of the c-fos gene and the FRAs in our model, we generated an antiserum to the synthetic peptide KVEQLSPEEEEKRRIRRERNKMAAA, a highly conserved region in Fos and the Fos-related antigens (FRAs). The antiserum was affinity purified against immobilized antigen and used for immunocytochemistry (ICC) and western blot analysis. Contrary to the short-lived elevation we expected from mRNA levels and previous ICC studies by others with nociceptive stimuli and an N-terminally directed antibody, a very prolonged increase (out to 4-6 days) was observed with ICC with our antibody. The initial pattern of cell labeling was complex during the first 8 hours, with several laminae in addition to I-II and V-VI showing immunoreactive cells. By 24 hrs and at later times the labeling was mainly found in laminae I-II and V-VI. The pattern of proteins seen on western blots was also complex. There was a rapid elevation (within 1 hr) in specific immunoreactive bands migrating at 55, 44, 41-38 kDa. The elevation in these bands was maintained through 24 hrs after which the 55 kDa band declined while the other bands (FRAs) remained elevated. These data indicate a specific and prolonged temporal sequence of increase in Fos proteins occurs in spinal cord induced by peripheral inflammation and suggest the participation of multiple Fos-reactive proteins in both triggering and sustaining expression of target genes in the spinal cord during inflammation.

187.6

SPINAL CORD DISTRIBUTION OF C-FOS PROTEIN IN VISCERAL VERSUS SOMATIC MODELS OF CHEMICAL INFLAMMATION. L.A. Birder*, J.R. Roppolo, M.J. Iadarola and W.C. de Groat (SPON: A. Moller). Univ. of Pittsburgh, Depts. Pharmacol. and Beh. Neurosci., Pittsburgh, PA 15261.

Activation of somatic nociceptive afferents (aff) stimulates expression of the c-fos oncogene in dorsal horn (DH) neurons of the spinal cord (SC). We have used immunocytochemical (IC) techniques to compare distribution of c-fos protein in the SC of the cat and rat following chemical irritation of the hindpaw or urinary bladder (UB) (intravesical 3-10% formalin for 2 hours). One decerebrate cat and neurally intact and spinal unanesthetized rats were studied. Animals were deeply anesthetized prior to perfusion and removal of the tissues. In both cat and rat UB irritation increased c-fos protein in lamina I neurons of the DH, in the dorsal commissure, lamina X and in the sacral parasympathetic nucleus (SPN) at the L_6-S_2 level of the SC. C-fos staining was markedly lower in the upper lumbar segments (L_1-L_3). Over distension of the UB produced only a slight increase in c-fos. Chemical irritation of the hindpaw increased c-fos in similar regions of the L_4-L_5 DH, excepting the intermediolateral area. These findings are consistent with the concept of viscerosomatic nociceptive aff convergence in the SC. They also reveal a difference between chemical and mechanical irritation of the UB and suggest that nociceptive input from the bladder is carried primarily by afferent pathways in the pelvic nerve to the lower lumbar and sacral segments of the SC.

THE CELLS OF ORIGIN OF THE SPINOHYPOTHALAMIC TRACT IN THE CAT. J.T. Katter, R. Burstein, & G.J. Giesler, Jr. Dept. Cell Biol. & Neuroanat., Grad. Prog. in Neurosci., Univ. Minn., Minneapolis, MN 55455.

Many spinal cord neurons in rats project directly to the hypothalamus. In this study, injections of retrograde tracers into the hypothalamus of cats were made in an attempt to define a similar projection. Injections of WGA-HRP, a mixture of WGA-HRP and B-HRP, or fast blue were centered in the hypothalamus in seven cats and did not spread into the thalamus, zona incerta, or midbrain. Retrogradely labeled neurons were observed bilaterally in all of the 17 examined spinal segments. Approximately 400-500 labeled neurons were observed in alternate sections in the most effective cases. Roughly 70% of these neurons were contralateral. Labeled neurons were found predominantly in the deep dorsal horn and in the area surrounding the central canal. A few were also noted in the superficial dorsal horn and ventral horn. Interestingly, the largest number of labeled neurons was observed in S1-2.

Overall, a smaller population of spinohypothalamic tract neurons was observed in cats than previously in rats. To test the sensitivity of our tracing techniques, WGA-HRP was injected into the thalamus, including the ventrobasal complex, in four cats. Thousands of spinal cord neurons were labeled in each cat. The results of this study suggest that a comparatively small number of spinal cord neurons project to the hypothalamus in cats. Supported by NS25932.

SENSITIZATION OF PRIMATE SPINOTHALAMIC TRACT NEURONS BY ELECTRICAL STIMULATION OF SENSORY AFFERENTS, P.M.Dougherty, C.Owens, D.Zhang and W.D.Willis, Dept. Anat. & Neurosci., Mar. Biomed. Inst., Univ. Texas Med. Br., Galveston, TX

Potentiation of evoked responses of somatosensory neurons by chemical, mechanical, and inflammatory stimuli present useful models of chronic pain. This study investigates the use of electrical stimulation of sensory root afferents in the production of sensitization of primate (M. fascicularis) spinothalamic tract neurons. Eleven physiologically identified cells located in spinal segments L2-L6 were studied in 10 anesthetized animals, using carbon-glass micropipettes (2-3MOhms). Upon mapping the receptive field size and response characteristics as well as the evoked field and single unit activity of graded dorsal root stimulation, a pair of conditioning shocks (100Hz, 1 s duration, 1 msec pulse width) at high intensity (200X threshold for field potential) was delivered by one dorsal rootlet (intact or cut). Receptive field and electrical-driven activities were again determined. The results suggest a preferential enhancement of low threshold (brush, press) vs. high threshold (pinch, squeeze) input in 8 cells. In addition, evoked field and driven spike activity demonstrated an increase in threshold and peak response in 10 cells. In summary, intense electrical stimulation of dorsal root afferents induces a sensitization of primate STT neurons potentially representing another model of chronic pain. ORGANIZATION OF VISCEROSOMATIC SPINAL AFFERENT INPUT TO C_3-T_4 SPINOTHALAMIC TRACT (STT) CELLS IN THE MONKEY. **S.F. Hobbs, D.C. Bolser, M.J. Chandler, & R.D. Foreman. Dept. of Physiol., Univ. Okla. HSC, Okla. City, OK 73190.**

To understand why visceral pain from the thoracic and upper abdominal organs is often felt as arising from chest muscle, we determined in STT cells the relationships between the following: 1) location of excitatory somatic fields, 2) input from hair, skin, and muscle, 3) visceral afferent input, and 4) spinal location of the ST cells. Responses of 89 STT cells from 19 chloralose-anesthetized monkeys were analyzed. In general, cells with somatic fields confined to the hand were maximally excited by skin pinch, but cells with somatic fields proximal to the hand were excited maximally by muscle input. Electrical stimulation of cardiopulmonary sympathetic or splanchnic afferents excited STT cells with chest or shoulder somatic fields more than cells with somatic fields confined to the forelimb. Also, cells excited by visceral input were excited more by muscle than skin or hair input. Cells with somatic fields confined to the forelimb were primarily found in segments C_7-C_8. Cells in segments C_3-C_6 and T_1-T_4 but not C_7-C_8 were excited by chest, shoulder, and/or forelimb input and by visceral input. These data indicate that visceral pain from thoracic and upper abdominal organs is often referred to the muscles of the chest because visceral input from these organs primarily excite STT cells whose major somatic input is from thoracic muscles. (OCAST & HL22732)

EVIDENCE THAT SUBSTANCE P MODULATES C-FIBER EVOKED DISCHARGES OF SPINAL CORD NOCICEPTIVE NEURONS IN THE RAT. D.E. Kellstein[1], D.D. Price[2], R.L. Hayes[3], and D.J. Mayer[1]. Depts. of [1]Physiology, [2]Anesthesiology, and [3]Neurosurgery, Medical College of Virginia, Richmond, VA 23298.

Previous studies suggest that the undecapeptide Substance P (SP) may function as a primary afferent neurotransmitter or neuromodulator of nociception. The present study investigated the effects of SP and an SP antagonist, [D-Pro^2,D-$Trp^{7,9}$]-SP (DPDT), on A- and C-fiber evoked firing of dorsal horn nociceptive neurons using extracellular electrophysiological recording.

Male Sprague-Dawley rats (450-550 g) were anesthetized with urethane (1.3 g/kg). A laminectomy was performed at spinal segments L4 and L5 and the dura was retracted. Single unit recordings were made at spinal segments L4 and L5 from wide dynamic range and nociceptive specific neurons of the dorsal horn (mean depth 1.07 $\pm$ 0.1 mm) during controlled repetitive electrical stimulation of the ipsalateral hind paw. Stimulation consisted of trains (6 pulses, 1 every 2 sec) of rectangular wave pulses supramaximal for C-fiber activation (3 mA, 2 msec duration). Following determination of pretreatment responses, SP or DPDT (4, 20, and 100 nmol in 10 μl) was applied onto the surface of the cord and evoked discharges were quantified at 1, 5, and 10 min after each dose. Whereas SP enhanced C-evoked firing with an apparent U-shaped dose response (100 > 4 > 20 nmol), DPDT inhibited C-evoked firing in a dose-related manner with an apparent ceiling effect at 20 nmol. Neither drug altered A-fiber evoked activity. In those neurons exhibiting C-evoked temporal summation, SP (4 and 100 nmol) flattened and maximized the temporal summation curve such that the response to first stimulation was nearly equivalent to the sixth. These findings suggest that SP may function as a neuromodulator of nociceptive transmission of C-fiber, but not A-fiber, mediated responses. Supported by PHS awards NS 24009-1A2 and DA 00576.

SPINAL CORD CODING OF PAIN: SPATIAL CODING REVEALED BY QUANTITATIVE 2-DEOXYGLUCOSE IMAGING. R.C. Coghill[1], D.D. Price[2], R.L. Hayes[3], and D.J. Mayer[1]. Dept. [1]Physiology, [2]Anesthesiology, and [3]Neurosurgery, Virginia Commonwealth University, Richmond VA 23298.

Direct evidence of spatial recruitment as a mechanism of coding nociception in the spinal cord requires simultaneous observation of whole populations of neurons which is not easily attained with electrophysiological techniques. We have analyzed spatial recruitment during nociceptive stimulation utilizing the quantitative ^{14}C-2-deoxyglucose (2-DG) technique of Sokoloff. Experiments were conducted in unanesthetized, T-2 spinalized rats paralysed with d-tubocurarine. Stimulation was delivered by cyclical immersion (5 sec in, 5 sec out) of the left hindpaw in a water bath. Groups of animals were stimulated with noxious (45°, 47°, 48°, 49°C) or non-noxious (35°C) water temperatures. At the beginning of the 45 minute period of stimulation 2-DG (50 μCi) was delivered through the jugular catheter, and sequential blood samples were drawn to monitor plasma glucose and plasma 2-DG levels during the 45 minute period of stimulation. Blood gasses, blood pressure, and core temperature were monitored to insure physiological normality. Spinal cords were removed, frozen, and sectioned at -20° C. Optic densities of autoradiographs of spinal cord sections were analyzed and converted to absolute rates of glucose utilization. Nociceptive stimulation produced somatotopically specific increases in glucose utilization; the ipsilateral dorsal horn was more active than the contralateral dorsal horn, and medial portions of the dorsal laminae (regions which represent the distal portions of the limb) were more active than lateral regions. Metabolic activity was at maximum levels at the fourth lumbar segment but, importantly, expanded rostrally and caudally in a graded manner as noxious temperature intensity increased. This spatial recruitment was more extensive for deeper (V-VII) as compared to superficial (I-IV) laminae. These findings indicate that substantial spatial recruitment occurs during painful stimulation and that this recruitment may serve as an important factor of nociceptive information encoding. Supported by PHS grant NS 24009-1A2.

187.12

EFFECT OF ERGOT ALKALOIDS ON CERVICAL SPINAL CORD NEURONS WITH CRANIOVASCULAR INPUT. P.Boers ,A.Lowy , G.A.Lambert ,H.Angus-Leppan and A.S.Zagami (SPON: J. Morley), Department of Medicine, University of New South Wales, Australia.

Previous work in our laboratory has demonstrated the presence of a region in the cervical spinal cord which responds to stimulation of craniovascular structures; this has been termed the dorsolateral area (dla). It has also been shown that intravenous injection of the antimigraine drug ergotamine can suppress or abolish both evoked potentials and single-unit responses, implying a central action of the ergot alkaloids. In order to test this hypothesis, single unit recordings were made in the dla of chloralose/urethane-anesthetised cats, and ergometrine was applied iontophoretically to these units. A length of the dura and falx containing the sagittal sinus (SS) was isolated and stimulated electrically with supramaximal shocks (40-120V, 250μsec, 0.2 s^{-1}). A tungsten-centred multibarreled glass electrode was used to record single-unit activity and to eject drugs. Units in the dla responded to electrical stimulation of the SS with A-delta and C-fiber latencies. About 1/3 of these responsive units had their response rate reversibly reduced to 75% or less of the control value by ergometrine currents of 50 nA. Another 1/3 showed a reduced response rate, with no recovery, and about 1/3 of units were unaltered in response rate. Most of the reversibly-inhibited units were also tested with iontophoretic application of D,L-homocysteic acid, and about 2/3 of these showed an acceleration in spontaneous firing rate. Iontophoretic ejection of equivalent currents from a NaCl-containing barrel were without effect on response rate. These results suggest that the previously-reported ability of ergot alkaloids to suppress craniovascular input may occur at a spinal cord level, a finding that has implications for migraine pathogenesis and therapy.

187.13

THE CERVICAL SPINAL CORD RELAYS CRANIOVASCULAR INPUT TO THE THALAMUS. H.Angus-Leppan*, P.Boers*, A.S.Zagami and G.A.Lambert* (SPON: S.Ghosh). Dept. of Medicine, Univ. of New South Wales, Australia.

Sensory information from the cranial vasculature is carried in the trigeminal nerve and is important in the transmission of headache pain. In general, the fibers of the this nerve terminate in the trigeminal nucleus, but it has been reported that elements in the cervical cord also receive such input. The thalamus, particularly the ventroposteromedial (vpm) nucleus, also contains neurons which receive craniovascular input, but it is unclear if this input is relayed in the cervical cord or the trigeminal nucleus. The experiments reported here have tested one of these possibilities. Cats anesthetized with chloralose/urethane were used. A length of the dura and flax containing the sagittal sinus (SS) was isolated and stimulated electrically with supramaximal shocks (40-120V, 250μs, 0.2sec^{-1}). Single unit recordings were made with glass-coated tungsten microelectodes in the vpm nucleus of the thalamus and the cervical cord. Cryoprobes cooled with circulating alcohol to -15° were applied to portions of the spinal cord to block neural conduction reversibly. Stimulation of the SS activated units in the dorsolateral area (dla) and the medioventral area (mva) of the cervical spinal cord and in the vpm nucleus of the thalamus, with A-delta and C-fiber latencies. Bilateral cooling of the surface of the cervical cord at the C2 level reversibly blocked the activation of a majority of vpm units. Block was slow to develop and slow to reverse. Selective cooling of the dla area reversibly blocked the response of neural elements in the mva. Units in both the mva and dla could be activated antidromically from the medial lemniscus. The results lend support to the idea that the cervical cord is a major relay centre for the perception of craniovascular pain and that both the dla and mva are intimately and sequentially linked in this relay process.

PAIN PATHWAYS: PRIMARY AFFERENTS

188.1

LOCAL APPLICATION OF CAPSAICIN OR NE-21610 DEPRESSES BOTH AFFERENT AND EFFERENT FUNCTIONS OF CUTANEOUS C-FIBRES IN THE RAT. B.Lynn* and W.Ye* (SPON: K.W.T.Caddy). Dept. of Physiol., University College, London WC1E 6BT.

Capsaicin (CAPS), the naturally occurring capsaicinoid in peppers, causes long-lasting local analgesia and loss of neurogenic inflammation when applied to nerves in the rat. We have examined the mechanism of these changes for CAPS and for the synthetic capsaicinoid NE-21610. Exposing the saphenous nerve of the rat to 0.1-1 mM CAPS or 2 mM NE-21610 caused a substantial immediate reduction in C-fibre, but not A-fibre, conduction. After exposure to 4 mM NE-21610 or 33 mM CAPS many C-fibres were abnormally small and were often not enclosed in their own Schwann cell mesaxon 1-2 weeks later. Electrophysiological examination of similarly treated nerves showed a long-lasting loss of around 75% of C-fibres of the polymodal nociceptor (PMN) type, even after 3 months. No other types, C or A fibre, were affected. Intradermal injection of capsaicinoids blocked afferent (heat and pressure) responses of C-PMNs (ED_{50}, NE-21610, 7-20 M; CAPS, <33 M) and antidromic vasodilatation (ADV) (ED_{50}, NE-21610, 10 M;CAPS, 2-7 M). ADV and substance P levels were substantially reduced for at least 2 days following 0.3 mM intradermal CAPS. It is concluded that capsaicinoids exert their analgesic and anti-inflammatory actions in adult rats by inactivating C-fibres of the PMN type.

188.2

PHARMACOLOGIC PROFILE OF NE-21610, A NEW ANALGESIC AGENT. E.F. Berman*, R.L. Bohne* and T. McPherson* (SPON: J.M. Meyer). Miami Valley Laboratories, The Procter & Gamble Co., Cincinnati, OH 45239-8707

NE-21610 (N-((4-(2-aminoethoxy)-3-methoxyphenyl)-methyl)-9z-octadecinamide) is an analog of capsaicin that has antinociceptive and anti-inflammatory activity after oral or parenteral administration. It does not appear to interact with opiate receptors or inhibit cyclooxygenase, but rather acts directly on peripheral sensory nerves. NE-21610 was evaluated in the mouse tail-flick, rat hot plate, mouse phenylquinone abdominal constriction, mouse formalin and rat Randall-Selitto paw pressure assays. The potency of NE-21610 in the phenylquinone and tail-flick assays after s.c. injection is similar to that of morphine. The potency of NE-21610 in the phenylquinone assay after oral dosing is better than that of codeine or aspirin. NE-21610 blocks both the early and late phase licking responses in the formalin assay, supporting our previous data indicating a direct action on C-fibers. Our results suggest that NE-21610 should be an efficacious drug for the treatment of moderate to severe pain and of inflammatory diseases.

188.3

EFFECTS OF NE-21610, A NOVEL CAPSAICIN ANALOGUE, ON THERMAL NOCICEPTIVE THRESHOLD IN THE RAT. R. B. Carter, Research and Development Dept., Miami Valley Laboratories, The Procter & Gamble Co., Cincinnati, OH 45239.

Capsaicin, the pungent principle of hot peppers, is the prototype for a new class of antinociceptive agents. The effects of one such analogue, NE-21610 [N-([4-(2-aminoethoxy)-3-methoxyphenyl]-methyl)-9Z-octadecenamide], were studied on the thermal nocirespons iveness of rats using latency to tail withdrawal from 45°-50.5°C water. Whereas NE-21610 (10-100 mg/kg, p.o.) produced dose-dependent increases in response latency at 47.5°C, it was inactive at 50°C. The thermal nociceptive threshold was determined by measuring latency to tail withdrawal as a function of water temperature. Latencies of control-treated rats were biphasic, decreasing rapidly with increasing temperature over a range of 45-47.5°C and more slowly from 47.5°-50°C. These data yielded a thermal nociceptive threshold in normal rats of 46.4°C. NE-21610 (100 mg/kg, p.o., 60 min post-dose) produced a rightward shift in the temperature-response function, indicating an increase in thermal threshold; latencies were likewise biphasic. The thermal nociceptive threshold in NE-21610-treated rats was calculated to be 48.3°C. By comparison, administration of the opioid agonist-antagonist pentazocine resulted in a threshold of 49.3°C. These data indicate that NE-21610 possesses antinociceptive efficacy approximately equivalent to that of an opioid mixed agonist-antagonist.

188.4

ANTINOCICEPTIVE ACTIVITY OF INTRATHECAL (I.T.) NEUROKININ (NK) AND N-METHYL-D-ASPARTATE (NMDA) ANTAGONISTS IN A MOUSE TONIC PAIN MODEL. C.W. Murray*, A. Cowan† and A.A. Larson. Dept. of Vet. Biol., Univ. of Minnesota, St. Paul, MN 55108 and †Dept. of Pharmacol., Temple Univ. Sch. of Med., Philadelphia, PA 19140.

While many lines of evidence support a role for the endogenous NK peptide substance P (SP, NK-1 receptor agonist) as a primary sensory transmitter of acute pain in mammalian spinal cord, its role in tonic pain is unclear. Excitatory amino acid (EAA) involvement in nociceptive processing is also uncertain. To test the hypothesis that NKs and EAAs contribute to signaling of *continuous (tonic) chemogenic* pain, we evaluated two NK antagonists ([D-Pro2,D-Trp7,9]-SP (DPDT-SP, 0.4–10 μg, non-specific) and [D-Pro4,D-Trp7,9,10,Phe11]-SP(4-11) (DPDTP-octa, 2–15 μg, somewhat NK-1 selective)), as well as dl-2-amino-5 phosphonovalerate (dl-AP5, an NMDA antagonist) and urethane (a kainic acid (KA) antagonist at the i.t. dose tested) for possible antinociceptive activity in the mouse formalin model. Neither NK nor EAA antagonists have previously been tested against tonic pain nor have they consistently reduced acute pain perception. DPDTP-octa is known to block SP-induced *behaviors* (reciprocal caudally directed biting and scratching (B&S)) but is *not* antinociceptive in *acute* models. In the current study, analgesia was defined as significantly reduced time spent licking a hind paw injected s.c. with 20 μl of 10% formalin compared to vehicle controls during a 25 min observation period under blind conditions (n=5–12/group; J. Pharmacol. Meth. 20:175). Our results indicate that both NK antagonists tested as well as 1 nmole of dl-AP5 were significantly antinociceptive. A 2.5 μmole dose of urethane (which inhibits B&S produced by 0.075 nmoles KA, i.t.) was inactive in this paradigm. A_{50} values for mean % analgesia, μg/mouse i.t. (95% CI) were: DPDT-SP, 1.7 (1.2-2.4); DPDTP-octa, 4.8 (2.9-7.5). Only minimal behavioral effects were produced by the NK antagonists. Neither agent alone produced NK-1 agonist activity (B&S) or motor impairment. dl-AP5 induced subtle postural and behavioral changes at 1 nmole. These data support the contention that NK, especially NK-1, and NMDA (but not kainate) receptors are involved in spinal processing of *tonic* chemical/inflammatory nociception in mice. The present results also suggest that inhibition of B&S is not predictive of antinociception in tonic pain models. [Grants DA04090, DA04190 and DA00124 to AAL and DA03945 to AC.]

CORTICOTROPIN RELEASING FACTOR (CRF) PRODUCES ANALGESIC AND ANTI-INFLAMMATORY EFFECTS BY MULTIPLE MECHANISMS OF ACTION. Kenneth Hargreaves*, Ann Costello* and Ronald Dubner. (Spon: E. Chudler). Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892.

We have previously reported that CRF produces analgesia in post-operative patients and in rats (Brain Res. 422:154;1987). The present studies evaluated the mechanism(s) of this effect in the carrageenan (Carra) model of inflammation. Carra (2mg) was injected sc into hindpaws; test drugs were then injected sc into the neck and animals (8/group) were evaluated 3 hours later. Thermal hyperalgesia was determined by exposing hindpaws to a beam of radiant heat as previously described (Pain 32:77;1988). Edema was measured by a plethysmometer and hindpaw temperature was assessed by a thermocouple. Data were analyzed by ANOVA and Duncan's test. In a dose-response study, CRF was approximately 1,000 times more potent than indomethacin for blockade of hyperalgesia, edema and hyperthermia. As compared to hypophysectomized rats injected with vehicle, CRF (20 nmole/kg) in hypophysectomized rats blocked hyperalgesia (9.22± 1.8 sec vs 4.7± 0.8 sec: $p<0.01$), hyperthermia (28.5±.2°C vs 30.0±.3°C; $p<0.01$) and edema (1.87±.06 cc vs 2.50±.11 cc; $p<0.01$). In adrenalectomized rats, CRF retained its blockade of hyperalgesia (5.8±1.1 sec vs 3.2±0.5 sec; $p<0.05$) but its effects on edema and hyperthermia were absent. The anti-inflammatory, but not the analgesic, effects of CRF were also blocked in rats pre-treated with the glucocorticoid antagonist RU486 (20mg/kg). The analgesic effects of CRF, at 30 min after injection, but not at 180 min, were blocked by naltrexone (3 mg/kg; injected at 0 & 150 min). We conclude that CRF analgesia in the carra model of inflammation is opioid-dependent within the first 30 min, and is opioid-, pituitary-, and adrenal-independent at 180 min. In addition, the anti-inflammatory effects of CRF are due to the actions of adrenal glucocorticoids.

ANTAGONISM OF PGE_2-INDUCED HYPERTHERMIA IN RATS BY ANTINOCICEPTIVE PROSTAGLANDIN ANTAGONISTS. M.F. Rafferty[1], E.J. Drower[1], and D.L. Hammond[2]. [1]G.D. Searle & Co.,Skokie, IL 60077, and [2]Dept. of Anesthesia and Critical Care, U. of Chicago, Chicago, IL 60637.

We recently reported the antinociceptive activities in rat of some novel dibenzoxazepine derivatives, SC-19220 and SC-25469, which are selective antagonists of PGE in vitro (Drower et al., Eur. J. Pharm. (1987)133:249). In an attempt to determine whether PGE antagonism in vivo could be relevant to the behavioral actions of these compounds, we have assessed the ability of antinociceptive doses of both compounds to antagonize the hyperthermic effect of i.v. administered PGE_2 methyl ester. Since the hyperthermia is a function of the amount of PGE_2 which enters the CNS, information about a possible central site of action of these drugs could also be obtained. The general methodology was as described by Eguchi et al. (JPET(1988) 247:671). As previously reported, i.c.v. SC-19220 pretreatment (0.56-2.25 umoles) dose-dependently blocked the hyperthermic response. Likewise, i.c.v. SC-25469 was found to completely block the effect at a dose of 0.56 and 1.15 umoles. The apparent rank order of potency correlates with pA_2 values for antagonism of PGE_2-induced contractions in guinea pig ileum. Oral pretreatment with an analgesic dose of either compound (150 mg/kg, formalin test) blocked the hyperthermic effect. These results indicate that the antinociceptive effects of these compounds may in part be centrally mediated.

PROSTAGLANDINS INCREASE THE RELEASE OF SUBSTANCE P FROM CULTURED SENSORY NEURONS. M.R. Vasko, J. Crider and W. Campbell, Depts. Pharmacol. & Tox., Indiana U. Sch. Med., Indpls, IN 46223; U.T. Southwest Med Ctr, Dallas, TX 75235.

Evidence suggests that eicosanoids facilitate activation of sensory neurons and nociception. Since substance P (SP) is an important neuroactive substance in nociceptive sensory neurons, we studied whether eicosanoids could stimulate the release of SP from cultured sensory neurons.

Dorsal root ganglia from 11 day chick embryos were dissected, cells dissociated, then plated onto collagen coated culture dishes. Cells were grown in a modified Eagle's Medium supplemented with NGF for 5-7 days. Release studies were performed by incubating cells for repeated 5 min periods with Krebs-bicarbonate buffer containing either 3.5mM KCl, 50mM KCl or various concentrations of eicosanoids. After exposure to cells, the buffer was removed and assayed for SP content using RIA. Exposure of cells to 50mM KCl resulted in a Ca^{++}-dependent increase in SP release from a mean ± S.E.M. of 37.4 ± 5.9 pg/dish/5 min to 128.1 ± 15.9 pg/dish/5 min. Both PGE_2 and PGD_2 at 10^{-6}M caused an increase in SP release similar in magnitude to that observed for 50mM KCl. In contrast, 10^{-6}M LTB_4, a lipoxygenase metabolite of arachidonic acid, did not stimulate SP release. These results suggest that certain eicosanoids can increase SP release from sensory neurons; this may be a mechanism underlying the enhanced nociception by these substances. (Supported by NS 21697)

8(R),15(S)-diHETE SENSITIZES C-FIBRE NOCICEPTORS IN THE HAIRY SKIN OF THE RAT. D.M. White*, A.I. Basbaum, E.J. Goetzl* and J.D. Levine*. (SPON: A.M. Williamson) Depts. Anatomy, Medicine, Oral and Maxillofacial Surgery and Division of Neurobiology, UCSF, CA, 94143.

8(R),15(S)-diHETE, a product of the 15-lipoxygenase arachidonic acid pathway, is a potent hyperalgesic compound in behavioural studies. In this electrophysiological study we examined the effects of 8(R),15(S)-diHETE on the mechanical threshold and thermal responses of C-fibre mechanoheat nociceptors (C-MH) isolated from the saphenous nerve of pentobarbital anaesthetized rats. Mechanical thresholds were evaluated with calibrated von Frey hairs. Thermal responses were induced with a contact thermal stimulator. Intradermal injection of 8(R),15(S)-diHETE significantly decreased the mechanical threshold of C-MH's (n=25) from 7.4±0.4g to 4.6±0.6g. This decrease in threshold was completely antagonized by a stereoisomer, 8(S),15(S)-diHETE. The stereoisomer did not antagonize PGE_2-induced sensitization. To test whether 8(R),15(S)-diHETE sensitizes thermal responses we used a test stimulus of 37°C for 5min. There was a significant increase in the total number of spikes in the 5min period after 8(R),15(S)-diHETE, but not after the saline vehicle. 8(R),15(S)-diHETE may contribute to the hyperalgesia associated with inflammation by sensitizing C-fibre nociceptors via a specific binding site that is separate from the PGE_2 binding site.

CAPSAICIN ANALOGS DIFFERENTIALLY ACTIVATE AFFERENT C-FIBERS T. R. LaHann[1], G. Daniell[1] and P. Stark[2]*. Univ of Montana, Missoula, Mt[1], and the Univ of Minnesota, Minneapolis, Mn[2].

Topical or intracutaneous injection of capsaicin stimulates cutaneous c-fibers, eliciting pain and a neurogenic inflammation. IV injection of capsaicin into rats stimulates cardiopulmonary c-fibers and elicits the Bezold-Jarisch reflex (apnea, bradycardia and hypotension). IV injection of equimolar doses of the capsaicin derivative, vanillyloleamide (VO), failed to activate the Bezold-Jarisch reflex but topical and intracutanous administration of VO did elicit marked plasma extravasation, as quantitated by dye leakage from the vascular system into the skin. The comparison of the cardio-pulmonary and cutaneous irritant actions of capsaicin and its analog (VO) suggests that the c-fiber receptors mediating neurogenic inflammation differ from those receptors eliciting the Bezold-Jarisch reflex. Capsaicin analogs may thus be useful probes for defining the function and neurochemistry of afferent receptor subtypes. In addition, the selectivity of function demonstrated by VO suggests that modification of capsaicin's chemical structure may improve the overall therapeutic index.

CAPSAICIN-INDUCED ANTINOCICEPTION : CENTRAL AND PERIPHERAL SITES OF ACTION. A.Dray, J.Bettaney*, A.H. Dickenson* and N.Ashwood*. Sandoz Institute for Medical Research, London and Department of Pharmacology, University College, London, England.

An acute dose of capsaicin (ED50= 20 µmols / kg,s.c.) produces behavioral antinociception which peaks some 30min. after administration and lasts 1-3 hours.The plasma concentration at the peak effect is 0.8-2µM. We have examined whether spinal and peripheral sites contribute to this effect of capsaicin.

Polymodal spinal dorsal horn neurons were recorded in adult rats anesthetized with 1% halothane. The C-fibre input, evoked by stimulation of a hind toe, was selectively reduced a) following capsaicin injected into the peripheral receptive field b) by capsaicin injected at a distant site. This occured with a time course similar to that observed in antinociceptive tests c) by 100nM capsaicin administered intrathecally. A nociceptive response was also measured *in vitro*, from a ventral root of the neonatal rat spinal cord, following noxious heat stimulation of the attached tail. Prolonged capsaicin superfusion, to mimic drug conditions *in vivo*, consistently attenuated the nociceptive reflex when administered to the cord (0.2-1.0µM). When administered to the tail, it was only effective at higher concentrations (20-50µM) and was less consistent.

These data suggest that an antinociceptive dose of capsaicin selectively attenuates C-fibre input to the spinal cord and that a spinal action is important for this effect.

TWO MECHANICAL HYPERALGESIAS IN HUMAN NEUROPATHY. J.Ochoa,W.J.Roberts,M.A.Cline,R.Dotson & D.Yarnitsky*. Good Samaritan Med.Ctr., OHSU, Portland, OR 97210 USA.

Abnormal reduction of threshold for pain in response to non-noxious mechanical or thermal stimuli to human skin may be due to sensitization of unmyelinated nociceptor terminals (Cline,et al,Brain,89). But, in neuropathy, mechanical hyperalgesia has often been better explainable through secondary hyperexcitability of central neurons responsive to large caliber myelinated tactile input.

This study of 22 patients with chronic mono- or polyneuropathic mechanical hyperalgesia separates two subgroups with ostensibly different pathophysiology. Type D hyperalgesia disappears early during selective large caliber A-fiber block,in keeping with the commonly accepted basis. Nerve biopsy in 3 selected patients has revealed that type D may exist despite selective absence of small caliber fibers. Type S hyperalgesia persists after selective A-fiber block, while only C-fibers conduct. Nerve fiber pathology in one patient has revealed that type S may occur even in absence of myelinated fibers. D & S hyperalgesias may coexist in the same patient.

A clinical sign usually distinguishes the two hyperalgesias:type D is dynamic;type S is static. In type D, touch-induced pain is triggered only at on-off and may improve by sustained mechanical pressure. In type S, pain is maximally evoked by sustained pressure.

Unilateral interpretation of pathophysiological mechanisms behind mechanical hyperalgesias,a plural phenomenon, is bound to confuse the literature.

MK-801 BLOCKS THERMAL HYPERALGESIA IN A RAT MODEL OF NEUROPATHIC PAIN. G. Davar*, R. Maciewicz. Pain Physiology Laboratory, Mass General Hospital, Boston, MA 02114

The placement of loose constrictive ligatures around the sciatic nerve in the rat produces thermal hyperalgesia in the ipsilateral paw which begins at 2-3d and peaks at 7-10d. This hyperalgesic response has been proposed as an animal model of neuropathic pain (see Bennett GJ et al, Pain, 33(1988) 87-107), and is associated with changes in structure and function in spinal dorsal horn. These changes could result from neurotoxic damage to dorsal horn neurons produced by excitatory amino-acids (EAAs) released at the primary afferent synapse.

MK-801, a specific glutamate (NMDA) receptor antagonist has protective effects in rodent models of ischemic brain injury, and spinal cord damage. Using the loose ligature model of neuropathic pain, we have administered MK-801 immediately pre-operatively (1.0mg/kg i.p.) and then Q12h (0.5mg/kg) for 9d. Equal numbers of lesioned rats were given normal saline over the same time course. The latency to withdrawal from a thermal stimulus was examined in the ipsilateral and contralateral hindpaw of each animal. A difference score (DS) was calculated by subtracting the averaged latency values for the contralateral paw from the averaged latency values in the ipsilateral paw. Mean positive DSs were obtained in the MK-801 treated animals, while mean negative scores were obtained in the saline controls. A significant absolute difference in the mean DS was observed between the two groups. These data are evidence for a potential protective effect of MK-801 on the development of thermal hyperalgesia following sciatic nerve ligation in the rat. This effect of MK-801 in animals suggests a role for glutamate antagonists in the treatment of human conditions of neuropathic pain.

ANALGESIC EFFECTS OF ANTIBIOTICS ON AN ACUTE (HOT PLATE) AND A CHRONIC (DEAFFERENTATION) ANIMAL MODEL OF PAIN. C. Suaudeau*, R. de Beaurepaire and C. Cimetière* (Spon. E. MacKenzie). Laboratoire de Pharmacol., C.H.U., 14032, Caen, France.

Antibiotics are anti-infective agents not known to have analgesic properties. During previous experiments using the deafferentation animal model of chronic pain we incidentally observed that an antibiotic, chloramphenicol, was able to prevent the self-mutilation behavior observed in this model. We therefore extended the study to other antibiotics and also to an other model of experimental pain, the hot plate test.

In the first experiment (deafferentation) unilateral section of dorsal roots C5 to T1 were performed in rats and changes in the scores of automutilation were recorded after daily subcutaneous injections of four antibiotics (300mg/kg): chloramphenicol, thiophenicol, amoxicillin and doxycycline. Eight animals and eight controls (injected with distilled water) were used for each experimental group. The results show that chloramphenicol and amoxicillin have a significant preventive effect on the self-mutilation behavior, and that thiophenicol and doxycyclin have no significant effect (Student t-test for unmatched pairs). Therefore at least two antibiotics have an effect on this model of phantom limb pain.

In the second experiment 9 antibiotics randomly selected were tested on the constant hot plate test. Testing occured 45 minutes after subcutaneous injection. Eight treated and eight controls were tested in each group. Chloramphenicol and ampicillin have a significant analgesic effect at 100mg/kg (therapeutic dose routinely used in humans) and not at 30mg/kg. Amikacin, amoxicillin, cefaprin, kanamycin and oxacillin have a significant effect with higher doses (300 and/or 600mg/kg). Doxycycline and thiamphenicol have no significant effect at any dose. Therefore, in our experimental conditions, 7 out of 9 antibiotics produce analgesia in rats.

This is to our knowledge the first report of analgesic properties for antibiotics.

188.14

AGE-DEPENDENT CHANGES IN DENSITY AND ORGANIZATION OF CORNEAL FREE NERVE ENDINGS. *R. Beuerman and H. Thompson*. LSU Eye Center, New Orleans, LA 70112*

The thresholds for perception of noxious and non-noxious stimuli in elderly subjects are increased, possibly as a result of neural or perceptual changes that may be caused by peripheral or central alterations in sensory pathways. We used gold impregnation, TEM, and LM to examine quantitatively the corneal innervation in young (2.2-3.2 mos) and old (27.9-30.5 mos) Fischer rats from the NIA. In young rats, the density of the subepithelial plexus was relatively constant from limbus to center (4.1±0.2;±SEM), while in the aged rat, degenerative changes were seen. Aged rats had more axon leashes in the basal epithelial layer (38.6±2.87) than young rats (14.5 ±0-.89;p<0.01). Higher level axon terminal endings were more numerous in young rats (9.5±0.59 vs 5.1±0.30;p<0.01). The terminal endings in the aged rat had greater numbers of neurofilaments. The aged rat stroma showed numerous transformed spindle-shaped keratocytes with extensive rough endoplasmic reticulum. Degenerative changes of the limbal nerves were not prominent, but vacuolation of axonal profiles and occasional myelin figures were seen within the subepithelial plexus. Schwann cell basal lamina was thickened in the plexus and in the limbal nerves. Aging changes of the peripheral nerves may be responsible for the observed psychophysical changes, but additional work must be done to define the central connections. (EY04074)

PRESYNAPTIC MECHANISMS: CALCIUM

189.1

INTERACTION OF ADENOSINE AND CALCIUM ON NEUROMUSCULAR TRANSMISSION. D.F.Wilson* and P.Zhong* (SPON: R.G.Sherman) Zoology Department, Miami Univ., Oxford, OH 45056.

The interactions of adenosine and calcium on spontaneous transmitter release was examined in an attempt to identify the mechanism of action of adenosine on neuromuscular transmission. Intracellular recording techniques were used to monitor miniature end-plate potentials (MEPPs) in the isolated rat diaphragm-phrenic nerve preparation. The preparation was bathed in saline containing 10 mM K^+ to enhance calcium influx and transmitter release. In order to maximize the level of inhibition by adenosine a concentration of 2 mM adenosine was used. The calcium dependence of this inhibition was tested by comparing control vs adenosine preparations in the presence of 0.4, 0.6, 1.0, 2.0, 2.4 , or 4.4 mM calcium chloride. Frequency output increased with calcium increment in the presence or absence of adenosine. In the presence of adenosine the frequency of MEPPs was significantly lower than controls. A double reciprocal plot of calcium concentration vs MEPP frequency demonstrates that adenosine increases the slope of the double reciprocal curve without changing the maximum frequency. These results support the hypothesis that adenosine is a competitive inhibitor of calcium influx. (Supported by NIH grant NS-23195).

189.2

SPIKE BROADENING IN MAMMALIAN NEUROHYPOPHYSIAL NERVE TERMINALS. C.W. Bourque. Center for Research in Neuroscience. Montreal General Hospital and McGill University, Montreal, Quebec. Canada. H3G 1A4.

Increased firing rate and bursting activity strongly potentiate the release of peptides from the axon terminals of mammalian magnocellular neurosecretory cells (MNCs). To examine the mechanism underlying this effect, intraterminal recordings were obtained from the isolated rat neurohypophysis in vitro. Impaled axon terminals were identified by their constant-latency response to neural stalk (NS) stimulation, by collision tests, and by direct injection of Lucifer Yellow. Following NS stimuli or current pulses, the duration of action potentials recorded from each of 54 axon terminals was found to increase with firing frequency, with a maximum near 25 Hz. Removal of Ca^{2+} from the extracellular medium eliminated a shoulder on the repolarizing phase of the spike and abolished its frequency-dependent prolongation. A modulation of Ca^{2+} influx caused by changes in spike width may therefore underlie the effects of discharge rate and bursting activity on peptidergic secretion from MNCs. Supported by F.C.A.R., F.R.S.Q. and the M.R.C. of Canada.

189.3

HIGH FREQUENCY CONTINUOUS STIMULATION IS MORE EFFECTIVE THAN BURSTS FOR EVOKING LHRH RELEASE IN BULLFROG SYMPATHETIC GANGLIA. Y. Peng and J. P. Horn Department of Physiology, University of Pittsburgh, School of Medicine, Pittsburgh, PA 15261.

The preganglionic C input to paravertebral ganglia 9 & 10 co-releases acetylcholine and leuteinizing hormone releasing hormone (LHRH) in response to repetitive stimulation. LHRH produces a slow epsp in B and C postganglionic neurons. These experiements assess whether bursts of stimuli are more effective for evoking peptide release than are continuous stimuli, and whether release is intrinsically dependent upon the stimulus pattern.

LHRH release evoked by stimulation of the preganglionic C pathway was monitored indirectly by measuring the magnitudes of postsynaptic currents (epscs) recorded from ganglionic B and C cells with a single-electrode voltage clamp. Control experiments with teleost and chicken LHRH applied from a puffer pipette showed that the peak amplitude and integral of the postsynaptic current are both saturable sigmoidal functions of puffer pulse duration.

In normal Ca [1.8 mM], the magnitude of the slow epsc increases as the number and frequency of stimuli is increased. The minimal parameters for eliciting a detectable response were 50 stimuli at 0.5 Hz. Continuous stimulation (100 or 200 shocks) at 2Hz always elicits a response. The magnitude of the response saturates near 20 Hz. Bursts of high frequency (e.g. 5, 10, 20 Hz) stimuli elicited responses that were: A) bigger than those produced by continous low frequency stimulation (same mean frequency in each comparison) and B) smaller than those elicited by continuous stimulation at the high frequency used in bursting. Thus high frequency continuous stimulation is more effective than bursting. This implies that inactivation of presynaptic Ca channels does not limit LHRH release during sustained high frequency stimulation at 20 Hz. In 5.4 mM Ca, all frequency-response curves were shifted to the left and the optimal frequency was altered to 5 Hz. The ratio of responses to 20 and 2 Hz was lessened. These results suggest that peptide release does not depend intrinsically upon stimulus frequency but simply on the availability of calcium. Supported by a AHA fellowship(YP) and NIH grant NS21065 (JPH).

189.4

NIFEDIPINE, A L-TYPE CA++ CHANNEL BLOCKER, ENHANCES ACH RELEASE FROM POPULATIONS OF TERMINALS ALSO EXPRESSING SOMATOSTATIN-LIKE IMMUNOREACTIVITY. D.B. Gray, N. Manthay*, and D. Zelazny*. Dept. Physiology & Neurobiology, Univ. of CT, Storrs, CT 06269.

We demonstrated previously that K+-evoked ^{3}H-ACh release from ciliary ganglion nerve terminals on choroid smooth muscle of chick eye is inhibited by the DHP Ca++ channel agonist Bay K 8644 (Gray & Pilar, Soc. Neurosci. Abstr. 14: 646 (1988)). This inhibition may be mediated by release of endogenous somatostatin (SS) since incubation with a SS antagonist, Cyclo (7-aminoheptanoyl-phe-D-trp-lys)BZL (CyCam), reverses the effect of Bay K 8644. However, incubation of choroids with the DHp antagonist nifedipine did not result in either enhancement or inhibition of K+-evoked ACh release in over 3 min, implying that SS was not released in 55mM K+ incubation (without Bay K 8644).

We now report that with increased time resolution in the assay, nifedipine doubles evoked ACh release during the first minute in 55mM K+, followed by a slight depression of release in the next 3 min. Although the nature of this biphasic response is not yet fully understood, the fact that CyCam also enhances release (>25%) specifically in the first minute of high-K+ implies that endogenous SS may be released during this time. Furthermore, Bay K 8644-induced inhibition can be reversed by 10mM nifedipine, providing further evidence that SS release in high-K+ may be mediated by L-type Ca++ channels.

Supported by NIH grants #NS 10338 and #NS 07324.

DEPOLARIZATION ACTIVATED Ca^{++}-CURRENTS AND QUANTAL RELEASE FROM CHICK CILIARY GANGLION NEURONS. D.C. Brosius*, J.T. Hackett and J.B. Tuttle. Depts of Physiol. and Neurosci., Univ of Virginia School of Medicine, Charlottesvl., Va 22908

To record synaptic Ca^{++}-currents, muscle was grown on 1 mm spots of collagen and ciliary ganglion neurons added after myotube formation. Neurons were whole-cell patch clamped with the pipet containing (in mM) 120 CsCl, 20 TEA, 1 $CaCl_2$, 11 EGTA- CsOH, 1 $MgCl_2$, pH 7.4. Standard saline had 5 mM $CaCl_2$, 2.5 mM KCl, 10 mM Glucose and 2 µM TTX. Postsynaptic quanta were recorded using whole cell patch recording from the myotubes. In simultaneous recording from nerve and muscle pairs, four results were obtained: 1) Spontaneous quantal release of < 0.1 sec^{-1}; 2) cells depolarization to between -40 and -60 mV activated maintained quantal transmission; 3) minimum synaptic delay was 1.7 msec when evoked by calcium tail currents, but the delay was highly variable with low voltage command steps; 4) Ca-stimulated release in high K^+ was not blocked by 25 µM Nitrendipine. We conclude that these synaptic Ca^{++} currents may reflect the activity of channels different from the T, N, and L types. Supported by NSF BNS 87-08162 and the Am. Heart Assoc. (Va Affiliate).

189.6

EFFECT OF DIVALENT CATIONS ON CALCIUM-DEPENDENT POTENTIALS ORIGINATING IN LIZARD MOTOR NERVE TERMINALS. K. Morita and E.F. Barrett. Dept. of Physiology and Biophysics, University of Miami School of Medicine, Miami, FL 33101.

In the presence of 10 mM tetraethylammonium (TEA) and 2 mM Ca the action potential recorded intra-axonally near lizard motor terminals is followed by a series of Ca-dependent afterpotentials (depolarizations D1 and D2, followed by a prolonged hyperpolarization (h.a.p)). These afterpotentials could also be evoked when strontium was substituted for bath Ca, but higher [Sr] were needed to achieve afterpotentials comparable to those seen in Ca. Barium (1-2 mM), in the presence or absence of 2 mM Ca, increased the axonal input resistance, increased and prolonged the depolarizing afterpotentials, and reduced the slow h.a.p. In 2 mM Ca, the depolarizing afterpotentials and the slow h.a.p. were completely suppressed by 10 µM cadmium, 100 µM cobalt, 300 µM manganese or nickel, or 1 mM zinc. For most of these Ca antagonists suppression of D1 began at lower concentrations than suppression of D2 or the slow h.a.p., but 30-100 uM zinc suppressed D2 and the slow h.a.p. more effectively than D1. These results suggest that zinc's actions differ from those of other divalent Ca antagonists. These antagonists blocked the end-plate potential recorded in curare (no TEA) in the order cadmium > nickel > zinc. Support: NIH NS 12404.

189.7

TRANSMITTER RELEASE EVOKED BY CALCIUM RELEASED FROM THE PHOTOLABILE CHELATOR DM-NITROPHEN IN CRAYFISH PRESYNAPTIC BOUTONS. R.S. Zucker and R.M. Mulkey. Dept. of Physiology-Anatomy, University of California, Berkeley,CA. 94720.

Approximately 10 mM DM-nitrophen loaded with 30% calcium was injected into the excitatory motor axon of the crayfish opener muscle. Nitrophen diffused to terminals within about 300 microns of the injection site. Variable exposures from a xenon light source (1 - 20 sec), photolyzed 35 to 100% of the nitrophen and gave rise to transmitter release recorded postsynaptically in the muscle fiber. Transmitter release produced a depolarization of 2 - 15 mV depending on the light duration, intensity and amount of nitrophen contained in the terminals. Transmitter release lasted from 10 - 37 sec when terminals were exposed to enough light to completely photolyze nitrophen. The peak miniature excitatory postsynaptic potential frequency ranged from 1800 - 13,000/sec. Presynaptic action potentials given during release of calcium from nitrophen gave facilitated excitatory postsynaptic potentials of 200%. In a zero calcium medium, evoked release was blocked but transmitter release still occurred when internal calcium concentration was increased during nitrophen photolysis. A rise in internal presynaptic calcium due to release from a photolabile chelator results in an increase in miniature excitatory postsynaptic potential frequency and facilitation of transmitter release to a spike. Supported by NIH Grant NS 15114.

TRANSMITTER RELEASE EVOKED BY PRESYNAPTIC CALCIUM RELEASED FROM THE PHOTOLABILE CHELATOR DM-NITROPHEN AT THE SQUID GIANT SYNAPSE. K.R. Delaney and R.S. Zucker. Dept. of Physiology-Anatomy, Univ. of Calif., Berkeley, CA 94720.

About 10 mM of DM-nitrophen loaded 30% with Ca^{2+} was injected into presynaptic terminals of squid giant synapses. A brief intense light flash photolyzed about 20% of the nitrophen and gave rise to transmitter release monitored postsynaptically as an EPSP-like response, reaching an amplitude of up to 14 mV in 2-3 ms and decaying with a time constant of about 15-20 ms to a level about 20% of the peak at 18°C. The transient response is due to both transmitter depletion and reabsorption and re-equilibration of released Ca^{2+} with unphotolyzed nitrophen, as confirmed by fura-2 measurements of free Ca^{2+} in micro-cuvettes containing nitrophen and artificial axoplasm. The postsynaptic response was reversibly blocked by 3 mM kainic acid and was not seen when nitrophen was not loaded with Ca^{2+}. When Ca^{2+} influx was blocked in a zero-Ca^{2+} medium, presynaptic action potentials timed to occur during the release of Ca^{2+} had no effect on the postsynaptic response. Transmitter release began after a 'synaptic delay' that was highly temperature dependent, increasing from 0.5 ms at 22°C. to 4.0 ms at 8.5°C. We have thus dissociated the effects of presynaptic Ca^{2+} from presynaptic potential in eliciting transmitter release, and begun to characterize the process of neurosecretion elicited directly by rapid changes in presynaptic Ca^{2+} concentration. Supported by NIH Grant NS 15114.

CHARACTERIZATION OF CALCIUM CHANNELS IN RAT HIPPOCAMPAL MOSSY FIBER SYNAPTOSOMES. D. Terrian, D. Damron*, R. Gannon and R. Dorman*., USAF School of Aerospace Med., Brooks AFB, TX. 78235.

The inhibitory effects of calcium (Ca^{2+}) antagonists on K^+-evoked dynorphin (Dyn) A (1-8) release and Ca^{2+} entry in rat hippocampal mossy fiber synaptosomes were examined to characterize the pharmacological properties of these presynaptic Ca^{2+} channels and their relative contribution to opioid release. Based on the IC_{50} values calculated for these antagonists, the order of inhibitory potency on 35 mM K^+-evoked Dyn release was: flunarizine and cinnarizine ($< 10^{-5}$ M) > omega-conotoxin and gadolinium ($< 3 \times 10^{-5}$ M) >> nimodipine, nifedipine, verapamil and diltiazem ($> 10^{-4}$ M). Bay K 8644 (10^{-6} M) significantly enhanced (33.1%) K^+-evoked Dyn release. Amiloride and phenytoin had no inhibitory effect. The inhibitory potency of these agents on depolarization-induced Ca^{2+} entry, based on fura-2 measurements, was essentially the same as shown above for Dyn release. These results indicate that presynaptic N-type Ca^{2+} channels make a major contribution to the overall inward Ca^{2+} current that initiates Dyn release and may play a prominent role in excitatory hippocampal mossy fiber synaptic transmission. Supported by AFOSR-2312W3 (DT) and AFOSR- 89-0245 (RD).

CONCENTRATION-DEPENDENCE OF THE EFFECT OF BARIUM ON ENDOGENOUS GLUTAMATE RELEASE FROM RAT BRAIN SYNAPTOSOMES. R.A. Nichols and T.S. Sihra*. The Rockefeller University, New York, NY 10021.

Barium has been previously shown to substitute for calcium in the release of neurotransmitter. There has also been found an elevated resting conductance to Ba^{2+} in most preparations, when compared to Ca^{2+}. We have found that the effect of Ba^{2+} on resting synaptosomes is dependent upon its extracellular concentration. Endogenous glutamate release from rat brain synaptosomes was monitored by a continuous fluorometric assay. At low concentrations of divalent cation ($\leq$ 0.3 mM), Ba^{2+} behaved similarly to Ca^{2+} with respect to both resting and K^+-evoked glutamate release (30 mM K^+). At higher concentrations of Ba^{2+}, resting glutamate release was increased, such that at 1 mM Ba^{2+} the resting release rate was increased over an order of magnitude above the low resting release rate observed in the presence of 1 mM Ca^{2+}. At 3 mM Ba^{2+} the rate of glutamate release approached that obtained upon addition of 30 mM KCl and 1 mM Ca^{2+}. Following several mins of release stimulated by Ba^{2+} at concentrations $\geq$ 1 mM, addition of 30 mM KCl, with or without Ca^{2+} present, to depolarize the synaptosomes had only a small effect on the glutamate release, indicating that the Ba^{2+}-evoked release and the Ca^{2+}-dependent, K^+-evoked release originated from a common glutamate pool. The glutamate release evoked upon simultaneous addition of 30 mM KCl and Ba^{2+} was similar to that observed upon addition of 30 mM KCl and Ca^{2+}. Ba^{2+} had no significant effect on ^{86}Rb efflux, indicating that Ba^{2+} did not appreciably depolarize the synaptosomes. The effect of Ba^{2+} on glutamate release was sensitive to cobalt and cadmium (10 μM each), indicating that Ba^{2+} was largely entering through calcium channels.

OMEGA CONOTOXIN GVIA (ω-CgTx) REDUCES STIMULATED RELEASE OF [^{3}H] DOPAMINE FROM MOUSE STRIATAL SLICES. A. Munoz , J. Fiedler , H.B. Pollard and G. Feuerstein. (SPON.: R.M. STEINMAN) Dept. of Neurology, USUHS and Lab. Cell Biology & Genetics, NIH. Bethesda, MD 20892.

It has been suggested that ω-conotoxin GVIA, a novel peptide toxin, interacts with a neuronal voltage sensitive presynaptic calcium channel (VSCC) that mediates neurotransmiter release. We prepared mouse striatal slices to study the role of ω-CgTx sensitive VSCC in regulating dopamine release in the central nervous system.

Striatal slices of 0.25 mm thickness were loaded with [^{3}H]-dopamine and incubated with 5 μM ω-CgTx for 30 min at 37^{0}C. The release of [^{3}H]-dopamine was determined in the presence of 1 mM Ca^{++}, and the values calculated from the ratio between stimulation for 1 min with 35 mM K^+ (S_2) and spontaneous release in the presence of normal Krebs (S_1) (n = 6). Under these conditions, we observed that ω-CgTx reduced the K^+-evoked [^{3}H]-dopamine release from mouse striatal slices by 20% compared to controls. In the absence of Ca^{++}, no release of [^{3}H]-dopamine was observed in presence and absence of ω-CgTx. These data support the hypothesis that ω-CgTx-sensitive VSCC mediates dopamine release from neural tissue in the presence of Ca^{++}.

189.12

CALCIUM MOBILIZATION IN HIPPOCAMPAL MOSSY FIBER SYNAPTOSOMES: PHOSPHOLIPASE A2 MODULATION. D.S. Damron*, D.M. Terrian and R.V. Dorman* (SPON: P. Morell). Dept. Biological Sciences, Kent State University, Kent, OH 44242.

Hippocampal mossy fiber synaptosomes (0.5 mg protein) were loaded with Fura-2/AM, prior to stimulation with high K^+ buffer (45 mM KCl) in the presence and absence of phospholipase A_2 (PLA_2) modulators. The effects of PLA_2 inhibitors dibucaine and 4-bromophenacyl bromide (BPB) on the K^+-evoked rise of intraterminal free Ca^{2+} were examined. Dibucaine had a dose-dependent inhibitory effect on calcium mobilization, since 1, 10 and 100 uM dibucaine reduced the K^+-induced rise of $[Ca^{2+}]_i$ by 11, 26 and 65%, respectively. A similar effect was seen with BPB, since 50, 100 and 200 uM BPB inhibited the K^+-evoked accumulation of free Ca^{2+} by 19, 36 and 51%, respectively. The PLA_2 activator melittin increased $[Ca^{2+}]_i$, since 88, 380 and 880 nM melittin stimulated increases in $[Ca^{2+}]_i$ of 19, 47 and 81 nmoles, respectively. We suggest that the depolarization-induced accumulation of unesterified fatty acids, in particular arachidonic acid, may play a regulatory role in the mobilization of intraterminal free Ca^{2+} in this nerve terminal preparation. Supported by AFOSR-89-0245.

NEURONAL EXCITABILITY IN LONG-SLEEP (LS) AND SHORT-SLEEP (SS) MICE: *I.* SYNAPTOSOMAL K^+-STIMULATED CA^{2+} UPTAKE. C. C. Duncan, B. C. Jones*, and V. G. Erwin. University of Colorado School of Pharmacy, Boulder, CO., 80309.

The LS and SS lines of mice are genetically selected for their differential sensitivity to hypnotic effects of acute ethanol (EtOH). EtOH is known to inhibit rat brain synaptosomal uptake of calcium and may thus have an effect on stimulus-secretion coupling mechanisms. In this study, tissue from 60-90 day old LS and SS mice was employed to investigated the effect of EtOH (100, 400, 800, & 1600mg%) and barbiturates (diethylbarbital (DB) 75, 150, 300mM and secobarbital (SB) 35, 75, 150mM) on the voltage gated K^+-stimulated Ca^{2+} uptake by synaptosomes. Calcium uptake ($^{45}Ca^{2+}$) was measured at 1 or 3 seconds following synaptosomal exposure to either 4.7, 9.4, 18.8, or 37.6mM K^+ Krebs-Hepes buffer containing $^{45}Ca^{2+}$. Ca^{2+} influx was determined using liquid scintillation counting. In experiments with EtOH or barbiturates, the drug was included in the uptake-stimulating buffer. Synaptosomes from LS and SS mice showed differential sensitivity to K^+ concentration for stimulation of Ca^{2+} uptake with LS tissue being excited at lower concentrations of K^+ than SS. EtOH effectively decreased synaptosomal Ca^{2+} uptake in these lines with greater sensitivity of LS tissue compared to SS at EtOH concentrations of 400 and 800mg% (88 & 177mM). EtOH 100mg% was ineffective in decreasing synaptosomal Ca^{2+} uptake. The barbiturates also decreased Ca^{2+} uptake by this tissue with line-dependent differential sensitivity seen with DB (LS>SS), whereas SB decreased uptake equally in the two lines. These findings suggest that inhibition of voltage gated synaptosomal Ca^{2+} uptake may mediate in part, the hypnotic effects of EtOH and barbiturates. (USPHS AA03527,AA07330)

Ca^{2+} EVOKED PHOSPHORYLATION OF A 43KB PROTEIN IN STRIATAL SYNAPTOSOMES. J. F. Bowyer and N. Weiner. Dept. of Pharm., Univ. Colo. Hlth. Sci. Ctr., 4200 E. 9th Ave, Denver CO 80262.

The exposure of striatal synaptosomes, which have previously been incubated in Ca^{2+} free buffer, to 1.25mM Ca^{2+} can evoke the release of dopamine. Furthermore, this release mimics many aspects of the physiological release of dopamine. In these experiments the effects of 1.25mM Ca^{2+} exposure on the phosphorylation of synaptosomal proteins were investigated in an attempt to correlate phosphorylation changes with release. Synaptosomes were exposed to Ca^{2+}-free ^{32}P-phosphate (0.5mCi/ml) Krebs-Ringer bicarbonate buffer for 30min to label internal ATP stores. Subsequent exposure of the synaptosomes to 1.25-mM Ca^{2+} produced a 64% increase in the phosphorylation of a 43KB protein compared to Ca^{2+} free controls. The phosphorylation of the 43KB protein produced by Ca^{2+} was reduced to a 36% increase relative to control by tetrodotoxin. None of the other proteins between 90 and 40KB showed noticeable increases in phosphorylation from Ca^{2+} exposure at 10 min or less. Although Ca^{2+} exposure increased phosphorylation in a 43KB protein it decreased phosphorylation (to 80% control) in a 40KB band. It is possible that the 40KB protein is pyruvate dehydrogenase which can be dephosphorylated by a Ca^{2+} activated phosphatase. Maximal phosphorylation of the 43KB band appears within 5min. Whether or not the apparent phosphorylation of the 43KB protein plays a role in neurotransmitter release from synaptosomes is under investigation.

4-AMINOPYRIDINE INCREASES B-50 (GAP-43) PHOSPHORYLATION AND CALCIUM LEVELS IN RAT BRAIN SYNAPTOSOMES. F.M.J. Heemskerk*, L.H. Schrama, P.N.E. DeGraan*, W.E.J.M. Ghijsen*+, F.H. Lopes da Silva*+ and W.H. Gispen* (SPON: J. Eichberg). Div. Mol. Neurobiol., Rudolf Magnus Inst., Lab. Physiol. Chem., and Inst. Mol. Biol. & Med. Biotechnol., Univ. of Utrecht, Padualaan 8, 3584 CH Utrecht, +Dept. Zool., Univ. of Amsterdam, Kruislaan 320, 1098 SM, Amsterdam, NL.

The convulsant drug 4-aminopyridine (4-AP) enhances the phosphorylation of the growth-associated phosphoprotein B-50 (GAP-43) as revealed by immunoprecipitation after labeling of hippocampal slices with $^{32}P_i$ (DeGraan et al., J. Neurochem., 52:17, 1989). This effect could be blocked by the protein kinase C (PKC) inhibitor staurosporine. The time and concentration dependency of this phosphorylation effect are closely correlated with the changes in basal [^{3}H]-norepinephrine release from the slices evoked by 4-AP. In order to get more insight in the mechanisms underlying the 4-AP-induced effects, we studied B-50 phosphorylation and Ca^{2+} levels in synaptosomes and compared the effects to those evoked by depolarization with K^+. 4-AP stimulated B-50 phosphorylation within 15 sec in a Ca^{2+}-dependent manner; longer incubations revealed a sustained increase by 4-AP. The enhancement of the intrasynaptosomal Ca^{2+} level by 4-AP, as measured with fura-2, followed a similar time course as the B-50 phosphorylation. Moreover, the effect of 4-AP on Ca^{2+} levels could be inhibited by the sodium channel blocker tetrodotoxin, indicating the involvement of repeated spontaneous depolarizations. Our results indicate that the effects of 4-AP on B-50 phosphorylation are mediated by a Ca^{2+}-dependent activation of PKC through repeated spontaneous depolarizations. These findings further support the involvement of B-50 phosphorylation by PKC in the regulation of neurotransmitter release.

189.16

PROTEIN KINASE C-MEDIATED PHOSPHORYLATION OF THE GROWTH-ASSOCIATED PROTEIN B-50 (GAP-43) IS AN ESSENTIAL STEP IN NOREPINEPHRINE RELEASE. P.N.E. DeGraan*, L.V. Dekker*, D.H.G. Versteeg*, A.B. Oestreicher* and W.H. Gispen* (SPON: A.J. Schecter). Div. Mol. Neurobiol., Rudolf Magnus Inst. and Inst. Mol. Biol. & Med. Biotechnol., Univ. of Utrecht, Padualaan 8, 3584 CH Utrecht, NL.

The neuron-specific protein B-50 (GAP-43) is an endogenous substrate of protein kinase C (PKC) in the membrane of the presynaptic terminal and neuronal growth cones. Based on the close correlation between *in situ* B-50 phosphorylation and neurotransmitter release in hippocampal slices, we have recently suggested a role for PKC-mediated B-50 phosphorylation in neurotransmitter release (Dekker et al., *J. Neurochem.* 52:24, 1989). In the present study we investigated whether B-50 antibodies, which are known to interfere with PKC-mediated B-50 phosphorylation in synaptosomal plasma membranes, affect neurotransmitter release. Antibodies were introduced into rat cortical synaptosomes permeabilized with streptolysin-O, [^{3}H]-norepinephrine (NE) release was induced by increasing the free Ca^{2+} concentration from 10^{-7} to 10^{-5} M. B-50 phosphorylation was measured with [γ-^{32}P]-ATP as phosphate donor. Anti-B-50 IgGs inhibited Ca^{2+}-dependent NE release in a concentration-dependent way, whereas control IgGs and heat-inactivated anti-B-50 IgGs were ineffective. Under identical conditions anti-B-50 IgGs specifically inhibited PKC-mediated B-50 phosphorylation in permeabilized synaptosomes. We conclude that PKC-mediated B-50 phosphorylation plays a crucial role in the molecular mechanism of NE release in a step distal to the Ca^{2+} trigger. Since B-50 is present throughout the brain in regions enriched in synapses, B-50 phosphorylation may be more generally involved in transmitter release. We propose that B-50 plays a role in the mechanism of synaptic vesicle fusion with the plasma membrane during neurotransmitter release and in membrane fusion processes in the growth cone during neurite outgrowth.

PRESYNAPTIC MECHANISMS: FACILITATION AND DEPRESSION

190.1

FOCAL RECORDING OF FACILITATION IN FROG NEUROMUSCULAR JUNCTION. M.I. Glavinovic. Depts. of Anaesthesia Research and Physiology and Biomedical Engineering Unit, McGill University, Montreal, Canada H3G 1Y6.

It is well established that at low levels of release the facilitation is caused by greater quantal content (del Castillo & Katz, J. Physiol. 124, 574, 1954). While same is reasonable to assume at normal levels of release other factors cannot be excluded. Repeated nerve stimulation may lead to release over the areas previously activated, and thus to either greater or lower quantal responses depending on whether postsynaptic potentiation or desensitization predominate. This is an attempt to examine whether such changes do occur. End-plate potentials (EPP's) were recorded focally in cutaneous pectoris frog neuromuscular junctions at room temperature (20-22 C). Release was locally restored by current through the recording electrode which contained 1 M $NaCl$-$CaCl_2$. In all cases examined (11 end-plates) the facilitation was associated with greater quantal content. In majority of cases (7 end-plates) the quantal size of EPP's did not change appreciably, but in 4 cases it increased (5 to 17%). Facilitation was primarily caused by a greater quantal content, with a small contribution of greater quantal size.

190.2

PRESYNAPTIC FACILITATION WITH AND WITHOUT NERVE IMPULSES. A.I. Bain* and D.M.J. Quastel
Dept. of Pharmacology & Therapeutics, Univ. of British Columbia, Vancouver, Canada V6T 1W5

In mouse diaphragm, tetanic nerve stimulation induces a progressive increase in EPP quantal content (*m*), and minEPP frequency (*Fm*). Components of facilitation can be distinguished by time course and by the relation between *m* and *Fm*. An early component (0.1s tau) raises *Fm* and *m* by the same factor, as does a later component, complete at about 30 s. Subsequently, *Fm* rises more than *m*. Only the last phase corresponds to a residual ion (Ca?) model, which accounts for facilitation in the presence of Ba or Sr, at under 10 Hz. All components are insensitive to external Ca. With direct nerve terminal depolarization (tetrodotoxin present) EPPs elicited by brief (~0.7ms) maximally effective pulses, in low Ca, are similar in *m* to EPPs elicited by nerve stimulation. However, only the fast component of tetanic facilitation is normal; the others are virtually absent. Thus, the major components of normal tetanic potentiation are due neither to Ca entry nor to a 'direct' effect of depolarization.

190.3

EFFECT OF INCREASED PRESYNAPTIC CALCIUM BUFFERING CAPACITY ON SHORT-TERM FACILITATION S.N. Duffy*, J.L. Winslow* and M.P. Charlton, Dept. of Physiology, University of Toronto, Toronto, Ontario M5S-1A8.

Evoked neurotransmitter release from excitatory synapses innervating the dactyl opener muscle of the crayfish Procambarus clarkii increases during brief trains of closely spaced stimuli, a property known as short-term facilitation. Facilitated release may result from the summation of incoming Ca ions with residual free Ca ions from prior stimuli. To test this hypothesis, facilitation was evoked under conditions where synaptic Ca buffering capacity was elevated by incorporation of the cell permeant form of the Ca chelator BAPTA. Such treatment, which should buffer the $[Ca]_i$ transients, might be expected to affect the accumulation and disposal of residual free Ca and thus alter facilitation. Although BAPTA produced a significant (60-90%) decrease in transmitter output, the magnitude and duration of facilitation was not significantly affected. These results suggest that short-term facilitation at these terminals is mediated either through a Ca-independent mechanism or by Ca ions which remain bound to some intracellular site. This conclusion is substantiated by the results of a 3-D diffusion model of $Ca+B \rightleftharpoons Ca\text{-}B$ where B is a mobile BAPTA-type buffer.

190.4

EFFECTS OF SODIUM ACCUMULATION IN PRESYNAPTIC BOUTONS OF CRAYFISH ON INTRACELLULAR CALCIUM CONCENTRATION MEASURED WITH FURA-2. R.M. Mulkey and R.S. Zucker. Dept. of Physiology-Anatomy, Univ. of California, Berkeley, CA. 94720.

Published evidence indicates that posttetanic-potentiation (PTP) in invertebrates may be due to internal sodium accumulation that occurs during the tetanic train. It has been proposed that sodium accumulation leads to raised presynaptic calcium through the effects of the Na/Ca exchanger. Recent experiments using Fura-2 have shown a rise in internal calcium during PTP. We used pharmacological methods (veratridine, a plant alkaloid which activates sodium channels and monensin, a sodium ionophore) to raise internal sodium in crayfish presynaptic terminals to determine if sodium accumulation could lead to an increase in internal calcium concentration. Free internal calcium was measured using the fluorescent dye Fura-2. Doses of veratridine (10, 20 & 100 μM) and monensin (1, 10 & 100 μM) in normal medium increased the free calcium from control values of 180 nM to a range of 1 to greater than 5 μM. Veratridine (20 & 100 μM) and monensin (100 μM) in a zero calcium medium with 2 mM EGTA produced a slight increase (100nM) in free internal calcium in the terminals. Upon return of normal medium, the free internal calcium in terminals rose to values in excess of 5 μM. This increase in internal free calcium upon return of normal medium was most likely due to the Na/Ca exchanger. This may be the source of the rise in free internal calcium during PTP. Supported by NIH Grant NS 15114.

190.5

BRADYKININ-EVOKED ACETYLCHOLINE RELEASE VIA INOSITOL TRISPHOSPHATE-DEPENDENT CALCIUM RISE. Haruhiro Higashida[1], Yasuhiro Myojo[1] and Akihiko Ogura[2]. [1]Dep. of Biophys. Kanazawa Univ. Sch. of Med. Kanazawa 920 and [2] Dep. of Neurosci. Mitsubishi Kasei Inst. of Life Sci. Machida 194, Japan.

The mechanism of the bradykinin(BK)-induced increase of acetylcholine was studied in NG108-15 mouse neuroblastoma x rat glioma hybrid cells and their synapses formed onto mouse muscle cells under culture condition. The BK-induced facilitation was observed even if the extracellular medium was changed to a lower Ca^{2+} concentration or Cd^{2+} (0.5-2 mM) added. Ba^{2+} (2-4mM) blocked the membrane hyperpolarization of hybrid cells in response to BK, but still the characteristic facilitation of MEPPs was observed in myotubes. Ionophoretic injection of inositol 1,4,5-trisphosphate (InsP3) into the cytoplasm of an NG108-15 cell briefly evoked MEPPs during the InsP3 -induced hyperpolarizing phase. However, the InsP3 -dependent facilitation was also observed whether or not InsP3 hyperpolized the cell. Real-time quantitative monitoring of the intracellular free Ca^{2+} concentration with fura-2 on a single NG108-15 cell showed that BK induced an elevation of the $[Ca^{2+}]i$ under any conditions mentioned above. These data suggest that the BK-induced initial facilitation results from the inositol 1,4,5-trisphosphate-dependent elevation of residual Ca^{2+}.

190.6

EFFECT OF CALCIUM ON DEPRESSION OF TRANSMITTER RELEASE AT THE FROG NEUROMUSCULAR JUNCTION. M.A. Sosa and J.E. Zengel. Depts. Neurosci./Neurosurg., Univ. of Fla. Coll. of Med. and VA Med. Ctr., Gainesville, FL 32610.

The amount of transmitter released by each nerve impulse varies as a function of previous synaptic activity. Under conditions of normal quantal release, repetitive stimulation leads to a decrease in the transmitter released per impulse. This depression of release has traditionally been attributed to a depletion of available transmitter. Depression could also result from an increase in intra-terminal Ca^{2+}, which could decrease release, perhaps by inducing a Ca-dependent inactivation of voltage-dependent Ca channels.

The purpose of this study was to describe depression in a quantitative manner and to examine the role of Ca^{2+} in the mechanism(s) underlying depression. End-plate potentials (EPPs) were recorded extracellularly from curarized frog (*Rana pipiens*) sartorius muscle in the presence of 1.8-7.2 mM Ca^{2+}. Typically, the nerve was conditioned with trains of 200 impulses at 20 imp./sec.

We observed what appear to be at least two phases of depression, an initial rapidly developing phase which reaches a maximum during the first sec of stimulation, followed by a second phase which develops more slowly during the remainder of the train. Increasing Ca^{2+} increased the magnitude and decreased the time course of both phases; this effect was more marked for the first phase. Addition of the Ca channel blocker Cd^{2+} increased the magnitude and decreased the time course of the first phase, while having the opposite effect on both parameters of the second phase.

These data suggest that there may be more than one mechanism underlying depression at the frog neuromuscular junction.

190.7

PROTEIN KINASE INHIBITORS AFFECT MOBILIZATION OF NEUTROTRANSMITTER IN MOTOR NERVE TERMINALS. W F Dryden and I G Marshall*, Dept. Pharmacology, Univ. Alberta, Edmonton, Alta, Canada, and Dept. Physiology and Pharmacology, Univ. Strathclyde, Glasgow, Scotland, U.K.

At least one component of neurotransmitter mobilization involves the transfer of quanta from secondary stores to the immediately available store within the nerve terminal. This may involve augmentation and/or potentiation, and require a phosphorylation step (Silinsky, Pharmacol Rev 37:81, 1985). To test this possibility, the depression of EPP amplitude during repetitive stimulation, and the recovery following a conditioning pulse were investigated in presynaptically blocked mouse phrenic nerve diaphragm preparations following incubation with a series of naphthalenesulfonamide protein kinase inhibitors (Inagaki et al. Mol Pharmacol 29:577, 1986).

Following 30-60 min incubation with 50 μM H-7 or 10 μM A-3 and in the presence of 0.3 μM alcuronium and 200 μM troxypyrrolium, rundown of EPP was enhanced at low frequencies, and at higher frequencies (30 - 50 Hz) failed intermittently or completely. In paired pulse experiments, recovery of EPP amplitude was delayed from 3 sec to > 5 sec. No such effects were seen following incubation with 10 μM W-7. At the concentrations used, H-7 and A-3 share specificity for only cyclic nucleotide dependent protein kinases indicating a phosphorylation step in the maintenance of transmitter release during repetitive stimulation.

HUMAN BEHAVIORAL NEUROBIOLOGY: EVENT RELATED POTENTIALS

191.1

MIDLATENCY AUDITORY EVOKED RESPONSES: COMPONENT ISOLATION AND TOPOGRAPHY. R.J.Erwin,M.Mawhinney-Hee* and R.C.Gur*. Dept. of Psychiatry,Univ. of Penn.,Philadelphia, PA 19104.

Evidence from both the human and cat model suggests that the P1 (50-65 msec latency) component of the midlatency auditory evoked response (MLR) is generated by the midbrain reticular activating system (Erwin and Buchwald, EEG suppl., 40:461, 1987). Other studies suggest that P1 is generated in temporal lobe (e.g., Reite et al., EEG, 70:490, 1988). To address this issue, the topographic distribution of the MLR component P1 was examined using a recovery cycle protocol.

MLRs were recorded from 20 normal adults in response to binaural clicks (.1ms, 50 db HL) presented at 3 rates: 1/sec, 5/sec and 10/sec. Recordings were from 19 scalp sites referenced to linked mandibles. MLR components were isolated using principal components analysis. Scalp distributions for each component and rate were examined by plotting factor scores on topological grids.

The distribution of P1 was characterized by a central maxima at the 1/sec rate and no distinct minima although amplitudes were lower over temporal regions. At faster rates of stimulation, the central positivity decreased and distinct frontal maxima and temporal minima were observed.

These findings indicate that separate MLR components, distinguished both by topography and parametric manipulations, exist at the P1 latency and could account for the conflicting reports regarding the P1 generator substrate.

191.2

NOVEL SOMATOSENSORY STIMULI GENERATE P3a EVENT-RELATED POTENTIALS S.Yamaguchi* and R.T.Knight (SPON:I.Kwee) Dept. of Neurology, Univ. of California, Davis, VAMC, Martinez, CA 94553

We recorded somatosensory event-related potentials (ERPs) to target and task-irrelevant novel stimuli. ERPs were recorded from twelve normal subjects in a somatosensory discrimination task. Subjects pressed a button to mechanical taps of the fifth finger (targets, P=.12), randomly interposed in sequences of taps to the second finger (standards, P=.76). Two infrequent novel stimuli were delivered; one was a mechanical tap to the third or fourth finger (tactile novels, P=.06), another was an electric shock at the wrist (shock novels, P=.06). Correctly detected targets generated a parietal maximal P300 (P3b, 19uV at Pz). Shock novels generated a central maximal P300 (P3a, 26uV at Cz). Tactile novels also generated a P3a with a scalp distribution comparable to the shock novels (12uV at Cz). P3a scalp topographies evoked by shock and tactile novels were different from the target P3b ($p<0.001$) although there was no significant latency difference between the P3b and P3a. Unlike the P3b, P3a amplitude to the shock novels habituated by 17% from the initial to the fifth shock. These results indicate that similar to the auditory and visual modality, task-irrelevant novel somatosensory stimuli generate a P3a ERP that may have independent intracranial generators from the P3b. Supported by NIH grant NS 21135.

191.3

EVENT RELATED POTENTIAL (ERP) ASYMMETRIES IN A DICHOTIC COMPLEX TONE TEST (CTT). C.E. Tenke, G.E. Bruder*, J.J. Sidtis, J.Towey*, H. Erhan*, M. Voglmaier*. Dept. of Psychophysiol., N.Y.S. Psych. Inst., N.Y., N.Y. 10032

The CTT is a nonverbal dichotic listening task that typically yields a behavioral left ear advantage in normal adults (Sidtis, 1981). Findings from neurological patients suggest a right hemisphere dominance for complex tone perception. The present study was conducted to provide a physiological measure of brain laterality by determining the form of ERP asymmetries produced by square wave complex tones during the CTT. ERPs of 10 right handed Ss with normal hearing were recorded from 12 scalp electrodes at midline and lateral locations, with a nose reference. EOGs were recorded for artifact rejection and eye movement correction. The following ERPs were evident: (1) a paired N100-P200 with frontocentral maximum; (2) a late positive complex with parietal maximum; and (3) a frontal negative and parietal positive slow wave. Preliminary analyses showed the following ERP asymmetries: (1) at frontal electrodes, there was significantly greater negativity over the right hemisphere than the left, which started at 80 msec poststimulus and peaked at 210 msec; (2) at central electrodes, there was a significant attenuation of P200 over the right hemisphere; (3) at parietal electrodes, there was an enhancement of the late positive complex over the right hemisphere in Ss with the largest left ear advantage. These results suggest lateralization at multiple stages of information processing. (Supported by NIMH grant MH36295).

LOCALIZATION AND TEMPORAL ACTIVITY FUNCTIONS OF BRAIN SOURCES OF THE HUMAN VISUAL ERP. G.V. Simpson, M. Scherg*, W. Ritter*, and H.G. Vaughan, Jr., Depts. of Neurology and Neuroscience, Albert Einstein College of Medicine, Bronx, New York 10461.

Characterization of the brain sources of human event related potentials (ERP) will increase our understanding of the brain processes in perception and cognition. This study examined the sources of human visual ERP using Scherg's method of Brain Electric Source Analysis (BESA), which yields a solution consisting of multiple dipole sources having stationary locations and orientations and time varying dipole strengths. The coordinates of the dipole sources in the spherical head model were then mapped onto the MRI of each subject's brain. This allowed visualization of the brain regions modelled by each of the equivalent-dipole sources. BESA also yields the amplitude function over time for each source (source waveform), thereby providing a real-time description of the activity pattern of each brain area represented by the dipole sources. The results showed multiple sources with sequential and overlapping activation. Localization of these sources in the MRI's indicated that the visual ERP was generated by the sequential and overlapping activation of multiple visual cortical areas consistent with the flow of cortical activation from striate to parietal and inferotemporal cortex, expected from primate vision research.

THE EFFECTS OF PRACTICE ON REACTION TIME AND P3 LATENCY IN A STIMULUS-RESPONSE INCOMPATIBILITY TASK. C. A. Christensen. Department of Psychology, Vassar College, Poughkeepsie, NY 12601.

Stimulus-response (S-R) incompatibility tasks have frequently been used to assess the functional significance of the P3 component of the ERP. In an earlier investigation (Pfefferbaum, et al., Electroencephal. clin Neurophysiol., 1986, 64: 424-437) we tested several S-R incompatibility tasks and observed that P3 latency was prolonged by incompatibility in some but not all tasks. We speculated that the effect is observed when speeded responding occurs in tasks that predispose to parallel stimulus and response processing, as when Ss are well practiced, for example. To evaluate this predicition 14 Ss were tested on a task in which others have failed to observe an S-R incompatibility effect on P3 latency. Ss saw an instruction stimulus (SAME or OPPOSITE) followed by an action stimulus (RIGHT or LEFT). Ss responded to the action stimulus by pressing the right or left of two response keys, depending on the instruction for that trial. Ss were tested for 10 blocks of 60 trials each. The EEG was recorded from Fz, Cz and Pz referenced to linked mastoids. Reaction times for both S-R compatible and incompatible trials diminished significantly across blocks showing a robust practice effect. P3 latencies at Pz were equivalent for compatible and incompatible trials for Block 1 but were significantly prolonged on incompatible trials by Block 10. The results indicate that P3 cannot reflect the duration of stimulus evaluation processes alone, as others suggest. In some instances, as when Ss are well practiced, it also reflects the duration of processes related to response initiation and execution.

FRONTAL LOBE CONTRIBUTIONS TO THE HUMAN AUDITORY P3a D. Scabini*, R.T. Knight and D.L. Woods, Neurology Dept., Univ. of California Davis, V.A.M.C., 150 Muir Rd., Martinez, Ca 94553

Novel auditory, visual and somatosensory stimuli generate a P300 (P3a) response which is maximal at fronto-central scalp sites. We investigated the contribution of human dorsolateral prefrontal cortex (PFCx) to P3a generation by recording event related potentials (ERPs) in an auditory discrimination task in controls (n=17) and in patients with unilateral PFCx lesions (n=13, left=8, right=5). Subjects were instructed to press a button to target tone pips (1.5Khz, 10% probability) randomly presented in a train of frequent tones (1Khz, 80% probability). P3a potentials were generated by delivery of task-irrelevant computer and environmental sounds (novels, 10% probability). In controls, the novel stimuli generated a P3a that was maximal at fronto-central scalp sites. The P3a was reduced in amplitude in the PFCx group at recording sites over lesioned hemisphere ($p<0.002$). The P3a reduction was maximal over lesioned right PFCx (Control, F3=9.45uv F4=9.45uv; right PFCx, F3=8.86uv F4=4.59uv; left PFCx, F3=6.86uv F4=8.00uv $p<0.001$). These data support PFCx involvement in generation of the scalp recorded auditory P3a. The results also indicate that PFCx may be asymmetrically organized for novelty detection. Intracerebral distribution of human late potentials associated with target, novel and missing auditory stimuli. C.Alain*, F.Richer, A.Achim*& J.M.Saint-Hilaire*. Neurology dept., Notre-Dame Hospital, Montreal, Canada.

We have recorded late auditory potentials from lateral and medial regions in the frontal, temporal and parietal lobes of 14 patients with temporal lobe epilepsy implanted with depth electrodes. Tone sequences were presented in three tasks: 1) auditory target detection, 2) target detection with interspersed novel stimuli, and 3) detection of targets and stimulus omissions. Frontal and parietal intracerebral responses to target tones showed a triphasic complex with peak latencies of about N200, P270 and N360 ms. The latency of the positive peak was similar to that of scalp N2. Temporal responses had a positive potential at 300 ms which could be accompagnied by a negative peak at 200 ms or at 420 ms. The potentials evoked by novel stimuli had shorter latencies than those elicited by target tones. The respones in the frontal and parietal lobes were attenuated or absent during stimulus omissions. The results support the multiple generator hypothesis of late potentials and suggest that some potentials are stimulus driven and others not.

191.8

EVENT-RELATED POTENTIALS FOR COMPLEX FORMS: EFFECTS OF MENTAL ROTATION. D.S. O'Leary and D.L. Johnson*. Psychology Department, Univ. of Health Sciences/Chicago Medical Sch., North Chicago, IL 60064.

This study investigated differences in event-related potentials (ERPs) elicited by 16-sided random visual forms during passive viewing and mental rotation conditions. Subjects were 45 right-handed adult males. ERPs recorded from left and right hemisphere parietal leads (P3 and P4) showed significant task-related differences in a series of components beginning with a negativity at about 160 ms and persisting until a positivity at about 375 ms post-stimulus onset. Latencies were significantly shorter for P245 and N300 components during the rotation condition and significant increases in amplitude occurred for N160 and P375. The P245 component was of smaller amplitude in the rotation condition. A late negative-positive complex, seen only in the rotation condition, was of significantly shorter latency over the right hemisphere. Other hemispheric effects were seen (shorter latency and higher amplitude at P4 than at P3), but were of smaller magnitude than reported in a previous study.

191.9

IS THE MISMATCH NEGATIVITY WAVE OF THE HUMAN AUDITORY ERP INDEPENDENT OF ATTENTION?

M.Woldorff*(1), S.A.Hackley*(2), and S.A.Hillyard(1). Dept. of Neurosciences, Univ. of Calif. at San Diego, La Jolla, CA 92093 (1) and Dept. of Psychology, Univ. of Missouri, Columbia, MO 65211 (2).

In the auditory modality, an infrequent, physically deviant stimulus in a sequence of repetitive "standard" stimuli elicits a negative event-related brain potential, termed the mismatch negativity (MMN). The MMN usually onsets around 100 msec after stimulus onset and peaks around 200 msec. Naatanen and associates have asserted that the MMN is unaffected by attention and reflects the operation of a strongly automatic mismatch detection process. This effect has been cited as evidence that the physical characteristics of stimuli are fully processed even when unattended.

Two dichotic listening experiments were designed to optimize the selective focussing of attention and the engagement of early stimulus selection. These conditions included 1) easily discriminable channels of tone pips distinguished by both frequency and ear of entry, 2) a rapid rate of stimulus presentation, and 3) a difficult target detection task for the attended channel that entailed responding to infrequent, slightly-fainter deviant tones. The first of these experiments, using interstimulus intervals (ISIs) of 120-320 msec and standard tone intensity of 55 dB SL, revealed a very early differentiation (ca. 20 msec) between the ERPs to the attended and unattended standard stimuli, indicating that attention was indeed highly focussed. The deviant tones elicited negative waves that onset just after 100 msec, peaked at around 200 msec, had frontal-central maxima on the scalp, and were larger contralaterally at central sites. However, in sharp contrast to previous reports by Naatanen's group, the negativity to unattended-channel deviants was drastically reduced (less than 1 uV) relative to the corresponding wave to attended-channel deviants (3-4 uV). The second experiment used shorter ISIs (65-205 msec) and louder tones (standard intensity 90 dB SL), with deviants again being occasional intensity decrements. Under these conditions, the MMN to unattended deviants was barely discernible, whereas the corresponding negative wave to the attended-channel deviants was clearly evident.

The present findings are at odds with the assertion that the MMN is independent of attentional influence, as well as with predictions that its amplitude should increase at short ISIs. The functional significance of this ERP component needs further examination.

191.10

GENERATORS OF THE NEUROMAGNETIC P3: J.D. Lewine, S.B.W. Roeder*, M.T. Oakley, D.L. Arthur, C.J. Aine, J.S. George and E.R. Flynn, P-6, Mailstop M715, Los Alamos National Laboratory, Los Alamos, N.M., 87545.

Neuromagnetic and neuroelectric measurements were obtained from nine subjects performing auditory and visual detection tasks. For these tasks, subjects had to count the number of times a target stimulus occurred within a sequence of target and non-target stimuli (auditory - 1000 vs 3000 hz tones : visual - horizontal vs vertical gratings). During half of the test blocks the target occurred with a probability of 80%, while during the remaining blocks it occurred with a probability of 20%. Electric potential data recorded at midline sites (referenced to linked ear lobes) revealed the expected, positive P3 complex when the target probability was 20%. In the auditory modality the peak-latency of the P3 was about 300 msec. In the visual modality the peak-latency was about 400 msec. Neuromagnetic recordings made with a 7-channel, 2nd-order squid gradiometer system revealed neuromagnetic correlates of the electrical P3 complex. Isofield maps constructed from data obtained at more than 16 dewar positions per subject suggest that the neural generators of the auditory and visual magnetic P3 are spatially distinct, and located within the temporal lobe (possibly within the hippocampus). Although the extent to which the generators of the magnetic P3 contribute to the electrical P3 remains to be determined, the data suggest that the magnetic P3 may prove to be a useful, non-invasive index of the functional integrity of the temporal lobe.

191.11

MONKEY P300-LIKE POTENTIALS IN A VISUAL PARADIGM: A ROLE FOR THE LOCUS COERULEUS-NORADRENERGIC SYSTEM? J. A. Pineda, D. Swick, and S.L. Foote, Depts. of Neuroscience and Psychiatry, UCSD, La Jolla, CA 92093 and Scripps Clinic and Research Foundation, La Jolla, CA 92037.

The similarities among human P300 potentials elicited in response to auditory, visual, or somatosensory stimulation suggest the existence of a common mechanism responsive to all sensory modalities. However, its neural substrates cannot be systematically investigated since the modality non-specific nature of P300 has not been extensively studied in animals, particularly non-human primates. A number of investigations have shown that monkeys exhibit auditory P300-like potentials similar to those recorded in human (Arthur and Starr, 1984; Paller et al., 1988; Pineda et al., 1987; 1988). To determine whether monkeys exhibit similar potentials in another sensory modality, visual evoked potentials (VEPs) were recorded from squirrel monkeys (Saimiri sciureus) using chronically implanted epidural electrodes. The results indicate that visually elicited monkey potentials resemble those reported for human P300s. Their sensitivity to stimulus probability and to trial-to-trial changes in stimulus sequence also resemble monkey auditory P300s. Additionally, since previous studies have suggested that the integrity of the locus coeruleus-noradrenergic system is critical for the production of auditory P300-like potentials (Pineda et al., 1989), the role of this system in generating or modulating VEPs was analyzed. VEPs were recorded before and after electrolytic lesions of the nucleus and before and after systemic administrations of the alpha-2 adrenergic agonist clonidine. P300-like potentials were substantially affected by the lesions, while drugs had less of an effect. The results support the hypothesis that monkey P300-like potentials reflect the activity of a modality non-specific mechanism and that the LC-NA may play such a role.

191.12

DISSOCIATION OF EARLY ATTENTION SENSITIVE ERP COMPONENTS DURING VISUAL-SPATIAL SELECTION.

G.R. Mangun(1), H.J. Heinze*(2) & S.A. Hillyard(1), University of California, San Diego, USA (1) & Medical School of Hannover, FRG (2)

Recent evidence suggests that the attentional modulations of the occipital P1 and N1 peaks of the visual event-related potential (ERP) during spatial selection may reflect functionally distinct processes; the P1 effect reflecting sensory pathway facilitation and the N1 effect indicating an orienting or "switching" of attention to stimuli at attended locations. To test the switching idea, we recorded ERPs from subjects attending a rapid sequence of bilaterally flashed letter pairs that were unpredictably followed by a unilateral pair appearing in either visual field. In one condition, subjects attended the letters pairs in one visual field (maintaining central fixation) and ignored all stimuli in the unattended field. The task was to determine whether the attended-side unilateral letters matched those in the attended field of the preceding bilateral array. In a second condition, the task was to determine whether the unilateral letters on either the attended or unattended sides matched those in the attended field of the preceding bilateral array. Thus, the occurrence of a unilateral stimulus in the unattended visual field required the subjects to switch their attention rapidly from the attended to the unattended field to detect target letter matches. If the N1 enhancement to attended-field stimuli reflects the switching of attention to an attended-location event, then one would expect an enlarged N1 component to unilateral stimuli on the "unattended" side that triggered a switch of attention.

ERPs to the bilateral stimuli displayed P1 components of enhanced amplitude when subjects attended the visual field contralateral to the recorded hemisphere. The ERPs to unilateral stimuli contained a broad positive deflection from 90-200 msec post-stimulus when in the attended versus unattended field. The early phase of this positivity coincided with the occipital P1 component and the later portion overlapped the N1 latency range. These attention effects were not significantly different as a function of whether or not subjects were required to ignore, or instead to switch to unilateral stimuli in the unattended visual field. These data support the idea that the P1 attention effect represents a facilitation of early visual inputs and question the generality of the proposal that the occipital N1 effect is an index of attentional switching.

EVENT-RELATED POTENTIALS RECORDED FROM SCALP AND HIPPOCAMPAL FORMATION IN HUMANS PERFORMING DETECTION TASKS. T. Scott, G. McCarthy, K.A. Paller, and C.C. Wood. VA Medical Center, West Haven, CT and Yale University, New Haven, CT 06516.

P300 is an event-related potential (ERP) thought to reflect neural activity associated with cognitive processing. In the *oddball* paradigm, P300 is elicited by target stimuli occurring in a random sequence with non-target stimuli. In this task, the amplitude of P300 is inversely proportional to the probability of the target. However, the relative contribution of event probability (Duncan-Johnson & Donchin, 1977) and temporal interval (Fitzgerald & Picton, 1981) in determining P300 amplitude is unclear, due to the confound between target probability and the temporal interval between successive targets. To examine the relative roles of probability and temporal interval on P300 amplitude and topography, we compared a condition in which target tones (p=.2) were presented in a random sequence with non-target tones to a condition in which identical targets were presented at the same intervals but with non-targets omitted. Based on recordings from 32 scalp locations, P300s in the two conditions were similar in amplitude and in scalp topography. These same two conditions were compared in recordings from electrodes implanted in the hippocampus and adjacent medial temporal lobe areas in a group of epileptic patients. Targets from both conditions elicited large negative ERPs with sharp spatial gradients in the region of the hippocampus. These results suggest that apparent probability effects observed for scalp P300 and related ERPs in the hippocampus may be due primarily to the temporal interval between task-relevant events. Furthermore, these results demonstrate additional task-dependent relationships between scalp-recorded P300 and ERPs elicited in the hippocampus.

Auditory Evoked Potential Asymmetry and Patterns of Human Abilities, in Normal and Disabled Readers. D.W. Shucard, K.R. Cummins*, J.L. Shucard*, Dept of Neurology, SUNY at Buffalo, School of Medicine and Biomedical Sciences, 100 High Street (D-6), Buffalo NY 14203.

The purpose of this investigation was to examine the relationship between electrophysiological measures of hemispheric asymmetry and spatial and sequential abilities in normal and disabled readers. In a sample of 90 normal and 90 disabled readers, spatial and sequential ability scores were derived from the Wechsler Intelligence Scale for Children-Revised (WISC-R) subtests according to Bannatyne's reclassification system. Subjects were categorized according to the difference between their spatial and sequential ability scores. These scores were then compared with auditory evoked potential (AEP) amplitude asymmetry measures obtained to probe stimuli while the subjects were processing visual sequential information related to language.

The findings indicated that the normal and disabled readers who had the higher spatial-sequential difference scores (spatial-sequential >10.00) also had higher left than right hemisphere AEP Peak amplitudes. In the lower spatial-sequential difference group (spatial-sequential < 10.00), this pattern of AEP amplitude asymmetry was present only for the reading disabled subjects. The normal readers showed an opposite pattern of asymmetry with higher right than left hemisphere AEP amplitude.

These findings suggest a lack of flexibility in cognitive responsivity in the disabled readers as reflected in the consistent pattern of cerebral asymmetry obtained in disabled readers both for higher and lower spatial-sequential difference groups. Electrophysiological patterns of asymmetry obtained during cognitive tasks may be sensitive to the functional organization of the brain and may aid in our understanding of the relationship between human abilities and brain processes. Supported in part by NICHD Grant HD11681.

SYMPOSIUM. OPTICAL IMAGING OF CNS DEVELOPMENT, ORGANIZATION AND FUNCTION. *A. Grinvald, IBM, The Rockefeller Univ. & Weizmann Inst. (Chairperson); W.N.Ross, N.Y. Med. College; J.A. Connor, Roche Inst. of Mol. Biol.; L.B. Cohen, Yale Univ.; G.G. Blasdel, Harvard Univ.*

Optical imaging techniques have begun to provide new information about the development, organization and function of the nervous system, at levels ranging from single growth cones to the living mammalian brain. These imaging techniques employ a fast diode array (Ross, Cohen, Grinvald) or slower imaging devices offering a much higher spatial resolution (CCD: Connor, Ross, Grinvald; Video: Blasdel). The imaging is based on the use of specific molecular probes for calcium (Ross, Connor), and membrane potential (Cohen, Ross Grinvald), as well as changes in intrinsic optical properties of brain tissue resulting from electrical activity (Grinvald).

Ross will discuss high time-resolution measurements of activity-dependent calcium changes in neurons, focusing on the spatial distribution of the conductance changes that cause them and how they can indicate the spread of membrane potential changes in a cell (in cerebellar Purkinje cells in slices and in invertebrate neurons). **Connor** will focus on high spatial-resolution measurements of the distribution of calcium channels in developing neurons, the effects of excitatory amino acids on intracellular calcium in the dendrites and the soma of acutely isolated CA1 neurons, and the distribution of calcium transients during spontaneous and driven electrical activity in Purkinje cells and CA1 neurons in slices. **Cohen** will present measurements of action potential activity in a substantial fraction of the neurons in the *Aplysia* abdominal ganglion. Measurements during the gill withdrawal reflex indicated that a light touch to the siphon skin activated approximately 300 neurons, suggesting that the neuronal basis of this reflex may be very complex. **Grinvald** will discuss the functional architecture of Macaque V1 & V2 revealed by high resolution imaging based on reflection measurements without dyes. Dynamic patterns in cortical cell assemblies revealed with the aid of dyes will also be presented. The relative merits and limitations of the two methodologies will be discussed. **Blasdel** will describe the functional organization of monkey V1 revealed by high resolution video technology, allowing the visualization of many different activity patterns, in a single patch of cortex. Their analysis reveals an unexpected degree of lateral organization, one characterized by at least two fundamental subpatterns, in which response properties of neurons may correlate with separate perceptual functions.

194

SYMPOSIUM. RECENT ADVANCES IN THE BIOLOGY OF AFFECTIVE DISORDERS. C.B. Nemeroff, Duke Univ. Med. Ctr. (Chairperson); S.Z. Langer, LERS; J. Egeland*, Univ. Miami; J.M. Weiss, Duke Univ. Med. Ctr.; F. Sulser, Vanderbilt Univ.

In the past decade, considerable progress has been made in the biology of the most severe forms of affective (mood) illness, unipolar depression and manic-depressive (bipolar) disorders. In this symposium the neuroendocrinology, neurochemistry, and molecular genetics of affective disorders will be reviewed as well as the preclinical literature on behavioral and neuropharmacological approaches to the study of these disorders. Specifically Nemeroff will review the now well-documented neuroendocrine alterations that occur in drug-free depressed patients concentrating on the hypothalamic-pituitary-adrenal axis and growth hormone responses to provocative stimuli such as clonidine, an α_2-adrenergic agonist. Langer will describe neurochemical studies that demonstrate alterations in serotonergic and catecholaminergic neurotransmission in depression. Egeland will review studies using modern techniques of molecular genetics to identify the loci of genetic vulnerability to these devastating psychiatric diseases. Weiss will discuss the available animal models of depression and mania and critically assess their validity. Sulser will discuss preclinical neuropharmacological strategies to elucidate the mechanisms by which tricyclic antidepressants exert their therapeutic effects.

EXCITATORY AMINO ACIDS: EXCITOTOXICITY I

195.1

GANGLIOSIDES EXERT A GLUTAMATE RECEPTOR ABUSE DEPENDENT ANTAGONISM (RADA). M. Favaron*, H. Manev, A. Guidotti, and E. Costa. FGIN, 3900 Reservoir Rd., Washington, DC, 20007

In primary cultures of rat cortical or cerebellar neurones the persistent overstimulation ("abuse") of glutamate receptors leads to neuronal death. Natural gangliosides prevent glutamate-induced neuronal death without affecting the immediate physiological responses elicited by glutamate receptor stimulation. Hence, their action could be defined as Receptor Abuse Dependent Antagonism (RADA). Structural changes in the molecule of gangliosides (GM1) resulted in semisynthetic derivatives (PKS and LIGA), which are more potent RADA agents than the parent natural compound. Unlike GM1, the PKS and LIGA derivatives lack the amide-linked fatty acid tail of the ceramide structure. If the NH_2 group is left free (as in LysoGM1), the compound possess cytolytic activity and therefore no protective action. However, blockade of the free NH_2 group resulted in compounds (PKS 3, LIGA 4 and 20) with decreased cytotoxicity and a potent protective (RADA) effect against glutamate-induced neuronal death. The rank order of RADA potency is LIGA 4≥, LIGA 20>PKS 3 >GM1 (EC50 = LIGA 4 and 20, 5uM; PKS 3, 30uM; GM1, 55uM). The semisynthetic compounds act faster than natural ganglioside (10 min preincubation for PKS 3 and no preincubation required for LIGA 4 and 20, vs. 60-120 min for GM1). Moreover, the protective effects of LIGA 4 and 20 last longer than those of GM1. Since these compounds do not affect the electrophysiological responses and the stimulation of c-fos mRNA expression triggered by stimulation of glutamate receptors they may be considered a new class of RADA effectors with improved onset and duration of action.

195.2

ROLE OF DELAYED CA++ INFLUX AND PROTEIN KINASE C (PKC) TRANSLOCATION IN GLUTAMATE-INDUCED NEURONAL DEATH. H.Manev, M.Favaron*, G.Brooker, A.Guidotti and E.Costa. FIDIA-Georgetown Institute for Neurosciences; Dept. Biochemistry and Molecular Biology ; Georgetown University, Washington, DC, 20007.

We studied the mechanism of delayed glutamate-induced (50 uM, 15 min, no Mg++) neuronal death using primary cultures of rat cerebellar granule cells. In the interval between the end of glutamate receptor stimulation and the onset of neuronal death (post-glutamate period; PGP) neurotoxic concentrations of glutamate induced a sustained increase of: a) 45Ca++ uptake; b) intracellular Ca++ levels assayed by microscopic fluorimetric (fura 2) technique accompanied by "Attofluor" image analysis; c) PKC translocation measured by 3H-phorbol ester binding. These changes were insensitive to PGP treatment with blockers of glutamate receptor or voltage-dependent Ca++ channel, but were reverted by the removal for 60 min of extracellular Ca++. This Ca++ removal rescued from death about 70% neurons. Pretreatment with ganglioside GT1b failed to reduce the Ca++ influx during glutamate receptor stimulation, but prevented the successive increases in Ca++ levels, PKC translocation and neurotoxicity. Protection was also obtained by 24 h treatment with 100 nM phorbol 12-myristate 13-acetate which led to a large depletion of 80 kDa type II PKC isoenzyme. The activation of PKC following glutamate receptor stimulation may play a role in maintaining the elevation of intracellular Ca++ levels in PGP which activate enzymatic processes leading to neuronal death.

195.3

FREE RADICAL SCAVENGERS REDUCE EXCITATORY AMINO ACID RELEASE INDUCED BY SIMULATED ISCHEMIA. D.E. Pellegrini-Giampietro*, G. Cherici*, V. Carla'* and F. Moroni. Dept. of Pharmacology, Univ. of Florence, Italy.

The excitatory amino acids aspartate (Asp) and glutamate (Glu) are released in excessive amounts following hypoxic or ischemic injuries to the brain (Rothman, S.R. & Olney, J.W., *Ann. Neurol.*, 19: 105, 1986). Another possible pathogenetic event leading to ischemic neuronal damage appears to be the formation of toxic free radicals (Raichle, M.E., *Ann. Neurol.*, 13: 2, 1983). This prompted us to study whether there is a link between these two events.

The release of endogenous Asp and Glu (detected by HPLC) was studied from male Wistar rat hippocampal slices studied in an *in vitro* model of ischemia. The simulated pathology was achieved by incubating the slices, after electrophysiological viability control (Corradetti R. et al., *J. Neurochem.*, 41: 1518, 1983), for 10 min in a glucose-free Krebs-bicarbonate solution saturated with N_2 95% / CO_2 5%. This treatment induced an increased release of both Asp and Glu (14- and 20-fold respectively versus basal release). No release of the cytoplasmic enzyme LDH was detected. When the "ischemic" slices were exposed to compounds able to "scavange" free radicals such as mannitol (1 mM), catalase (50 µg/ml) or superoxide dismutase (50 µg/ml) the ischemic-induced release of Asp and Glu was significantly reduced. Compounds able to inhibit enzymatic free radical production such as indomethacin (50 µM) or corticosterone (50 µM) were also protective, although to a lesser degree. Furthermore, when "non-ischemic" slices were exposed to an enzymatic reaction leading to free radical formation (xanthine plus xanthine oxidase), endogenous Asp and Glu release was significantly increased. This release was again inhibited by mannitol, catalase and superoxide dismutase.

These results suggest that free radical formation during and after ischemic injuries to the brain lead to the output of excitatory amino acids. These two events may mutually contribute to the pathogenesis of the death of neurons, and the interruption of this vicious circle may be of therapeutic importance.

195.4

21-AMINOSTEROIDS REDUCE CORTICAL NEURONAL INJURY INDUCED BY IRON OR BY "ISCHEMIA" IN VITRO. H. Monyer, D.M. Hartley and D.W. Choi. Dept. of Neurology, Stanford Univ. Med. Sch., Stanford CA 94305.

Murine neocortical cell cultures exposed to 50 µM Fe^{2+} + 50 µM Fe^{3+} for 24 h developed substantial neuronal degeneration without overt glial damage. This iron neurotoxicity probably reflected a substantial contribution from iron-facilitated free radical formation, as it could be markedly reduced by 5 µM concentrations of the novel Upjohn 21-aminosteroids, U74500 and U74006, which have been shown to be potent lipid peroxidation inhibitors. As lipid peroxidation has been postulated to be important in the pathogenesis of ischemic neuronal injury, we examined the effect of these drugs against combined oxygen and glucose deprivation in the same cultures. Such in vitro "ischemia" for 45 to 60 min produced widespread neuronal degeneration in untreated cultures. Addition of optimal (5 µM) concentrations of U74500, U74006 and U75412 reliably attenuated resultant neuronal damage, although this attenuation (30 - 80% reduction of injury) was not generally as large as that produced by the NMDA antagonist, dextrorphan. In fact, lipid peroxidation may be an important downstream event following NMDA receptor activation, as the neurotoxicity of exogenously applied glutamate could also be partially attenuated by these 21-aminosteroids.

195.5

NIFEDIPINE ATTENUATES AMPA OR KAINATE NEUROTOXICITY. J.H. Weiss, J. Koh and D.W. Choi. Dept.of Neurology, Stanford Univ. Med. Sch., Stanford CA 94305.

Murine cortical cultures exposed for 5 min to glutamate or other NMDA agonists go on over the next hours to develop widespread neuronal degeneration. This late degeneration depends on the presence of extracellular calcium and may be at least partially mediated by calcium influx through NMDA channels. In contrast, 5 min exposure to the selective non-NMDA agonists, kainate and AMPA, produces little neuronal degeneration; substantial neuronal degeneration is seen only after exposure times of more than an hour. To test the hypothesis that calcium influx through voltage-dependent channels may contribute to the slow neurotoxicity of these compounds, we investigated the effect of the dihydropyridine calcium channel antagonist, nifedipine. Cultures exposed for 24 h to either 10 μM AMPA or 30 μM kainate developed widespread neuronal degeneration, apparent both by morphological examination and by the efflux of lactate dehydrogenase from damaged neurons. Addition of 10 - 100 μM nifedipine to the exposure solution produced concentration-dependent partial attenuation in this non-NMDA agonist-induced neurotoxicity. Calcium ion influx through voltage-dependent calcium channels may contribute to the neuronal injury induced by prolonged over-activation of non-NMDA glutamate receptors.

195.6

INCREASED EXCITATORY NEUROTRANSMISSION RESULTS IN THE DEATH OF CULTURED RAT HIPPOCAMPAL PYRAMIDAL NEURONS. April E. Abele*, Wendy K. Scholz, Kenneth P. Scholz, and Richard J. Miller (Sponsored by: S. Glusman). Department of Pharm. & Physiol. Sci., U. of Chicago, Chicago IL 60637

We investigated the consequences of increased glutamate mediated neurotransmission on the viability of cultured hippocampal pyramidal neurons(HPN). HPN were cultured from 17 day old fetuses according to the method of Banker and Cowan(1977) as modified by Scholz(1988). Cells were used after 10-20 days in culture. Immunohistochemical studies revealed that these cultures were composed primarily of neurons(3-5% astrocytes) that reacted with antibodies against glutamate. Approximately 5% of the neurons reacted with antibodies against GABA. Furthermore, electrophysiological studies revealed that the majority of synapses are excititatory in these cultures. We monitored $[Ca^{2+}]_i$ in single neurons using fura-2 based microfluorimetry. When Mg^{2+} was removed and >10nM glycine added, $[Ca^{2+}]_i$ showed large oscillations(see Miller et al. this volume). These fluctuations could be blocked by tetrodotoxin(TTX) or AP5 . We assessed the viability of the HPN following various treatments using a combined fluorescein/propidium staining procedure. When cells were incubated in Mg^{2+}-free medium for 15 minutes and examined 24 hours later, the percentage of dead cells in each culture increased from a baseline value of 10-15% to 30-40%. The increase in cell death induced by Mg^{2+}-free medium could be further enhanced by the addition of glycine to the medium during the Mg^{2+}-free period. Agents that reduced Mg^{2+}-free/glycine induced $[Ca^{2+}]_i$ oscillations such as TTX or 2-Cl-adenosine prevented the increase in cell death. Addition of exogenous NMDA or glutamate(100μM-1mM) in Mg^{2+}-free medium to the cultures resulted in the death of >75% of the cells present. Thus increased NMDA receptor mediated synaptic activity can produce "excitotoxicity" in cultured cells. This may be a model for cell death resulting from seizure activity.

GLUTAMATE NEUROTOXICITY IN VITRO: ANTAGONIST PHARMACOLOGY AND INTRACELLULAR CALCIUM CONCENTRATIONS. R.L. Michaels* and S.M. Rothman, Depts. of Biological Chemistry and Anatomy & Neurobiology, Washington University School of Medicine, St. Louis, MO 63110

The accumulation of extracellular glutamate (GLU) is likely responsible for neuronal death in a number of human diseases. However, the role of different GLU receptors in producing cell death has not been adequately determined. In addition, there is little information correlating free intracellular calcium levels (Ca_i) with eventual excitotoxic death. We used cultured neonatal rat hippocampal neurons to try to address these issues.

Approximately 75% of our neurons died after a 20 minute exposure to 500 μM GLU. The potent kainate/quisqualate antagonist CNQX (200 μM) blocked GLU currents by 85%, but did not significantly ameliorate GLU toxicity, while the noncompetitive N-methyl-D-aspartate (NMDA) antagonist MK-801 blocked GLU toxicity for at least two hours. Interestingly, kainate (1 mM) was still toxic for these neurons, but the kainate damage was also blocked by MK-801. Ca_i at the end of 20 minute exposures to GLU, kainate or 123 mM potassium (± various antagonists) correlated poorly with eventual cell death. As expected, GLU elevated steady-state Ca_i. Neurons treated with GLU + CNQX had normal Ca_i levels at 20 minutes, yet most still died 18 hours after return to control solution. MK-801 kept the Ca_i low and prevented eventual death. On the other hand, 123 mM potassium elevated Ca_i without causing significant delayed cell death.

These results are consistent with previous reports emphasizing the importance of NMDA receptors in GLU toxicity. However, they suggest that the link between Ca_i and eventual cell death is not so direct.

A POSITIVE FEEDBACK LOOP GENERATING EXTRACELLULAR GLUTAMATE IN CORTICAL CULTURES EXPOSED TO GLUTAMINE. D. Crawford* and P.A. Rosenberg (SPON: S. Fischel). Dept. of Neurol., Children's Hosp., Harvard Med. Sch., Boston, MA 02115

The existence of a positive feedback loop contributing to glutamate neurotoxicity (GNT) in the forebrain has been postulated on the basis of the observation that a reduction in GNT is achieved by exposure of hippocampal (Rothman et al., Neuroscience, 22: 471, 1987) and cortical (Choi et al., J. Neurosci., 8: 185, 1988) cultures to glutamate antagonists following exposure to glutamate. By using astrocyte-poor (neuron-enriched) cultures of rat cerebral cortex (containing 50% neurons), it has been possible to demonstrate a positive feedback loop in which, in the presence of glutamine, cortical cultures generate extracellular glutamate by a process which can be completely blocked by the NMDA antagonist APV. Exposure of astrocyte-poor cultures to MEM plus 2 mM glutamine for 17-24 hours resulted in the accumulation of 255±158 μM glutamate (n=31) in the medium, and a proportionate reduction in glutamine. This phenomenon was neither seen in the absence of cultures nor in the presence of astrocyte-rich cultures (with 6% neurons). Coincident with this accumulation of glutamate is the death of most neurons in these cultures. Both the accumulation of glutamate and neuronal death can be blocked by APV. Supported by the Grass Foundation and NS00993.

L-CYSTEINE, AN ENDOGENOUS NMDA-MIMETIC EXCITOTOXIN THAT INDUCES GENERALIZED ISCHEMIA-LIKE NEONATAL OR FETAL BRAIN DAMAGE. J.W. Olney, J. Labruyere*, M.T. Price,Washington Univ., St.Louis, MO

Following systemic administration to infant or pregnant rodents, L-glutamate (Glu) and L-cysteine (Cys) induce a similar type of brain damage, but Glu damages only brain regions that lack blood brain barriers and Cys induces generalized damage throughout the infant or fetal brain (Olney et al., Br. Res., 45, 309, 1972). Recent evidence suggests that excitotoxic (including hypoxic/ischemic) brain damage in the immature brain is mediated primarily by the N-methyl-D-aspartate (NMDA) subclass of Glu receptor. Interestingly, injection of nmol amounts of NMDA into the immature rat brain causes disseminated Glu-like lesions affecting the frontoparietal neocortex, hippocampus, septum, caudate and thalamus, which is the same pattern of damage induced in immature rodent brain by hypoxia/ischemia or systemic Cys administration. In the isolated chick embryo retina, Cys and NMDA have identical cytopathological effects, and NMDA antagonists, including those acting at the NMDA, glycine, zinc, PCP or Mg^{++} sites, block Cys toxicity with potencies directly proportional to their potencies in blocking NMDA toxicity. Antagonists that act preferentially at non-NMDA receptors, such as CNQX, do not block Cys toxicity except when used in concentrations high enough to also block NMDA receptor activity. The powerful NMDA antagonist, MK-801, protects the infant rat brain against systemic Cys neurotoxicity. Based on evidence not detailed here, we consider Cys an unconventional excitotoxin that acts by a complex mechanism involving Zn^{++} and/or glycine components of the NMDA receptor channel complex. Since Cys is naturally present in brain, it can be added to the list of endogenous excitotoxins that might participate in neurodegenerative diseases. Moreover, since it penetrates both blood-brain and placental barriers, it is a valuable *in vivo* systemic tool for probing the vulnerability of developing CNS neurons to NMDA receptor-mediated excitotoxic processes. FOLATE AND QUISQUALATE CYTOTOXICITY IN FROG RETINA Z.H. Zhang,J.C. Blanks and S.R. Snodgrass. Neurol. Research Lab., Childrens Hospital Los Angeles and Doheny Eye Institute, Depts. Neurol. and Ophthal., Univ. So. Calif. Schl. of Med., Los Angeles, CA 90027

Various folates cause excitotoxic brain lesions. Only neural cells are folate-sensitive, and they vary greatly in sensitivity. All studies have found folic acid (FA) to be a more potent neurotoxin than 5-methyltetrahydrofolic acid (MTHF),the predominant extracellular folate. We incubated the frog retinal eyecup preparation with folates or excitatory amino acids, using morphological change to assess cytotoxicity. Thirty minute incubations with 1 mM FA produce cytotoxic changes in the inner nuclear layer, mainly in amacrine cells. Quisqualate (500 uM) destroyed multiple retinal elements, approaching the severity of kainate lesions. Our Quis lesions resembled those described by Sattayasi in the chick. FA and Quis cause translocation of Protein kinase C, shown by altered binding of ^{3}H phorbol dibutyrate. This simple model facilitates study of the role of protein kinases and excitatory amino acid receptors in cell death due to folates or Quis. The link between cytotoxicity and altered phorbol binding suggests that C kinase may mediate cytotoxicity.

195.11

REQUIREMENT FOR GLYCINE IN NMDA-INDUCED EXCITOTOXICITY IN RAT CORTICAL CELL CULTURE. D. McNamara* and R. Dingledine. (Spon: J.D. Mann). Dept. Pharmacology, Univ. North Carolina, Chapel Hill, NC 27599-7365.

The production of cation currents by NMDA in both mRNA-injected Xenopus oocytes and neurons appears to require glycine. Glycine also potentiates NMDA-induced excitotoxicity in rat cortical neurons (McNamara and Dingledine, Soc. Neurosci. Abs. 14: 236, 1988). NMDA is excitotoxic in the absence of added glycine, however, perhaps due to the presence of glycine released from cultured neurons. If this were the case, a selective glycine antagonist should abolish excitotoxicity incurred by exposure to NMDA. To test this hypothesis, E19 rat cortical neurons were exposed after 11 days in culture to 100μM NMDA and 0-1000 μM glycine for 5-60 min at 36 C. Following removal of the exposure solution, cells were incubated for 18-22 hours in growth medium containing 100μM D,L-APV to eliminate further action by residual NMDA and subsequent glutamate released from dying neurons. Degree of cell death was inferred by the amount of lactate dehydrogenase (LDH) activity released into the medium and expressed as a percentage of the total LDH available. In each of four experiments in which cells were exposed to 100μM NMDA with no added glycine for 10-30 minutes, 21% of the available LDH was released. When either 30μM 7-Cl-kynurenate or 100μM D-APV was included, however, no release of LDH above control was observed. 7-Cl-kyn also produced a shift to the right of the glycine dose-response curve in the excitotoxicity assay. In Xenopus oocytes 7-Cl-kyn has no effect on the potency of NMDA but is a competitive glycine antagonist with 40-fold selectivity over the quisqualate receptor (Kleckner and Dingledine, this meeting). These results indicate that glycine is required for NMDA-induced excitotoxicity, and suggest that glycine site blockers should be equally efficacious as NMDA antagonists in treating ischemic neuronal injury.

195.12

DOSE-DEPENDENT DECREASE OF VASOACTIVE INTESTINAL PEPTIDE (VIP) BUT NOT CHOLECYSTOKININ (CCK) FOLLOWING KAINIC ACID LESIONS OF THE STRIATUM.
M.F.Mazurek, K.J.Swartz, S.Garside*, M.F.Beal. McMaster Univ. Med. Ctr., Hamilton ONT. and Mass. Gen Hosp, Boston

We have recently shown that striatal concentrations of VIP are elevated 3- to 4-fold in Huntington's disease and 4- to 5-fold in rats with chronic quinolinate (QUIN)-induced lesions. Striatal levels of CCK, which like VIP is thought to arise for the most part from extrastriatal cell bodies, are normal in HD and increased only 2-fold in chronic QUIN-lesioned rats. We studied the dose-response profiles of VIP and CCK following excitotoxic striatal lesions induced by the selective glutamatergic agonists kainate (KA), QUIN, quisqualate (QUIS) and AMPA. KA produced a dose-dependent decrease in striatal VIP-like immunoreactivity, with levels reduced by 35% after 7.5 nmol KA lesion and by 43% following 10 nmol KA. CCK measured in the same samples was unchanged from control values. Neither VIP nor CCK was affected by increasing doses of QUIN, QUIS or AMPA. These results suggest that up to 40% of striatal VIP may be in a neuronal compartment that is sensitive to KA but not to the NMDA-receptor-agonist QUIN or the quisqualate agonists QUIS and AMPA. The VIP-containing cells appear to be up-regulated in Huntington's disease and in rats with chronic QUIN lesions Striatal CCK measured in parallel to VIP does not show the changes observed with VIP.

196.1

CATEGORY TYPICALITY EFFECTS IN ALZHEIMER'S DISEASE (AD). A. Cronin-Golomb, M.M. Keane, S. Corkin, J.H. Growdon. Dept. of Brain and Cognitive Sciences, MIT, Cambridge MA 02139 and Dept. of Neurology, Mass. General Hospital, Boston MA 02114.

Categorization deficits occur in AD, but no explanation has been suggested for deficient performance. We asked whether such deficits could be related to reduced category typicality effects in AD. In the normal effect, subjects are faster to judge high- (HTE) than low-typical exemplars (LTE) as members of a category. Subjects with AD of a wide range of dementia severity (N=8) and age-matched healthy control subjects (HCS: N=8) were compared on a category decision task. Words were derived from 12 categories, each of which included 6 HTE and 6 LTE. Subjects were asked,"Is the next word a kind of [category name]?" and responded 'yes' or 'no' to the word presented on the monitor. The measure was voice-activated reaction time (RT). Analysis of variance indicated that the two groups differed neither in overall speed nor in the effect of typicality; RTs were significantly faster for HTE than LTE ($p<.05$). Inspection of the data suggested that some AD patients have an enhanced typicality effect that may be accounted for by slowed RTs to LTE: AD patients were on the average 12% slower than HCS on HTE but 25% slower on LTE. Further, for the AD group, mean RT for LTE correlated strongly with dementia severity ($r=0.64$), whereas the correlation was relatively weak for HTE ($r=0.26$). The results suggest that category typicality effects are robust in AD. Categorization deficits in other tasks are probably not related to abnormally reduced typicality effects, but may occur when tasks involve LTE specifically.

196.2

DISRUPTION OF HAND AND JOINT KINEMATICS IN LIMB APRAXIA. H. Poizner, J.F. Soechting, M. Bracewell, L.J. Rothi, and K.M. Heilman. The Salk Institute, La Jolla, CA 92138, The University of Minnesota, The University of Florida, and V.A. Medical Center, Gainesville.

Apraxia is a disorder of the execution of learned, skilled movements in subjects with intact afferent and efferent systems, and its study can help illuminate the nature of cerebral organization in relation to movement. A major problem, however, in investigating the nature of this disorder has been the difficulty of obtaining objective measurement of movement in three-dimensional space. Three subjects with unilateral lesions in the left hemisphere and apraxia, two matched subjects with lesions in the right hemisphere, and five neurologically intact control subjects were asked to produce gestures requiring programming of complex trajectory timing and spatial relationships. Movements were digitized in three dimensional space and reconstructed graphically. Amplitudes and phase relations among relevant joint motions were computed, and joint and hand kinematics analyzed. Strikingly, the movements of subjects with right hemisphere lesions were virtually indistinguishable from those of control subjects. The apraxic subjects, however, showed marked distortions in both hand and joint kinematics even when imitating gestures or when given an actual tool to use. These data imply that the right hemisphere by itself may not contain all the information necessary to program the spatial or temporal aspects of skilled movements. Furthermore, since apraxic subjects showed errors in timing, spatial trajectory, and joint control even when imitating gestures and when manipulating tools, the basis of apraxia is likely not to rest on a disconnection between language and motor areas, but rather on a disturbance of spatiotemporal representations of skilled motor acts.

196.3

STRUCTURE OF OBJECTS IN CENTRAL VISION AFFECTS THE DISTRIBUTION OF VISUAL ATTENTION IN NEGLECT. M.J. Farah*, J.L. Brunn*, M.A. Wallace* and N. Madigan* (SPON: M. Oscar-Berman) Department of Psychology, Carnegie-Mellon University, Pittsburgh, PA 15213.

Is visual attention allocated to locations, objects, or both? The attentional deficit for one side of space in neglect suggests that location per se plays a role. By varying the structure of objects in central vision while holding the locations of stimulus targets constant we found evidence that attention is also allocated to objects per se. In one experiment, subjects with left neglect viewed pairs of meaningless forms that either straddled midline or were contained one within each of the two hemifields, and performed a visual search task for superimposed letters scattered throughout the visual field. There was less neglect of the left hemispace when background shapes straddled the hemifields. In a second experiment, more abstract 'objects' were used: subjects viewed either words or nonword letter strings, each letter of which was printed in a different color ink. Subjects named more colors on the left side of words than nonwords. These results imply that attention is allocated to entire objects, whether the objects are defined by low-level physical features or by familiarity of pattern, in addition to spatial location per se.

196.4

PULVINAR ACTIVITY IN HUMANS DURING A VISUAL ATTENTION TASK AS MEASURED BY PET IMAGES **David LaBerge and Monte S. Buchsbaum, Depts of Cognitive Science and Psychiatry, Univ of California, Irvine, CA 92717.**

We compared glucose uptake of the right and left pulvinars of 7 human subjects after they had performed a 32-minute visual identification that presented an attention-demanding display in one hemifield and a non-attention display in the other hemifield (and vice versa in a second session approximately a week later). The attention-demanding display, presented to one side of the central fixation dot, consisted of the letter O surrounded by other letters (G and Q) in a 3-by-3 item ensemble, and subjects were instructed to press a button if the center letter was the letter O, but not to respond if the center letter was a C or Ø. The non-attention display, presented to the other side of the dot, consisted of a single large letter O to be discriminated against the letter C or Ø, and subjects were to press a second button if the letter O appeared. The second session reversed the sides of the display types.

The pulvinar and mediodorsal (as a control) nuclei of each subject's thalami were traced on her MRI record, and then the glucose uptake within the corresponding areas of her PET images were compared across the two sessions. The results showed that, averaged across the two sessions, the pulvinar showed greater glucose uptake when it was contralateral to the attention-demanding display than when it was contralateral to the non-attention-demanding display. Parallel analyses of the mediodorsal nuclei, frontal white matter, and 20 occipital subareas revealed no significant task by hemisphere interactions.

The results support the hypothesis that the pulvinar operates interactively with cortical structures when an identification process demands attentional filtering. **(Supported by ONR and the MacArthur Foundation.)**

196.5

FOCUSING AND SHIFTING OF ATTENTION IN AUTISTIC SUBJECTS: ERP AND BEHAVIORAL FINDINGS. N. Akshoomoff*, E. Courchesne* and K. Ciesielski* (SPON: J. Johnson). Neuropsychology Research Lab., Children's Hospital, San Diego, CA 92123 and Dept. of Neurosciences, UCSD.

Abnormalities in the ability to focus and shift attention appear to exist in autistic individuals. ERPs were recorded from in a group of 10 nonretarded autistic subjects (mean age 23.5 years) and a group of 11 Performance IQ-matched normal control subjects (mean age 21.2 years). Subjects performed simple sustained visual and auditory attention tasks, as well as a divided attention task. They were then given a task which required them to rapidly shift their focus of attention back and forth between on-going sequences of auditory and visual stimuli. Cues that signal attention shift were randomly placed in these sequences. Within 1.5 sec following a cue to shift, controls made very few false alarms to stimuli in the "old" modality, and missed very few target stimuli in the "new" modality. Autistic subjects had many false alarms and misses within several seconds following a cue to shift. These time-related errors were not evident during the focused attention tasks. Control subjects showed ERP components associated with the on-going maintenance of focused attention (Nd, N270, Nc). A parietally maximal P700 response and a P3a response, which were specifically associated with the cue to shift attention, were also found. These ERP responses were absent in the autistic subjects. Thus in the autistic subjects there was no evidence of the normal neurophysiological responses which reflect shifts of attention between auditory and visual modalities and they demonstrated considerable difficulty disengaging from one focus of attention and moving to and engaging a new one.

196.6

THE ANTERIOR CINGULATE CORTEX MEDIATES RESPONSE SELECTION IN THE STROOP ATTENTIONAL CONFLICT PARADIGM. J.V. Pardo, P.J. Pardo*, K.W. Janer*, and M.E. Raichle. Washington University School of Medicine, St. Louis, MO 63110.

Regional cerebral blood flow was measured using positron emission tomography (PET) during the performance of the classic Stroop "color/word" task in eight healthy right-handed subjects. In the first condition subjects name the color of the words presented on a video monitor. All the words are the color names congruent to the color presented. In the second condition the color of the words presented are color names incongruent to the color presented. The difference in brain activity between these two conditions could reveal brain systems involved in the attentionally mediated resolution of the conflict between the habitual response of reading words vs. the task demands of naming color. The most robust responses occurred in the anterior cingulate cortex. Other responses noted were in the left premotor cortex, left postcentral cortex, left putamen, right superior temporal gyrus, and bilateral extrastriate cortices. These data provide support for the role of the anterior cingulate cortex in attentional processing through the selection and recruitment of processing centers appropriate for task execution. Furthermore, the extensive distributed network of activated regions suggests that the Stroop interference effect can not be explained simply in terms of stimulus encoding or response interference.

196.7

STEREOPSIS: LOCAL AND GLOBAL MEASURES. A. Ptito*, R.J. Zatorre, and W.L. Larson*. (SPON: B. Milner) Montreal Neurol. Inst. McGill Univ. and School of Optometry, U. de Montréal, Canada.

In man, an impairment of stereopsis may occur following damage outside the occipital lobes. If local and global stereopsis can be dissociated, this may imply that different mechanisms mediate these functions. We tested 35 patients with unilateral temporal-lobe lesions and 18 normal control subjects on 2 tasks. In the local stereopsis task subjects indicated which of two pins varying in disparity between 4 and 512 sec of arc was closer. Results showed no threshold impairment in any groups. In the global condition, random-dot stereograms varying in binocular correlation were presented in random order, and subjects indicated if the squares perceived in depth were in front of or behind the screen. At binocular correlations between 50% and 70%, left and right temporal lobectomy resulted in a deficit, which was more marked following right-sided excisions. This study suggests, therefore, that separate mechanisms come into play for local and global stereopsis, and is consistent with earlier work [Ptito & Zatorre, Neuropsychologia 26, 547, 1988] implicating temporal neocortex in global stereopsis.

196.8

RIGHT-NOSTRIL ADVANTAGE FOR ODOR DISCRIMINATION IN RIGHT HANDERS. R.J. Zatorre and M. Jones-Gotman*. Montreal Neurological Institute, McGill University. Montreal, Quebec, Canada H3A 2B4

To investigate hemispheric asymmetry in odor processing, olfactory discrimination was tested in 96 normal subjects using a same-different task with 8 pairs of odors. Half the subjects were right-handed and the other half left-handed. Each subject's detection thresholds for phenylethyl alcohol were also measured with a staircase method separately in each nostril, and the fused words dichotic listening test was given. Results indicated a marked asymmetry favoring the right nostril in odor discrimination among the right-handers ($p<.01$), but not among the left-handers. This cannot be accounted for by sensitivity differences, as there was no significant difference between the nostrils in detection thresholds. Direction of perceptual asymmetry on the dichotic test did not correlate with the olfactory asymmetry. These results replicate earlier data [Zatorre & Jones-Gotman Soc. Neurosci. Abs. 14, 219, 1988], and together with severe olfactory discrimination deficits observed following right orbitofrontal lesions, suggest a relative right-hemisphere superiority in certain aspects of olfactory processing.

NEUROTRANSMITTER DIFFERENTIATION IN VIVO BETWEEN CONTROL AND DEVELOPMENTAL LEARNING DISABILITY HUMANS
K.A.Bonnet,J.M.Luccioni,C.Walsh,A.J.Friedhoff, Millhauser Laboratories,New York University School of Med.,New York, New York 10016

Control and developmental learning disability young adults were studied on five successive days each with baseline records and with three hours of subsequent record after challenge with substances effecting selective potentiation in individual neurotransmitter systems. Baseline and postchallenge records consisted of resting EEG and auditory and visual evoked potentials. At baseline, the learning disabled (LD) individuals showed significantly greater right frontal reduction in frequency than controls, and reduced 300 ms component with increased 200 millisecond component in the P300 procedure, most definitive at the midline frontal region. Dopamine enhancement improved the 300 ms. component of the P300 in the controls, but the LD group showed decreased 300ms. component and increased 200 ms. component. Cholinergic potentiation produced significant increase in 200 ms. compoments and decreased 300 ms. componenets of P300, as well, in the LD group compared to controls. Serotonergic potentiaion potentiated the 300 ms. components in the P300 of the LD group only, and suppressed the 200 ms. components in both groups.

MRI AND VISUAL PSYCHOPHYSICAL STUDIES OF INHERITED DYSLEXIA. K. Gross-Glenn, R. Duara, A. Kushch*, S. Pascal*, W. Barker*, B. Jallad*, H.A. Lubs*. Univ. of Miami School of Medicine, Miami, FL 33101 and Mt. Sinai Medical Ctr., Miami Beach, FL 33141.

The role of visual functioning in the etiology of inherited dyslexia is poorly understood. Previous PET scan studies during oral reading (Duara, R., Gross-Glenn, K., Barker, W. et al., Neurol., 39 (suppl. 1):165, 1989) showed that significant differences between dyslexics and normal readers were localized to extra-striate visual cortex, specifically the lingual region. To further explore this problem we have combined MRI and visual psychophysical studies on right-handed adult dyslexics and normal readers. Morphometric area measurements were made on axial MRI scans (N=51) at the level of the Foramen of Monro. From these data laterality indices [200(R-L)/(R+L)] were calculated for homologous regions. No significant differences were observed in anterior areas, however mid-posterior regions revealed significantly more rightward asymmetry for dyslexics as compared with the leftward asymmetry observed in normal readers ($p=.005$). Normalized measurements of mid-sagittal corpus callosum area showed dyslexics to have a relatively larger splenium than normal readers ($p=.005$).

A subset of these individuals (12 dyslexics, 10 normal readers) participated in a visual psychophysical study. Spatial and temporal parameters were varied in a visual forward-masking paradigm that assessed contrast sensitivity thresholds for luminance sine wave gratings displayed on a video screen. Grating duration was varied and targets were presented either with or without a visual mask. These studies revealed very specific differences between dyslexics and normal readers that was limited to detection of masked high spatial-frequency gratings. The mask reduced perceptibility of low spatial frequency gratings for both groups equally. However, for high spatial frequency gatings, the time required to escape from the effects of the visual mask was significantly extended for dyslexics as compared with normal readers ($p < .05, .01, .04$ for targets durations of 17, 33, 100 msec, respectively). These studies point to very specific visual system differences in both functioning and anatomy for dyslexics as compared with normal adult readers.

196.11

RESOLUTION OF MULTIPLE SOURCES IN VISUAL EVOKED NEUROMAGNETIC RESPONSES. C.J. Aine, J.S. George, P.A. Medvick*, S. Supek* and E.R. Flynn. Life Sciences and Physics Divisions, MS M882, Los Alamos National Laboratory, Los Alamos, NM, 87545.

Although magnetoencephalography (MEG) offers increased spatial and/or temporal resolution relative to other noninvasive mapping techniques (e.g., ERPs and PET), the technique is limited by the assumptions of the models used to localize the source(s) of neuromagnetic field distributions. Visual neuromagnetic data suggest the existence of multiple sources when large areas of cortex are examined; therefore, we have developed procedures for resolving multiple, temporally synchronous and/or asynchronous sources.

Neuromagnetic field maps in response to small sinusoidal gratings placed in different locations of the visual field were obtained from four right-handed human subjects. In response to central field stimulation, left and right hemisphere sources with opposing orientations were resolved in three of the four subjects. When the stimulus was presented at 7° along the horizontal meridian in the right visual field, two sources were evident in the left hemisphere: one close to midline and another more lateral (approximately 5-6 cm from the midline). In other examples, two asynchronous sources were evident in the field distributions. In several subjects we have observed an apparent source at 100 msec poststimulus followed by a distinct second source at 120 msec. In conclusion, if multiple source models are utilized, MEG allows powerful inferences concerning spatial and temporal patterns of activation within the human visual system.

PRESYNAPTIC MECHANISMS II

197.1

PAIRING-SPECIFIC, ACTIVITY-DEPENDENT FACILITATION OF *APLYSIA* SENSORY-MOTOR NEURON SYNAPSES IN ISOLATED CULTURE. L.S. Eliot*, S. Schacher, E.R. Kandel, and R. D. Hawkins (SPONS: L.K. Simmons). Ctr. Neurobiol. & Behav., Columbia Univ., HHMI, & NYSPI, NY, N Y 10032.

When tetanic stimulation of a sensory neuron is combined with 5-HT, it produces longer-lasting facilitation of *Aplysia* sensory-motor synapses in culture than either tetanus or 5-HT alone (Montarolo and Schacher, *Soc. Neurosci. Abstr.* 14:909). We have now begun to analyze the temporal specificity of this effect. In cultures containing two sensory neurons (SNs) synapsing on a single LFS motor neuron, one SN received tetanus (20 Hz, 2s) paired with 5-HT, while the other received tetanus 1 min before 5-HT application. Paired training produced greater facilitation overall than unpaired training ($n = 14$, $F = 7.17$, $p < .02$). At 5', 10' and 15' the paired EPSP was more facilitated than the unpaired EPSP ($p < .02$ in each case; average = 114 ± 11% vs. 68 ± 7% of pre-tests). Similar results were obtained when a single SN was given two rounds of training, either paired followed by unpaired or vice-versa. Pairing produced an overall enhancement of facilitation at 5', 10' and 15' ($n = 20$, $F = 5.49$, $p < .05$). At each time point, the paired EPSP was more facilitated than the unpaired EPSP ($p < .05$, one-tailed in each case; average = 94 ±8% vs. 74 ±6%). These experiments demonstrate that pairing-specific facilitation can occur at single sensory-to-motor neuron synapses in culture, even in the absence of extra circuitry.

197.2

IP_3 RELEASES INTRACELLULAR CALCIUM IN *APLYSIA* SENSORY NEURONS. H. Blumenfeld, E.R. Kandel, and S.A. Siegelbaum. Ctr. Neurobiol. & Behav., Columbia Univ., HHMI, New York, New York 10032.

The sensory-motor neuron connection in *Aplysia* is modulated through two second messenger systems. 5-HT causes presynaptic facilitation through a cAMP cascade and FMRFa causes presynaptic inhibition through an arachidonic acid cascade. Is IP_3, which releases calcium from internal stores, also involved in the actions of these neuromodulators? To directly test the ability of IP_3 to release calcium in *Aplysia* sensory neurons, we injected IP_3 while measuring Ca_i with fura-2. Brief (10-50 ms) pressure pulses from electrodes containing 1.0 mM IP_3 caused a transient rise in Ca_i of 113 ± 11 nM (mean ± SEM; n = 21). Myo-inositol caused little or no response. Removal of external Ca eliminated Ca_i transients produced by action potentials but did not affect the response to IP_3. Since 5-HT and FMRFa do not increase resting Ca_i in sensory neurons, neither transmitter appears to stimulate significant IP_3 production.

We next asked whether 5-HT alters the Ca_i transient in response to IP_3, since 5-HT causes a 50% increase in the Ca_i transient produced by action potentials or voltage clamp depolarizations. The amplitude of the IP_3-induced Ca_i transients was not affected by 10 μM 5-HT (n = 13). However, in four out of seven experiments with IP_3 injections, 10 μM 5-HT caused a two-fold increase in the time constant of recovery of Ca_i.

PRESYNAPTIC INHIBITION OF TRANSMITTER RELEASE AT A GIANT SYNAPSE: I. FMRFa MODULATION OF ION CURRENTS. M. J. Zoran, H. J. Man-Son-Hing, L. R. Funte*, K. Lukowiak, and P. G. Haydon. Department of Zoology, Iowa State University, Ames, IA 50011.

The neuropeptide, Phe-Met-Arg-Phe-NH_2 (FMRFa; 1μm) modulates cholinergic connections between buccal neurons B5 and B19 of *Helisoma* in cell culture. Under conditions that inhibit neurite extension, sperical somata adopt synaptic functions. **Using giant synapses, we have demonstrated that FMRFa causes a presynaptic inhibition of acetylcholine release.** Neuron B5 (Pre) and neuron B19 (post) were voltage clamped using whole cell patch pipettes. Presynaptic B5 was depolarized from -60mV to command potentials ranging from -20mV to +10mV (duration 4s) to evoke desynchronized release of acetylcholine (ACh). Transmitter release was detected as tubocurarine-sensitive inward postsynaptic currents (p.s.c.s) in B19 (-80mV). Application of FMRFa (1μM) reversibly reduced the number of evoked p.s.c.s (n=9) while having negligible effects on postsynaptic sensitivity to ACh. The sub-cellular mechanisms involved in this FMRFa effect are multiple. First, FMRFa causes a reversible hyperpolarization of neuron B5 and increases the membrane (input) conductance. Second, FMRFa reversibly reduces a high voltage activated (HVA) calcium current within secretory membrane of neuron B5 (n=18)

Presynaptic inhibition of synaptic transmission also occurs at growth cones of neuron B5. Utilizing the calcium sensitive probe Fura-2, we have demonstrated that, like the giant synapse, FMRFa reversibly reduces AP-evoked intracellular Ca^{2+} transients in growth cones of B5.

197.4

PRESYNAPTIC INHIBITION OF TRANSMITTER RELEASE AT A GIANT SYNAPSE: II. FMRFa MODULATION OF SECRETORY APPARATUS. P. G. Haydon., M. J. Zoran, H. J. Man-Son-Hing, and K. Lukowiak. Department of Zoology, Iowa State University, Ames, IA 50011.

The neuropeptide Phe-Met-Arg-Phe-NH_2 (FMRFa; 1μm) modulates cholinergic connections between buccal neurons B5 and B19 of *Helisoma* in cell culture. **Using the synapse which forms between spherical somata we have demonstrated that FMRFa causes a decrease in the sensitivity of secretory apparatus to internal Ca^{2+}.**

The photolabile calcium cage Nitr-5 was dialysed into a voltage clamped presynaptic cell (B5) to control internal calcium independent of ion conductances. In response to UV light, calcium was released from Nitr-5 and ACh secretion was stimulated. Under conditions of elevated internal calcium, we applied FMRFa (1-10μM) from a puffer pipette to the synapse while measuring the rate of desynchronized ACh release, detected as inward postsynaptic currents (p.s.c.s) in the voltage-clamped postsynaptic cell (B19). **FMRFa caused a 65% reduction in the rate of p.s.c.s (n=9) without affecting the level of internal free calcium.**

Thus, FMRFa causes a presynaptic inhibition of transmitter release by modulating multiple subcellular processes. FMRFa reduces the influx of calcium in response to action potentials by regulating ion conductances of the secretory membrane (Zoran et al., Neurosci. Abst 1989; Man-Son-Hing and Haydon, Neurosci. Abst, 1989) and, as demonstrated here, reduces the sensitivity of the secretory apparatus to internal calcium. Supported by a grant from the NIH, NS26650.

CALCIUM INDICATOR LOADING IN MOUSE MOTOR NERVE TERMINALS. Z.-P. Fang* and N. Robbins (SPON: R. J. Lederman). Center for Neurosciences, School of Medicine, Case Western Reserve University, Cleveland, OH 44106.

Calcium-sensitive dyes have proven useful in measuring intracellular calcium concentrations. Recently the dye fura-2 was used to examine presynaptic calcium concentration at motor nerve terminals in invertebrates (K. R. Delaney, et al., Soc. Neurosci. Abstr. 14:1206, 1988). However, this methodology has not been applied to mammalian motor nerve terminals because of the difficulty of injecting the dye into small (<5um) myelinated motor axons.

We have developed a technique for loading fura-2 into the presynaptic nerve terminals at mouse neuromuscular junction. The soleus and sternocleidomastoid muscle were stained in vitro with fluorescent dyes to visualize the junction areas. The muscle was then transferred to a bath chamber on the stage of an upright microscope. A fine-tip glass micropipette (150-300MOhm with 100mM KCl) was back filled with 10mM fura-2 in 100mM KCl. A piezoelectric jolter was used to aid the penetration of the electrode tip through the myelin sheath and the nerve membrane at an internode close to the terminal. The dye was injected iontophoretically (-10uA) into the axon and the whole terminal arborization, including fine processes, was filled within a few minutes.

The technique of loading the calcium indicator into mouse nerve terminals will provide a means to study the presynaptic mechanisms in mammals. Work is in progress using fura-2 to examine calcium distribution and dynamics in motor nerve terminals of young and old mice. Supported by NIH Grant AG00795.

PREPARATION OF THE 'CHICK GIANT SYNAPSE' FOR ELECTROPHYSIOLOGICAL RECORDING: CA CURRENTS IN A VERTEBRATE PRESYNAPTIC NERVE TERMINAL. E.F. Stanley[1] and G. Goping[2], [1]LB, NINDS; [2]LCBG, NIDDK, NIH, Bethesda, MD 20892.

The small size of nerve terminals in most experimental preparations precludes the direct recording of ion currents. We have used the calyx synapse of the chick ciliary ganglion (CG) as a model for voltage clamp of the presynaptic nerve terminal.

The CG neuron is enveloped in a capsule of Schwann cells and the capsules are enmeshed in a collagen matrix within the ganglion. Electron microscopy was used to develop an enzymatic dissociation technique, based on collagenase and neutral protease, to isolate the CG neurons with the presynaptic nerve terminal intact. The nerve terminal is often very extensive, covering most of the CG neuron surface, but is very thin with a maximum thickness of less than 3 μm.

Standard patch clam techniques were used to record from the presynaptic nerve terminal. Ca currents were isolated by ion substitution and Na and K channel blocking agents. The main component of the calcium current had a high threshold, showed little inactivation during a 25 ms pulse, and appeared to wash out rapidly.

197.7

SPIKE BROADENING IS PARADOXICALLY ASSOCIATED WITH REDUCED JUNCTIONAL POTENTIAL AMPLITUDE AT A NEUROMUSCULAR SYNAPSE. A. N. Spencer, J. Przysiezniak and J. Acosta-Urquidi*. Bamfield Marine Station and Dept. of Zoology, Univ. of Alberta, Edmonton, Alberta, Canada, T6G 2E9.

Presynaptic modulation of action potential duration is known to regulate synaptic efficacy in both vertebrates and invertebrates. In the hydrozoan jellyfish Polyorchis penicillatus changes in the durations of motor neuron APs serve to synchronize swimming contractions. As APs propagate through the network of electrically coupled motor neurons their duration progressively decreases as they invade more hyperpolarized regions. The EJPs that are elicited by the propagating motor spike become increasingly larger and appear with reduced delay as the duration of the motor spike decreases. This decreased delay automatically compensates for the conduction time of the motor spike. Identified motor neurons can be isolated, grown in culture, and used for giga-ohm seal, whole-cell recording.

Current clamp recordings show that the duration of action potentials decreases with membrane hyperpolarization prior to stimulation. Voltage-clamp studies demonstrated that the loss of the plateau is due to the removal of inactivation of a transient potassium current (Ik-fast). This current peaked within 2 to 15ms, decayed with a time constant of 200ms, and was half-inactivated at a holding potential of -47mV. A rapidly activating (tau=2ms), and inactivating (tau=20ms) calcium current, which appears to be responsible for transmitter release, can be recorded at synaptic release sites. To determine the dynamics of voltage-gated calcium influx when APs of varying duration invade a pre-synaptic release site, we stimulated motor neurons using voltage commands shaped like APs. Short duration APs elicit large calcium currents with fast onsets, while long APs result in small currents with slow onsets. Although the total amount of calcium that enters during a long AP is greater than for a short AP, it is less effective at releasing transmitter since the calcium concentration at cytosolic binding sites may be mostly dependent on the rate of influx. This would be the case if Ca++ removal by diffusion, active pumping or sequestration is particularly rapid in these cells. Supported by NSERC grant A0 419.

197.8

SIGNAL TRANSDUCTION AND THE ADENOSINE RECEPTOR INHIBITORY TO ACETYLCHOLINE RELEASE IN FROG MOTOR NERVE ENDINGS. J.K. Hirsh* and E.M. Silinsky. Dept. of Pharmacology, Northwestern Univ. Med. Sch., Chicago, IL 60611.

The mechanism whereby adenosine receptors inhibit ACh release from motor nerve endings was studied. Electrophysiological measurements were made of acetylcholine (ACh) release in the frog nerve-cutaneous pectoris preparation. The role of protein phosphorylation in this process was examined using the protein kinase inhibitor H-7. H-7 reduced the epp and mepp amplitudes in parallel without altering levels of release. In addition, H-7 (30-100 μM) blocked the stimulatory effects of chlorophenylthio cAMP (250 μM) on ACh release. However, H-7 did not alter the effects of adenosine under conditions where we and others found that A, C, and G kinases are inhibited (Hidaka, H. et al, Biochemistry 23:5036, 1984; Caratsch, et al Naunyn-Schmeideberg's Arch. Pharmacol. 337:9, 1988). Additional studies examined the role of GTP-binding proteins in the action of adenosine. In preliminary experiments, GTP-γ-S- and Li-containing liposomes increased and decreased, respectively the level of inhibition produced by adenosine. The results suggest that adenosine receptors which inhibit ACh release from motor neurons may be coupled to GTP-binding protein(s) that are directly linked to a cellular effector.

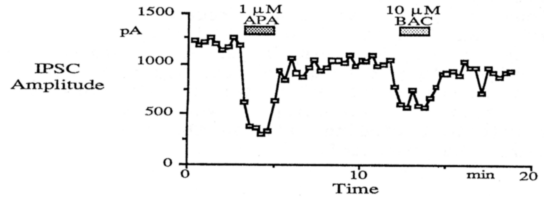
197.9

BAPTISM OF FROG MOTOR NERVE TERMINALS DOESNOT IMPAIR THE INHIBITORY ACTIONS OF ADENOSINE ON ACETYLCHOLINE RELEASE. J.M. Hunt* and E.M. Silinsky (SPON R.W. Berry). Dept. of Pharmacology, Northwestern University, Chicago, Ill. 60611.

Motor nerve terminals in the frog cutaneous pectoris muscle were loaded with the Ca^{+2} chelator BAPTA (100-500μM BAPTA-AM, predissolved in 5μl DMSO.) The effectiveness of this treatment was assessed by examining whether the effects of agents which normally elevate cytosolic Ca levels are blocked (caffeine) or delayed (K^+ depolarization, Ca ionophores) by BAPTizing the nerve terminal.

The affinity of BAPTA for Ca is such that, in frog, cytosolic Ca levels are only modestly reduced. This is reflected as a decrease in miniature end plate frequency, mepp frequency, (see Kojima, H. and Tanabe, N. J. Physiol. 403:135, 1988) similar to that which is produced by maximal concentrations of adenosine. In BAPTized preparations we have found adenosine to exert its characteristic inhibition of acetylcholine release. Given the similar apparent ability of BAPTA and adenosine to reduce mepp frequency, the absence of an occlusive effect of BAPTA upon adenosine suggests adenosine is not inhibiting acetylcholine release by modulation of calcium levels in the nerve terminal.

197.10



FOCAL APPLICATION OF SEROTONIN ENHANCES SPONTANEOUS AND EVOKED COMPONENTS OF INHIBITORY SYNAPTIC NOISE. J. Mintz* and H. Korn. Neurobiologie Cellulaire. INSERM U 261. Institut Pasteur. 75015 Paris. France.

Synaptic noise in central neurons comprises two components 1) single quanta most generally produced by spontaneous exocytotic events and 2) large multiquantal postsynaptic responses evoked by randomly occuring presynaptic impulses. Such is the case for inhibitory activity produced by glycinergic afferents at the Teleost Mauthner (M) cell (Korn et al., Proc. Natl. Acad. Sci. USA 84:5981, 1987). To clarify the presynaptic control of noise by 5-HT, experiments were achieved on goldfish (Carassius auratus) anaesthetized with tricaine and immobilized with gallamine. KCl-microelectrodes were used for M-cell current clamp and single electrode voltage clamp (chopping frequency 15 to 25 KHz) recording. 5-HT (5mM) was applied through a second micropipette, close to the M-cell membrane. 1) Resolution, in its quantal subunits (see ref.), of background activity recorded over long periods before and after 5-HT indicated that the amine markedly increased the intensity of synaptic noise by enhancing the number and amplitude of its largest (spike-dependent) components. 2) The frequency of single events remaining in the presence of TTX (20uM, applied on the 3rd ventricle) was also increased, although less dramatically, by about 15 to 30%. Thus, 5-HT controls the probability of transmitter release at terminal regions of inhibitory afferents, i.e. at presynaptic active zones.

197.11

3-AMINOPROPANEPHOSPHINIC ACID: A POTENT AGONIST AT PRESYNAPTIC $GABA_B$ RECEPTORS ON CULTURED GABAERGIC HIPPOCAMPAL NEURONS FROM THE RAT. N.L.Harrison, G.Hofer*, J.Ong*, J.L.Barker and D.J.B.Kerr* Laboratory of Neurophysiology, NINDS, NIH, Bethesda, MD and *Dept. of Pharmacology, The University of Sydney, N.S.W., Australia.

We have studied the actions of 3-aminopropanephosphinic acid (APA) and (-)baclofen (BAC) at inhibitory synapses between rat hippocampal neurons in culture. Simultaneous whole-cell recordings were made from pre- and postsynaptic neurons, using patch pipettes filled with an intracellular solution based on 145mM K gluconate. Individual bicuculline-sensitive IPSPs were elicited by a single electrically evoked presynaptic action potential. Both BAC and APA decreased the amplitude of evoked IPSPs and synaptic currents (IPSCs). Like BAC, APA did not reduce Cl^- current responses of postsynaptic neurons to GABA or increase somatic membrane conductance. APA was 10-20 times more potent than BAC (see Figure). Both BAC and APA reduced transmitter output from the presynaptic terminal, as assessed by calculating (mean IPSC amplitude)^2 / (variance). We conclude that BAC and APA reduce inhibition by acting at a presynaptic $GABA_B$ receptor on the terminals of GABAergic neurons.

SEROTONIN RECEPTORS III

HALLUCINOGENIC INDOLEALKYLAMINES ARE SELECTIVE FOR 5-HT_{2A} BINDING SITES. D.J. McKenna, D.B. Repke*, and S.J. Peroutka. Dept. of Neurology, Stanford University, Stanford, CA 94305 and *Syntex Research, Palo Alto, CA 94304.

The affinities of 21 indolealkylamine derivatives, some with hallucinogenic activity, were determined at 5-HT_{1A}, 5-HT_{2A}, and 5-HT_{2B} binding sites using radioligand competition studies. Most derivatives have the highest potency at the 5-HT_{2A} receptor labeled by ^{125}I-R-(-)DOI in rat cortex and display 2 - 10 times lower affinity at the 5-HT_{2B} receptor labeled by ^{3}H-ketanserin in bovine cortex. 5-substituted derivatives display approximately equal potency at the 5-HT_{2A} site and at the 5-HT_{1A} site labeled by ^{3}H-8-OH-DPAT. The 4-hydroxylated derivatives are selective for the 5-HT_{2A} site vs. the other two sites, while the 6-substituted derivatives display weak affinity for all of the recognition sites examined. Derivatives lacking ring substituents and N-cycloalkyl-tryptamines display lower affinities for all of the recognition sites compared to derivatives substituted in the 4- or 5-position of the indole ring. The size of the N,N-dialkyl substituent is a secondary determinant of affinity, with groups larger than N,N-diisopropyl resulting in a marked reduction in affinity at both the 5-HT_{2A} and 5-HT_{1A} recognition sites. This study demonstrates that 4-hydroxy-indolealkylamines display selectivity for the 5-HT_{2A} recognition site labeled by ^{125}I-R-(-)DOI and provides further evidence indicating that this recently described 5-HT_2 receptor subtype may partially mediate the action of hallucinogenic agents.

198.2

INVOLVEMENT OF 5-HT AND SUBTYPES OF 5-HT RECEPTOR IN THE ACTIVATION OF ENTERIC NEURONS BY INTRALUMINAL CHOLERA TOXIN M. D. Gershon, A. L. Kirchgessner and P. R. Wade. Department of Anatomy and Cell Biology, Columbia Univ. P & S, New York, NY.

Previous studies by Lundgren and co-workers have suggested that 5-HT and enteric neurons participate in the mediation of the action of cholera toxin (CT) on the gut. We tested this hypothesis by investigating the effects of intraluminal application of CT (10 μg in 250 μl for 2.5-3 hrs) on the activity of neurons in the myenteric and submucosal plexuses of the guinea pig small intestine (3 cm) *in vitro*. Neuronal activity was assessed by measuring histochemically demonstrated cytochrome oxidase (CO) activity by computer assisted video microdensitometry. This parameter has been shown to vary directly with the rate at which action potentials are generated in enteric neurons. CT increased CO activity in neurons of both plexuses (myenteric > submucosal). This effect was blocked by lidocaine (4.3 mM), tetrodotoxin (1 μM), and desensitization to 5-HT (2 mM). It was also antagonized by inhibitors of specific subtypes of 5-HT receptor, including the 5-HT_3 antagonist, ICS 205-930 (0.1 μM), and the 5-HT_{1P} antagonists, N-acetyl- > N-hexanoyl-5-hydroxytryptophyl-5-hydroxytryptophan amide (10 μM). CT-stimulation of myenteric CO activity was also reduced by substituted benzamides (which interact with both 5-HT_3 and 5-HT_{1P} receptors), including BRL 24924 (1 μM), zacopride (0.1μM), and its stereoisomer, AHR 4965 (0.1 μM). These observations suggest that CT in the lumen of the bowel activates enteric neurons through a mechanism that involves the release of 5-HT. The released 5-HT appears to act on both 5-HT_3 and 5-HT_{1P} receptors. Blockade of either receptor subtype prevents the CT-stimulated increase in enteric neuronal activity. Supported by NIH grants NS 12969, NS 07062, and AH Robins Co.

198.3

PRE- AND POSTSYNAPTIC ACTIONS OF ZACOPRIDE ON ENTERIC NEURONS: RELATIONSHIP TO 5-HT RECEPTOR SUBTYPES. P.R. Wade* and M.D. Gershon. (Spon. T. Rothman) Dept. Anatomy & Cell Biology, Columbia Univ. P&S, New York, NY 10032

A substituted benzamide, BRL 24924, has been shown to antagonize responses of enteric neurons mediated by at least two 5-hydroxytryptamine (5-HT) receptor subtypes (5-HT_{1P} and 5-HT_3); BRL 24924 also mimics the ability of 5-HT to presynaptically inhibit nicotinic fast EPSPs. To explore the enteric neuronal actions of substituted benzamides further, we investigated the actions of zacopride, and its stereoisomers, AHR-4964 and -4965. Intracellular recording was used to study type II/AH neurons in the myenteric plexus of the guinea pig small intestine. Postsynaptic responses to microejected 5-HT include: (i) A "slow response" (mediated by 5-HT_{1P} receptors): a prolonged depolarization, antagonized by dipeptides of 5-hydroxytryptophan (5-HTP-DP), during which input resistance and neuronal excitability increase. (ii) A "fast response" (mediated by 5-HT_3 receptors): a brief depolarization, antagonized by ICS 205-930, during which input resistance decrease. (iii) A hyperpolarization (reported to be mediated by 5-HT_{1A} receptors). Presynaptic inhibition of fast EPSPs, which is mimicked by 8-hydroxy-dipropylaminotetralin but antagonized by 5-HTP-DP may be mediated both by 5-HT_{1A} and 5-HT_{1P} receptors. Zacopride and AHR-4965, but not AHR-4964, mimicked the slow response to 5-HT. This effect was prevented by desensitization to 5-HT (1μM) and thus is probably the result of an interaction with the 5-HT_{1P} receptor. AHR-4965 also mimicked the presynaptic inhibition of fast EPSPs by 5-HT. AHR-4964, -4965, and zacopride all reversibly blocked fast responses to 5-HT. It is suggested that substituted benzamides act on myenteric neurons at 5-HT_3 receptors and also at a strereospecific benzamide site that is linked to 5-HT_{1P} receptors. Supported by NIH grants NS 12969, NS 22637, NS 07062, the PMAF and A.H. Robins Company.

SEROTONIN MOBILISES INTRACELLULAR FREE CALCIUM IN RAT CEREBROVASCULAR SMOOTH MUSCLE CELLS IN CULTURE. Y. Wang, K.G. Baimbridge and D.A. Mathers. Department of Physiology, University of British Columbia, Vancouver, B.C., Canada, V6T 1W5.

The effect of serotonin on cytosolic calcium mobilization was studied in short-term cultured smooth muscle cells dissociated from rat cerebral arteries. Free cytosolic calcium levels, $[Ca^{2+}]i$ were measured using the calcium sensitive fluorescent dye fura2-acetoxy-methyl ester. The resting $[Ca^{2+}]i$ was 39±3.6 (mean ± S.E.M., 34 cells). Serotonin (10 nM - 100 μM) induced a transient increase in $[Ca^{2+}]i$ in 39/110 cells tested. The latency of the increase in $[Ca^{2+}]i$ following the application of 5-HT was 23±3 sec (n=58 responses in 39 cells). The effects of two potent 5-HT antagonists were examined in 10 cells to determine the receptor type which mediates these agonist induced changes in $[Ca^{2+}]i$. Simultaneous application of 5-HT (1 μM) and the 5-HT_2 receptor blocker ketanserin (10 mM) reversibly and powerfully attenuated the response of the cell to 5-HT. In contrast, the selective 5-HT_1 receptor antagonist cyproheptadine (10 mM) had no effect on the mobilization of cytosolic calcium by serotonin.

198.5

DISTRIBUTION OF SEROTONIN 5-HT_{1C} RECEPTOR mRNA IN ADULT RAT BRAIN. B.J. Hoffman and E. Mezey. Laboratory of Cell Biology, NIMH, Bethesda, MD 20892.

Based on in situ hybridization histochemistry (ISHH), we describe the anatomical distribution of the serotonin 5-HT_{1C} receptor mRNA. In addition to the very high levels in epithelial cells of the choroid plexus, 5-HT_{1C} receptor mRNA is found throughout the limbic system, in catecholaminergic cell areas and in regions of serotonergic neurons. Receptor transcripts are also present in the hypothalamus, numerous motor nuclei and the subthalamus. Our results correlate well with serotonin (5-HT) innervation and receptor binding. Receptor mRNA is present in many brain structures in addition to regions previously shown to have 5-HT_{1C} receptor binding. The distribution of this receptor mRNA suggests that the 5-HT_{1C} receptor may mediate a number of the central effects of 5-HT.

198.6

ISOLATION AND CHARACTERIZATION OF A HUMAN SEROTONIN 5-HT_2 RECEPTOR CLONE. H.-T. Kao*, M.A. Olsen* and P.R. Hartig, (SPON:T. Branchek) Neurogenetic Corporation, 215 College Road, Paramus, NJ 07652

Pritchett et al. (EMBO J. 13:4135 (88)) reported the isolation and characterization of a rat cDNA clone encoding the serotonin 5-HT_2 receptor. This clone was isolated by screening a rat cDNA library with oligonucleotides derived from the sequence of the rat 5-HT_{1C} receptor. We now report the isolation of a human 5-HT_2 receptor cDNA clone. A human brain stem cDNA library was screened with a cDNA clone for the coding region of the rat 5-HT_{1C} receptor. Several homologous clones were isolated, including one (clone 15) which exhibited over 90% amino acid identity with the rat 5-HT_2 receptor. Clone 15 shows greatest homology to the rat 5-HT_2 receptor in the transmembrane regions (98% identity vs. 83% identity to the rat 5-HT_{1C} receptor). Clone 15 shows significant divergence from the rat 5-HT_2 sequence in the COOH terminal tail region where 16 amino acid substitutions were observed. Pharmacological binding data on the transfected clone will be presented.

198.7

RAPID DESENSITIZATION AND RESENSITIZATION OF 5-HT_2 RECEPTORS. P.J. Pauwels*, P. Van Gompel* and J.E. Leysen Dept. of Biochemical Pharmacology, Janssen Research Foundation, B-2340 Beerse, Belgium.

Regulation of peripheral 5-HT_2 receptors was studied in calf aortic smooth muscle cultures. Confluent cultures were washed and incubated for at least 24 h in a (5-HT)-free, synthetic medium before (5-HT)-induced inositol phosphates formation was measured. The latter had the characteristics of a 5-HT_2 receptor according to the profile of agonist concentration response curves and the inhibition of the response by 5-HT_2 antagonists at nanomolar concentrations. Cultures pretreated with 10 µM 5-HT, washed and stimulated with 10 µM 5-HT for 1 h in the presence of 10 mM LiCl, showed a diminished response. Already after 15 min pretreatment, the response was significantly reduced by 20 %, after 1 h pretreatment the response was reduced by 80 %, and the response was completely abolished after 6 h treatment. Pretreatment with 10 µM of the selective 5-HT_2 receptor agonist 1-(2,5-dimethoxy-4-methylphenyl)-2-aminopropane produced a similar time-course and degree of desensitization. In cultures pretreated for 2h and 24 h respectively with 10 µM 5-HT, and then kept for various time periods in a (5-HT)-free medium, the (5-HT)-induced inositol phosphates formation gradually returned to normal levels with half-times of 5 h and 12 h, respectively. The rapid desensitization followed by a relatively rapid resensitization points to decoupling/re-coupling or internalization/recycling phenomena.

198.8

5-HT1A AUTORECEPTORS: DEMONSTRATION OF A LARGE RECEPTOR RESERVE FOR 8-OH-DPAT AND PARTIAL AGONIST PROPERTIES OF NONBENZODIAZEPINE (NBD) ANXIOLYTICS. E. Meller, M. Goldstein and K. Bohmaker* (SPON: J.C. Miller). Dept. of Psychiatry, NYU Medical Center, New York, NY 10016.

Inhibition of 5-HT synthesis in rat brain by selective 5-HT1A agonists appears to be mediated by somatodendritic autoreceptors in the raphe nuclei. NBD anxiolytics display full intrinsic activity at 5-HT1A autoreceptors but are partial agonists at postsynaptic sites. Similar observations for dopamine (DA) agonists in the nigrostriatal DA system have been explained by a differential receptor reserve at pre- vs. postsynaptic sites. We now report that somatodendritic 5-HT1A autoreceptors display a large receptor reserve for the selective agonist 8-OH-DPAT.

Irreversible 5-HT1A receptor inactivation with N-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ; 6 mg/kg) shifted the dose-response curves for 8-OH-DPAT-induced inhibition of 5-HTP accumulation 8- and 6-fold to the right in cortex (CTX) and hippocampus (HIPP), respectively; those for the NBD buspirone (BUS) were shifted only 2- and 1.6-fold, respectively. A steep nonlinear relationship between receptor occupancy and response for 8-OH-DPAT was obtained (50% of maximal response at 3.3 and 6.5% receptor occupancy for CTX and HIPP, respectively). Shallower relationships were obtained for BUS (50% of maximal response at 14.6 and 21.2% occupancy, respectively); the efficacy of BUS was about 0.25 that of 8-OH-DPAT. The relative efficacies of other NBDs will be reported. Supported by NS 23618.

SPECIES DIFFERENCES IN THE ABILITY OF 5-HT_{1A} AGONISTS TO INHIBIT FORSKOLIN-STIMULATED ADENYLATE CYCLASE. L.J. Cornfield, S.S. Nikam*, E.W. Taylor* & D.L. Nelson. Col. of Pharmacy, Univ. of Arizona, Tucson, Arizona 85721.

Several purported 5HT_{1A} agonists were tested in the forskolin-stimulated adenylate cyclase (FSC) assay in Sprague-Dawley rat hippocampal membranes. These compounds, which included spiroxatrine and certain aryltryptamines, produced shallow, multicomponent curves, suggesting the involvement of interactions other than 5HT_{1A}. Use of pindolol, a 5-HT_{1A} selective antagonist, resulted in only a slight shift to the right of these inhibition curves, also suggesting that only a small proportion of the observed inhibition could be attributed to a 5-HT_{1A} interaction. Since the usefulness of calf hippocampus in the FSC assay was recently proposed (Schoeffter & Hoyer, Br. J. Pharmacol., 95:975, 1988), we have investigated the inhibition of FSC in bovine, as well as New Zealand White rabbit, hippocampal membranes. Results for spiroxatrine showed steeper inhibition curves and greater shifts to the right with pindolol than in the rat, suggesting a greater involvement of 5-HT_{1A} receptors. Overall, the bovine hippocampus appeared to have the greatest amount of 5-HT_{1A} receptor interaction associated with the ability of spiroxatrine to inhibit FSC. Consequently, the effect of species choice is an important consideration when attempting to use FSC as a screen for novel 5-HT_{1A} compounds. (Sup. by NS16605 and NS01009)

198.10

IDENTIFICATION OF 5-HT_{1A} RECEPTORS IN HUMAN GANGLIONEUROBLASTOMA BUT NOT RELATED TUMORS. J. Balletti* and M. R. Pranzatelli. (SPON: T. Pedley). Departments of Neurology and Pediatrics, Columbia University, NY 10032.

In exploring the hypothesis that neurotransmitter receptors may be a useful biologic marker of human neural tumors, we measured 5-HT_{1A} sites in human neuroblastoma (n=12), ganglioneuroblastoma (n=4), and ganglioneuroma (n=3). 5-HT_{1A} sites were measured in saturation studies by radioligand binding assays using 6 concentrations of [^{3}H]DPAT and 10 µM unlabelled 5-HT to define nonspecific binding. 5-HT_{1A} sites were found on ganglioneuroblastomas but not on the other tumors. B_{max} was 87 ± 29 fmol/mg protein, K_d was 2.33 ± 0.58 nM, and n_H was 0.94 ± 0.03. Competition experiments *in vitro* with 8-OH-DPAT, DOI, RU 24969, methysergide, ketanserin, and methiothepin identified parallel trends but significant differences in IC_{50}s between 5-HT_{1A} sites in ganglioneuroblastoma and rat frontal cortex (n=3). These data suggest that differences in receptor populations on human neural tumors may be a useful clinical diagnostic marker. (M.R.P. supported by NCI-Cooperative Human Tissue Network, NIH grant NS01158 (CIDA), the Myoclonus Research Fund, the United Cerebral Palsy Education and Research Foundation (R381-88), and the William Randolph Hearst Foundation).

NEONATAL 5,7-DIHYDROXYTRYPTAMINE LESIONS IN THE RAT: RESPONSE TO SELECTIVE 5-HT_{1A} AND 5-HT_2 AGONISTS. M. R. Pranzatelli, V. Hlibczuk, and A. M. Dollison. Columbia University, Departments of Neurology and Pediatrics, New York, NY 10032.

To study the involvement of 5-HT receptor subtypes in brainstem hyperinnervation following neonatal 5,7-DHT lesions made by intraperitoneal (ip) but not intracisternal (ic) injection, we measured behavioral responses to selective 5-HT_{1A} (8-OH-DPAT) and 5-HT_2 (DOI) agonists compared to 5-HTP after either route of 5,7-DHT injection. Effects of DOI, such as shaking behavior and forepaw myoclonus, were enhanced by 5,7-DHT lesions made ic whereas 8-OH-DPAT-evoked behaviors, such as forepaw myoclonus and head weaving, were enhanced with either route of 5,7-DHT injection, somewhat more ip. In contrast, 5-HTP-evoked shaking behavior was increased only after ip 5,7-DHT-injections, which decreased other 5-HTP-evoked behaviors. Behavioral supersensitivity to 5-HTP, which was orders of magnitude greater than that elicited by direct receptor agonists, more clearly differentiated between rats with 5,7-DHT lesions and their controls, and between routes of 5,7-DHT injection, than responses to 5-HT agonists. 5,7-DHT-induced dysregulation of 5-HT receptors, including both presynaptic and post-synaptic changes, better explains these data than post-synaptic changes alone. (Supported by NIH grant NS01158 (CIDA); the Myoclonus Research Fund; the United Cerebral Palsy Education & Research Foundation (R381-88); the William Randolph Hearst Foundation.)

INVOLVEMENT OF VENTRAL MEDULLARY 5-HT_2 RECEPTORS IN CARDIORESPIRATORY CONTROL IN THE CAT. K.A. King* and J.R.Holtman, Jr (SPON: W. R. Revelette). Department of Pharmacology, College of Medicine, University of Kentucky, Lexington, Kentucky 40536.

Central serotonergic mechanisms have been implicated in the control of cardiorespiratory activity. However, the specific effects of activation of the various serotonin receptor subtypes are not entirely clear. The purpose of the present study was to characterize the cardiorespiratory effects of the 5-HT_2 receptor agonist, 1-(2,5-dimethoxy-4-iodophenyl)-2-aminopropane, (DOI), at the intermediate area of the ventral medulla. Application of DOI (0.3-100 µg) to this site produced dose-related hypertension (+29.4±3.7 mm Hg at 100 µg, N=5) with no change in heart rate. In addition, DOI (100 µg) produced decreases in the amplitude of the phrenic and recurrent laryngeal nerve signals to 82.5±10.8 and 77.0±13.2% of control, respectively (N=4). A decrease in respiratory rate from 11±2 to 5±1 breaths/min accompanied the inhibition of the nerve amplitude. Pretreatment of the intermediate area with the 5-HT_2 receptor antagonist, ketanserin (20 µg), antagonized both the hypertensive (N=7) and respiratory depressant (N=3) effects of DOI. These results demonstrate the involvement of 5-HT_2 receptors at the intermediate area in changes in cardiorespiratory function produced from the ventral medulla. (Supported by HL-36050 to JRH).

FURTHER CHARACTERIZATION OF THE UNIQUE 5-HT_{1R} BINDING SITE IN RABBIT BRAIN. D.L. Nelson and W.-C. Xiong*. Col. of Pharmacy, Univ. of Arizona, Tucson, AZ 85721.

Recently, we have reported a unique high-affinity binding site for [^{3}H]5-HT ([^{3}H]5-hydroxytryptamine) in the rabbit caudate nucleus (CN), designated 5-HT_{1R}, that is distinct from previously defined 5-HT_1 subtypes (Xiong & Nelson, FASEB J. 3: A119, 1989). While similar to the 5-HT_{1D} site, the 5-HT_{1R} was shown to differ both pharmacologically and in its sensitivity to GTP and Ca^{++}. The present work extends these findings, confirming the differences between the 5-HT_{1R} and 5-HT_{1D} sites, defined respectively in the rabbit and bovine CN. [^{3}H]5-HT binding was measured as described for the 5-HT_{1D} receptor (Heuring & Peroutka, J. Neurosci. 7: 894, 1987), using pharmacologic masks of 5-HT_{1A} and 5-HT_{1C} receptors. At the 5-HT_{1R} site the divalent cations Mn^{++}, Mg^{++}, and Ca^{++} all facilitated the ability of GTP to inhibit [^{3}H]5-HT binding, while at the 5-HT_{1D} site all three cations reduced the ability of GTP to inhibit binding. Treatment of the CN membranes with N-ethylmaleimide (NEM) showed differences between the tissues as well. A maximum of about 40% of 5-HT_{1R} binding could be inhibited by NEM while 100% of 5-HT_{1D} binding was inhibited. The pharmacologic profile of the 5-HT_{1R} was consistent with that expected for a 5-HT receptor, but further work remains to determine if it may represent the rabbit's version of the 5-HT_{1D} receptor. NEUROPEPTIDE Y IN CEREBRAL CORTEX AND CAUDATE PUTAMEN NUCLEI OF RAT BRAIN: ULTRASTRUCTURAL BASIS FOR INTERACTIONS WITH GABA. C. Aoki & V.M. Pickel, Neurobiol. Div, Cornell U. Med. Coll., NY, NY 10021.

Neuropeptide Y (NPY)-containing neurons are believed to be mostly GABAergic in cerebral cortex but not in the caudate-putamen nuclei (CP). Thus NPY and GABA may play different roles in the intrinsic circuitry of these two regions. We tested this possibility by comparing the ultrastructure of NPY-containing neurons between (1) cortex (somatosensory and anterior cingulate areas) vs. dorsolateral CP; and (2) GABAergic versus non-GABAergic NPY-neurons within each area. Single sections were dually labeled for GABA and NPY by combining immunoautoradiography with the immunoperoxidase method. The ultrastructural features of NPY-perikarya in both regions were morphologically similar regardless of whether the cells also contained GABA. In both regions, nearly all NPY- and NPY-GABA labeled terminals formed symmetric junctions, the majority of which were with unlabeled dendrites. Unlike most singly-labeled GABAergic neurons, the NPY-receptive GABAergic neurons were sparsely innervated by other unlabeled terminals at proximal dendrites and soma. Thus, NPY may play a more prominent role in inhibitory modulation of certain GABAergic neurons than would be predicted by the observed frequency of contacts in the two regions. One notable regional difference was the greater prevalence of axo-axonic associations involving NPY-terminals in cortex. This difference may indicate greater presynaptic modulation of the release of NPY or co-existing transmitter in cortex. Alternatively, NPY, particularly in cortex, may modulate the release or postsynaptic action of transmitters within neighboring terminals. TWO FORMS OF GLUTAMATE DECARBOXYLASE (GAD), WITH DIFFERENT N-TERMINAL SEQUENCES, HAVE DISTINCT INTRANEURONAL DISTRIBUTIONS. D.L. Kaufman[1], C.R. Houser[2,3], and A.J. Tobin[1,3,4] Departments of Biology[1] and Anatomy[2], Brain Research Institute[3], and Molecular Biology Institute[4], University of California, Los Angeles, California 90024

The human and rat genomes contain only one GAD gene, but human and rat brains contain two forms of GAD, with M_rs of approximately 68,000 and 61,000 (GAD_{68} and GAD_{61}). We have produced an antiserum against GAD_{68} by immunizing rabbits with bacterially produced feline GAD. Epitopes specific to GAD_{68} reside in the amino terminal segment, consistent with the derivation of GAD_{61} from GAD_{68} by proteolytic removal of an amino terminal peptide, a region enriched in PEST sequences. Immunoprecipitation and immunohistochemistry suggests that proteolytic processing may regulate both the activity and the intraneuronal distribution of GAD. Supported by NS 21908, NS 22256, and NS 20356, and VA Medical Research Funds.

IMMUNOCYTOCHEMICAL STUDIES USING A NEW ANTISERUM AGAINST BACTERIALLY PRODUCED FELINE GLUTAMATE DECARBOXYLASE.
C.R. Houser, J.E. Miyashiro*, D.L. Kaufman and A.J. Tobin. Depts. of Anatomy and Biology, Brain Research Institute and Molecular Biology Institute, UCLA, and VA Medical Center, Los Angeles, CA 90024.

A rabbit antisera to GAD that was produced in bacteria programmed with feline GAD cDNA and recognizes a polypeptide of M_r ~68k has been immunocytochemically characterized. Using standard methods in rat tissue perfused with 4% paraformaldehyde, the regional distribution of GAD-immunoreactivity was similar to that observed with other GAD antisera. However, in many brain regions, the new antisera (K2) produced strong staining of neuronal cell bodies that have been difficult to label with previous antisera unless colchicine or special fixatives were used. Staining patterns were compared to those of a monoclonal antibody to GAD (MAb-6, generously provided by D. Gottlieb) that reacts primarily with a polypeptide of M_r ~60k. Some cell body and axon terminal staining was observed with each reagent, but cell body staining was consistently greater with K2 whereas terminal staining was pronounced with MAb-6. These findings support the hypothesis that a larger GAD polypeptide is present in the cell body and is converted to a smaller form that is concentrated in axon terminals. Supported by NS21908, NS22256, NS20356 and VA Medical Research Funds.

199.4

ISOLATION AND FUNCTIONAL ANALYSIS OF THE PROMOTER FOR HUMAN GENE ENCODING GLUTAMATE DECARBOXYLASE (GAD).
M.G. Erlander[1] and A.J. Tobin[2,3,4]. [1]Neuroscience Program, [2]Department of Biology, [3]Brain Research Institute, and [4]Molecular Biology Institute, University of California, Los Angeles, CA 90024-1606

Primer extension, nuclease protection, and nucleotide sequencing experiments suggest that the 5' flanking sequence of the GAD gene resembles that of constitutively expressed genes: (1) it contains four identical "GC boxes"; (2) it lacks any CAAT and TATA consensus sequences; (3) the mRNA is heterogeneous, with multiple start sites for transcription, all about 200 bases upstream from the AUG initiation codon. In transient transfection experiments, three flanking genomic fragments all drive the expression of a luciferase reporter in three rat cell lines, C6, B104, and rat 1 fibroblasts. Of these lines, only C6 produces GAD and GAD mRNA. The longest of the three fragments extended 1750 bases upstream from the transcription start site. The sequences responsible for the specificity of GAD gene expression must therefore lie outside this region. Supported by NS 22256, NS 20356, and the Ursula Mandel Scholarship.

CHRONIC Ro15-1788 AND FG 7142 ADMINISTRATION AUGMENT GABAa RECEPTOR FUNCTION IN CULTURED NEURONS.
L.G. Miller, F. Lopez,* A. Schatzki,* S. Chesley,* J. Heller,* D.J. Greenblatt.* Div. of Clinical Pharmacology, Depts. of Psychiatry and Pharmacology, Tufts-New England Medical Center, Boston, MA 02111.

After acute administration, Ro15-1788(Ro) is an antagonist at the benzodiazepine binding site on the GABAa receptor, and FG 7142(FG) is an inverse agonist. We assessed the effects of acute and chronic treatment with these agents on GABA-stimulated chloride uptake in primary chick cortical neurons in culture. Acute (1 hr) Ro(1 μM) treatment had no effect on uptake; however, after 2, 4, and 10 days(d) of treatment uptake was increased compared to vehicle (V) (Max: V 60.4; Ro: 2d 112.2; 4d 99.6; 10d 102 nmol/mg prot). Acute(1 hr) treatment with FG(1 μM) decreased chloride uptake (Max: V 54.6; FG 31.1 nmol/mg prot). However, chronic FG (1 μM) treatment at 2, 4, and 10 d markedly increased uptake (Max: FG 2d 182.6; 4d 164.8; 10d 172.2 nmol/mg prot). Neither compound altered non-GABA related chloride uptake, neuronal survival, or growth of non-neuronal cells. These results indicate that chronic inverse agonist treatment with FG 7142 augments GABAa receptor function and chronic treatment with Ro15-1788 may unmask inverse agonist effects.

199.6

ACUTE ETHANOL ADMINISTRATION DECREASES THE LEVEL OF GABA RECEPTOR α-SUBUNIT mRNAs IN RAT CEREBRAL CORTEX.
A.L. Morrow, P. Montpied*, E. I. Ginns*, B. M. Martin*, S. M. Paul* Clinical Neuroscience Branch, NIMH, Bethesda, MD 20892.

Pharmacologically relevant concentrations of ethanol have been shown to have direct and indirect effects on GABA receptor-mediated Cl^- flux in isolated synaptic vesicles and cultured neurons. To determine whether ethanol has an effect on the expression of genes encoding the GABA-A receptor, we have investigated the effects of acute and chronic (cf Montpied et al., this vol.) ethanol administration on the levels of GABA-A receptor (α-subunit) mRNA in the cerebral cortex. Rats were administered ethanol (2.0 g/kg, i.p.) or saline and sacrificed at various time points. Total RNA was purified from rat cerebral cortex, separated by gel electrophoresis and hybridized under high stringency with a 800bp human GABA-A receptor α-subunit ^{32}P-labelled cRNA probe, which labels multiple mRNA species in rat brain (J. Neurochem. **51**,652,1988).

Acute ethanol administration resulted in a rapid decrease in the two most abundant GABA receptor α-subunit mRNA's in cerebral cortex (4.4 and 4.8 kb mRNA's: Δ ~ 25-40%, $p<.05$, n=12-24). These effects were first observed 20 min following ethanol administration, were maximal 40 min post administration and were still present, although reduced, after 80 min. There was no effect of ethanol administration on the level of ribosomal RNA, poly(A)+ RNA, or the mRNAs coding for glutamic acid decarboxylase or β-actin. These data suggest that acute ethanol administration results in a rapid alteration in GABA-A receptor gene expression and/or mRNA processing.

199.7

CHRONIC ETHANOL EXPOSURE IN VIVO DECREASES THE LEVEL OF GABA-A RECEPTOR mRNAs IN RAT CEREBRAL CORTEX.
P. Montpied*, A. L. Morrow, P. Damshroder-Williams*, J. Karanian*, E. I. Ginns*, B. M. Martin*, S. M. Paul* (SPON: S. Koslow) Clinical Neuroscience Branch, NIMH, Bethesda, MD 20892.

Several lines of evidence suggest that ethanol's depressant effects are mediated in part by augmentation of GABAergic inhibitory neurotransmission. We have recently demonstrated that chronic exposure of rats to ethanol significantly decreases GABA-A receptor-mediated $^{36}Cl^-$ uptake in cerebral cortical synaptoneurosomes (J.P.E.T. **246**,158,1988). We have postulated that this adaptative response may be associated with an alteration of GABA-A receptor gene expression. To answer this question, a human GABA-A receptor α-subunit cDNA was used to synthesize a ^{32}P-labelled cRNA probe (J. Neurochem. **51**,652,1988). Rats were administrated ethanol by inhalation for 14 days, producing blood ETOH concentrations of 180 +/- 17.6 mg/%. Total RNA was extracted from the cerebral cortices of individual animals and analysed by Northern blots.

Chronic ethanol exposure resulted in a significant decrease in the levels of both GABA-A receptor (α-subunit) mRNA species in rat cerebral cortex, (4.8 Kb mRNA: 40%, $p< .05$; 4.4 Kb mRNA: 30%, $p< .05$, n=14). Glutamic acid decarboxylase mRNA, ribosomal RNA and poly(A)+ RNA levels were not significantly reduced following chronic ethanol exposure. Levels of β-actin mRNA were modestly reduced following chronic ethanol exposure (14% $p< .05$, n=14).

These data suggest that chronic ethanol exposure alters the level of GABA-A receptor gene expression and/or mRNA processing and may contribute to the development of ethanol tolerance and withdrawal.

199.8

NATURALLY OCCURING BENZODIAZEPINES IN CSF OF PATIENTS WITH HEPATIC ENCEPHALOPATHY
M. Olasmaa, A. Guidotti, J.D. Rothstein[1], S.M. Paul[2] and E.Costa FGIN-Georgetown Univ., Washington, D.C., [1]Dept. of Neurology, Johns Hopkins, Univ., Baltimore, M.D., [2]Clinical Neuroscience Branch, NIMH, Bethesda, M.D.

The reports that flumazenil, a benzodiazepine (BZ) antagonist, improves the neurological status of patients with hepatic encephalopathy (HE) led us to investigate the possible role of endogenous BZs in HE. Here we report that the content of BZ-like immunoreactivity in cerebrospinal fluid (CSF) of patients with HE was nearly four fold that of healthy subjects. An increase of the same order of magnitute was also observed in serum of patients with HE. In contrast, the corresponding values for patients with liver disease without encephalopathy and for patients with non-hepatic encephalopathy were comparable to those of healthy controls. Reverse phase HPLC analysis of control CSF revealed at least five separate peaks of BZ-like activity assessed by binding assay and three antibodies directed towards three specific BZs. The two peaks with the longest retention times corresponded to N-desmethyldiazepam and diazepam, whereas the three other peaks emerged in positions different from any known BZs that we tested. The material in the major peaks was more potent in displacing ^3H-flumazenil bound to membranes prepared from rat cerebellum than from spinal cord. This suggests that some of the BZ-like material present in CSF differs from diazepam. We are now investigating whether it is from dietary origin.

199.9

INCREASE OF DIAZEPAM BINDING INHIBITOR (DBI) IMMUNOREACTIVITY IN RAT BRAIN AREAS AFTER ACUTE NOISE STRESS. C.Ferrarese, T.Mennini[1], I.Appollonio*, M.Frigo*, M.Gobbi[1], N.Pecora*, M.Perego* and L.Frattola. Clinica Neurologica Universita'di Milano, Ospedale San Gerardo, Monza and (1)Istituto "Mario Negri", Milano, Italy.

DBI is a 10-kDa neuropeptide which allosterically modulates GABAergic transmission by binding to benzodiazepine recognition sites. Its brain levels are increased in benzodiazepine tolerant rats and it displays a proconflict activity when injected intraventricularly in rats (PNAS,80:3531,1983; PNAS,84:1444,1987).

We investigated the effects of acute noise-induced stress on brain levels of DBI and of its processing products. Rats were chronically habituated to handling and to the microwave box. On the day of the experiment stressed rats were sacrified at various times after noise-induced stress. After microwave fixation different brain areas were collected and stored at -80 c until the day of the assay. DBI was measured by a specific radioimmunoassay (RIA), its processing products were evaluated with a RIA for the synthetic 18 AA fragment of DBI, called octadecaneuropeptide (ODN). The different immunoreactivities were characterized by reverse-phase HPLC.

DBI levels were increased in parallel to its putative products of processing in cerebral cortex and hippocampus 15 minutes after acute stress and persisted elevated up to 90 minutes. No change of HPLC elution time was observed. The increase was significantly higher in left cortex and hippocampus compared to the right side. These data indicate that acute noise stress increases DBI turnover in rat brain; the increase is lateralized in left cortical and limbic areas.

199.10

β-ALANINE INDUCES CHANNELS OF HIGH CONDUCTANCE IN CULTURED SPINAL CORD NEURONS. D.A. Mathers, A. Grewal* and Y. Wang. Dept. of Physiology, Faculty of Medicine, University of British Columbia, Vancouver, B.C., Canada V6T 1W5.

β-Alanine (BALA) is a naturally occurring amino-acid, intermediate in structure between the putative inhibitory neurotransmitters γ-aminobutyric acid (GABA) and glycine. BALA exerts a marked inhibitory effect on the firing of certain cells in the spinal cord and brain of mammals. The molecular mechanisms which underlie this action were studied in cultured spinal cord neurons maintained in dissociated cell culture. Patch-clamp recordings were obtained from outside-out membrane patches using a List EPC-7 amplifier. Patches were voltage-clamped to a potential of -80 mV at 21-22°C. Patch electrodes contained 11 mM EGTA and $Tris^+$ replaced K^+. Bath application of BALA (10-40 μM) induced inwardly directed single channel currents in nearly all patches tested. These events inverted to outward currents at 0 mV, the chloride equilibrium potential. Amplitude histograms revealed that BALA-induced channels can adopt at least five conductance levels (8.3, 16.9, 26.5, 43.8 and 82.1 pS, means from 5 patches). The lower four conductance states are very similar to values previously reported for GABA and glycine in this preparation. The 81 pS level is, however, apparently unique to channels activated by BALA.

199.11

BENZODIAZEPINE RECEPTORS MODULATE 5-HT RELEASE: AN IN VIVO ELECTROPHYSIOLOGICAL STUDY IN THE RAT HIPPOCAMPUS. A. Lista*, P. Blier and C. de Montigny. (SPON: A. Gjedde). Dept. of Psychiatry, McGill Univ., Montréal, Canada.

Benzodiazepines facilitate the electrically-evoked release of [^{3}H]5-HT from slices of rat frontal cortex or hippocampus via the type 1 benzodiazepine receptor (BZ-R) (Lista et al., J. Neurochem. 51:1414, 1988). The present study was undertaken to investigate in vivo the effect of BZ-R activation on the efficacy of the 5-HT synapse in the dorsal hippocampus. Male Sprague-Dawley rats were anesthetized with chloral hydrate. Extracellular recordings were obtained from CA_3 hippocampus pyramidal neurons with five-barrelled glass micropipettes. 5-HT and GABA were applied by microiontophoresis and all other drugs were administered intravenously. The ascending 5-HT pathway was electrically stimulated and the effect of the stimulations was determined from peristimulus time histograms. The BZ-R agonists diazepam (0.05-2 mg/kg), lorazepam (0.05-2 mg/kg) and CL 218 872 (1-10 mg/kg) enhanced in a dose-dependent manner the effectiveness of the stimulation of the 5-HT pathway, whereas the BZP-R inverse agonist FG 7142 (0.05-1 mg/kg) dose-dependently decreased it. These effects of both diazepam and FG-7142 were blocked by the BZ-R antagonist flumazenil. Picrotoxine and bicuculline reduced the effectiveness of the 5-HT pathway stimulation; the subsequent administration of diazepam restored the efficacy of the stimulation. Neither the effect of 5-HT nor that of GABA, applied by microiontophoresis onto the same dorsal hippocampus pyramidal neurons, were modified by diazepam, FG-7142 or flumazenil. Hence, taken together, these data indicate that, in vivo, BZ-R ligands modulate 5-HT synaptic efficacy via a presynaptic mechanism by activating type 1 BZ-R coupled to the $GABA_A$-Cl channel complex.

199.12

COMPARATIVE EFFECT OF DIFFERENT BENZODIAZEPINE RECEPTOR LIGANDS UPON SINGLE CELLS' ACTIVITY. G.P. MEREU AND G. BIGGIO, Dep. Exp. Biology, University of Cagliari, Italy.

The action of structurally unrelated ligands for the benzodiazepine (BDZ) receptors upon the spontaneous activity of Substantia Nigra-Pars Reticulata (SNR) neurons was evaluated by using "in vivo" single cell recording and systemic (i.v.) administration. The tested drugs included both "positive" and "negative" modulators of the BDZ receptors, as well as preferential ligands for one of the receptor subtypes (1, 2 and P). SNR cells were inhibited by various BDZ ligands classified as "positive" modulators (or agonists). Rank order of their potency was: Flunitrazepam >> Zolpidem > Triazolam > ZK93423 > Alprazolam > Diazepam > Alpidem > Quazepam ~ Flurazepam. On the contrary, BDZ ligands considered "negative" modulators (or inverse-agonists) activated cell firing. Rank order of their potency was: β-CCM > DMCM > β-CCE > RO15-4513 > RO5-6993 >> FG7142. The two antagonists which were tested, Flumazenil (RO15-1788) and ZK93426, were almost inert per se, yet they antagonized the response of both positive and negative modulators, except RO5-6993, which was blocked by PK11195. The results indicate that in spite of their chemical origin, BDZ-ligands behave in the SNR model coherent with their action on Cl^- channels. However, their relative potency and intrinsic efficacy is likely related to their affinity and selectivity for BDZ receptor subtypes.

TRANSPLANTATION II

200.1

CURRENT CLINICAL STATUS OF THE FIRST MEXICAN AUTO- AND FETAL HOMOTRANSPLANTED PARKINSONIANS. I. Madrazo (1), R.E. Franco-Bourland*(2), F. Ostrosky-Solís*(3), M.C. Aguilera*(1), V. Díaz*(1) and C. Cuevas*(1). 1-Ctro. Med. La Raza, IMSS; 2-Inst. Nal. Nutrición SZ; 3-UNAM, México, D.F., Mex.

Three years after the initiation of adrenal medullary autotransplantations (AT), and 19 months after ventral mesencephalon and adrenal gland fetal homotransplantations (HT) to the caudate nucleus for the treatment of Parkinson's disease in our department, the clinical evaluations of the first 5 AT patients, and of the first 2 parkinsonians with fetal HT have revealed that they have maintained the level of recovery they attained approximately 4 months to 1 year after surgery. All patients were evaluated using internationally approved rating scales, and well defined neuropsychological and neurophysiological tests. Currently, of the 5 AT parkinsonians, the clinical scores of 3 of them continue to be rated as "good", those of another have remained steady at a "moderate" level, and the scores of the 5th patient still show his "poor" response to surgery. The scores obtained by the fetal ventral mesencephalon HT patient were "very good", and those obtained by the fetal adrenal gland HT patient were "good". We therefore conclude, that the patients' responses to any of the alternative transplantation procedures reached in the first 4-12 months postsurgery are likely to remain unaltered for at least 24-30 months in the case of the AT individuals, and for at least 15-16 months in the case of the parkinsonians with fetal HT.

200.2

BEHAVIORAL RECOVERY FROM MPTP-INDUCED PARKINSONISM IN MONKEYS AFTER INTRACEREBRAL TISSUE IMPLANTS IS NOT LINKED TO CSF CONCENTRATION OF DOPAMINE METABOLITES. K.S.Bankiewicz, R.J.Plunkett*, I.Mefford, I.J.Kopin, E.H.Oldfield*. Surgical Neurology, NINDS, NIH, Bethesda

Implantation of fetal dopaminergic (FDA) tissue into preformed cavities in the caudate nucleus leads to behavioral recovery. Recovery may be related to 2 sources of dopamine(DA): the grafted cells or sprouted fibers from host ventral tegmental DA neurons. After implantation of adrenal tissue(AD) behavioral recovery occurs but does not significantly differ from monkeys that are implanted with adrenal cortex, fat or cavitated only. However, their behavioral recovery is significantly less then that in FDA implanted animals. 7m after implantation, surviving AD was detected only in one monkey which had no behavioral recovery. All other AD implanted or controls showed behavioral recovery which was correlated with the presence of sprouted host DA fibers. We measured CSF concentrations of HVA, MHPG and 5-HIAA in all animals before and after MPTP administration and at intervals after tissue implantation or cavitation only. There was a dramatic drop of CSF HVA after MPTP (1100±220 pmol/ml baseline, 243±79 pmol/ml after MPTP). In 1 of 4 FDA implanted monkeys increased HVA sustained for 6m (800 pmol/ml before MPTP, 200 pmol/ml after, 450 pmol/ml 2m after implant, 740 pmol/ml 6m after implant). However in this monkey behavioral recovery was modest and the graft at autopsy was not TH-positive. In 3 AD implanted monkeys there was a transient increase of HVA after implantation and it then returned to post-MPTP levels. These results indicate that 1) implants do not have to be DA to induce functional recovery in MPTP-lesioned primates, 2) functional recovery does not correlate with HVA levels in CSF, 3) implant-induced host DA sprouting plays a role in behavioral recovery and 4) CSF catecholamine metabolites are not adequate indicaters of graft survival or functional recovery.

200.3

ADRENAL MEDULLARY IMPLANTS IN THE CAUDOPUTAMEN OF THE MUTANT MOUSE WEAVER. S. Roffler-Tarlov, R. Koeleveld, M. Kaniucki, A.M. Graybiel, and M. Bohn. Prog. in Neurosci. & Dept. of Neurosurg., Tufts Univ. Sch. Med., Boston, MA 02111; Dept. Brain & Cog. Sci., MIT, Cambridge, MA 02139; Dept. Neurobiol. & Anat., Univ. Rochester, Rochester, NY 14642

The disorder in mice caused by the autosomal recessive gene known as weaver results in a pattern of dopamine loss in the nigrostriatal system that is strikingly similar to that seen in idiopathic Parkinson's disease and in parkinsonism induced in man and in animals by the neurotoxin MPTP.

We report here the results of experiments in which adrenal implants were placed stereotaxically into the striatum of normal control mice and mice carrying the weaver mutation. The implants, enriched for adrenal medullary tissue, were taken from young normal donors. Pieces of adrenal medullary tissue were placed unilaterally into the control caudoputamen (CP), the dopamine-depleted CP of adult weaver mice and the developing CP of 7 day-old weavers, in which the nigrostriatal system had not yet degenerated. Grafted tissue survived in controls and in both adult and immature weavers, and included small numbers of tyrosine hydroxylase (TH)-positive cells that did not grow processes. The implants did not induce convincing reinnervation originating in the adult weaver host, in contrast to the results reported for similar implants in MPTP-treated adult mice (Bohn et al., Science 237:913, 1987). However, the implants in the 7 day-old weavers appeared to rescue partially TH-containing innervation. Viewed with TH-immunohistochemistry 4 weeks after implantation, the catecholamine innervation typical of the weaver's CP was markedly altered with a much greater density of TH-positive innervation in the dorsolateral CP bilaterally than in unimplanted weavers. The new pattern of innervation displayed a compartmental organization characterized by fields of heavy innervation surrounding pale-staining zones reminiscent of striosomes.

COMPARISON OF CAUDATE LESIONING AND ADRENAL MEDULLA GRAFTING IN 6-OHDA RATS. G.M. Friehs*, L.S. He*, R.G. Parker*, C.L. Ojakangas, D.A. Turner, S.J. Haines*, T.J. Ebner. (SPON: D. Onstott). Dept. Neurosurgery, Univ. of MN, Mpls., MN 55455.

A central issue concerning the efficacy of adrenal grafting for parkinsonian motor abnormalities is the mechanism underlying any improvement. In this study we compared the effects of adrenal medullary transplantation and radiofrequency lesions of the caudate nucleus in 6-OH dopamine (6-OHDA) rats. Using a randomized 2 by 2 design, 4 groups of 4 6-OHDA rats were studied for their rotational behavior to apomorphine: a) controls, b) radiofrequency (RF) lesion, c) heterologous adrenal medullary transplants and d) radiofrequency lesion followed by transplant. The RF lesion group showed a more than 90% reduction relative to control ($p<0.001$). The transplanted group showed a reduction in rotations of 28% ($p<0.05$). The caudate lesion plus graft group showed a persistent reduction (85%, $p<.001$), which did not differ from the RF lesion group. Immunohistochemical and histological findings documented the extent of the 6-OHDA lesion, the presence of the graft and lesion extent. The results show that disruption of the caudate nucleus alone is highly effected in reducing rotational behavior in this model. Supported by Minnesota Medical Foundation and AANS Research Foundation.

NORMALIZATION OF SUPERSENSITIVE D-1 AND D-2 DOPAMINE RECEPTORS IN THE 6-OHDA DENERVATED RAT AFTER TRANSPLANTATION OF FETAL MESENCEPHALON. J.K. Wamsley,* F.H. Gage,# V.L. Dawson,* L.J. Fisher,# and T.M. Dawson.** *Depts. Psych., Pharm., West. Inst. Neuropsych., Univ, UT, Sch. Med., SLC, UT; #Dept. Neurosci., Univ. CA, San Diego, La Jolla, CA; **Dept. Neurol., Hosp. Univ. Penn., Phila, PA

Transplantation of fetal substantia nigra (SN) into the 6-OHDA lesioned rat has been shown to result in the reversal of many of the behavioral dysfunctions associated with this rat model of Parkinson's Disease. Following transplatation and behavioral recovery one would expect normalization of supersensitive D-1 and D-2 dopamine (DA) receptors. Inorder to test this hypothesis we examined D-1 receptors labeled with [^{3}H]SCH 23390, D-2 receptors labeled with [^{3}H]sulpiride and the DA transport complex (DA-TC) labeled with [^{3}H]BTCP in the striatum of the DA denervated rat, with or without, homologous fetal SN transplants. In lesioned animals, which exhibited marked ipsilateral turning after subcutaneous amphetamine administration (<95% depletion of DA), there was a significant loss (-60%) of the DA-TC and a concomitant increase in D-1 receptors (+26.2%) and D-2 receptors (+57.6%) in the caudate-putamen. 10 to 12 months after transplantation a group of animals ceased rotating in the ipsilateral direction after amphetamine adminstration and in these animals D-1 and D-2 receptor densities were comparable to control values. These results provide evidence that functional recovery of SN transplants may be, in part, a receptor mediated phenomena.

EXPRESSION OF CELL ADHESION MOLECULES FROM THE L2/HNK-1 FAMILY IN RAT ADRENAL MEDULLA IN SITU, IN VITRO, AND AFTER INTRAVENTRICULAR TRANSPLANTATION. M. Poltorak*, K. Shimoda*, M. Schachner+, C.R. Rodgers* and W.J. Freed (SPON: N. Breslin). NIMH at St. Elizabeths, Washington, DC 20032 and +University of Heidelberg, FRG.

The cell adhesion molecules (CAMs) play an important role in regeneration and development of the nervous system and may be involved in the functional effects of adrenal medulla grafts. We have studied the expression of the CAMs L1/Ng-CAM, N-CAM, J1 molecules, MAG, and their common L2/HNK-1 epitope, in normal rat adrenal gland sections, in adrenal medulla cell cultures with and without NGF stimulation, and after intraventricular transplantation. In situ L1/Ng-CAM and N-CAM were observed on chromaffin cell clusters and surrounding extracellular matrix (EM). J1 immunoreactivity was associated only with EM. In vitro NGF stimulation enhanced both L1/Ng-CAM and N-CAM immunolabeling on chromaffin cells and their neurites, and L1/Ng-CAM on Schwann cells. The outgrowth of neurites was greater in chromaffin cell clusters containing S-100 positive Schwann cells as compared to dispersed single chromaffin cells. Chromaffin cells were grown on a layer of N-CAM and fibronectin positive fibroblasts, and often were associated with laminin immunoreactive material. These findings are currently being compared with the expression of CAMs in adrenal medulla grafts. Our results suggest that the increase in CAM expression on chromaffin and Schwann cells produced by NGF may be implicated in the survival of grafted tissue and its effects on host brain.

ENCAPSULATED PC12 CELLS SURVIVE CROSS-SPECIES NEURAL TRANSPLANTATION. P.A. Tresco *, S.R. Winn, P. Aebischer, C. B. Jaeger, L.A. Greene (SPON: J. McIlwain). AOL, Brown University, Providence, RI; CPR Purdue University, W. Lafayette, IN & Dept. Path., Columbia Univ., New York, NY, USA.

We are investigating polymer encapsulation as a means to immunoprotect neurosecretory tissue from rejection following cross-species transplantation into the CNS. Encapsulation with a permselective polymeric membrane (Mw cut-off of 50,000 Da) allows exchange of small molecules such as nutrients, growth factors and neurotransmitters to diffuse but prevents immunoglobulins and host cells from crossing the membrane. Acrylic copolymer U-shaped capsules were stereotaxically implanted into the striatum of six adult male guinea pigs and then loaded with PC12 rat pheochromocytoma cells. Five weeks later, PC12 cells were observed in 4 of the 6 capsules. The capsules contained well preserved tyrosine hydroxylase immunopositive cells and numerous mitotic figures. Histological analysis indicated that one of the failed implants most likely was a result of damage to the capsule wall. In this case, abundant lymphocytes were observed within and around the polymeric capsule. In contrast, only a mild astrocytic reaction was observed around intact polymer capsules containing PC12 cells. Unencapsulated PC12 cells did not survive transplantation into the guinea pig striatum. These findings indicate that polymer encapsulation provides immunoprotection of a neurosecretory cell line following cross-species transplantation without the need for immunosuppessive therapy. We conclude that the transplantation of encapsulated dopamine secreting cell lines may provide an alternative for the treatment of Parkinson's disease.

POLYMER ENCAPSULATION OF DOPAMINE SECRETING TISSUE: AN IN VITRO EVALUATION. P. Aebischer, P.A. Tresco *, S.R. Winn, C.B. Jaeger, L.A. Greene. AOL, Brown University, Providence, RI, CPR Purdue University, W. Lafayette, IN and Dept. Pathology, Columbia University, New York, NY, USA.

Transplantation of polymer immunoisolated dopaminergic tissue may constitute an alternative for the treatment of Parkinson's disease. The encapsulation of secretory tissue within a permselective polymer capsule not only restricts the outgrowth of mitotically active cells but may prevent host rejection allowing cross-species transplantation. The effect of encapsulation on cell viability and dopamine secretion was assessed by loading a variety of cell types into acrylic copolymer capsules. These included dissociated mouse E14 mesencephalon, adrenal medulla, PC12 rat pheochromocytoma cells and NX31-T28 mouse hybrid cells. Basal and potassium-stimulated (56mM) release of catecholamines from the capsules was quantified under static incubation conditions by HPLC-EC. After one month of encapsulation, all cell types continued to release dopamine in the unstimulated state. High potassium treatment increased dopamine release from all cell types except NX31-T28. Encapsulated NX31-T28 cells did, however, increase their release of l-dopa under nicotine stimulation. The tumor cell lines increased their output of dopamine over time, whereas embryonic mesencephalon and chromaffin cells did not. Basal release of PC12 capsules (5 mm long, 0.8 mm ID) kept in culture for 2 months averaged 336 ng of dopamine per day. The increased output of dopamine from the encapsulated tumor cell lines is believed to be due to cell proliferation within the polymer capsule. We conclude that a variety of dopamine-secreting cell types survive encapsulation and continue to release dopamine over several weeks.

EVALUATION OF MELANOCYTES AS A POTENTIAL CELL SOURCE FOR DOPA REPLACEMENT. P. J. Kontur, A. Y. Deutch, A. Jotkowitz*, M. Lee*, A. B. Lerner*, R. Halaban* and R. H. Roth. Departments of Pharmacology and Dermatology, Yale University School of Medicine, New Haven, CT 06510.

Melanocytes contain the enzyme tyrosinase which catalyzes the hydroxylation of L-tyrosine to L-DOPA and the oxidation of L-DOPA to DOPA-quinone. Melanocytes may serve as an alternative to adrenal or neuronal cells for transplantation in animal models of Parkinson's disease because they have the capacity to synthesize L-DOPA. The ability of neonatal human melanocytes to secrete DOPA into culture medium and to survive after intrastriatal transplantation were evaluated. Significant levels of DOPA were detected in the medium using HPLC 30 min after incubation in media containing 10^{-5} - 4 x 10^{-4}M tyrosine. The levels continued to increase over 24 hrs. The ability of the melanocytes to survive after transplantation to the striata of non-immunosuppressed rats was evaluated in animals with or without unilateral 6-OHDA-induced lesions of nigrostriatal dopamine (DA) neurons. Melanocytes were seen in discrete cell clusters in the striata and did not appear to proliferate when examined 4-5 months post-transplantation. Melanocytes survived in both DA-denervated and intact striatal regions. These data suggest that melanocytes may serve as an alternative transplantable cell source of DOPA for the treatment of Parkinson's disease. Supported in part by USPHS Grant MH 14092 and the United Parkinson Foundation.

DEFICIENT LEARNING DURING HEPATIC ENCEPHALOPATHY IN THE RAT: EFFECTS OF FETAL STRIATAL GRAFTS. R. Tapia, A.L. Piña*, M. Díaz-Muñoz*, J.C. López-García* and F. Bermúdez-Rattoni. Inst. de Fisiología Celular, Univ. Nacional Autónoma de México, 04510-México D.F.

A useful model of hepatic encephalopathy in rats is provided by chronic treatment with carbon tetrachloride, which produces liver damage closely resembling human cirrhosis. We have studied the effect of such treatment on passive avoidance conditioning (PAC) and locomotor activity (LA). The cirrhotic animals showed a marked deficiency in the acquisition of the PAC and a 70% increase in LA, as compared to controls. Six of 8 cirrhotic rats homotopically transplanted with fetal striatum showed a notable improvement in the PAC 8 weeks after surgery, whereas the increased LA was not modified. Control cirrhotic rats with sham transplant did not recover the response. Striatal glutamate decarboxylase activity was decreased in the cirrhotic rats (J. Neurosci. Res. 20:376, 1988) and the grafting did not reverse this decrease. Striatal choline acetyltransferase activity was found unchanged in both the control and the grafted cirrhotic rats. Histochemical examination of AChE revealed an incomplete integration between graft and host tissue, although patches of low AChE-positive reaction were observed in the graft. This is the first experimental demonstration of a behavioral alteration due to liver failure and of its reversal by fetal transplants. Supported in part by the CoNaCyT (grant PCEXCNA-050290).

ACETYLCHOLINE RELEASE FROM INTRAHIPPOCAMPAL SEPTAL GRAFTS IS UNDER CONTROL BY THE HOST BRAIN: AN INTRACEREBRAL MICRODIALYSIS STUDY. O.G. Nilsson*, P. Kalen*, E. Rosengren*+ and A. Björklund. Departments of Medical Cell Research and Pharmacology+, University of Lund, Lund, Sweden.

Extracellular levels of acetylcholine (ACh) were measured in the hippocampal formation using *in vivo* microdialysis coupled to high performance liquid chromatography with electrochemical detection. Normal rats, rats with chronic (12 months) fimbria-fornix (FF) lesions, and rats with FF lesions plus intra-hippocampal septal suspension grafts (12 months post-lesion and grafting) were used. The effects on ACh release of handling (stroking), electrical stimulation of the lateral habenula (15 Hz, 0.3 mA), and addition of potassium chloride (KCl, 100 mM), or tetrodotoxin (TTX, 1 uM) to the perfusate were studied in awake animals. In order to reach stable and reliably measurable baseline levels of ACh, neostigmine (5 uM) was added to the perfusate during all manipulations. Baseline levels of ACh in normal rats before manipulations were on average 1.8 pmoles/30 ul of perfusate. Handling produced a 110% increase and lateral habenula stimulation increased ACh levels 4-fold. KCl produced a 5-fold increase in ACh levels and addition of TTX to the perfusate produced an approx. 75% reduction. While the FF lesioned rats had very low levels of ACh (about 30% of normal) and showed no reaction to the different manipulations, the grafted rats exhibited normal or supranormal baseline levels of ACh (about 2-5 pmoles/30 ul). Similar to the normal rats, they responded to handling (55% increase), habenula stimulation (3-fold increase), KCl (3-fold increase) and TTX (80% decrease). It is concluded that the intrahippocampal septal grafts restore baseline extracellular ACh levels and that the graft-derived ACh release is dependent on axonal impulse flow. The response to handling and habenula stimulation, moreover, indicate that the activity of the ectopically placed septal grafts can be regulated from the host brain and modified during ongoing behavior.

NERVE GROWTH FACTOR INCREASES SIZE OF FETAL BASAL FOREBRAIN GRAFTS IN CORTEX OF NUCLEUS BASALIS LESIONED RAT BRAINS. *P.R. MOUTON*, T. EBENDAL*, L. OLSON* (SPON:S. SWIHART). Dept. Neurobiology & Histology, Karolinska Institute, S-10401 Stockholm, Sweden.*

Nerve Growth Factor (NGF) may act on central cholinergic neurons as a trophic factor. This hypothesis was tested on immature rat basal forebrain, an area rich in cholinergic neurons and analogous to a primary region which degenerates in the brains of Alzheimer's disease patients.

Ibotenic acid lesions of the right nucleus basalis provided cholinergic denervation of the ipsilateral frontal cortex. Two weeks to two months later, some animals received multiple 2 ul implants of basal forebrain cell suspension into the right cortex. On the same day, continuous infusion of NGF or cytochrome-C was started via osmotic minipump and continued for one month. Animals were killed and their brains processed for histochemical analyses. Planimeter measurements revealed a reduction in transplant size of 34% in NGF-untreated rats, while NGF-treated rats showed an increase of 65% (mean values, relative to initial volume), suggesting a trophic role for NGF on developing basal forebrain tissue. Further studies are needed to confirm the cholinergic-specific nature of these findings.

200.13

MAGNETIC RESONANCE IMAGING OF RAT BRAIN IN VIVO: USE OF GADOLINIUM-DTPA IN NEUROPATHOLOGIES AND FETAL STRIATAL TISSUE TRANSPLANTS. A.B. Norman, S.R. Thomas*, R.G. Pratt*, R.C. Samaratunga*, M. Kolmonpunporn and P.R. Sanberg. University of Cincinnati College of Medicine, Div. of Neuroscience and Dept. of Radiology, Cincinnati, OH 45267.

The contrast agent gadolinium (Gd)-DTPA is used in humans to enhance various neuropathologies that are not normally distinguishable in magnetic resonance (MR) images. We investigated the ability of intravenously administered Gd-DTPA to enhance various neuropathological models in rat brain in vivo.

Male Sprague-Dawley rats were used in all studies. Unilateral models of various pathologies were employed: a) mechanical trauma induced by insertion of a needle into the brain; b) hyperosmotic disruption of blood-brain barrier (BBB) following intravenous and intracarotid infusion of mannitol; c) C6 glioma cell tumor; d) rat fetal striatal tissue transplants.

Enhancement of brain regions by Gd-DTPA requires disruption of the BBB or anomolous vascular formations. Gd-DTPA produced no observable enhancement of structures within the normal side of any brain. Hyperintense areas corresponding to mechanical trauma were evident at 24 hours, but not 2 hours or 5 days post-surgery. Mannitol infusions produced marked enhancement of brain regions in the frontal and hind brain. The tumors formed by the C6 glioma cells were greatly enhanced following Gd-DTPA administration. In two rats with 4 week transplants, no significant enhancement by Gd-DTPA was observed. Gd-DTPA is a useful tool for investigating in vivo the vascular changes produced by various neuropathologies in rat brain.

PHASE RESPONSES TO TEMPERATURE PULSES IN LABORATORY RATS. A.J.Francis* and G.J.Coleman* (SPON:B. Oldfield) Dept of Psychol., Latrobe Univ., Bundoora Vic 3083 Australia.

Compared to light, ambient temperature (Ta) appears to be a relatively weak zeitgeber for the mammalian circadian system. Species which have been convincingly demonstrated to entrain to cycles of high and low Ta (TaHL) are Macaca nemistrina (Tokura, H. and Aschoff, J., Am. J. Physiol., 245:800, 1983) and Rattus norvegicus (Francis, A. and Coleman, G., Physiol. and Beh., 43:471, 1988). The discrete effects of short pulses (2 hours duration) of high Ta (35 °C) upon the free running locomotor rhythms of male and female laboratory rats, maintained in dim LL and 21 °C, were examined to determine the phase-shifting properties of Ta as a zeitgeber. A phase response curve was obtained. Phase responses were largely delaying with a negative correlation between period length and magnitude of phase shift.

201.2

POTASSIUM CHANNEL BLOCKADE LENGTHENS THE PERIOD OF THE HAMSTER CIRCADIAN WHEEL-RUNNING RHYTHM. Harry Klemfuss and Daniel F. Kripke,* Veterans Administration Medical Center and University of California, San Diego.

We recently reported that dietary intake of potassium can influence the phase and period of circadian wheel-running in the hamster (Brain Research, in press). This finding led us to examine whether drugs affecting ion transport alter circadian rhythms in this species.

Adult male Syrian Golden hamsters, housed in running wheel cages in constant darkness, were given drinking water containing 20 mg/L of the potassium channel blocker 4-amino-pyridine (4AP).

The period of wheel-running was significantly lengthened by 4AP compared to water control. During days 4 to 11 of 4AP treatment, tau averaged 24.23 $\pm$ 0.17 (SD) hr by periodogram analysis vs. mean control tau of 24.08 $\pm$ 0.14 hr ($p<0.05$; n=14 and 9).

Linear regression on activity onsets produced similar estimates also indicating that 4AP significantly lengthened tau.

These results are consistent with the proposal that intracellular potassium may be involved in the control of circadian rhythms in the hamster, as has been suggested for plants and invertebrates. Preliminary results using verapamil (400 mg/L) suggest a similar lengthening of tau following calcium channel blockade.

Supported by the Veterans Administration and NIMH MH00117.

RESTRAINT CAN INDUCE PHASE DEPENDENT DELAYS IN THE HAMSTER CIRCADIAN CLOCK. O. Van Reeth*, J.M. Tecco* and F.W. Turek. Lab. of Interdisciplinary Research Institute in Human and Nuclear Biology, Université Libre de Bruxelles, Campus Erasme, Brussels, Belgium, and Department of Neurobiology and Physiology, Northwestern University, Evanston, IL 60208, USA.

Using the rhythm of locomotor activity as an assay of the clock, we have recently demonstrated that the phase-advancing and phase-delaying effects of dark pulses or triazolam on the hamster circadian clock are mediated through an acute stimulation of locomotor activity. These findings raise important questions about the role exerted by activity on the circadian system of mammals. In order to address this question directly, male golden hamsters free running in constant light ($\approx$ 600 lux) were submitted on 1-3 occasions (separated by at least 14 days) to a 3-h restraint procedure. The beginning of restraint was timed to occur at the following circadian times (CT): 0, 3, 6, 9, 12, 15, 18 and 21, with the onset of locomotor activity defined as CT12. While restraint during the periods of inactivity (i.e. between CTs 0 and 12) or reduced activity (i.e. between CTs 18 and 0) had little or no phase shifting effect on the circadian rhythm of locomotor activity, restraint during the period of normally intense activity induced phase-delays in the activity rhythm (CT 12-15: -52 $\pm$ 9 min, CT 15-18: -38 $\pm$ 10 min). The results of this experiment indicate that activity may have a feed-back effect on the circadian system, and thus may be part of the regulatory system for normal circadian time-keeping.

201.4

AGING ALTERS THE PHASE SHIFTING EFFECTS OF LIGHT PULSES ON THE HAMSTER CIRCADIAN CLOCK. P.C. Zee*, R.S. Rosenberg and F.W. Turek, Dept. of Neurobiology and Physiology, Northwestern University, Evanston, IL 60208.

We have recently reported age-related changes in the rate of reentrainment of the circadian rhythm of locomotor activity following shifts of the light-dark cycle in golden hamsters. One explanation for this differential rate of reentrainment is that aging alters the response of the circadian pacemaker to light. To test this hypothesis, the effects of aging on the phase shifting effect of single one hour saturating light pulses on the circadian rhythm of locomotor activity in golden hamsters was determined at circadian times (CT) 14, 16 and 19. All age groups (2, 5, 8, 13, 16 or 21 months at the start of the study), showed phase delay shifts of similar magnitude to light pulses administered at CT 14. However, in old (16-21 months) animals, phase advances in response to light pulses given at CT 16 and CT 19 were significantly greater in magnitude than in young animals. Unusually large (>300 minutes) phase shifts were seen in response to light pulses administered at CT 16 in 73% of animals in the two oldest groups, whereas, none of the animals younger than 6 months showed shifts of similar magnitude. These results indicate that the advance region of the phase response curve to light increases in amplitude with age in hamsters.

201.5

EFFECTS OF LIGHT ON THE CIRCADIAN CLOCK IN INBRED STRAINS OF GOLDEN HAMSTERS. M.M. Hotz and F.W. Turek. Dept. of Neuro. & Physiol., Northwestern Univ., Evanston, IL 60208.

In order to investigate genetic influences on circadian rhythmicity, four inbred strains of golden hamsters are being studied, measuring the circadian rhythm of locomotor activity. Significant strain differences have been observed in both the phase angle of entrainment to a light-dark cycle and the free-running period, indicating genetic influences on both parameters. The strain rank order is the same for both measures, suggesting common genetic control of these two parameters. To determine whether the strain differences in entrainment to a light-dark cycle may result from differences in how the clock is reset by light, we have studied the phase-shifting response to one hour light pulses in animals kept in constant darkness. Our preliminary results (50 light pulses per strain) show no significant differences between strains. This suggests that the between-strain variance in the phase angle of entrainment results from differences in free-running period and not from any genetic variance in the phase-shifting response to light. The lack of strain differences in the phase response curve to light is in sharp contrast to our previous findings of pronounced differences in the phase response curves to the benzodiazepine, triazolam, in these strains. This contrast indicates that light and triazolam act on the clock via distinct mechanisms.

201.6

THE HAMSTER CIRCADIAN PACEMAKER IS MOST SENSITIVE TO LIGHT PULSES OF 300 SECONDS IN DURATION. Dwight E. Nelson and Joseph S. Takahashi, Department of Neurobiology and Physiology, Northwestern University, Evanston, IL 60208

The physiological properties of the neural pathway that carries environmental light information to an internal circadian pacemaker in the mammal are poorly understood. To characterize the fundamental properties of this pathway for the golden hamster we have used the phase-shifting response of the activity rhythm to light as a functional assay. To quantify the ability of this system to integrate light signals over time, we have measured the stimulus-response relationships for light pulses of 3ms to 1h in duration. Golden hamsters were entrained to a 14L:10D cycle and then placed in darkness. After 7 days a single photic stimulus (503nm) with a duration of 3ms, 3s, 30s, 300s or 3600s was administered to each hamster at circadian time 19 and the steady-state phase shift was measured. Stimulus-response curves for the various durations showed different degrees of light sensitivity. The absolute threshold to irradiance was 1.4×10^{11} photons $cm^{-2}s^{-1}$. The greatest efficiency of light integration occurred in 30s to 1h pulses. The maximum sensitivity to total photons was to 300s pulses. This temporal summation is longer than that seen in any other visual system. These results suggest that the hamster pacemaker may also be differentially sensitive to identical "doses" of other inputs (such as pharmacological agents) that persist for different durations. PHASE OF CIRCADIAN RHYTHMS RESTORED BY SUPRACHIASMATIC NUCLEUS(SCN) TRANSPLANTS. F. C. Davis. Dept. of Biology, Northeastern Univ., Boston, MA 02115.

The SCN appear to contain a circadian pacemaker that regulates overt behavioral rhythms. A critical test of this hypothesis is the transplantation of donor-specific pacemaker properties such as period or phase. The transplantation of phase requires that entrainable oscillations are generated by the donor tissue at the time of transplantation. To determine this, the phases of restored rhythms on the day of transplantation were estimated by backward extrapolation of freerunning restored rhythms. Adult hamsters(Mesocricetus auratus) were kept in dim LL and lesioned 3-7 weeks before receiving fetal tissue. Pregnant hamsters were kept on a light/dark cycle and transplantations were performed at one time of day. The distribution of phases was non-random, indicating that the underlying oscillations were entrained at or before the time of transplantation. Eight of 11 phases fell within a 6 hr range around 0130 and 3 fell within a 2 hr range around 1100. Whether phase is related to maternal rhythmicity before transplantation or to the timing of the transplantation procedure is unknown. It is unlikely that the restored phases were determined by phases of the hosts before transplantation since the hosts received SCN lesions and were kept in dim LL for a variable number of weeks before receiving fetal tissue. Supported by NIH grant HD18686, and Northeastern Univ., Dept. of Biology.

LIGHT REGULATES FOS EXPRESSION IN THE SUPRACHIASMATIC NUCLEI. W.J. Schwartz and N. Aronin. Depts. of Neurology and Medicine, Univ. Massachusetts Medical School, Worcester, MA 01655

Fos, the product of the c-fos proto-oncogene, is a DNA-binding protein that activates gene transcription. Increased Fos expression has been hypothesized to couple transient extracellular stimuli to long-term changes in cellular function. Using an affinity-purified antibody to $Fos_{132-154}$ for immunohistochemistry (provided by S.M. Sagar and F.R. Sharp), we determined whether light affects Fos levels in the SCN of male Sprague-Dawley rats entrained to a 12h:12h light-dark cycle.

Fos immunoreactivity was clearly detected in the ventrolateral SCN during the light period (4h after lights-on). Both the number of cell nuclei stained and the intensity of their labeling were markedly diminished at this circadian phase if lights were not turned on and rats remained in the dark. Comparably low Fos levels were also found during the normal dark period (4h after lights-off). If instead lights remained on for these 4h, Fos expression was high and similar to that seen during the normal light period. Interestingly, cells in the intergeniculate leaflet were clearly immunoreactive for Fos when the lights were on, but no labeled cells were observed in the dorsal or ventral lateral geniculate and superior colliculus.

Thus, expression of the transcriptional activator, Fos, is physiologically regulated in the SCN by environmental light. This regulation appears selective for the visual system for light entrainment of circadian rhythms, since no change in Fos expression was detected in the visual pathways responsible for image formation and reflex oculomotor function. We speculate that transcriptional events may be part of the cellular basis for photic entrainment, and Fos may be a link in this signal transduction mechanism.

201.9

INDUCTION OF C-FOS EXPRESSION IN THE SUPRACHIASMATIC NUCLEUS (SCN) OF HAMSTERS BY LIGHT EXPOSURE. B. Rusak and H.A. Robertson, Depts. of Psychology and Pharmacology, Dalhousie Univ., Halifax, Nova Scotia, Canada B3H 4J1.

The SCN functions as a major circadian pacemaker and as a site of integration of photic entrainment information in mammals. Wewere interested in whether SCN cells would show spontaneous rhythms or light-evoked changes in the expression of proto-oncogenes, in particular c-fos. The protein products of these genes have been proposed to function as "tertiary" nuclear messengers, acting to alter the expression of other genes.

We prepared brains of Syrian hamsters sacrificed at various times in light-dark (LD) cycles or in constant darkness for immunocytochemical identification of Fos protein. There was little or no Fos immunoreactivity (ir) in the SCN of hamsters sacrificed during mid-L and mid-D phases, nor in animals sacrificed at any time in constant darkness. Light exposure (~30 lux) for 0.5-1.0 h caused a dramatic increase in c-fos expression in SCN cells. The pattern or Fos-ir closely resembled the distribution of retinal ganglion cell terminals in the SCN region. Pre-treatment with the NMDA receptor antagonist MK-801 blocked increases in Fos-ir. Other retinorecipient areas did not show similar increases in Fos-ir in response to light. These results suggest that rapidly induced changes in gene expression may play a role in mediating photic effects on circadian clocks. They provide a novel approach for the analysis of entrainment and the cellular clock mechanism.

201.10

EFFECT OF SUPRACHIASMATIC NUCLEI LESIONS ON BENZODIAZEPINE-INDUCED SLEEP IN THE RAT. Dale M. Edgar, Wesley F. Seidel and William C. Dement. Sleep Research Center, Stanford University School of Medicine, Stanford, CA. 94305.

The hypnotic efficacy of benzodiazepines (BZ) vary as a function of time of day. In humans, efficacy also depends on the amount of prior sleep (regardless of time of day). The neural substrate for these variations in BZ efficacy is not known, although it is assumed to involve the central neural circadian pacemaker-- the suprachiasmatic nucleus (SCN). This study examines the role of the SCN in the regulation of sleep induction by triazolam in rats.

Eight SCN-lesioned rats (SCNx) and ten intact rats were surgically prepared for physiological sleep recording. All animals were housed individually in cages equipped to monitor sleep-wake stages and drinking patterns continuously using "SCORE," a computerized sleep-wake and circadian rhythm bioassay system. Intact rats were entrained to a light-dark cycle (LD 12:12). SCNx rats were maintained in constant dark. Intact rats were administered triazolam (0.2 mg/kg I.P.) or vehicle (0.25% methylcellulose) at circadian time (CT) CT-5, CT-14 and CT-20. SCNx rats were similarly treated except that the absence of circadian rhythms precluded reference to CT.

Levels of sleep induced by TZ at this dosage varied as a function of circadian time in the intact rats. Triazolam was most effective at CT-20 increasing total sleep time an average of 20 min, and was least effective at CT-5. In contrast, SCNx animals showed no increase in sleep following treatment with TZ at this dose.

Attenuated sleep responses to BZs in SCNx animals implicates the biological clock in circadian dependent BZ receptor upregulation. Additionally, the induction of normal sleep by BZs may require sleep pressure which may be reduced in SCNx animals. Studies are underway to address these possibilities.

TEMPERATURE-DEPENDENCE OF SLOW WAVE SLEEP-LIKE EEG STATES IN THE CHRONIC CERVEAU ISOLE CAT. D. McGinty and R. Szymusiak. Neurophysiology Research, Sepulveda VAMC, Sepulveda, CA 91343.

Human slow wave sleep (SWS) and associated body cooling are increased after body heating while awake, and SWS may be elicited by preoptic/anterior hypothalamic (POAH) warming in cats. We tested the hypothesis that a normal physiological stimulus for SWS is brain warming, associated with waking, acting on specialized hypnogenic warm-sensitive POAH neurons. In the intact animal hypothalamic temperature (T_{hy}) cannot be manipulated without exposure to extreme ambient temperatures (T_a). However, in the chronic cerveau isole (CI) preparation thermoeffectors are disconnected from the hypothalamus, and T_{hy} varies with T_a. CIs were prepared by complete caudal midbrain transections using a subtentorial approach and were sustained for at least 4 weeks. After several days, animals exhibited alternating periods SWS-like EEG synchrony and waking-like EEG desynchrony. T_{hy} was then held at 37.5 or 39.5 °C during 8 hour recording sessions. Percent time in EEG sleep-like states was more than doubled (40% v. 17%) in the warm compared to the cooler condition. This study shows that forebrain warming is sufficient to tonically increase SWS. This result supports the hypothesis that SWS is driven by brain warming, normally associated with waking, and that this stimulus acts on forebrain structures.

EXPOSURE TO HEAT REVERSES PREOPTIC/ANTERIOR HYPOTHALAMIC LESION-INDUCED INSOMNIA IN CATS. R. Szymusiak, J. Danowski* and D. McGinty. Dept. Psych., Univ. Calif., Los Angeles and V.A. Med. Ctr., Sepulveda, CA 91343.

We have hypothesized that warm sensitive neurons of the preoptic/anterior hypothalamus (POAH) are a component of the basal forebrain hypnogenic mechanism. To test this hypothesis, POAH cell loss was induced in 6 adult cats by microinjections of neurotoxin. Postlesion amounts of slow-wave (SWS) and REM sleep were significantly reduced during 14 hr recordings at an ambient temperature (Ta) of 23°C. Reductions in SWS persisted through the seventh postlesion week. Loss of POAH warm-sensing neurons was indicated by a significant elevation in hypothalamic temperature (Thy) thresholds for panting; from a prelesion average of 39.5± 0.1°C to 41.3±0.3°C at 2 weeks postlesion.

At 2 and 4 weeks postlesion, cats were exposed for 6 hrs to Ta's of 13, 23 and 33°C. At the lower Ta's, amounts of SWS were significantly below prelesion levels. However, amounts of SWS at 33°C were significantly elevated compared to values at lower Ta's. At 4 weeks, SWS time at 33°C was equal to maximal prelesion values. Enhanced sleep at 33°C was accompanied by elevated Thy's, to an average of 40.1°C.

After POAH damage, abnormally high Thy's were required to elicit both panting and normal amounts of SWS, suggesting that loss of warm sensitive neurons produced both deficits. This supports the hypothesis that such neurons are an important facilitory input to SWS-regulating mechanisms.

202.1

INTER-ASTROCYTIC GAP JUNCTIONS INCREASE IN RAT RETINA FOLLOWING PHOTORECEPTOR DEGENERATION. M.S. Burns and N.K. Tyler*. Ophthalmology Research Laboratories, University of California, Davis., Davis, CA 95616.

Astrocytes are present in normal rat retina only in the inner retina, with processes frequently apposing retinal vessels. These astrocytes are connected by gap junctions, which have a frequency of 2.8 +/- 1.1 um per 1000 um of glial cell membrane contact length. Gap junctions are not found between Muller cells nor between Muller cells and astrocytes.

Urethane administration to newborn rats produces a photoreceptor cell specific degeneration which is complete in the central retina by 24 weeks. There is no apparent cell loss in the inner retina but the glial cells are reactive. The Muller cells retract from the inner limiting membrane and sometimes form desmosome like connections as though their normal polarity were reversed. Astrocytic hypertrophy and extensive production of intermediate filaments occurs in the innermost retina. By 56 weeks the interastrocytic gap junctions occupy close to 2% of the glial cell membrane contact length in inner retina, a 10 fold increase compared to normal. The size of individual junctions is increased two-fold.

We interpret this up-regulation of gap junctions as an attempt to increase spatial buffering of the extracellular compartment of the retina.

202.2

DOCOSAHEXAENOIC ACID (DHA) UPTAKE AND DISTRIBUTION WITHIN THE FROG RETINA. **W.C. Gordon* and N.G. Bazan, (SPON: R. Roskoski) LSU Eye Center and Neuroscience Center, New Orleans, LA 70112.**

Retinal uptake of ^{3}H-DHA shows different patterns among cell types. Rod outer segments (ROS) demonstrated two labeling patterns: a diffuse uptake throughout the layer, and a specific label that began at the base and spread apically as new membrane was synthesized. The label front co-migrated with the ^{3}H-leucine band. HPLC analysis of extracted retinas showed ^{3}H present only in DHA. Retinal protein showed no ^{3}H, implying that the migrating label results from a non-covalent association between the ^{3}H-DHA-rich molecules and rhodopsin. This pattern persists up to 50 days, then disperses. During this time labeling occurs in oil droplets of the pigmented epithelium and cone photoreceptors (PR), as well as at the PR terminals. Dense labeling occurs in the nerve fiber layer (>5 days), and in vitro retinas incubated 3 hrs with ^{3}H-DHA have dense cell profiles that resemble Muller cells (MC). This pattern is seen only after short incubation times, and also includes oil droplet-like regions near MC somas. We suggest that DHA in eye cups is incorporated by MC into DHA-rich molecules, delivered as needed to other cells, and then added to neural membranes and ROS. (Supported by NIH EY04428).

DEVELOPMENTAL EXPRESSION OF HUMAN CONE MATRIX SHEATH-SPECIFIC MOLECULES. **J.C. Blanks, K. Anderson*, C. Spee*, and G.S. Hageman*. Doheny Eye Institute, Los Angeles, CA; and Bethesda Eye Institute, St. Louis, MO.**

Cone photoreceptor outer segments (OS) in mature human retina are surrounded by cone matrix sheaths (CMS), domains of interphotoreceptor matrix that contain chondroitin and 6-sulfate glycosaminoglycan and an unidentified PNA-binding glycoconjugate. Little is known about expression of CMS-specific molecules during human retinal development, but cone-specific domains might serve as mediators of differentiation, development and cellular interaction of cone photoreceptors. We studied the expression of CMS-specific molecules as related to morphologic differentiation of cone photoreceptors. Eyes from preterm and one term infant were used. Cone photoreceptors were first noted at 13 wks. A single cilium was seen at the apical end of the cell, where junctions occur between photoreceptors and RPE. At 18 wks, these junctions were absent in the central retina and an obvious subretinal space was visible. Rudimentary OS were numerous. By 24 wks, cone photoreceptors were polarized and had inner segments, axons and synaptic pedicles. Domes of interphotoreceptor matrix were differentially associated with cone inner and outer segments. Most cone OS had stacks of disc membranes, evidence that their differentiation occurs prior to that of rods. Chondroitin 6-sulfate was first expressed at 17 to 18 wks and was associated solely with cone OS. PNA-binding glycoconjugates were present in the subretinal space at 12 weeks but concentrated accumulations were not seen until 17 to 18 weeks. These studies show that two major CMS constituents are expressed when OS first differentiate, about 10 weeks prior to differentiation of disc membranes. These findings suggest that CMS constituents may be necessary for OS differentiation and survival.

202.4

POSTNATAL DEVELOPMENT OF CHOLINERGIC AMACRINE CELLS IN THE KITTEN RETINA. J. F. DANN* (SPON: W. R. Levick). Vision, Touch & Hearing Res. Ctr., Dept. Physiol. Pharmacol., Univ. of Qld., St. Lucia 4067, Qld., Australia.

Rat monoclonal antisera directed against the ACh-synthesing enzyme, choline acetyltransferase (ChAT) at a dilution of 1:5 was applied to wholemounted kitten retinae which were Rat-PAP (dilution 1:100) reacted to determine the populations of immunoreactive (cholinergic) amacrine cells. From birth (postnatal day (P) 0) cholinergic amacrines were located either in the inner nuclear layer (INL) or were displaced to the ganglion cell layer (GCL). By P21 the number of cholinergic cells and their distribution in central and peripheral retina approached adult values. Between PO and P21 their number increased 5 fold in the GCL and 3.5 fold in the INL. In the periphery of the GCl the density increased dramatically between PO and P5 and decreased between P5 and P21. However, in contrast to the GCL, there was a steady increase in the number of cells expressing ChAT in the periphery of the INL.. The differences in the establishment of their density gradients and in soma diameter enlargement between PO and P21 indicate differential development of the two populations of cholinergic amacrines in the kitten retina.

DENDRITIC GROWTH OF DISPLACED CHOLINERGIC AMACRINE CELLS IN THE POSTNATAL RABBIT RETINA. R.O.L. Wong* and S.P. Collin. National Vision Res. Inst., Carlton, Vic. 3053 and Vision, Touch and Hearing Res. Ctr., Uni. of Queensland, Qld. 4067, Australia.

The relatively simple, symmetric and consistent dendritic tree morphology of cholinergic (Cb) amacrine cells enables a systematic analysis of their structure during postnatal development. The dendritic arbors of displaced Cb amacrine cells in adult and developing rabbit retinae were revealed by intracellular injection with lucifer yellow. Like immature retinal ganglion cells, developing Cb amacrine cells possess numerous short appendages (1-5μm) on their dendrites. The majority of these protrusions are lost by three weeks after birth, in parallel with the maturation of amacrine cell function (Dacheux, R.F. and Miller, R.F., *J. Comp. Neurol.* 198:327, 1981). If the protrusions are excluded, the number of dendritic branches remains constant after birth, unlike many ganglion cells which lose a large number of branches during postnatal growth. Comparisons of the area enclosing equivalent inner and outer regions of the developing and adult tree demonstrates that the increase in tree size is due to the elongation of both proximal and distal dendrites.

202.6

SOMATOSTATIN-LIKE IMMUNOREACTIVITY (SRIF-I) IN GANGLION AND OTHER CELLS OF THE DEVELOPING CAT RETINA. C.A. White and L.M. Chalupa. Dept. of Psychology, and Neurobiology and Physiology Graduate Groups, University of California, Davis, Davis CA 95616

In the adult cat retina, SRIF-I occurs in two types of cells: a wide-field amacrine cell and a large, granular-staining cell, both found predominantly in the ganglion cell layer (GCL) of the inferior retina (White et al., 1988a,b). The ontogeny of SRIF-I was studied in developing cat retinas using immunocytochemical techniques with a mouse monoclonal antibody (from the MRC Regulatory Peptide Group) to SRIF 14. Specific staining was eliminated by preabsorption of the primary antibody with synthetic SRIF 14. In vertical sections, SRIF-I was detected in cells of the GCL as early as embryonic day (E) 35 (gestation=65 days). In wholemounts at E42, E51 and E60, two types of SRIF-I cells were observed in the GCL. One type resembled the SRIF-I amacrine cell of the adult in both morphology and distribution. The second type, not seen in the adult, had irregularly shaped SRIF-I clusters within a concentric soma. Early in development the cells with irregular clusters were distributed throughout the retina. By P23, they were no longer present, and the adult pattern of wide-field amacrine and large granular-staining cells was evident. Central injections of rhodamine beads revealed that during early development at least some of the SRIF-I cells are ganglion cells.

SYNTHESIS OF THE GROWTH-ASSOCIATED PROTEIN, GAP-43, BY DEVELOPING RETINAL GANGLION CELLS IN THE CAT. D.T. Hess*, C.J. Shatz, D.J. Schreyer and J.H.P. Skene. (SPON: M. Siegel) Dept. of Neurobiology, Stanford University School of Medicine, Stanford, CA 94305.

Increased neuronal synthesis of GAP-43 is correlated consistently with developmental and regenerative growth of axons by vertebrate central and peripheral neurons (Ann. Rev. Neurosci., *12*:127, 1989). We have identified GAP-43 among proteins synthesized and transported rapidly by developing retinal ganglion cells (RGC) of the cat, a species in which the stages of growth of the retinofugal pathway are both temporally discrete and well-characterized morphologically (Ann. Rev. Neurosci., *9*:171, 1986). Intraocular injection of ^{35}S-methionine was employed to label proteins synthesized and transported by RGCs in fetal, neonatal and mature cats. A polypeptide was identified provisionally as cat GAP-43 based on its electrophoretic mobility in 2-D gels of samples prepared from optic nerve and primary optic targets. This polypeptide was recognized by a monoclonal antibody to rat GAP-43 on Western blots of target tissue. Immunohistochemistry with this antibody revealed GAP-43 within the primary optic pathway of fetal cats (and within other developing structures including the intermediate zone of the cerebral cortex). GAP-43 is relatively abundant within primary optic projections at embryonic day 43 (E43), after the majority of RGC axons have grown into their targets but prior to binocular segregation. It is significantly less abundant by E56, after binocular segregation is largely complete, and by birth is barely detectable. These observations suggest that elevated synthesis and transport of GAP-43 by developing mammalian RGCs is a concomitant of both initial innervation of and active axonal remodeling within primary optic targets.

PHYSIOLOGICALLY IDENTIFIED RETINOGENICULATE X AXONS IN FERRETS WITH NEONATAL ABLATION OF VISUAL CORTEX: SIZES OF TERMINAL ARBORS DEPEND ONLY PARTLY ON TARGET SIZE. J. Hahm*, A. Roe, S. Pallas, and M. Sur (SPON: R. Held). Dept. Brain & Cognitive Sciences, M.I.T., Cambridge, MA 02139.

Ablating visual cortical areas 17, 18 and parts of 19 in ferrets at birth (E42) leads to extensive loss of X cells in the LGN, of medium sized ganglion cells in the retina, and of X retinogeniculate axons (Sur et al., Soc. Neurosci. Abst. 13: 590, 1987; cf., in cats, Tong et al., Science 217:72, 1982). We now report that a smaller ablation of visual cortex, including area 17 and parts of 18, in neonatal ferrets does not cause a similar loss of LGN X cells or of retinogeniculate X axons. LGN X cells can apparently project to alternative cortical targets following very early lesions of area 17. However, the LGN is shrunk in overall size, and soma sizes in the LGN corresponding to ablated area 17 are smaller than normal.

How are individual retinal X axon arbors in the LGN affected by these changes in their target? Single X axons (n=5) injected intracellularly with HRP have fewer boutons than normal and terminal arbors that are reduced up to 30% in volume compared with normal X arbors. The size of the LGN, however, is reduced by up to 75% following the neonatal lesions. These results indicate that retinogeniculate X arbor size is only partly influenced by target size, and that there is relative conservation of arbor size. Thus, each arbor occupies a proportionately larger volume of the LGN compared to normal (cf. Weber et. al., J. Comp. Neurol., in press, 1989). Since the cortical ablations occur before retinal axons have recognizable terminal arbors or have segregated into eye-specific laminae in the LGN (Hahm & Sur, Soc. Neurosci. Abst. 14:460, 1988), retinogeniculate X axons must have a significant intrinsic component in determining the size of their arbors.

202.9

RETINAL AXON ARBORS IN A NOVEL TARGET: MORPHOLOGY OF GANGLION CELL AXONS INDUCED TO ARBORIZE IN THE MEDIAL GENICULATE NUCLEUS OF FERRETS. S.L. Pallas, J.-O. Hahm and M. Sur. Dept. of Brain & Cognitive Sci., M.I.T., Cambridge, MA 02139.

Retinal ganglion cell axons project into the auditory thalamus (MGN) following partial removal of retinal targets and deafferentation of the MGN in neonatal ferrets. We have used bulk HRP filling of retinal axons in vitro to study the morphology of individual axon arbors in operated ferrets reared to adulthood.

There are at least two types of retinal axons in the MGN. The first type, which constitute the majority of retinal axons in the MGN, make only en passant boutons on their way through the nucleus and do not branch. These axons often enter the MGN in fascicles. The second type have well-formed terminal arbors in the MGN and they tend to occur in clusters. The extent of their arbors (average of width and height) varies from 112 μm to 508 μm (mean=244 μm, n=7). In both types of axon, boutons vary substantially in size. Axon diameters of both types vary from 0.3 μm to 1.5 μm (mean=0.7 μm, n=18).

Physiological recordings of visual activity in the MGN of neonatally lesioned ferrets, as well as retinal backfills, suggest that retinal W cells provide the major input to the MGN (Sur et al., Science 242:1437, '88; Roe et al., Soc. Neurosci. Abstr. 13:1023, '87). In normal cats and ferrets, one population of retinal W cells projects to the LGN-C lamina and another population projects to the superior colliculus (Leventhal et al., J. Comp. Neurol. 237:216, '85; Stanford, J. Neurophysiol. 57:218, '87; Roe et al., unpub.). We hypothesize that the two axon types we observe correspond to these two W cell populations: those passing through the MGN may innervate the remaining fragment of LGN, and those which arborize in the MGN may normally innervate the superior colliculus, which has been ablated in our animals.

LIMITED TOPOGRAPHIC SPECIFICITY IN THE TARGETING OF MAMMALIAN RETINAL AXONS. D.K. Simon and D.D.M. O'Leary (SPON: J.Volpe) Dept Neurosurgery, Washington U Sch Med, St.Louis, MO 63110

A central issue of developmental neurobiology is how vertebrate axons establish ordered connections within their target fields. The retinotectal projection has been a model system for studies of the development of topographic order in vertebrate axonal projections. In frogs and fish developing retinal axons reportedly grow directly to and arborize at topographically appropriate sites in the optic tectum. These findings have led to the generalization that topographic specificity in the targeting of vertebrate retinal axons is evident from the time they arrive in the tectum [Dodd & Jessell (1988) Science 242:692]. In contrast, we find in rats that developing retinal axons make major topographic targeting errors along both the medial-lateral and rostral-caudal axes of the superior colliculus, the mammalian homologue of the tectum. Localized injections of the tracer, DiI, covering 1% or less of the retina were made into peripheral retinal regions of E20 to P12 rats. In perinatal rats, axons originating from such an injection in temporal retina grow over the entire contralateral colliculus suggesting that many initially fail to recognize their target region in rostral colliculus. Many nasal axons branch along their entire course through the colliculus. A dense zone of arbors develops, but covers a much greater amount of colliculus than at maturity. Topographic order is established by P12. At this age, it is evident that some mistargeted axons make corrections and are retained; most do not and are lost. Cross sections of the optic nerves from the perinatal and P12 cases reveal that the labeled axons are dispersed throughout the nerve, indicating that preordering of axons contributes little to the development of topography within the colliculus. Our finding that the topographic targeting of retinal axons in rats lacks the specificity reported in lower vertebrates indicates that mechanisms other than directed axon growth are required to establish topographic order in axonal connections in the mammalian brain.(Support: NEI grant EY07025)

202.11

CHRONIC APPLICATION OF NMDA OR APV AFFECTS THE NMDA SENSITIVITY OF THE EVOKED TECTAL RESPONSE IN *RANA PIPIENS*. E.A. Debski, H.T. Cline and M. Constantine-Paton. Dept. of Biology, Yale University, New Haven, CT 06511.

Chronic treatment of three-eyed tadpoles with the NMDA antagonist APV desegregates eye-specific segregation zones in the optic tectum; chronic treatment with NMDA sharpens the boundaries of these zones (Cline et al., PNAS, 84: 432, 1987).

We have assessed the sensitivity of chronically treated animals to exogenously applied NMDA. In normal animals, perfusion of 6 μM NMDA blocks approximately half of the tectal response evoked by electrical stimulation of the optic nerve. Perfusion of 12 μM NMDA blocks most of the response (Debski and Constantine-Paton, Neurosci. Abstr., 14: 674, 1988). Animals chronically treated with NMDA show a decreased sensitivity to applied NMDA: application of 6 and 12 μM NMDA cause significantly less decrease in the tectal response than in normal animals. Conversely, at least part of the response in animals chronically treated with APV is more sensitive to exogenous NMDA. Preliminary results with animals chronically treated with L-APV indicate that their sensitivity is unchanged.

We conclude that chronic treatment with NMDA may either decrease the number and/or sensitivity of NMDA receptors in these animals. Chronic treatment with APV appears to have the opposite effect. Supported by NIH EY05829, EY05818 and EY06039.

Protein kinase activity is not required for the selective stabilization of coactive inputs in eye-specific segregation in the frog. H.T. Cline, M. Constantine-Paton. Yale Univ., Biology Dept. New Haven, CT. 06511

NMDA receptor activation is required for the development of eye-specific stripes and normal retinotopic maps in the optic tectum of frogs. It is thought that a calcium transient through the NMDA-gated channel might activate protein kinases and thereby initiate the stabilization of coactive retinal inputs. We exposed the tecta of three-eyed tadpoles to drugs thought to activate or block protein kinases. Exposure for 6 weeks to either phorbol esters, a protein kinase C activator, or sphingosine and H-7, both kinase blockers, did not alter the eye-specific stripe pattern. We are confident that the drugs were released from the Elvax and reached the tissue because ^{3}H-thymidine autoradiography reveals that tectal cell proliferation is increased following exposure to phorbol ester or sphingosine compared to stage-matched controls.

The role of the NMDA receptor in neural plasticity in the developing and mature brain invites comparison between potentiation in the hippocampus and neural map formation. In the hippocampus, the early post-tetanic component called slowly decaying potentiation (SDP) lasts for about 30-45 min and is independent of kinase activity. In the developing retinotectal projection, retinal terminals are mobile and synapses are transient. It is possible that the type of synapse stabilization seen in the developing retinotectal projection is comparable to SDP in the hippocampus, where coactive synapses are selectively stabilized, but for a limited period of time. Support by NIH EY06039&05818.

CLONING AND DNA SEQUENCING THE unc-29 AND unc-38 LEVAMISOLE RECEPTOR GENES OF THE NEMATODE CAENORHABDITIS ELEGANS. J.A. Lewis. Division of Life Sciences, University of Texas at San Antonio, San Antonio, TX 78285.

I have cloned the unc-29 and unc-38 receptor genes of the nematode C. elegans by Tcl transposon tagging. These genes are likely to encode structural peptides of the levamisole receptor, a nicotinic acetylcholine receptor present on nematode muscle. Spontaneous, putative transposon-induced mutants in these and other genes needed to make the receptor can be selected by means of the drug resistance that mutationally-induced receptor deficiency confers against the toxic muscle-contracting effects of levamisole, a potent nicotinic acetylcholine analog.

For unc-29, genomic probes derived from a Tcl insert revealed RFLP's in 6 unc-29 spontaneous mutants, with restoration of wild-size in revertants of several mutants. An RFLP was found in 1 of 5 unc-29 gamma-ray mutants in the same region. For unc-38, 4 of 5 different spontaneous Bergerac mutants were found to carry the same novel 4.7 kb HindIII Tcl-containing restriction fragment. Three of six gamma-ray unc-38 mutants showed a size difference in the HindIII fragment identified by Tcl tagging.

DNA sequencing reveals strong homology at the amino acid level of the putative unc-29 protein to ard, a putative Drosophila acetylcholine receptor structural gene, and somewhat less but still impressive homology to vertebrate nicotinic acetylcholine receptor subunits.

203.2

CLONING THE DOMAIN CONTAINING THE FOUR EXTRACELLULAR CYSTEINES OF SNAKE ACETYLCHOLINE RECEPTOR α-SUBUNIT. D. Neumann*, D. Barchan*, M. Horowitz*, E. Kochva* and S. Fuchs. (SPON:A.S. Gordon). Dept. of Chemical Immunology, The Weizmann Institute of Science, Rehovot, Israel, and Dept. of Zoology, Tel Aviv University, Tel Aviv, Israel.

Muscle acetylcholine receptor (AChR) of elapid snakes binds cholinergic ligands but unlike other muscle AChRs does not bind α-bungarotoxin (α-BTX). Previous studies indicate that the ligand binding site of the AChR includes cysteine residues at positions 192,193 of the α-subunit. In attempt to elucidate the structural basis for the unique binding properties of snake AChR, the domain of the α-subunit from Natrix and cobra AChR (amino acid residues 119-222), which contains the four extracellular cysteines (128,142,192,193) was amplified by reverse transcription of mRNA and the polymerase chain reaction, and then sequenced. Sequence comparison revealed that the cloned region of the snake α-subunit is highly homologous (75-80%) to other muscle AChRs and contains the two tandem cysteines at positions 192,193 like all other AChR α-subunits. In the presumed ligand binding site, in the vicinity of cysteines 192 and 193, four major substitutions occur in the snake sequence at positions 184 (Trp to Phe), 185 (Lys to Trp), 187 (Trp to Ser) and 194 (Pro to Leu). In addition, Asn 189 is a putative N-glycosylation site, present only in the snake. These changes or part of them may explain the lack of α-BTX binding to snake AChR.

203.3

cDNA CLONES CODING FOR SUBUNITS OF THE NEURONAL α-BUNGAROTOXIN-BINDING PROTEIN. R. Schoepfer, P. Whiting, W.G. Conroy,* J. Lindstrom. The Salk Institute, La Jolla, CA 92037

α-Bungarotoxin (α-Bgt) binds to the acetylcholine binding site of muscle-type nicotinic acetylcholine receptors (AChRs) and also binds to some vertebrate neuronal proteins with nicotinic binding properties. The function of these neuronal α-Bgt binding proteins (α-Bgt-BPs) is unclear; there is a large body of evidence indicating that the α-Bgt-BPs which have been most carefully studied are not ACh-gated cation channels. The subunit composition of neuronal α-Bgt-BPs is uncertain. It is certain that neuronal α-Bgt-BPs are functionally, structurally, immunologically, histologically, and pharmacologically distinct from functional vertebrate neuronal AChRs which do not bind α-Bgt.

Using an oligonucleotide probe based on the N-terminal amino acid sequence of a polypeptide of the α-Bgt-BP from chicken brain reported by Conti-Tronconi et al. (1985, *PNAS USA 82*, 5208) we have isolated a partial cDNA clone (Ch29) from a chicken brain cDNA library. The deduced amino acid sequence of Ch29 is identical at 19 of 21 amino acids of the reported sequence. By low stringency hybridization using Ch29, a second full-length cDNA clone (Ch31) was isolated which has 80% amino acid sequence identity to Ch29, suggesting that it codes for another subunit of the α-Bgt-BP. A unique sequence of Ch31 was expressed in bacteria. Antisera to this bacterially expressed protein efficiently precipitated authentic chicken brain α-Bgt-BPs. Thus, we have now determined part of the primary structure of one neuronal α-Bgt-BP subunit and the complete sequence of another.

203.4

SUBUNIT STOICHIOMETRY OF NEURONAL NICOTINIC ACETYLCHOLINE RECEPTORS. P. Whiting, J. Cooper,* W.G. Conroy,* and J. Lindstrom. The Salk Institute, La Jolla, CA 92037

Muscle-type nicotinic acetylcholine receptors (AChRs) have been shown by a variety of chemical and physical techniques to be pentamers consisting of two ACh-binding subunits (α) and three structural subunits (β, γ, δ) arranged like barrel staves around a central ion channel. Recently, using both monoclonal antibodies and cDNAs as probes, it has been shown that neuronal nicotinic AChRs are members of the same gene family as muscle AChRs. In contrast, however, the major subtype of neuronal AChRs appears to consist of only two types of subunits, ACh binding (α4) and structural (also termed β2 or non-α).

Using a chemical modification technique we have investigated the subunit stoichiometry of the neuronal AChR. Purified AChRs from *Torpedo* electric organ (control) and the brains of chickens, rats, and cows were denatured in 1% SDS and 4M urea, radioiodinated (to label tyrosine residues), and the subunits resolved by SDS-PAGE. After autoradiography, the subunits were excised, radioactivity quantitated, and the stoichiometry determined after correction for the number of tyrosines in each subunit. *Torpedo* AChR had the expected stoichiometry (α:β:γ:δ, 2.1:0.99:0.84:1). AChRs from brains of chicken, rats, and cows had stoichiometries (ACh-binding:structural subunit) of 1.1:1, 1.0:1, and 1.0:1, respectively. The calculated molecular weight of the structural subunits is ~54kD, the molecular weight of the ACh-binding subunits is ~68kD, and the molecular weight of the native neuronal AChR is ~300kD. Thus, the data is consistent with a tetrameric arrangement of two structural and two ACh-binding subunits.

INHIBITION OF ^{125}I-THYMOPOIETIN BINDING TO BRAIN MEMBRANES BY α-BUNGAROTOXIN AND NICOTINIC RECEPTOR LIGANDS. M. Quik, R. Afar*, T. Audhya* AND G. Goldstein* (SPON: P. Braun). Dept. Pharmacol., McGill Univ., Montreal, Can. & Immunobiol. Res. Inst., Annandale, NJ.

The identity of the nicotinic α-bungarotoxin (α-BGT) site in neuronal tissue is currently unclear because the toxin does not block nicotinic responses. It was thus of interest to determine whether agents other than acetylcholine could interact with the neuronal α-BGT receptor to possibly act as a regulator of this site. Current studies in our laboratory showed that the thymic polypeptide thymopoietin potently inhibited α-BGT binding to brain membranes (IC_{50} = 3.1 nM). In the present work, experiments were done using ^{125}I-thymopoietin. Binding studies showed that radiolabelled thymopoietin bound to brain membranes in a receptor specific fashion. The specific binding was saturable, reversible and of high affinity (Kd = 0.3 nM). Binding of ^{125}I-thymopoietin could be displaced, not only by cold thymopoietin, but also by α-BGT (Kd = 0.4 ηM) and nicotinic receptor ligands. On the other hand, a wide variety of other receptor ligands (muscarinic, adrenergic, dopaminergic) did not affect ^{125}I-thymopoietin binding. Thus, ^{125}I-thymopoietin binds with high affinity to a receptor site in brain; furthermore, binding is affected by α-BGT and nicotinic ligands. This may suggest that thymopoietin is a regulator of the neuronal nicotinic α-BGT receptor.

CYCLIC AMP-DEPENDENT PHOSPHORYLATION OF NICOTINIC ACETYLCHOLINE RECEPTORS IN CHICK CILIARY GANGLION NEURONS. S. Vijayaraghavan*, H.A. Schmid*, and D.K. Berg. Dept. of Biology, Univ. of Calif., San Diego; La Jolla, CA 92093.

Chick ciliary ganglion neurons have nicotinic acetylcholine receptors (AChRs) that mediate primary synaptic transmission through the ganglion. The ACh response of the neurons in culture can be enhanced by a cAMP-dependent process in which AChRs appear to be converted from a "silent" state to a functionally available one. We report here that 2 major species of subunits can be identified in AChRs immunopurified from the neurons in culture, and that both can be phosphorylated *in situ* in a cAMP-dependent manner. Moreover, cAMP analogs increase the ACh response and subunit phosphorylation to a comparable relative extent and do so after a similar lag period.

AChRs were immunoaffinity purified from ciliary ganglion neurons in culture, radioiodinated, and shown by SDS-PAGE to contain major subunit species with M_rs of about 50 and 58 kD. Both are phosphoproteins: incubating the neurons with $^{32}P_i$ prior to isolating AChRs produced ^{32}P-labeled subunits. Exposing the neurons to membrane-permeant cAMP analogs for 6 hours increased the amount of phosphorylation about 3-fold for both types of subunits, reaching levels of approximately 0.5 mole of P_i incorporated per mole AChR for each. No change was observed in the total number of AChRs or in the specific activity of the intracellular pool of ATP. AMP and a cGMP analog were unable to mimic the effects of the cAMP analogs. The ACh response was increased about 2-fold by a 6 hour incubation with cAMP analogs, and neither the ACh response nor the subunit phosphorylation showed an increase during the first 30 minutes of the incubation. These findings encourage the speculation that a cAMP-dependent process either directly or indirectly phosphorylates AChRs and thereby shifts the ratio of postulated "silent" and functionally available receptors on the neurons. (Supported by NIH grants NS12601 and NS25916)

TARGET-DERIVED COMPONENTS REGULATE THE NUMBER, FUNCTION, AND CYCLIC AMP MODULATION OF ACETYLCHOLINE RECEPTORS ON CHICK CILIARY GANGLION NEURONS IN CULTURE.
S.W. Halvorsen, H.A. Schmid*, A.E. McEachern, and D.K. Berg. Dept. of Biology, Univ. of Calif., San Diego; La Jolla, CA 92093.

Chick ciliary ganglion neurons have nicotinic acetylcholine receptors (AChRs) for synaptic input from preganglionic terminals, and innervate muscle tissue in the eye. Previous studies have shown that postganglionic axotomy greatly reduces the number of AChRs on the neurons *in vivo*, suggesting that contact with synaptic targets in the eye may be necessary for maintenance of AChRs on the neurons. We now report that a component of about 50 kD from eye tissue increases the number of AChRs on the neurons in culture. The component, or one of similar size, causes an even greater increase in the ACh response, and confers on the neurons the ability to have their ACh response increased by cyclic AMP (cAMP) analogs.

The 50 kD component was discovered by using gel filtration to fractionate extracts prepared from embryonic eye tissue. Testing the fractions on ciliary ganglion neurons in culture at low cell density indicated that a component of about 50 kD caused a 2-fold increase in the number of AChRs over a 1 week period without changing cell growth. AChRs were measured with a radiolabeled anti-AChR monoclonal antibody. Intracellular recordings revealed a 7-fold increase in the ACh-induced membrane conductance. In addition, the ACh response was doubled when the neurons were treated with a cAMP analog for 6 hours; no cAMP-dependent change in ACh response was observed for neurons grown without the 50 kD component. The active material is heat-labile and trypsin-sensitive, as expected for protein. Other tissues, including liver, have components of similar size that enhance the ACh response, but the specific activity of the 50 kD fraction from eye extract is 10-fold that of the liver fraction. The number of distinct active components in the 50 kD fraction is unknown. The component(s) may provide a means by which tissues regulate neurotransmitter receptors on the neurons that innervate them. (Supported by NS12601 and NS21725)

EFFECT OF DENERVATION UPON ACETYLCHOLINE RECEPTOR NUMBER ON THE SURFACE OF CARDIAC GANGLION CELLS.
P.B. Sargent and G.K. Bryan, Division of Biomedical Sciences, University of California, Riverside, CA 92521.

The effect of denervation upon the number of nicotinic acetylcholine receptors (AChRs) on the surface of autonomic neurons was examined in the cardiac ganglion of the frog *Rana pipiens*. ^{125}I-Neuronal bungarotoxin (kappa-bungarotoxin, toxin F, bungarotoxin 3.1) was used as a specific ligand for AChRs. Bath-applied neuronal bungarotoxin (n-bgt) reversibly blocked synaptic transmission in the cardiac ganglion, as monitored by intracellular recording. Excitatory post-synaptic potentials were reduced to subthreshold levels with 5 and 20 nM n-bgt in a dose-dependent manner. Binding studies showed that ^{125}I-n-bgt recognizes two classes of sites in ganglion homogenates; a high affinity binding site with a K_d of 5 nM and a B_{max} of 0.05 fmol/μg protein and a low affinity binding site with a K_d of 60 nM and a B_{max} of 0.3 fmol/μg protein. Comparison of the binding and electrophysiological results strongly suggests that the high affinity binding site represents the synaptic AChR.

Light microscopic autoradiography using 20 nM ^{125}I-n-bgt revealed an accumulation of grains at synaptic sites in normally innervated ganglia. The total number of grains at the surface of neurons denervated for 2-3 weeks was significantly reduced as compared with normal. This suggests that, in contrast to muscle, denervation of neurons leads to a decrease in the number of surface AChRs. The denervation-induced increase in acetylcholine sensitivity that is observed in cardiac ganglion cells may result from a change in receptor distribution, in receptor properties, and/or in cell surface acetylcholinesterase. (Supported by NIH NS24207).

LIGAND BINDING AND FUNCTIONAL PROPERTIES OF NICOTINIC ACETYLCHOLINE RECEPTORS EXPRESSED BY THE SH-SY5Y AND IMR-32 HUMAN NEUROBLASTOMA CLONAL LINES.
Ronald J. Lukas. Div. Neurobiol., Barrow Neurological Inst., Phoenix AZ 85013.

Pharmacological profiles were obtained for high-affinity 3-H-labeled acetylcholine (T-ACh) and 125-I-labeled alpha-bungarotoxin (I-Bgt) binding sites and for functional nicotinic acetylcholine receptors (nAChR) mediating 86-Rb efflux, all of which are expressed by cells of the human neural crest-derived SH-SY5Y and IMR-32 neuroblastoma (NB) clonal lines. For both NB lines (as is the case for the PC12 rat pheochromocytoma line) relatively poor inhibition (IC_{50} > 10 uM) of T-ACh and I-Bgt binding is observed for decamethonium and succinyldicholine (SCh), which inhibit T-ACh and I-Bgt binding to muscle nAChR by more than 50% at concentrations less than 1 uM. Suberyldicholine and SCh, which are strong and weak agonists, respectively, for muscle nAChR, are a poor agonist and an antagonist for functional nAChR responses measured in NB (and PC12) clones. Moreover, mecamylamine is a more potent antagonist of NB (and PC12) cell functional nAChR than is d-tubocurarine, and neither alpha- nor kappa-bungarotoxin produce significant inhibition of nAChR function at concentrations of 1 uM, in contrast to results obtained with muscle nAChR. The results indicate that SH-SY5Y and IMR-32 NB cell lines express high-affinity T-ACh and I-Bgt binding sites and functional nAChR that are more closely related to their neuronal analogues than to muscle nAChR.

203.10

HIGH AFFINITY STATE OF THE CLONED M_1 MUSCARINIC RECEPTOR IS FUNCTIONALLY COUPLED TO THE HYDROLYSIS OF INOSITOL LIPIDS IN TRANSFECTED MURINE FIBROBLAST B82 CELLS.
L. Mei, J. Lai, H.I. Yamamura and W.R. Roeske. Department of Pharmacology, University of Arizona, Tucson, AZ 85724.

The relationship between the M_1 muscarinic receptor (mAChR) density and the receptor-mediated hydrolysis of inositol lipids was studied in a series of 7 clones of transfected B82 cells. Carbachol(CCh)/[^{3}H](-)MQNB competition curve for the LK3-1 cells (receptor density of 12 fmol/10^6 cells) had a Hill coefficient (n_H) close to the unity while the competition curves in the clones with higher receptor densities (30-360 fmol/10^6 cells) had n_H less than one. The percentage of the M_1 mAChR which had high affinity for CCh (K_H of 1.9-7.7 μM) decreased as the receptor density increased, suggesting that endogenous factor(s) in these cells may be important for the agonist affinity state of the receptor. A significant correlation was observed between the M_1 mAChR density with high affinity for CCh and the maximum [^{3}H]IP_1 accumulation in these cells. In contrast to the K_L values of 34-53 μM, the K_H values were not significantly different from the CCh EC_{50} values (3.5-26 μM), or its functional dissociation constants (1.9-7.4 μM) obtained by the Furchgott method. These results suggest that the high affinity state for CCh may be the functional state of the M_1 mAChR in the transfected B82 cells. In addition, spare M_1 mAChR was observed in the clones with higher receptor density but not in those with low receptor densities. Supported by USPHS grants.

203.11

LIGAND BINDING AND FUNCTIONAL PROPERTIES OF A MUSCARINIC ACETYLCHOLINE RECEPTOR EXPRESSED BY THE TE671 CLONAL LINE.
Merouane Bencherif and Ronald J. Lukas. Division of Neurobiology, Barrow Neurological Institute, Phoenix AZ 85013.

TE671 human medulloblastoma clonal cells exhibit muscarinic acetylcholine receptors as revealed by specific, high-affinity binding of tritium-labeled quinuclidinylbenzilate (^{3}H-QNB). Functional studies have indicated that phosphoinositide hydrolysis is increased by carbamylcholine (1mM), the muscarinic agonist acetyl-beta-methylcholine bromide (1mM) but not by nicotine. Phosphoinositide metabolism is completely inhibited by atropine (1uM) and pirenzepine (10^{-6}M) but not by alpha-bungarotoxin (1 uM). Carbamylcholine stimulates inositol-1-phosphate accumulation with an EC_{50} = 10 uM. Atropine exhibits an IC_{50} = 1nM whereas pirenzepine was much less effective (IC_{50} = 300 nM) for displacement of ^{3}H-QNB binding and for inhibition of carbachol-stimulated accumulation of inositol-1-phosphate. These results indicate that a muscarinic acetylcholine receptor subtype with intermediate/low affinity for pirenzepine and coupled to phosphoinositide hydrolysis is expressed by TE671 human medulloblastoma cells.

Expression and Pharmacological Characterization of a Human Muscarinic Acetylcholine Receptor in Saccharomyces cerevisiae.
P. Payette*, F. Gossard*, M. Whiteway* and M. Dennis* (SPON: J. Magnan) Biotechnology Research Institute, Montreal H4P 2R2.

Muscarinic acetylcholine receptors are encoded by (at least) five distinct genes (M1-M5). The five structural subtypes fall into three pharmacological classes (m1-m3) and couple differentially to two G-protein-mediated response pathways. In an effort to develop systems which will permit detailed studies of ligand specificity and coupling selectivity of individual subtypes, we have examined the yeast S. cerevisiae as a host for expression of a gene encoding the human mAchR M1 subtype. The HM1 coding sequence was cloned into the yeast expression vector pVT102U, placing the gene under control of the promoter for the yeast alcohol dehydrogenase gene. Yeast transformed with this construct, but not with vector alone, produced HM1 transcripts as assessed by Northern blotting. Membrane preparations exhibited saturable binding of the muscarinic antagonist [3H]-N-methyl scopolamine to a single class of sites (KD = 179 pM, Bmax = 1-20 fmol/mg protein). A series of muscarinic agonists and antagonists inhibited binding with Ki values and a rank order of potency comparable to those described for m1 in tissues. We conclude that yeast can synthesize a mammalian G-protein- coupled receptor with appropriate pharmacological properties. (Supported by NRC and MRC.)

CELL INTERACTIONS DETERMINE ASYMMETRIC, ALTERNATING DISTRIBUTION OF SCP NEURONS IN LEECH CNS. S.S.Blair, M.Q.Martindale* and M.Shankland. Dept. Anatomy, Harvard Med. Sch., Boston, MA 02115.

The nerve cord of the leech is formed by a bilaterally distributed set of segmentally iterated precursor cells, which give rise to identifiable neurons that are for the most part bilaterally paired and identical from segmental ganglion to ganglion. However, some neurons are laterally asymmetric and segment specific in their distribution. The Rostral and Caudal Alternating SCP neurons (RAS and CAS) are two such neurons, identified by their staining with antisera against molluscan small cardiac peptide (SCP) and FMRFamide. Though born as bilaterally symmetric pairs, the cells within each ganglion "compete" so that only one neuron retains immunoreactivity; ablation of postmitotic AS neurons on one side leads to the retention of AS staining on the unablated side over 90% of the time, as long as the ablation is performed within a certain critical period.

An interesting feature of RAS and CAS distribution is that the side on which each neuron is retained normally alternates between successive ganglia with a fidelity of 95%. This is apparently determined by interactions between cells in successive ganglia. We ablated AS neurons or their precursors in single or small groups of ganglia; when CAS sidedness in one ganglion was biased by the ablation of the contralateral homologue, it influenced sidedness in the next posterior but not the next anterior ganglion, while the opposite appeared true of RAS. Since there is a corresponding difference in the projection of RAS and CAS axons in the nerve cord (posterior-contralateral for RAS, anterior-contralateral for CAS), it raises the possibility that AS neurons interact directly via axons to determine final cell fate. In this scheme, the axon would detect the AS cell asymmetry in the adjacent ganglion, and feed that information back to its cell body, reinforcing the peptidergic AS phenotype. AS distribution would thus be controlled by a combination of interactions within and between ganglia.

CONTACTS BETWEEN EMBRYONIC RETZIUS NEURONS AND GENITAL MESENCHYMAL CELLS MODIFY DEVELOPMENT. K.A. French, S.M. Jordan*, and W.B. Kristan, Jr., Dept. of Biology, UCSD, LaJolla, CA, 92093.

The Retzius (Rz) neurons in the central nervous system of the leech are alike in all mid-body segments, except in the segments containing the reproductive organs (segments 5 and 6). Although the Rz neurons in those two segments [Rz(5,6)] initially resemble their homologues, they begin to develop differently during the 10th day of embryonic life. On day 10, Rz(5,6) processes approach their future target organs, the reproductive ducts (RDs), and it has been shown previously that when embryonic RDs are removed on day 10, Rz(5,6) develop more like other Rz neurons.

During the 10th day of embryonic life, the RDs also undergo major morphogenetic changes. Early on day 10, the embryonic RD tissue is a mass of undifferentiated cells lying on either side of the ventral midline in segments 5 and 6. During the 10th day, while the processes of the Rz(5,6) reach the embryonic RDs and branch repeatedly, the RD tissue separates into two populations of cells: a tube, one epithelial cell thick, that demarkates the future basic morphology of the RDs and a cloud of apparently mesenchymal cells surrounding the epithelial tube near the midline. In embryos incubated with 5'-bromodeoxyuridine (BrdU) and labeled with antibody to BrdU, RD mesenchymal cells remained mitotically active on day 10 and for several days afterwards. During the next several days, RD mesenchymal cells appear to differentiate into the muscles of the RD walls, the eventual target organ of Rz(5,6). In serial sections of 10 day embryos, Rz processes were seen to contact the mesenchymal cells, but neither to contact the epithelial tube nor to extend beyond the mesenchyme. Between days 10 and 13, as the mesenchymal cells increased in number and extended toward the midline posterior to the epithelial tube, the processes of Rz(5,6) grew into this new territory. We hypothesize that Rz(5,6) processes follow a pathway marked by RD mesenchymal cells and that in this system - as in several other systems - contact with mesenchymal cells modifies the developmental program of embryonic cells, in this case Rz(5,6). This work was supported by a March of Dimes grant and NIH Research Grant HS25916 to WBK and a University of California, San Diego, BSRG grant to KAF.

204.3

MORPHOGENESIS OF AN IDENTIFIED LEECH MOTOR NEURON MAY INVOLVE BOTH STEREOTYPED AND PLASTIC DEVELOPMENTAL PHASES. W.B. Kristan, Jr. & J. Jellies. Dept./Biology, UCSD, La Jolla, CA, 92093.

Our interests in the ontogeny of behavior and neuromuscular organization have led us to examine the morphogenesis of cell 3, a behaviorally important excitor of dorsal longitudinal muscle in Hirudo medicinalis. HRP was injected into 118 cells 3 that were 10 to 40 days old (embryonic through early postembryonic). The initial axonal projection is highly stereotyped, but neuropilar processes added secondarily exhibit variability that implies plasticity. In the profuse arbor of anterior-projecting neurites contralateral to the soma, the number of primary neurites increases throughout embryogenesis, stabilizing close to the peak of 5.4/cell ±1.2(SEM) at 18 days. Neuritic complexity, measured as branch-points per neurite, also increases- to a high of 9.2/neurite ±1.08(SEM) at day 25. Overall complexity subsequently decreases postembryonically as only 1 or 2 of the primary neurites retains an elaborate branching pattern. Additionally, many cells 3 possessed extraganglionic neuritic branches during embryogenesis (≈35%of cells at late stages), which were lost postembryonically (<9% of cells). Thus, the final identifiable morphology of this motor neuron may arise by stereotyped axonal pathfinding followed by a period of overproduction of neurites that are then selectively pruned by as yet unknown mechanisms.
This work was supported by NIH NS25916 (WBK).

202.4

INDEPENDENT TARGET INNERVATION BY TWO AXONS ON THE SAME RETZIUS CELL DURING DEVELOPMENT OF THE LEECH. J. Jellies & W.B. Kristan, Jr. Dept./Biology, UCSD, La Jolla, CA, 92093.

Retzius (Rz) neurons in the two reproductive segments (5&6) of Hirudo medicinalis innervate reproductive structures rather than body wall muscle and skin, the targets for their segmental homologs. Rz(5,6) differ from their segmental homologs in morphology and physiology and development of the Rz(5,6) phenotype depends upon apparent contact with the reproductive primordia early in development. Rz(6) in the female segment innervates male tissue via a nerve (SNA(6)) found only between those two segments. Removing a single peripheral cell (the ARC) early in development prevents SNA(6) formation. We asked how the male innervation influences development of Rz(6) by ablating ARC at embryonic day 9, followed by intracellular HRP-filling at day 18 to determine the branching of Rz(6) axons. In each of 6 cases the anterior axon of Rz(6) branched laterally in the body wall, as in non-reproductive segments, and did not project toward male or female tissue. The posterior axon made its usual contact with female tissue and retraction of the CNS axons was induced. From these results we conclude that in early development; 1) Rz(6) peripheral axons can act independently to innervate different targets simultaneously, 2) the reproductive phenotype predominates when both peripheral targets are innervated by the same cell, 3) male tissue attracts axons to it only over relatively short distances.
This work was supported by NIH NS25916 (WBK).

GIANT DROSOPHILA NEURONS DIFFERENTIATED FROM CYTOKINESIS-ARRESTED EMBRYONIC NEUROBLASTS. C.-F. Wu, K. Sakai* and Y. Hotta*. Dept. of Physics, Univ. of Tokyo, Tokyo, JAPAN 113 and Dept. of Biology, Univ. of Iowa, Iowa City, IA 52242 USA.

Cells in cleavage-arrested early embryos of ascidians and nematodes can develop in correct lineage pattern several tissue-specific enzymes, antigens and ion channels, demonstrating differential segregation of cytoplasmic determinants for developmental potentials of daughter cells. However, effects of cleavage arrest on more complex features differentiated in late embryos have not been extensively studied, especially in species other than those of typical mosaic development. For example, some classes of neuronal differentiation might be initiated solely by intrinsic factors already present in the neuroblast even though normal differentiation occurs in daughter cells after a sequence of neuroblast divisions. We found that isolated neuroblasts from Drosophila gastrulae were able to differentiate neuron-specific properties even when cell divisions were inhibited by cytochlasin B. The resultant giant multinucleated neurons display thickened neurites with a variety of branching patterns and express action potential activity and neuron-specific antigens. These results indicate that the factors for initiating neuronal differentiation programs are present in a neuroblast, and that the expression does not depend on processes following further cell divisions.

202.6

MEMBRANE EXCITABILITY AND SYNAPTIC ACTIVITY IN CELL DIVISION-ARRESTED NEUROBLASTS IN *DROSOPHILA* CNS CULTURE.
M.Saito* and C.-F.Wu (spon:M.Gorczyca), Dept. of Biology, Univ. of Iowa, Iowa City, IA 52242

Drosophila is well-suited for molecular genetic analysis of channels and other proteins involved in neuronal signalling mechanisms. A growing collection of behavioral mutants is available which can be used to identify genes encoding such components in excitable membranes and to correlate their structural mechanisms to their functional activity *in vivo*. However, studies of *Drosophila* neurons have often been hampered by their small size. We found that gastrula neuroblasts in dissociated cultures can develop into giant multinucleated cells with typical neuronal morphology when neuroblast divisions are inhibited by cytochalasin B (Wu,Sakai & Hotta, this volume). These cells are more accessible to electrophysiological studies and may provide a useful model system for characterizing mutant phenotypes. We examined the electrical properties of these giant neurons by the whole-cell recording technique. Action potentials could be elicited by current injection in 1-13 day cultures. The firing pattern varied among cells but the frequency of spikes in general increased in response to stronger membrane depolarization. In voltage-clamp mode, some cell bodies showed large inward current followed by outward current. The amplitude of inward and outward currents varied from cell to cell. These giant neurons were capable of forming functional synaptic connections. In high density cultures, spontaneous excitatory synaptic currents of up to 30pA (holding potential -60mV) could be detected in some cells. Further experiments are underway to determine the ionic species and pharmacological sensitivity of these currents.

204.7

EXPRESSION OF THE SINGLE-MINDED GENE IN DROSOPHILA. John R. Nambu and Stephen T. Crews. Dept. of Biology, UCLA, Los Angeles, CA 90024.

The single-minded (sim) gene encodes a nuclear protein which plays an important role in the development of the embryonic central nervous system. Mutations in the sim locus yield a recessive embryonic lethal phenotype, characterized by a collapse of the ventral nerve cord due to a loss or misplacement of midline nerve cells. The gene appears to be contained within 14 kb of genomic DNA and is comprised of at least seven exons. To expand upon previous studies of sim expression, we have generated a sim/lac-Z fusion construct which contains sim 5' upstream sequences and most of the sim coding region fused in frame to beta-galactosidase. This construct was used to transform flies, and expression of beta-galactosidase, as directed by the sim sequences, was monitored via X-gal or anti-beta-galactosidase staining. In wild type embryos, expression is detected after gastrulation in midline nerve cell precursors as well as in cells of the stomodeal and posterior midgut invaginations. The midline nerve cell precursors continue to stain during germ band retraction and sim-expressing glial cells are later found at the dorsal surface of the nerve cord. Sim expression is greatly reduced after nerve cell differentiation. Similar to previous immuno-cytochemical studies on the native sim protein, the sim/lac-Z fusion protein is localized to cell nuclei. The fusion construct is also expressed in sim mutant embryos, however the positions of sim-expressing cells during germ band retraction and neurogenesis appear to be altered. These and related studies are useful for further defining the roles of sim expression in the normal differentiation and function of the midline nerve cells, as well as in facilitating the identification of cis and trans regulatory elements.

A NEW MONOCLONAL ANTIBODY, 3H6, SPECIFICALLY STAINING THE MOLECULAR LAYER OF THE CEREBELLUM, USED TO STUDY CELL INTERACTIONS IN MURINE NEUROLOGICAL MUTANTS. A. M. Smith* and R. J. Mullen. Dept. of Anatomy, Univ. of Utah Sch. of Med., Salt Lake City, UT 84132.

The mouse MAb 3H6 is an IgM which specifically stains the neuropil in the molecular layer of the cerebellum in both mice and rats. The cognate antigen is first detectable at postnatal day 14 and remains on in the adult. The objective of these experiments was to determine where the antigen is localized and how it is regulated. Sections of fixed, polyester wax or paraffin embedded brain were immunohistochemically stained using Vector ABC with HRP.

In adult weaver (wv) mutants, which lose most of their granule cells, the epitope for 3H6 is not detected. However, in the heterozygote and wild-type it is present. The mutants Purkinje cell degeneration (pcd) and nervous (nr), which lose Purkinje cells postnatally, do not express this epitope in regions where Purkinje cells have degenerated. In postnatal day 42 pcd, when most degeneration has occurred, there is strong staining only in the cerebellar nodulus, the last region to lose Purkinje cells, while in the adult the staining is absent. In nr, where some Purkinje cells survive even in adults, staining is present only in close proximity to surviving Purkinje neurons. These preliminary data support our working hypothesis that the cognate antigen is on the granule cell parallel fiber and that continuing interaction with Purkinje cells is necessary to induce and maintain its expression. Examination of additional mutants and biochemical characterization of this antigen has begun. (Supported by NIH Grant EY07017.)

204.9

AN ANTIBODY THAT RECOGNIZES NEURONAL CELL NUCLEI: CELL SPECIFICITY AND DEVELOPMENTAL REGULATION. R. J. Mullen, A. M. Smith*, and C. R. Buck. Dept. of Anatomy, Univ. of Utah Sch. of Med., Salt Lake City, UT 84132.

An objective of our research has been to produce monoclonal antibodies directed against cell nuclei in the nervous system. BALB/c mice were immunized with purified brain nuclei from other species of mice. One anti-nuclear antibody, A60, is of particular interest as it appears specific to the nervous system, including the peripheral nervous system, and does not stain glia. The antibody recognizes most adult neuronal cell nuclei with three exceptions: cerebellar Purkinje cells, mitral cells in the olfactory bulb, and photoreceptor cells. Immunohistochemically, the cognate antigen is detectable as early as embryonic day 9 in mice. The epitope is not detectable in ventricular zones but becomes evident after the cells become post-mitotic and/or have migrated. In adults, the staining is most intense in nuclei although it is also detectable in the cytoplasm. It appears there can be significant variations in the intensity of staining in nuclei between neighboring cells. The antibody cross-reacts with rat, chick, and human. On Western blots, the antibody stains at least two bands in the 40-44 Kd range. The observations that the epitope is early-appearing, nervous system specific, cell type specific, and that amounts vary between cells of the same type, lead to the working hypothesis that the cognate antigen is involved in neuronal differentiation and regulation. Molecular characterization of this antigen has begun. (Supported by NIH Grant EY07017).

204.10

THE DEVELOPMENTAL EXPRESSION OF OZ42 IN WILD-TYPE AND WEAVER CEREBELLA. R.J. Smeyne[1], J. Napieralski[1], L.B. Pickford[2], R.V. Rouse[2], and D. Goldowitz[1]. Dept. of Anatomy[1], Thomas Jefferson University, Philadelphia, PA. Dept. of Pathology[2], Stanford University School of Medicine, Stanford, CA.

In the external granular layer (EGL) of the developing cerebellum, granule cells proliferate, exit their cell cycle, extend processes, and prepare for migration into the internal granular layer (IGL). We have suggested that the weaver (wv) gene deleteriously affects one of these processes; leading to the death of granule cells in the EGL. A method to dissect these developmental stages is immunocytochemical localization of stage-specific antigens. One antibody, OZ42 is suggested to specifically recognize a protein on post-mitotic premigratory cerebellar granule cells during the early stages of axon outgrowth. Fresh frozen sections of cerebellum from P0-P10 +/+, wv/+ and wv/wv mice were cut at 6μm, mounted onto slides, and immunostained for the presence of OZ42. Immunoreactive granule cells are first detected at P1 in the posterior lobules of +/+ and wv/+ cerebella. The expression of OZ42 progresses in a posterior-to-anterior direction, so that by P3 a discrete 1-2 cell thick layer of cells in the deep EGL is stained over the entire EGL. Immunopositive staining is qualitatively lighter in the wv/+ cerebellum. In the wv/wv EGL, OZ42-positive cells are not seen at P0 or P1. At P3, immunopositive cells are found throughout the EGL, rather than in the discrete layer seen in the +/+ & wv/+. At P10, in the +/+ and wv/+ EGL a well defined layer of immunoreactivity is seen through the entire medial-to-lateral extent of the cerebellum. In the P10 wv/wv vermis, few OZ42-positive cells are seen. More normal appearing OZ42-positive cells are present in the hemispheres. The expression of the antigen recognized by OZ42 is abnormal in the wv/wv cerebellum, and suggests that axonal outgrowth is affected in the wv/wv cerebellum, as previously suggested by the in vitro studies of Willinger et al.

ISOLATION OF GENES INVOLVED IN MOUSE CORTICAL DEVELOPMENT. J.L.R. Rubenstein*, M. Porteus*, E. Brice*, and R. D. Ciarenello. Lab. of Developmental Neurochemistry, Stanford Univ. Sch. of Med., Stanford, CA 94305

We have been developing techniques to use subtractive hybridization to isolate and characterize genes which are preferentially expressed in the mouse embryonic telencephalon. Our goal is to isolate genes which regulate the development of the mammalian neocortex. The method involves construction of cDNA libraries in which the cDNA is directionally inserted into an M13 phagemid vector. We have been successful in making several such libraries with complexities of 4×10^7 individual clones. cDNA libraries from adult and embryonic libraries have their cDNA inserts aligned in opposite orientations. The libraries are then converted to a single-stranded form, using m13 helper virus rescue. The single-stranded adult library is biotinylated and then mixed with the single-stranded embryonic library. Sequences common to both libraries will hybridize, and will be removed using streptavadin (Duguid et al PNAS 1988, Vol. 85, 5738-5742). cDNAs which are preferentially expressed in the embryonic brain will be analyzed with respect to their sequence, their homology to genes known to be involved in cell-type determination and cell-cell recognition, their transcription and their tissue specific expression.

REGULATION OF β_1- and β_2-ADRENERGIC RECEPTOR mRNA IN C6 GLIOMA CELLS. C. Hough* and D.-M. Chuang (SPON: B. Schrier). Lab. Preclin. Pharmacol., NIMH, Neuroscience Center at St. Elizabeths, Washington, D.C. 20032.

Exposure of C6 glioma cells to β-adrenergic (β-AR) agonist, isoproterenol (1 μM), leads to a rapid down-regulation of β_1- and β_2-adrenergic receptor mRNA. Using Northern blotting, we studied the nature of the signal pathway underlying this response. The down-regulation induced by isoproterenol is blocked by the presence of 10 μM β-adrenergic antagonist, alprenolol. Alprenolol, however, exhibits an effect of its own on C6 expression of β_1- and β_2-AR mRNA either alone or in concert with isoproterenol. Agonist-induced down-regulation of β-AR mRNA can also be prevented by the action of protein synthesis inhibitor, cycloheximide (10 μg/ml). While forskolin (10 μM) and phorbol 12-myristate 13-acetate (1 μM), each alone, can partially induce β-AR mRNA down-regulation, 8-BrcAMP (300 μM) and dibutyryl-cAMP (300 μM) did not. The data suggest that β-AR mRNA levels are regulated by more than one mechanism.

205.2

DEVELOPMENTAL EXPRESSION OF ACH RECEPTOR γ AND ε SUBUNIT GENES IN MOUSE MUSCLE. J.C. Martinou* & J.P. Merlie. Dept. of Pharmacology, Washington University, St. Louis, MO.

AChRs of fetal and neonatal muscle exhibit primarily channels of a low conductance class whereas adult muscles contain high conductance AChR channels. This change in properties appears due to a change in subunit structure of the AChR; γ subunit mRNA is replaced by ε subunit mRNA in the adult ($\alpha_2\beta\gamma\delta \rightarrow \alpha_2\beta\varepsilon\gamma$). In order to study the developmental regulation of the expression of these subunits, we measured the levels of mRNA encoding the ε and γ subunits during embryonic (E) and post-natal (PN) development in mouse. We found that γ and ε mRNA levels change in antithetic fashion during the first two post-natal weeks. γ mRNA is expressed at a high level during embryonic days E_{17} - E_{19}, then decreases to an undetectable level after PN 15. Conversely, ε mRNA is detectable at E_{19}, increases transiently about 10 fold between PN2 to PN12 then decreases in older mice to reach in one adult a level comparable to PN3. Mice at PN 4-5 express equal quantities of γ and ε mRNA. We also studied the expression of γ and ε mRNA in vitro, in aneural cultures of mouse embryonic muscles and in the muscle cell lines C2 and BC3H1. We found that ε was not detectable in myoblasts but appeared a few days (between 2 to 5) after cell differentiation in amounts comparable to that found in neonatal mice. The fact that these cells express ε without receiving any neural influence suggests that, *in vivo*, the nerve may not be required for the expression of the ε gene. However, our results do not exclude a role for the motorneuron in modulating selectively the expression of the γ and ε subunit genes.

205.3

DISTRIBUTION OF THE D_2 DOPAMINE RECEPTOR mRNA IN MOUSE BRAIN: IN SITU HYBRIDIZATION STUDIES USING A NOVEL OLIGONUCLEOTIDE PROBE. F. Szele, J.F. Chen, G. Bai and B. Weiss, Dept. Pharmacol., Med. Col. Pa., Philadelphia, PA. 19129

The D_1 and D_2 subtypes of dopamine receptors are differentially distributed in brain, mediate different behaviors and can be regulated independently. In an initial attempt to study the molecular events associated with these receptor mediated behaviors, we measured the mRNA for the D_2 receptor in mouse brain. An oligonucleotide probe directed at a portion of the mRNA coding for the D_2 receptor was designed and radiolabelled with [^{35}S]dATP. Specificity of the probe was determined using in situ hybridization and Northern blot analyses: 1) Hybridization of the probe to mouse striatal sections was RNase sensitive; 2) Excess unlabeled D2 probe eliminated the hybridization signal, whereas excess unlabeled proenkephalin probe did not; 3) Varying post-hybridization temperatures revealed a sharp, monophasic curve with an experimental T_m value of 46°, which was similar to the theoretical Tm; 4) Northern analyses demonstrated a single species of mRNA of about 2.5 Kb; 5) Emulsion autoradiography of brain sections revealed a high signal associated with cells, with both neurons and glia labeled. Levels of the D_2 receptor mRNA in mouse brain were highest in the striatum, olfactory tubercle, and substantia nigra pars compacta; moderate levels were found in the nucleus accumbens and hypothalamus; relatively low activity was seen in the cerebral cortex, septum, hippocampus, thalamus, cerebellum and pars reticulata. This distribution correlates well with that of D_2 receptors as determined from radioligand studies. The high specificity of this probe should allow investigations into the molecular mechanisms responsible for selective dopaminergically mediated behaviors. (Supported by MH42148)

CLONIDINE REGULATES PNMT GENE EXPRESSION IN CHROMAFFIN CELL CULTURES. M.J. Evinger, P. Ernsberger, T. Joh & D.J. Reis. Divs. Neurobiology and Molecular Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.

Neurotransmitters regulate expression of the catecholamine (CA) synthetic gene phenylethanolamine N-methyltransferase (PNMT) in adrenal chromaffin cells. The antihypertensive agent clonidine binds to imidazole receptors on these cells (Ernsberger et al., these proceedings), thereby inhibiting CA secretion through a nonadrenergic mechanism (Powis and Baker, *Molec. Pharmacol.* 29: 134, 1987). We sought to determine whether PNMT gene expression may be regulated by the actions of clonidine on imidazole receptors in primary cultures of bovine adrenal medullary chromaffin cells.

Quantitative Northern blot hybridization of PNMT cDNA to total adrenal RNA reveals that clonidine stimulates PNMT mRNA production in a dose- (10 nM-100 μM) and time-dependent manner. Maximal PNMT mRNA production (5-6-fold stimulation above controls) at 20 hr is paralleled by a ~1.5-fold increase in enzymatic activity. Clonidine analogs active at imidazole receptors likewise stimulate PNMT mRNA with a potency less than that of clonidine: clonidine > cimetidine > rilmenidine, naphazoline, IAA.

Although clonidine inhibits nicotine-induced CA release, 100 μM clonidine does not attenuate the ability of nicotine (10 μM) or carbachol (200 μM) to stimulate PNMT mRNA production. Therefore, these studies indicate that clonidine can regulate PNMT gene expression in the adrenal medulla via activation of specific imidazole receptors.

205.5

TYROSINE HYDROXYLASE mRNA REGULATION FOLLOWING NIGRAL NEUROTOXIN LESIONS. G.M. Pasinetti, M.A. Myers*, D.G. Morgan, C.E. Finch. Andrus Gerontology Center and Dept. of Biological Sciences, Univ. of Southern California, Los Angeles, CA, 90089-0191.

Nigral 6-hydroxydopamine (6-OHDA) lesions induce atrophic changes in the remaining s. nigra dopaminergic neurons (tyrosine hydroxylase (TH) immunopositive neurons) including >50% loss of TH mRNA concentration per neuron measured by in situ hybridization 270 days post lesion (Pasinetti et al. Mol. Brain Res. 5:203-209 (1989). We extend these findings examining TH mRNA prevalence in the remaining s. nigra dopaminergic neurons, striatal TH activity and striatal TH protein, DA, DOPAC content at 2, 21, 90, 270 days following nigral 6-OHDA lesions. Nigral lesions were obtained by unilateral stereotaxic injection of 6-OHDA (8 ug/3 ul volume) in the rostral portion of the s. nigra pars compacta. TH mRNA concentration was assayed by in situ hybridization combined to immunocytochemistry using primary TH antisera (Dr. J. Reinhard, Wellcome Res. Lab.). Striatal TH catalytic activity was estimated by DOPA accumulation and TH protein was measured by TH immunoassay (ELISA). Striatal catecholamine content was assayed by HPLC with electrochemical detection. Nine months after nigral 6-OHDA lesion the cross sectional area and the TH mRNA concentration of the remaining s. nigra TH immunopositive neurons was reduced by about 40% vs. contralateral control values, which were the same as unoperated control values. These results confirm previous findings. The cross sectional area of the remaining nigral TH immunopositive neurons at 2,21,90 days after 6-OHDA lesions was reduced by 10%, 12% and 27% respectively vs. contralateral control values. Experiments are in progress to determine the time dependent correlation of the TH mRNA concentration in the remaining nigral dopaminergic neurons in respect with striatal TH enzymatic activity, TH protein and catecholamine content. (Supported by National Parkinson Foundation and United Parkinson Foundation to CEF and GMP and by John D. and Katherine T. MacArthur Foundation Research Program on Successful Aging to CEF).

205.6

STIMULATION OF ADRENAL MEDULLARY CELLS INDUCES EXPRESSION OF C-FOS PROTO-ONCOGENE. M.K. Stachowiak, M. Sar*, S. An*, E.K. Stachowiak*, A.M. Poisner*, M.J. Iadarola, J.S. Hong. Barrow's Neurol. Inst., Phoenix, AZ 85013, Univ. North Carolina, Chapel Hill, NC 27599, LMIN, NIEHS/NIH, Research Triangle Park, NC 27709.

Adaptation of adrenal medullary (AM) cells to increased catecholamine and peptide secretion during stress involves coordinated activation of genes encoding AM hormones and their biosynthetic enzymes. Here we report that the activation of the rat AM cells In vivo during insulin shock, and bovine AM cells in vitro by nicotine (NIC) or angiotensin II (ANG) produces rapid and transcient elevation of c-fos mRNA levels. Induction of the c-fos mRNA by by ANG and NIC were accompanied by the appearance of c-fos protein, initially in the cytoplasm and later in the nucleus and was colocalized with tyrosine hydroxylase. Nulear expression of the c-fos protein was also induced by veratridine, forskolin, and the calcium ionophore A23187. The role of Ca^{++} and protein kinase C in the regulation of the c-fos gene by ANG was further indicated by the inhibition of the effects of ANG with nifedipine and sphingosine, protein kinase C inhibitor. Activation of the c-fos gene may play a role in the coordinated induction of genes involved in the long-term adaptation of AM cells to increased functional demands.

205.7

REGION SPECIFIC INDUCTION OF C-FOS mRNA BY RESERPINE IN THE RAT. T. Shirao, K. Onel, M.J. Evinger and D.J. Reis. Div. of Neurobiology, Cornell Univ. Med. Coll., NY, NY 10021.

In vitro depolarization of adrenal medulla (ADR) induces the trans-acting transcriptional regulator c-fos and also the mRNA for tyrosine hydroxylase (TH). *In vivo* transynaptic depolarization by reserpine (RES) induces the mRNA for tyrosine hydroxylase in adrenals (ADR) as well as noradrenergic neurons of the locus ceruleus (LC) but not in dopaminergic neurons of the substantia nigra (SN). Since the cis-acting site to which the c-fos protein binds is present in the promoter of the TH gene, we sought to establish whether reserpine will induce fos mRNA in adrenal and brain and, if so, whether the pattern of fos expression is similar to that of TH.

RES (1-8 mg/kg i.p.) elicited a dose-dependent induction of fos mRNA, detected by quantitative Northern blot hybridization to a 3.2 kb portion of the mouse c-fos gene, in the ADR of Sprague-Dawley rats. Induction is rapid, appearing within 15 min, peaking at 30 min and returning to baseline by 2 h. 8 mg/kg RES elicits maximal response in fos mRNA--a 2-fold increase relative to adrenals of vehicle-injected rats. RES also induces fos mRNA in LC with comparable dosage range and time-course. However, no change in c-fos mRNA was detectable in SN or prefrontal cortex. RES also increases ADR c-fos mRNA in spontaneously hypertensive rats (SHR). We conclude that reserpine can induce c-fos mRNA and that the pattern of distribution parallels that of the induction of TH. Conceivably, c-fos may be an intracellular mediator leading to induction of TH in ADR and noradrenergic neurons in brain.

205.8

INDUCTION OF C-FOS mRNA IN BOVINE ADRENAL CHROMAFFIN CELL CULTURES. K. Onel, M.J. Evinger and D.J. Reis. Div. of Neurobiology, Cornell Univ. Med. Coll., NY, NY 10021

The proto-oncogene c-fos protein is a trans-acting transcriptional regulator. It binds to the cis-acting AP-1 site, the base sequence of which has been detected in the promoter regions of neural genes, e.g., TH and enkephalin. Since both genes are expressed in the neuro-ectodermally derived adrenal chromaffin cells, we sought to determine: (1) whether fos mRNA can be induced in this system; (2) whether physiologically relevant neural stimuli can mediate this induction.

Depolarization of bovine chromaffin cell cultures by 50mM K^+ induces a rapid and transient increase in fos mRNA levels within 15 min, as determined by northern blot analysis with a 3.2 kb fragment of the mouse c-fos gene. Maximal levels (14x above control) are reached within 30 min and return to control by 2 hr. The transcriptional inhibitor α-amanitin (1μM) blocks this response. Pretreatment with cycloheximide permits superinduction of fos mRNA by high K^+.

In vivo, the major neural input to the adrenals is cholinergic. To determine whether cholinergic stimuli influence fos expression in adrenals, primary chromaffin cell cultures were challenged with the general cholinergic agonist carbachol (200μM) and the nicotinic cholinergic agonist nicotine (50μM). Increases in steady state fos mRNA levels were observed within 15 min. The nicotinic antagonist hexamethonium blocks this induction, implicating nicotinic receptors in this response. The chelator EGTA also prevents induction of fos mRNA by cholinergic agonists, implying a Ca^{++}-dependent mechanism.

These data indicate that c-fos mRNA is rapidly altered in bovine adrenal chromaffin cells by cholinergic agents. As other mRNAs are also induced in in this system by these stimuli, it is important to resolve whether fos may act to regulate expression of these mRNAs.

THE MAS ONCOGENE IS DEVELOPMENTALLY REGULATED IN THE RAT CENTRAL NERVOUS SYSTEM. K.A. Martin[1], S.G.N. Grant[2], and S. Hockfield[1]. Sect. of Neuroanatomy, Yale University School of Medicine, New Haven, CT 06510[1] and Cold Spring Harbor Lab., Cold Spring Harbor, NY 11724[2].

Many oncogenes, and their cellular homologs, have structural and functional similarity to elements of signal transduction pathways that transmit information from the cell surface to the nucleus. This class of genes plays an important role in regulating cell growth and differentiation. MAS is the only identified oncogene that encodes a protein which belongs to the seven-transmembrane-domain family of G-protein coupled receptors. This family includes the adrenergic, muscarinic, and substance K receptors. MAS expression has been shown by in situ hybridization (Grant et al Soc. Neuro.Sci. Abs. 1989) to be restricted to specific subsets of neurons in the adult rat CNS. We have performed in situ hybridizations using ^{35}S-UTP labelled mRNA probes to analyze the developmental regulation of MAS. In the embryonic day 10.5 (E10.5) rat MAS is expressed throughout the CNS, including the mitotic neural precursor cells of the cerebral vesicles . High levels of MAS continue to be expressed in the precursor cells in the ventricular zone of the developing telencephalon throughout the major period of cortical neurogenesis, E15-E21. During this time cells that express MAS are also found in the cortical plate, which is populated by differentiated neurons. At postnatal day 5, MAS expression in the telecephalon is restricted to subpopulations of neurons in the hippocampus, dentate gyrus, and cortex, as it is in the adult rat. MAS early expression in neuronal precursors and later restriction to a subset of cells generated by these precursors suggests it may play a role in the determination of specific neuronal phenotypes. NERVE GROWTH FACTOR (NGF) INCREASES CALMODULIN (CaM) mRNA AND CaM ACTIVITY IN PC12 CELLS **G. Bai*, J.F. Chen* and B. Weiss, (Spon. J. D. Winkler). Dept. Pharmacol., Med. Col. Pa., Philadelphia, PA 19129**

Although CaM is found in high concentrations in brain and has been shown to regulate a number neuronal processes, it is still unclear what role CaM plays in neuronal differentiation. PC12 cells, which can be induced into sympathetic-like neurons by NGF, were used in these studies as a model of neuronal differentiation. Cells were cultured on collagen-coated flasks, and NGF was added every 2 days. CaM activity was quantitated by its ability to activate a CaM sensitive phosphodiesterase. CaM mRNA was monitored by Northern analysis using a 36 mer radiolabeled oligonucleotide probe complementary to the coding region of rat CaM gene I. A Northern analysis showed that this probe hybridized to two transcripts of 1.7 and 4.0 Kb. Studies using actinomycin D (10 uM) to inhibit DNA transcription showed that the CaM mRNA had a half-life of approximately 8 hr. The addition of NGF (50 ng/ml) to the PC12 cells for 2 days increased both CaM mRNA and CaM biological activity per cell. The high CaM activity was maintained for more than 2 weeks, during which time NGF-induced outgrowth of neurites was apparent. A concentration response curve showed that NGF had an ED_{50} of about 8 ng/ml for increasing CaM activity. When CaM activity was calculated on a protein basis, a smaller effect of NGF was seen, since NGF increases protein concentration per cell. Our studies demonstrating that NGF increases CaM mRNA and CaM activity suggest that CaM may be involved in NGF-induced neuronal differentiation. (Supported by GM34334).

CALMODULIN mRNA AS A MARKER FOR GENETIC INTEGRITY OF MUTANT CEREBELLAR PURKINJE CELLS. A. Messer, J.A. Plummer-Siegard*, and Bonnie Eisenberg*. Wadsworth Ctr. for Labs. and Res., NYS Dept. of Health & Sch. of Public Health Sci., SUNY, Albany, N.Y. 12201.

Calmodulin (CaM) mRNA can be used to assess the nature and timing of deficits in cerebellar mutants with intrinsically affected Purkinje cells. In wild-type mouse cerebellum, the CaM mRNA shows developmental increases during the first 14 days postnatally, and is found predominantly within Purkinje cells, with lower levels in granule cells and interneurons.

The surviving Purkinje cells of the staggerer (sg/sg) mutant, which are grossly stunted and lack tertiary dendritic spines, contain no detectable CaM mRNA, as assayed by Northern blot or an enhanced biotinylated in situ hybridzation. This is in contrast to both Lurcher (Lc) Purkinje cells and sg/sg granule cells, which express near-normal levels of this mRNA up until the time they disappear.

Thus, in Lc Purkinje cells, CaM mRNA transcription must be separate from the primary chain of mutant events. In sg/sg however, CaM mRNA is apparently part of the primary chain of abnormal function in Purkinje cells. Regulation of this gene must still be secondary to another genetic process, since other brain cells within and outside of the cerebellum have the mRNA, but lack of CaM may affect further dendritic development as well as other functions, and/or be part of a "cassette" of differentiated Purkinje cell genes. (Supported by NS17633.)

206.1

INFLUENCE OF GRAVITY ON RESPONSE TO CALORIC STIMULATION OF THE PIGEON VESTIBULAR SYSTEM. H.P. Wit, H.A.A. Spoelstra*, and J.M. Segenhout*. Dept. of Exp. ENT, Univ. Hosp., P.O. Box 30.001, 9700 RB GRONINGEN, The Netherlands.

Responses to caloric stimulation under minimal influence of gravity show that the actual stimulus to the cupula-crista system in this situation is of mechanical (fluid expansion?) origin (Wit, H.P. and Segenhout, J.M., Acta Otolaryngol (Stockh), 105:338, 1988). By measuring gross electrode responses in the pigeon to caloric stimulation, both with and without gravity influence, by a special microphonic modulation technique (Wit, H.P. et al. Advances Oto-Rhino-Laryngol (Basel), 42:59, 1988), the relative influence of the above mentioned effect could be measured. It is of the same order of magnitude as the response due to convection (Bárány's theory). A specially designed Peltier-element miniprobe was used for controlled caloric stimulation of the horizontal semicircular canal. From the results the force on the cupula-crista system as a function of probe temperature and time could be derived using the simple overdamped torsion pendulum model.

206.2

PECULIAR POSTURE IN THE ADULT FLATFISH FOLLOWING HEMILABYRINTHECTOMY AND SELECTIVE OTOLITH LESIONS. W. Graf and R. Baker. Marine Biol. Laboratory, Woods Hole, MA 02543

The relative contribution of the two labyrinths and of single otolithic endorgans to maintain posture in the adult winter flounder, Pseudopleuronectes americanus was studied. Lesion of the down-side labyrinth (n=7) resulted in spiralling towards the lesioned side in some animals as observed in upright fish. Extirpation of the up-side labyrinth (n=14), in contrast, made the animals perform several full pitch-down rotations before settling. If "translated" into upright fish movements, this response would be a rotation about the dorso-ventral axis away from the lesioned side. Thus, two fundamental differences occur compared to upright fish. First, a change in direction of the lesion symptoms from movements about the rostro-caudal axis to rotations about the dorso-ventral axis. Second, a change in laterality from body movements towards the lesioned side to rotations away from the lesion. Selective neurectomy of the utricular nerve produced identical body movements as those following hemilabyrinthectomy (up-side: n=3; down-side: n=1). Sacculus (up-side: n=4) and lagena lesions (up-side: n=2) caused inconsistent movement patterns or none at all. We suggest that the peculiar bilaterally asymmetric labyrinthine organization in the adult flatfish reflects the functional contribution of the vestibular system for maintaining the flatfish as a flatfish. (Supported by NIH grant NS20358).

COMPUTER-ASSISTED VISUALIZATION*, ANIMATION* AND MODELING* OF VESTIBULAR* MACULAS. M.D. Ross*, L. Cutler*, G. Meyer*, J. Dayhoff*. (SPON. R. Fox) NASA-Ames Research Center, Moffett Field, CA 94035.

The 3-dimensional (3-D) organization of the vestibular macular neural network is under investigation by computer-assisted methods in preparation for studies of macular adaptation to microgravity. Fifth sections of a series of 570 ultrathin sections of rat utricular macula were photographed in a Phillips 400 trasmission electron microscope. Two small parts of the neural network and 16 receptive fields were traced from the montages, digitized into a PC, reconstructed as shaded solids and animated using an IRIS high performance workstation, then recorded on film using a Dunn camera and Abekas equipment. Results show that type I and type II hair cells are incorporated into receptive fields that overlap. No two receptive fields are identical. Synapses are spatially distributed and numerically different for each unit. Some portions of the network are innervated by 3 kinds of nerves based on their myelination patterns, but others are supplied only by nerves with long unmyelinated preterminals. Configurations of hair cell stereocilia differ with network complexity. Findings indicate that spatiotemporal factors are important in macular functioning, and that maculas are organized for parallel distributed processing of information. Redundancy and constrained randomness may contribute to robustness. Results are being included in symbolic, animated models.

206.4

REGIONAL VARIATIONS IN THE SYNAPTIC ORGANIZATION OF THE CHINCHILLA CRISTAE. A. Lysakowski and J. M. Goldberg. Dept. Pharmacol.-Physiol. Sci., Univ. of Chicago, Chicago, IL 60637.

The present ultrastructural study was motivated by two considerations. First, previous efforts at reconstructing the afferent innervation of the cristae (Fernández et al., 1988) led to the conclusion that there should be large differences in the innervation of type II hair cells in the central and peripheral zones. Second, it has been suggested that the relative contributions of calyx and bouton endings to afferent discharge are related to the relative number of afferent synapses made on these two structures (Baird et al., 1988). Data on both of these points were lacking. Results of the present serial-section EM study indicate that there are regional variations in type II innervation. As predicted from the afferent reconstruction, there is a 5- to 6-fold difference in bouton numbers in the two zones (3-5 boutons centrally as opposed to 25-30 peripherally). Despite differences in the numbers of boutons, type II hair cells make similar numbers of synaptic contacts in the two regions. There are two reasons for this. First, each central bouton receives multiple (3-4) ribbon synapses, while each peripheral bouton receives a single ribbon synapse. Second, many central type II hair cells make multiple ribbon contacts with the outer surface of adjacent calyces, while this type of contact seems rare in the periphery. Other features did not vary from region to region. For example, type I hair cells, in which ribbon synapses have been described as "exceedingly rare", were found to contain 10-20 ribbon synapses regardless of region. There were also no regional variations in numbers of efferent boutons contacting type II hair cells or calyces. These data should all prove useful in constructing a model of the functional organization of the cristae.

CNQX (6-CYANO-7-NITRO QUINOXALINE-2,3-DIONE) BLOCKS EXCITATORY SYNAPTIC TRANSMISSION IN THE VESTIBULAR LABYRINTH AND VESTIBULAR NUCLEUS OF THE FROG. S.L. Cochran, Dept. Life Sciences, Indiana State Univ., Terre Haute, IN 47809

Synapses between hair cells and VIIIth nerve afferents and between these afferents and second order vestibular neurons (VN's) are glutamatergic. At both, transmitter appears to act through kainate/quisqualate (KA/QUIS) receptors. Some components of EPSP's in VN's can be blocked by N-Methyl-D-Aspartate (NMDA) antagonists. CNQX reportedly blocks selectively KA/QUIS receptors and its effects have been studied at these synapses. In the labyrinth, bath-applied CNQX (25 μM) reduces the amplitudes of EPSP's without affecting their frequency of occurrence, suggesting subsynaptic blockade. NMDA agonists have little or no effect, while quisqualic acid causes an increase in EPSP frequency and afferent depolarization. In VN's high (100 μM) concentrations of CNQX reversibly block EPSP's arising from the ipsilateral VIIIth nerve and those from the contralateral vestibular nucleus. Low concentrations of CNQX (10 μM) block an initial component of the ipsilaterally-evoked EPSP and to a varying extent, components of the contralaterally-evoked EPSP. The resultant ipsilateral EPSP has a slower rise time and smaller amplitude than the control. These findings to date confirm that CNQX is a specific and potent blocker of KA/QUIS synaptic receptors, but its selectivity is dependent upon the concentration employed. Supported by NSF grant BNS-8616738 and NASA grant NAG-498 to SLC.

RESPONSES OF VESTIBULAR NUCLEUS NEURONS DURING EYE MOVEMENTS IN AWAKE RABBITS. J.S. Stahl and J.I. Simpson. Dept. Physiol. & Biophysics, NYU Med. Ctr., New York, NY 10016.

Neurons of the vestibular nuclei were recorded in the awake rabbit. We focused on neurons excited by rotation about the vertical axis toward the side of recording (Type vI) and identified by electrical stimulation as receiving from the flocculus (FRN, n=19), projecting to the midbrain (MPN, n=13), or having both relationships (FRN/MPN, n=4). These neurons were concentrated in the vestibular complex at the level of the caudal pole of the VIth nucleus. The neurons were tested during vestibular and optokinetic behaviors. The modulation of all neurons correlated strongly with eye movements. Qualitative inspection of the data failed to reveal neurons modulating strongly during VOR suppression (head and optokinetic drum rotated together) as do the vestibular and vestibular plus eye movement neurons in the primate. Also unlike the primate, neurons pausing for fast phases in the "on" direction were not seen; the response for "on" fast phases varied from nothing to bursts similar to those of rabbit motoneurons. Eye position and eye velocity sensitivities (r and k, respectively) were determined for the responses to sinusoidal rotation in the light (0.2 Hz, $\pm 2.5^{0}$). The ratio r/k was compared for the 3 groups and their combinations. The ratio differed significantly ($p<.001$) based on whether or not the neurons received from the flocculus (FRN, FRN/MPN versus MPN groupings). The respective values were 1.35 ± 0.67 (mean $\pm$ SD) vs. 0.52 ± 0.28. The value of r/k for the neurons not receiving flocculus input (the MPNs) is close to that of rabbit VIth nucleus neurons recorded during identical stimuli ($r/k=0.49 \pm .09$, n=22). In sum, the dynamics of neurons receiving direct flocculus input differ from at least two types of eye movement neurons lacking that input. Supported by NS-13742.

206.7

CAT VESTIBULAR SINGLE UNIT ACTIVITY DURING IMPOSED, FREE, AND ATTEMPTED HEAD MOVEMENTS. James H. Fuller. Dept. of Oral Anatomy, University of Illinois, Chicago, IL 60612.

Units were recorded in the caudal (P8-P9.5) portions of the medial and inferior vestibular nuclei in cats which could be rotated horizontally with the head fixed to the platform (whole body rotation, WBR), or with the head fixed in space (HFS); imposed rotations resembled active head movements (passive head saccades). Additionally, the cats were trained to make active head movements (free head saccades), or with the head fixed, to make ballistic, accurate, attempted head movements (head torque saccades). Units were selected based on the response to a brief interruption of free head saccades, which consisted of asymmetric and irregular stimulus-locked discharges (category 3 units; Fuller, in, Control of Head Movement, pp. 120-129, Ed. Peterson and Richmond, Oxford Univ. Press, 1988). The three relatively similar events (passive, free, and head torque saccades) were compared to distinguish the relative contributions of primary sensory, secondary sensory, and premotor signals contributing to the overall discharge patterns.

TIMING OF VERTICAL EYE MOVEMENTS INDUCED BY HORIZONTAL ROTATION AFTER CROSS-AXIS VOR PLASTICITY. B.W. Peterson, T.T. Khater*, K.D. Powell, K.J. Quinn*, J.F. Baker. Northwestern University Medical School, Chicago, IL 60611

The short (19 msec) latency of adaptive changes in horizontal VOR after monkeys have worn magnifying lenses for several days is taken as evidence for plastic changes in relatively direct VOR pathways (Lisberger, Science 242:771). To obtain comparable latencies for plastic changes in VOR direction, we recorded eye movements evoked by alternating 2.5 sec periods of ±10 °/sec horizontal whole body rotation (HWBR) in total darkness with a CNC eye coil system in 2 cats before and after "cross-axis" training. This training consisted of 2-3 hours of HWBR coupled with vertical pitch rotation of a projected random dot pattern with identical phase and 1.5-3 X the amplitude. The HWBR was either a 0.25 Hz, 12°/sec sinusoid or a sum of 6 sinusoids from 0.2 - 1.7 Hz.

Vertical VOR responses to ±10 °/sec HWBR were absent before but clearly present with gain ~ 0.2 after training. Latencies between changes in HWBR and vertical eye velocity, measured from computer-averaged records, were 50-74 msec after 0.25 Hz training and 35-45 msec after 0.2-1.7 Hz training. This difference may reflect frequency tuning in the adaptive process. Regardless of the training stimulus, latencies exceeded those reported by Lisberger and were long enough for more complex (eg trans-cerebellar) pathways to be involved. We are disinclined to invoke species differences in such a phylogenetically old behavior. Rather, since VOR plasticity appears to have 2 time constants on the order of 0.5 and 8 hours, we speculate that the faster learning, produced by our 2-3 hour sessions, may involve more complex pathways than learning that occurs over several days. STATIC ROLL AND THE VESTIBULO-OCULAR REFLEX (VOR) T.C. Hain and U.E. Buettner. Depts of Neurology and Otolaryngology, Johns Hopkins University, Baltimore MD, 21205.

In 5 normal subjects we measured the effect of static tilt in roll on the time constant of the VOR, by recording both the horizontal and vertical components of eye velocity for rotation about earth vertical with the head rolled away from upright. We used steps of chair rotation at 60 deg/sec in darkness to elicit the VOR and the scleral eye coil to record eye movements.

The mean time constant of the horizontal VOR in the upright position was 19.2 ± 3.2 sec. The horizontal time constant decreased to 15.7 ± 4.0 sec for 30 deg roll and to 12.7 ± 2.7 sec for 60 deg roll. The time constant of the vertical component was 11.0 ± 1.4 sec for 30 deg roll and 7.5 ± 1.6 sec for 60 deg roll. The gain of the space-horizontal VOR did not vary with roll but an inappropriate space-vertical component appeared in the roll positions. This built up over about 5 seconds and then gradually decayed.

These data suggest that orientation to gravity modulates storage of semicircular canal signals, and that horizontal and vertical components of the VOR can decay at different rates.

GRAVITY INFLUENCES HUMAN VESTIBULO-OCULAR REFLEX GAIN DURING FAST ACTIVE HEAD MOVEMENTS. D.P. O'Leary, M. Gee* and L.L. Davis*. Dept. Otolaryngology-Head & Neck Surgery, Univ. Southern Calif., Los Angeles, CA 90033.

Human horizontal vestibulo-ocular reflex (HVOR) dynamics were analyzed during 18 seconds of active head shaking, sweeping in frequency from 2 to 6 Hz. Subjects fixating on a near target were tested three times in each randomized position: supine, sitting, prone, and on the right side. Head velocity was recorded with a headstrap-mounted rotational velocity sensor. Corrections were applied for systematic headstrap slippage. Eye velocity, computed by digital differentiation of electro-oculographic records, was corrected for near-target vergence during head movements. HVOR gains and phases (2-6 Hz) from 23 subjects were compared at the four test positions. Supine-prone gain differences exceeded +0.1 for all subjects, with reduced phase lags. Additional control experiments imply that these effects resulted from different gravitational force directions on inner ear receptors. However, a physically-equivalent force, linear acceleration, could also be relevant to VOR control during common head movements. We propose a new hypothesis: periodic linear acceleration forces, acting forward and backward on the head during locomotion, modulate the HVOR dynamics for finely-tuned head, eye, and body coordination. SUBJECTIVE RESPONSES DURING INTERACTION OF SMOOTH PURSUIT WITH OPTOKINETIC AND VESTIBULAR STIMULI. V. Honrubia, M.D.,[1] R.W. Baloh, M.D.,*[2] and R. Khalili, B.S.*[1] [1]Div. of Head and Neck Surgery and [2]Dept. of Neurology, Goodhill Ear Center, UCLA School of Medicine, Los Angeles, CA 90024.

Subjects were asked to visually track a moving laser light 1 degree in diameter that was projected from the back of the subject's chair onto the inner surface of 1) a rotating optokinetic (OK) drum with the subject stationary in the light, or 2) a stationary black drum while the subject was rotated in the dark. The laser target (LT) had a sinusoidal trajectory of ± 18 degrees at 0.2 and 0.4 Hz. In clockwise and counterclockwise directions, OK drum velocities ranged from 10 to 100 deg/sec and subjects were rotated with constant angular accelerations from 0.4 to 8.0 deg/sec^2. By pressing levers under each hand, subjects indicated the moment when the LT appeared to reverse direction. The signals were used to compute the velocity of the LT at the moment of direction reversal.

The perceived motion of the LT was influenced by the optokinetic and vestibular stimuli in a predictable manner. The perceived duration of the two half-cycles of sinusoidal LT movement was asymmetrical; the half-cycle of LT movement against the direction of the OK drum or in the direction of chair acceleration was longer. That is, the LT appeared to travel for a longer period when it moved in the same direction as that of the subject's sensation of self-motion (circular vection). The computed LT velocity at the apparent time of reversal was a power function of the magnitude of the interactive stimuli, with maximum effects leading to 100% error – the perceived LT motion became unidirectional. It was concluded that the brain judges the velocity of the LT in relationship to an internal reference that depends on the operational state of the vestibular system. The internal reference level can be changed by interactive stimuli, leading to predictable errors in the judgment of LT motion.

EFFECTS OF GRAVITY ON ASYMMETRICAL VELOCITY STORAGE. T. Raphan, H. Cohen, M.J. Dai*, B. Cohen. Depts. of CIS, Brooklyn College of CUNY and Neurology, Mount Sinai School of Medicine of CUNY, New York, N.Y

Rotation of the visual surround that induces vertical optokinetic nystagmus (VOKN) activates the velocity storage mechanism in the vestibulo-ocular reflex (VOR) and induces vertical optokinetic after-nystagmus (VOKAN). The VOKAN time constant depends on the orientation of the head with regard to gravity. The time constant is smallest in the upright position and largest in the 90° roll position, accompanied by a corresponding increase in the gain of VOKAN. Under these conditions, VOKAN has a longer time constant for slow phases in the upward than in the downward direction. When the head is tilted such that the roll angle relative to the spatial vertical is greater than 90° the upward and downward time constants tend to equalize. These modifications in the time constants are obtained while maintaining velocity storage along the animal's pitch axis as an eigenvector i.e., the OKAN is in the same direction as the OKN. The results indicate that some asymmetries observed in the dynamics of the VOR are due to gravitational effects on the physiological structure of the neural network that realizes the velocity storage integrator. The changes in velocity storage in the absence of gravity may have profound effects on inducing space sickness.

MAGNETIC RESONANCE IMAGING OF THE CAUDA EQUINA SYNDROME ASSOCIATED WITH ANKYLOSING SPONDYLITIS
N.K. Gulati*, (SPON: B. Gallagher) Department of Neurology; Medical College of Georgia; Augusta, GA 30912

This is the first report of Magnetic Resonance Imaging (MRI) in a case of Cauda Equina Syndrome (CES) associated with Ankylosing Spondylitis (AS). Cauda Equina Syndrome has been reported as a late complication of AS and involves lumbosacral sensorimotor deficits with asymmetric hyporeflexic paresis. The patient reported is a 73 year old man who had an 18 month history of urinary incontinence. He recalled having back pain once during his mid 20's. He was found to have mild paraparesis, poor anal sphincter tone, and decreased sensation in the sacral dermatomes. Lumbosacral MRI revealed a widened subarachnoid space, a fluid-filled extradural sac lesion at L3, squaring of the vertebral bodies anteriorly with scalloping posteriorly, and a fine linear density along the anterior border of the vertebral column, perhaps representing ligamentous thickening or calcification. Plain spine radiographs revealed the classic 'Bamboo spine' of AS. It was felt that the patient's CES was secondary to AS which initially presented itself decades earlier. In conclusion, patients with CES and the MRI findings discussed above deserve careful investigation for long standing, unsuspected Ankylosing Spondylitis.

HYPOTHALAMIC EFFECTS ON MEDULLARY RETICULAR ACTIVATION OF DEEP BACK MUSCLE EMG. D.W. Pfaff, S.L. Cottingham, A. Korotzer & S. Schwartz-Giblin. Lab. of Neurobiol. & Behav., Rockefeller University, New York, NY 10021.

Medullary reticular stimulation activates deep back muscles (Am.J.Physiol. 246:R389). Midbrain central grey stimulation facilitates brainstem control over these muscles' EMG (Exp.Neurol.97:704 & Brain Res.421:397). Since this motor control hierarchy parallels lordosis behavior circuitry, we tested the hypothesis that medial hypothalamic lesions that decrease lordosis can also reduce medullary reticular activation of deep back muscle EMG. Urethane anesthetized rats were tested systematically for amplitude of lateral longissimus (LL) and medial longissimus (ML) EMG responses to NGC stimulus trains before and after electrolytic lesions of VM hypothalamus (N=18) or control sites (N=30). Bilateral VM lesions were able to greatly reduce EMG responses in LL and ML, often with a time course similar to previous behavioral results (J.Physiol.288:203). Surprisingly, lesions at the anterior VM pole were particularly effective, and may reflect importance of intra-VM neurons (J. Comp. Neurol. 1989). Although, on the average, various control lesions were less effective, the VM effect was not unique. EMG loss was not well correlated with cortical EEG changes. It appears that VM hypothalamic neurons can affect medullary reticular control of back muscle EMG, but must share this role with other forebrain elements.

A BRAIN STEM SITE THAT SUPPRESSES SYNCHRONOUS DISCHARGES OF GAMMA MOTONEURONES IN THE CAT. **P. H. Ellaway*, N. J. Davey*, M. C. Catley* and J. R. Baker* (SPON:Douglas G. Stuart). Dept. of Physiology, Charing Cross and Westminster Med. Sch., London W6 8RF, England.**

The background and reflexly induced discharges of gamma motoneurones in the decerebrated cat show no tendency towards synchrony, but do so following section of the dorsolateral funiculus of the spinal cord (Davey & Ellaway, J. Physiol. 72:249, 1988). We postulate that a reticulospinal tract may inhibit segmental inputs which, through shared connections to gamma motoneurones, cause synchrony of discharge. To locate the origin in the brainstem of this descending pathway experiments were performed on unanesthetised decerebrated, decerebellate cats with hemisection of the dorsolateral funiculus of the spinal cord contralateral to motoneurone recordings. Cross correlation of control recordings from pairs of individual gamma motoneurones (12 to 40 m/s) to the gastrocnemius muscle in this preparation showed no synchronous firing. Electrolytic lesions of the ipsilateral brainstem in the region of the nucleus reticularis magnocellularis (RMC) caused synchrony which could be as marked as that seen following total spinal cord section. Synchrony was evident as a peak in the correlogram indicating increased probability of discharge of one motoneurone within ± 2-10ms of the discharge of the other gamma motoneurone. Lesions of the midline nucleus raphe magnus did not produce synchrony and lesions of the locus coeruleus (LC) were less effective than those of RMC. We conclude that the descending spinal pathway originates in the medullary reticular formation close to RMC but that the LC may also be involved.

SPONTANEOUS AND EVOKED ELECTRICAL ACTIVITY IN THE ISOLATED CNS OF THE NEWBORN OPOSSUM (Monodelphis domestica) R.R. Stewart, J.G. Nicholls, S.D. Erulkar and N.R Saunders*, Dept. Pharmacology, Biocenter, CH 4056 Basel, Switzerland and Dept. Physiol. & Pharmacol., Univ. Southampton, U.K.

At birth, the opossums are equivalent to rats at fetal stage XIV. Limbs and eyes are rudimentary; the forebrain and cerebellum have not developed. The animal's behavior consists of breathing and suckling. Newborn opossums were anesthetized with ether or by cooling; the brain and spinal cord were rapidly removed and maintained in oxygenated Krebs's fluid. When the spinal cord was stimulated electrically at one end, compound action potentials were evoked. Electrical excitability persisted for up to 4 days after isolation of the CNS. Evoked activity was reversibly blocked by 0.1 μM Tetrodotoxin. Following dorsal root stimulation at cervical and thoracic levels, volleys of action potentials were recorded in the ventral roots. These reflex responses were reversibly eliminated within 20 min by 20mM Mg^{++}. In some animals spontaneous rhythmical bursts of activity were recorded from ventral roots. Thus, the entire isolated CNS of the newborn opossum is hardy, rapidly penetrated by drugs and rhythmically active. It offers advantages for studying anatomical and functional development of a mammalian central nervous system.

SPONTANEOUS ACTIVITY IN THE SPINAL CORD AND INFERIOR OLIVARY NUCLEUS OF NEONATAL RAT RECORDED *IN VITRO*. Kerry D. Walton, Department of Physiology and Biophysics, New York University School of Medicine, 550 First Ave., New York, NY 10016.

Harmaline directly effects the oscillatory properties of inferior olivary (IO) cells *in vitro* (Llinas & Yarom, J. Physiol. 376:163, 1986) and is a well-known tremorgen. However, *in vivo* studies in rat report that harmaline-induced tremor was not seen before P9 (Phillips et al, 1978). Harmaline has been used as a probe to study the functional development of the olivo-cerebellar-spinal system using *in vitro* spinal cord-brain stem-cerebellum isolated from P0-P6 rats. Spontaneous bursts of subthreshold oscillatory activity (3.5-4 Hz at 25-27°C) have been recorded from ventral roots and from motoneurons (Walton & Llinas, *Soc Neurosci. Abst*, 12, 1986). Addition of Harmaline (0.1mg/ml) elicited 8-10 Hz damped oscillations with waveforms similar to emgs recorded from harmaline-treated adult rats.

The spontaneous activity in the IO was characterized by 8 Hz damped oscillations and complex rhythmic activity. Fourier analysis revealed activity at 8Hz and its harmonics, with prominent activity near 30 Hz. In animals P3 and older, after addition of harmaline to the brainstem compartment, the 30 Hz oscillations disappeared leaving highly synchronous 8-11Hz oscillations. Addition of picrotoxin (50μM) seemed to increase the correlation of activity in adjacent IO regions and enhanced the harmaline effect. The results indicate that the conductances underlying IO rhythmic firing (1) are present at birth, (2) are sensitive to harmaline and picrotoxin by P3 but, (3) do not yield the uniform 10Hz osillations seen in adult. Also, the similarity in subthreshold rhythmic activity in these networks points to a role for such oscillations in synchronizing activity in the motor system. Supported by NS22975 and the Irma T. Hirshl Trust.

DESCENDING PROJECTIONS FROM THE DORSAL MESENCEPHALON W. R. Mehler, G. Holstege and R. J. Cowie[2] Dept. Anatomy Univ. Calif. San Francisco CA 94143 and [2]Dept. Anatomy Howard University Washington D.C. 20059

It is well known that the superior colliculus projects contralaterally to the spinal cord via the so-called tectospinal tract, distributing many collaterals to the medial tegmentum of caudal pons and medulla. Recently an ipsilateral tectobulbar pathway has also been demonstrated. However, the relation between the ipsi- and contralateral pathways remains unclear. To gain better insight in the organization of these different pathways, the retrograde HRP and the anterograde autoradiographic tracing techniques were used. Four cats were injected with HRP in the brainstem or spinal cord and 15 cats were injected with ^{3}H-leucine injections in various parts of the superior colliculus and/or the periaqueductal gray (PAG).

The results reveal that from the contralateral tectobulbospinal tract thick labeled fibers were not only distributed to the dorsal two thirds of the bulbar medial tegmental field, but some also to the lateral tegmental field. Furthermore, from the tectospinal tract, several recrossing fibers were observed, that terminated ipsilaterally in the medial and lateral tegmental field. The ipsilaterally descending (thin) tecto-tegmental fiber-system descended through the lateral tegmentum of caudal mesencephalon and pons, but then shifted medially to terminate in the ventral part of the medial tegmentum of caudal pons and medulla. These fibers originated in the deep layers of the superior colliculus and in the PAG. The results demonstrate that the thick fibers of the contralateral tectobulbospinal pathway terminate in different parts of pons and medulla than the thin fibers of the ipsilateral pathway. In our view the two descending pathways belong to different descending systems. The tectospinal tract takes part in the visuomotor system, controlling eye- and head movements, while the ipsilateral pathway belongs to the limbic descending system, involved in emotional behavior.

RETICULOSPINAL NEURONS IN THE LAMPREY: BIOPHYSICAL PROPERTIES AND INPUTS FROM THE MESENCEPHALIC LOCOMOTOR REGION. A.D. McClellan, Dept. of Physiology. & Biophysics, Univ. of Iowa, Iowa City, IA 52242

In the lamprey, spinal cord lesion and brainstem chemical microstimulation studies (McClellan, J. Neurosci. Meth. 21,251, 1987) suggest that reticulospinal (RS) neurons in the middle and posterior reticular nuclei (MRN and PRN) contribute to the initiation of locomotion. The purpose of this study was to examine the membrane properties of RS neurons, to characterize some of the inputs to these nuclei, and to determine the importance of these neurons in initiating locomotion.

Biophysical properties. Some RS neurons displayed postinhibitory rebound, delayed excitation, or spike-frequency adaptation. Most RS neurons fired at a rate which was dependent on injected current level with little adaptation or post-burst hyperpolarization.

Inputs to MRN and PRN. Pressure ejection of a retrograde tracer (HRP or WGA-HRP) into the MRN or PRN labeled neurons in the mesencephalon, ipsilateral and contralateral rhombencephalon, and spinal cord. The labeled neurons in the mesencephalon may correspond to the mesencephalic locomotor region (MLR), an area that can elicit locomotor activity when electrically stimulated. Pulsed microstimulation in the MLR could elicit 1:1 synaptic responses in RS neurons which changed amplitude when the membrane was artificially polarized, consistent with chemical transmission. Some of these MLR-evoked responses were depolarizing and capable of producing action potentials in RS neurons. Work is now in progress to determine if these evoked responses are monosynaptic and to examine their pharmacology.

Lesions in the MRN and PRN. Bilateral lesions which destroyed a significant part of either the MRN or PRN did not abolish locomotion, suggesting that neither nuclei is required for locomotor behavior. Lesion experiments are being performed to determine if both of these nuclei are necessary for the initiation of locomotion.

Supported by SCRF grant NBR 501-5 and NIH grant NS23216.

IDENTIFICATION OF A LIMITED REGION OF THE MEDULLA THAT MAY CONTAIN NEURON POPULATIONS GENERATING RESPIRATORY RHYTHM IN MAMMALIAN BRAINSTEM *IN VITRO*. J.C. Smith, J.J. Greer & J.L. Feldman. Systems Neurobiology Laboratory, Department of Kinesiology, UCLA, Los Angeles, CA 90024-1568.

Regions of the mammalian brainstem containing neuron populations generating respiratory rhythm have not been identified. We have developed a novel method for locating these regions using *in vitro* neonatal rat brainstem-spinal cord preparations and precision sectioning of the neuraxis with a vibratome. Brainstem-spinal cord preparations, or isolated medulla preparations, are maintained in physiological solution in the vibratome bath and spinal or cranial respiratory motoneuron discharge is recorded during serial sectioning of the medulla (50 μm thick sections) starting from either the rostral or caudal ends of the medulla. Analysis of the perturbations of the motor pattern induced by removal of caudal or rostral regions indicates that a very limited medullary region (~200 μm thick slice) extending from the level of the rostral end of the ventral respiratory group to the caudal end of Bötzinger Complex is essential for rhythmogenesis. Sectioning through this region induces instabilities in the respiratory rhythm and removal of the region results in cessation of rhythmic motor discharge. Perturbations of rhythmogenesis do not occur after removal of more rostral or caudal medullary regions; this result does not support the recent proposal (Onimaru et al., Neurosci. Lett., 78: 151, 1987; *ibid*, Brain Res. 44:314, 1988) that more rostral medullary regions are primary sites for rhythm generation. Our previous transection experiments (Smith and Feldman, Soc. Neurosci. Abs 14: 1060, 1988) indicate that cell populations in the ventral medulla are sufficient for rhythmogenesis, and a map of the neuron activity in the critical region indicates the presence in the ventrolateral reticular formation of several distinct classes of respiratory neurons with inspiratory and expiratory phase discharge patterns (Greer et al., this volume). Our recent anatomical tract tracing studies in the adult rat show a concentration of propriobulbar interneurons in the critical region projecting to other major medullary respiratory cell populations and this anatomical feature is consistent with the hypothesis that this region contains respiratory rhythm generating cells. Supported by NIH Grants HL 40959 and HL 02204.

207.9

INVOLVEMENT OF EXCITATORY AMINO ACIDS (EAAs) IN NEUROTRANSMISSION OF RHYTHMIC EXCITATORY DRIVE TO MOTONEURONS DURING LOCOMOTION IN THE RAT SPINAL CORD *IN VITRO*. B.J.Schmidt, J.C.Smith, and J.L.Feldman. Dept of Medicine, Univ. of Manitoba, Winnipeg Canada R3E 0W3, and Systems Neurobiology Lab, Dept of Kinesiology, UCLA, Los Angeles CA 90024.

We previously reported that the *in vitro* neonatal rat brainstem-spinal cord preparation is capable of generating rhythmic limb activity and motoneuronal drive potentials similar to those observed during locomotion in mammals *in vivo* (Smith et al FASEB J 2:2283, 1988; Schmidt et al Soc. Neurosci. Abst 14:427.2 1988). In the present studies we have used the *in vitro* system to investigate the role of EAAs in the transmission of oscillatory synaptic drive to spinal motoneurons during fictive locomotion. Studies in lower vertebrate systems indicate that EEAs mediate rhythmic excitation of spinal motoneurons during locomotion and the presence of EEA receptors on motoneurons in the mammalian spinal cord has been established. However, it is not known whether EAAs are involved in locomotor drive transmission pathways in the mammalian spinal cord. Intracellular recordings were obtained from identified lumbar motoneurons during fictive locomotion induced by the bath application of acetylcholine. The effect of EAA antagonists acting at N-methyl-D-aspartic acid (NMDA) and non-NMDA EAA receptors was examined. Block of NMDA receptor activation with 2-amino-5-phosphonovaleric acid (10-100 μM) and non-NMDA receptors with 6-cyano-7-nitroquinoxaline-2,3-dione (2-20 μM) abolished spike discharge and reduced the amplitude of the rhythmic locomotor drive potential in a dose dependent manner. The similar potency of NMDA and non-NMDA receptor block in reducing the drive potential amplitude (to < %10 of the control amplitude) is consistent with multi-component excitation of motoneurons and/or premotor neurons, mediated by several EAA receptor subtypes. These results suggest that endogenous EEAs are importantly involved in the transmission of rhythmic excitatory drive to spinal motoneurons during locomotion in mammals.

LEARNING AND MEMORY: PHYSIOLOGY II

208.1

Long Term Learning-Specific Changes in the Distribution of Protein Kinase C within the Rabbit Hippocampus. J.L. OLDS, D.L. MCPHIE*, M.L. ANDERSON AND D.L. ALKON LMCN,NINDS, NIH, Bethesda MD. 20892 (SPON: M.E. Olds)

Pavlovian Conditioning has been previously shown to induce differences in the amount and distribution of Protein Kinase C (PKC) 24 h after classical conditioning (Olds et al Science 1989). Conditioned and control rabbits were studied 3 d after the end of the behavioral paradigm. Group 3C received 90 trials/day over 3 d (paired tone and airpuff). Group 3UP received the same same number of stimulii as Group 3C but in an explicitly unpaired manner. Group N remained in their home cages. Autoradiographic images of [3H]-PDBU, a highly specific radioligand for PKC, were analyzed for changes in the distribution of the label within the CA1 cell field. Images were compared between groups by constructing a ratio of specific-binding in the stratum pyrimidale to that in the stratum oriens (SP/SO) along a predetermined image transept-line. Group 3C showed a statistically significant decrease in this ratio (SP/SO=0.64±.08, N=5 each group) compared with Group 3UP (SP/SO=0.97±.02) and Group N (SP/SP=0.91±.05; $p<0.01$ one way ANOVA). This change in the distribution of PKC 3 days after the end of acquisition represents a learning-specific movement of the label from the area of the CA1 somata (24 h after conditioning) to the dendrites (3 days after conditioning). The time domain for this neurochemical change in the hippocampus is significantly longer than those previously reported and supports the hypothesis that PKC is critically involved in memory storage.

208.2

Isolated Pharmacological Activation of Three Neurotransmitter Systems Produces Differential Translocation of PKC in the Rabbit Hippocampus. D. L. MCPHIE* J. L. OLDS J. V .SANCHEZ-ANDRES* and D. L. ALKON (SPON:J.L. Olds) LMCN, NIH, Bethesda, MD, 20892.

The neurotransmitters GABA, Glutamate and Acetylcholine have been shown to play important roles in the hippocampus. In this study the relative contribution of each of these systems to the translocation of protein kinase C (PKC) was assessed. Physiological slices (500μm) were incubated for 20 min in transmitter agonist and antagonist combinations with tetrodotoxin(TTX) at 1μM to eliminate impulses and most chemical synaptic interactions. Controls of Artificial Cerebral Spinal Fluid (ACSF) and ACSF+TTX were also run. The slices were then frozen and sectioned at 20μm. Translocation of PKC was assessed by determining the specific binding of 3HPhorbol-12,13-dibutyrate (PDBU), a highly specific ligand for membrane associated PKC. (Worley et al., J. Neurosci. 6(1):199, 1986).

Glutamate incubation (10μM) produced the largest increase in 3H-PDBU binding, 41.6±1.5 nCi/g, followed by carbachol and GABA with valuesof 34±.97 and 34.8±1.6 respectively. All three of these conditions were significantly above controls ($N=20$-30:$p<.001$)ANOVA. Incubation with appropriate agonist + antagonist + TTX showed reversibility. Agonists applied without TTX produced smaller increases perhaps due to synaptic interactions.

This study shows a convergent effect on 2nd messenger systems by the three agonists tested and the putative translocation response of single neurons to each of the agonists. Taken together with evidence for PKC's integral invilvoment in memory storage (Alkon and Rasmussen, Science 239:988, 1988), these results suggest that known GABA, Acetylcholine and Glutamate inputs to the hippocampus may play an important role in learning-specific PKC distributional changes previously reported by this laboratory.

208.3

LEARNING-SPECIFIC CHANGES IN A CALCIUM-DEPENDENT-POTASSIUM CURRENT FROM CA1 HIPPOCAMPAL CELLS OF RABBIT. J.V. Sanchez-Andres* and D.L. Alkon (SPON: J.W. Cosgrove). LMCN/NINDS, National Institutes of Health. Bethesda, MD 20892.

Previously it was found in this laboratory that Pavlovian conditioning of the rabbit nictitating membrane produces a learning-specific decrease in the afterhyperpolarization of CA1 pyramidal cells (Disterhoft et al. 1986). We now report that the ionic basis of this phenomenon is a conditioning-specific decrease in a Ca^{++}-Dependent-K^+ current. Cells were studied from rabbits that received: (1) three days of classical conditioning (P); (2) three days of explicitly unpaired stimulus presentation (U) or (3) were left in their home cages (N). Single-electrode voltage clamp recordings were made from a total of 74 cells (P: 22; U: 19; N: 33). Cells from conditioned rabbits (Group P), unlike cells from the U or N groups, showed a highly significant change in the frequency distribution of blocked Ca^{++}-Dependent-K^+ currents (Chi^2, $P<0.01$). Additionally, we showed that application of phorbol 12,13 dibutyrate (PDBU), an activator of protein kinase C, blocked a Ca^{++}-Dependent-K^+ current. This effect was reversed by the protein kinase C inhibitor H7. Since this enzyme has already been implicated in memory storage both in the marine snail *Hermissenda crassicornis* and in the rabbit hippocampus (Alkon et al. 1988; Olds et al. 1989), we hypothesize that this enzyme may inactivate the Ca^{++}-Dependent-K^+ current and may be involved in the learning-specific changes observed in this study.

208.4

LONG-TERM CHANGES OF TEMPORAL PROPERTIES OF SINGLE CELLS IN AN ASSOCIATIVE LEARNING MODEL. C. Chen and C. Koch. Computation & Neural Systems Program, 216-76, Caltech, Pasadena, CA 91125.

Studies of neuronal plastisity focus exclusively on changes in the amplitude of the synaptic potential (*e.g.* in *Aplysia* or mammalian LTP). Associative learning in *Hermissenda* is mediated by cellular interactions between two sensory pathways and is stored by modulation of two potassium channels (g_A and $g_{Ca\text{-}K}$) in B-photoreceptors. Computer simulations of their biophysical properties reveal changes in timing of the light-mediated depolarization as a result of modulating the activation rate of these two conductances. The reductions of g_A and $g_{Ca\text{-}K}$ observed are in agreement with voltage-clamp data. The latency of the peak photoresponse is reduced by 20~100 *ms* and the spike frequency is increased from 8 *Hz* to 10 *Hz*. This result has two significant implications. 1. Both changes can increase the interaction between two sensory inputs to activate the intracellular messenger system for channel modulation. 2. The frequency increase will directly turn on the newly learned motor pathway, leading to clinging behavior. Thus learning-induced changes in properties of the ionic channels can modify the temporal dynamics of the neuronal response. To apply this result to machine learning, we are currently simulating a large neural network with variable time delays to learn temporal sequence of patterns.

A BIOPHYSICAL MODEL FOR ASSOCIATIVE LEARNING IN CEREBRAL CORTEX. B. W. Mel* and C. Koch (SPON: A. Feng). Division of Biology, Caltech, Pasadena, CA 91125.

We propose a neural network model for associative learning in the cerebral cortex called *sigma-pi* learning, and discuss a biophysical implementation. The learning scheme is based on the *sigma-pi* neuron, which computes its activation level as a sum of contributions from independent multiplicative clusters of input synapses (see figure). Perceptron-based learning schemes (e.g. back-propagation) adjust hyperplanes in order to best fit a set of input-output examples. In contrast, *sigma-pi* units act as smoothly-interpolating lookup tables, explicitly storing input-output associations as distinct clusters of synapses.

$c_j = \Pi_i w_i x_i$

$y = \sigma(\Sigma_j W_j c_j)$.

Owing to its nature as a lookup-table algorithm, *sigma-pi* learning exhibits several biologically-desirable properties: i) it is fast, ii) it is simple: only excitatory weights are modified, and with only a simple Hebb-like rule, and iii) groups (e.g. columns) of *sigma-pi* units can directly pool their resources to increase total memory capacity. Several features of neural anatomy and physiology have influenced the form of *sigma-pi* learning, including i) the existence of dendritic channels (e.g. NMDA) capable of supporting AND-like computations among neighboring synapses, ii) dendritic spike activity in a variety of cell types, iii) the physiological observation of Hebb-like rules for synaptic plasticity, and iv) the availability of enormously large numbers of synapses (up to $10^9/mm^3$ in cortex). We show how the highly decoded sensory and motor representations of the cerebral cortex and the complex 3-D form of axons and dendrites are ideally suited to such a tabular learning scheme.

DIFFERENTIAL CONDITIONING MODIFIES AUDITORY PATTERNS OF 2-DEOXYGLUCOSE UPTAKE IN A SENSORY MAP. F. Gonzalez-Lima and J. Agudo*. Dept. Med. Anat., Texas A&M Univ., College Station, TX 77843, and Universidad de Valladolid, Spain.

We tested whether auditory responses to the same stimulus change due to reinforcement contingency. 2-deoxyglucose (2-DG) techniques applied during differential conditioning were used to discriminate sensory (tonotopic) from learned (reinforcing) effects of auditory stimuli. Rats were stimulated with two FM tones of low (4-5 kHz) and high (16-20 kHz) frequencies. Each tone was either reinforced (CS^+) or not reinforced (CS^-) with aversive reticular stimulation (US). Taking advantage of the inferior colliculus (IC) tonotopic organization, the IC was used as its own control to compare the effects of CS^+ vs. CS^-, i.e., differences between dorsal and ventral 2-DG bands in the same structure. The reinforced sound (CS^+) was found to evoke always significantly greater 2-DG uptake than the CS^-, independently of whether the CS^+ was the low or the high tone. The perimeter of the 2-DG band also became significantly greater when the sound was reinforced. Thus, enhanced 2-DG activity patterns in the IC were dependent on the learned signal value of sounds as opposed to their purely sensory stimulation. The findings visualized for the first time a direct "side-to-side" comparison of the representations of physical as well as learned behavioral parameters of a stimulus in a sensory map. Supported by NIMH grant R01 MH43353.

CONDITIONED STIMULUS DURATION: BEHAVIORAL ASSESSMENT OF A PREDICTION OF THE SUTTON-BARTO-DESMOND (SBD) MODEL. Diana E.J. Blazis & J.W. Moore. Neuroscience and Behavior Program and Department of Psychology, Univ. of Massachusetts, Amherst, MA 01003.

The SBD model is a neuron-like element that describes many features of rabbit nictitating membrane response (NMR) conditioning (Blazis & Moore, *Soc Neurosci Abstr* 14:842, 1987; Moore et al, *Behav Brain Res* 21:143, 1986), including the interstimulus interval (ISI) function for both forward-delay and trace conditioning. Changes in connection strength V depend on the magnitude of the eligibility trace $\bar{x}$. Appropriate ISI functions in the model are predicted from assuming that the rate of decay of $\bar{x}$ decreases as conditioned stimulus (CS) duration increases. For trace conditioning with a fixed trace interval (CS offset to unconditioned stimulus (US) offset) this assumption implies that V increases with CS duration, leading to the anomalous prediction that conditioning occurs more readily when a long rather than a short ISI is used. We tested this assumption with two intensities of an auditory CS. We used 4 groups of 8 albino rabbits. Each group received either an 83 or 63 db tone (1200 Hz) of duration 350 or 700 ms (denoted Short and Long, respectively). For all groups the trace interval was 300 ms, and the intertrial interval averaged 20 sec. The US was electrostimulation (DC, 1.5 ma, 50 ms) of the right eye. Subjects received 100 trials per day. Data presented here are the mean percent conditioned responding obtained over eight days of training. For groups receiving the 63 db tone, percent CRs obtained for group Short was greater than for group Long, but the difference was not significant (Long, mean = 31.87, SE = 10.10; Short, mean = 53.69, SE = 6.86, $t(14) = 1.79$, 2-tailed $p < .10$). For groups receiving the 83 db tone, percent CRs obtained for group Long was significantly greater than for group Short (Long, mean = 76.13, SE = 3.15; Short, mean = 54.26, SE = 6.25, $t(14) = 3.12$, 2-tailed $p < .01$). These results support the SBD model.

ADAPTIVELY TIMED CONDITIONED RESPONSES AND THE CEREBELLUM: A NEURAL NETWORK APPROACH. J.W. Moore, J.E. Desmond, and N.E. Berthier. Dept. of Psychol., Univ. of Mass., Amherst, MA 01003.

Desmond and Moore (*Biol Cybern*, 58:353-358, 1988) described a network that learns to generate appropriately timed CRs in a variety of paradigms, including trace and long-delay conditioning, mixed CS-US intervals (Millenson, J., et al, *Learn & Mot*, 8:351-366, 1977), blocking, and conditioned inhibition. The model consists of two neuron-like computing units. One unit computes changes in connection stengths between CSs and the US and also generates the network output. The other unit computes the expected arrival time(s) of the US and reinforces computation of connection weights by the output unit. Both units receive CS input from a tapped delay-line which represents the temporal dimension of input to the network. A proposed implementation of the model in the cerebellum assumes Hebbian synaptic plasticity at synapses of parallel fibers (PFs) on the dendritic spines of Purkinje cells (PCs) in a manner consistent with physiological studies showing that concurrent stimulation of PCs by PF stimulation or application of glutamate (analogous to a CS) and climbing fiber (CF) stimulation (analogous to a US) causes long-term depression (LTD) of quisqualate (QA) receptors at the PF fiber/PC synaptic interface (Ito, M., *Ann Rev Neursci*, 12:85-102, 1989). We hypothesize that similar mechanisms for postsynaptic receptor depression exist at PF/Golgi cell synapses. As in the case of PF/PC synapses, these changes are assumed to require conjoint stimulation of Golgi-cell dendritic processes by PF activity induced by a CS with CF excitation induced by the US. Thus, our implementation assumes that CFs contribute to associative LTD of postsynaptic receptors at PF synapses in both PCs and Golgi cells.

SINGLE UNIT ACTIVITY IN SPINAL TRIGEMINAL ORALIS AND ADJACENT RETICULAR FORMATION DURING CLASSICAL CONDITIONING OF THE RABBIT NICTITATING MEMBRANE RESPONSE.

T.N. Ricciardi,* W.G. Richards, and J.W. Moore. Neuroscience and Behavior Program and Dept. of Psychol., Univ. of Mass., Amherst, MA 01003.

Spinal trigeminal nucleus pars oralis (Spo V) subserves the nictitating membrane response (NMR). We recorded the activity of 66 single neurons in the vicinity of Spo V during classical conditioning of the NMR from 24 albino rabbits which had been pretrained on a two-tone disrimination (CSs: 1.6 vs .4 kHz counterbalanced, 78 db SPL, 350 ms duration; US: eye-shock, 1.0-1.5 mA, twin .2-ms dc pulses 4 ms apart; CS^+-US interval = 350 ms; intertrial interval = 20 sec). Neural and behavioral responses were recorded on tape and analyzed off-line. Twenty cells were in Spo V and 26 were in adjacent reticular formation (RF). Thirty-nine of these cells had activity patterns related to the occurence of CSs, the US, and/or CRs in various combinations: (a) Nine cells showed activity time-locked to CSs. Of these, 2 were located in Spo V, and 7 were in RF. (b) Twenty-seven cells responded with short latency to the US. In Spo V, 13 of these cells responded with increased activity, and 1 responded with decreased activity. In RF, 5 cells responded with increased activity, and 8 responded with decreased activity. (c) Fifteen cells showed increased activity time-locked to CRs, and 2 showed CR-related decreased activity. The timing of neural responses relative to CRs ranged from a lead of 110 ms to a lag of 32 ms. Five CR-related cells were in Spo V. They increased their activity in relation to CRs and also to the US. The remaining 12 CR-related cells, including the 2 with decreased activity, were in RF. Four of these responded to the US. This study has implications for brain implementation schemes of neural network computational models (e.g., Blazis, D. & Moore, J., *Soc Neurosci Abstr*, 14:143, 1987; Desmond, J. & Moore, J., *Biol Cybern*, 58:353-358, 1988).

208.10

TEMPORARY BLOCKADE OF THE RED NUCLEUS IN THE RABBIT AFFECTS PERFORMANCE OF CONDITIONED AND UNCONDITIONED NICTITATING MEMBRANE RESPONSES.

V.Bracha*, S.L.Stewart* and J.R.Bloedel. Division of Neurobiology, Barrow Neurological Inst., Phoenix, AZ 85013.

Previous studies showed that permanent lesions of the red nucleus (RN) specifically disrupt the classically conditioned but not unconditioned nictitating membrane response (NMR). In a series of experiments designed eventually to determine whether this effect is due to the selective involvement of the RN in the critical pathway for conditioned response (CR) or whether this nucleus exerts primarily an indirect action on this pathway, initial studies were performed to examine the effect of reversible lesions of the RN on execution of both CRs and URs.

Awake rabbits were trained using a standard delay paradigm: a 100 ms right corneal air-puff served as the unconditioned stimulus (US) and a 450 ms, 1kHz tone as the conditioned stimulus. Once the conditioned behavior was acquired the effect of RN block was tested by comparing the effects of injecting either 1µl of 4% lidocaine or 1µl of saline into the left RN in sessions in which the paired trials were alternated with US alone trials. Incidence, latency and amplitude of CRs and unconditioned responses (UR) before and after injection were compared.

Unilateral lidocaine injection substantially reduced both the incidence and amplitude of CRs in the contralateral eye. Although UR incidence was not affected, its time course and amplitude were markedly altered: UR amplitude decreased while time to response peak increased. These findings indicate that the effects of RN lesions may be the consequence of interfering with its role in regulating NMR performance rather than its selective involvement in the conditioned reflex pathway.(NIH Grant NS21958)

A PLASTIC SLOW-DECAYING RESPONSE COMPONENT IN ISOLATED TURTLE CEREBELLUM.

C.Y. Chan and A. Lee*. Dept. of Physiol., CUNY Med. Sch., New York, NY 10031.

Short-term plasticity in the cerebellar cortex may involve special physiological substrates. We report here a slow-decaying response component (SDC) recorded intracellularly in Purkinje cells (Pc) of the isolated turtle cerebellum. It appeared in the climbing fiber response (CfR) and mossy fiber response (MfR) evoked by peduncular stimulation, and CfR by strong pial stimulation. In normal Ringer, SDC was 0-4 mV and up to 300 ms in duration. It was graded, and habituated readily when activated at high frequency. Apparently, it was mediated by NMDA receptors, as it was blocked by 50-200 µM 2-amino-5-phosphonovalerate (APV), but enhanced in 0-Mg Ringer or by 5 µM glycine. Picrotoxin also enhanced it, suggesting involvement of Golgi or stellate cells. Though reflected in the Pc, the Mf-SDC probably occurred in the Mf-granule cell synapse, since 1) we found no sensitivity of Pc dendrite to iontophorezed NMDA; 2) depolarization of Pc dendrite did not enhance SDC; 3) APV blocked the disynaptic Mf-SDC but spared the parallel fiber response (PfR). Subtracting Mf-SDC from just-threshold CfR revealed no other SDC, suggesting that the Cf-SDC was merely a superimposed Mf-SDC. The Mf-SDC was inhibited by a prior (200-1000 ms) PfR or CfR. This interaction was enhanced in glycine or 0-Mg Ringer, but blocked by APV. Thus, the SDC appears to be the physiological substrate for Mf homosynaptic depression and depression of Mf pathway by Cf, possibly involving Golgi cells.

CHAOS IN THE OLFACTORY BULB OF THE CONSCIOUS RABBIT: REDUCED CORRELATION DIMENSION (D2) IN THE SURFACE POTENTIALS DURING RECOGNITION OF A FAMILIAR ODOR

JE Skinner, M Mitra*, CE Landisman*, and K Fulton*. (SPON: B. Saltzberg) Neurophysiology Section, Neurology Department, Baylor College of Medicine, Houston, Texas 77030.

Rabbits were implanted with an 8 x 8 electrode-array placed on the lateral surface of the olfactory bulb; the electrodes were separated by 0.5-mm intervals. After recovery from surgery, each animal was familiarized with the nose-cone and recording chamber during 2-hrs sessions conducted for 6 consecutive days. On the 7th day the same faint novel odor was presented briefly during each of 4 consecutive trials (3-min intertrial intervals). Compared to the surface potentials recorded during the 1st post odor-detection interval (i.e., determined by the first reduced inspiratory interval), those following the 4th post odor-detection interval showed a frequency-reduction and D2-decrease. All analyses were conducted by a completely automatic computer algorithm using the following parameters: epoch length, 0.5 to 1.5 sec; data points per electrode, 10^4; Tau-interval, 24 data points; embedding dimensions, 1 through 15. The values of D2 at rest prior to odor presentation ranged, between-subjects, from 6.60 to 6.58; the D2-values after odor-detection ranged from 6.50 to 6.08. We interprete our data to indicate that a lower dimensional chaotic attractor (D2-value) is used by the olfactory bulb during ODOR-RECOGNITION when the odor is familiar.

GLIOBLASTOMA INFILTRATION INTO CNS TISSUE IN VITRO: INVOLVEMENT OF TWO DISTINCT PROTEASES.

P.A. Pagancetti and M.E. Schwab, Brain Research Institute, University of Zurich, A-Forel Strasse 1, CH-8029 Zurich/Switzerland.

Differentiated oligodendrocytes and CNS white matter have strong non-permissive substrate properties for regenerating neurites and migrating cells. This property is due to inhibitory proteins of 35 and 250 kD and is specifically neutralized by monoclonal antibody IN-1 (Caroni P. and M.E.Schwab; 1988. Neuron 1: 85-96). Using CNS tissue explants, cultured oligodendrocytes or CNS myelin as substrates, we have shown that the highly invasive rat C6 glioblastoma cells were not inhibited by these myelin-associated inhibitory components (Pagancetti P.A. et al.; 1988. J.Cell Biol. 107: 2281-2291). However, protease blockers specifically impaired C6 cell spreading on CNS myelin as well as C6 infiltration into CNS explants. At least two different type of proteolytic activities seem to be involved. One protease is a metalloprotease, since in the presence of o-phenanthroline or of synthetic oligopeptides C6 cells were unable to spread and migrate on CNS myelin or 35 or 250 kD inhibitors, a behavior similar to that of normal fibroblasts, astrocytes, or of B16 melanoma cells. C6 cell infiltration of CNS tissue explants was strongly reduced by the presence of these blockers. The other protease shows a thrombin-like specifity and plays a role in the early stages of C6 cell spreading on CNS myelin. Our results suggest that C6 cell infiltrative behavior into CNS white matter in vitro occurs by means of at least two distinct proteolytic activities, which probably act on the myelin-associated inhibitory substrates. (SPON: D. Kuffler)

209.2

MIGRATION OF TRANSPLANTED ASTROCYTES IN NEONATAL RATS.

Candace Andersson*, Judy K. Brunso-Bechtold and Michael Tytell (SPON: R. M. Grossfeld). Program in Cell Biology and Neuroscience, Department of Anatomy, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, NC 27103.

As part of a study to determine changes in neuroglial relationships during development, we were interested in determining the ability of transplanted astrocytes to migrate in neonatal rat cortex. Accordingly, a purified population of type I cortical astrocytes was obtained from postnatal day (PD) 1 rats (McCarthy and DeVellis, 1980) and characterized by immunocytochemistry using antibodies to glial fibrillary acidic protein and by electron microscopy. A confluent culture of astrocytes was fluorescently labeled with Fast Blue. A 1 µl suspension (10^6 cells/µl) of labeled cells was unilaterally injected into PD2 host animals using a Hamilton syringe fitted with a 26 gauge needle. The injection site was 1.0 mm anterior to bregma, 1.0 mm lateral to the midline, and 1.5 mm below the surface of the brain. Five days post-injection, labeled astrocytes were present beyond the limits of the injection site suggesting that there is a migration of transplanted astrocytes by this time. (Supported by EY05028 and EY07616).

MIGRATION OF GRAFTED TRANSFORMED ASTROCYTES.
W.J. Goldberg, E.R. Laws Jr. and J.J. Bernstein. Laboratory of CNS Injury and Regeneration, VA Medical Center and Departments of Physiology and Neurological Surgery, George Washington University School of Medicine, Washington, DC.

Grafted fetal astrocytes migrate throughout the host brain on basal lamina-lined surfaces and in parallel and intersecting white matter fascicles [Goldberg and Bernstein, J. Neurosci. Res. 20:38-45, 1988]. In the present experiments 10^6 C6 glioma cells were homografted as suspensions into freshly made implantation pockets in host rat cerebral cortex. Animals were prepared for transmission and scanning electron microscopy 1-7 days postimplantation [DPI]. A large mass grew out of the implantation pocket and by 3 DPI vacuolated C6 cells had migrated and/or invaded onto the glia limitans on the surface of the brain and into the corpus callosum, subependymal space, perivascular space and the cortex under the implantation pocket. By 7 DPI individual C6 cells had migrated into the corpus callosum and internal capsule and were observed in a perineuronal position in the hippocampus and other gray matter structures inferior to the corpus callosum [i.e. habenula]. Pockets were found surrounding each C6 cell and the processes of these cells had replaced host parenchyma. The preferred routes of migration were on basal lamina and parallel and intersecting nerve fiber bundles. Invasion occurred through gray and white matter. The movement of homografted C6 cells in the brain suggests that these cells actively migrate as individual cells as well and invade as a mass.

DIFFERENTIAL SORTING OF ASTROCYTES EXPRESSING EPIDERMAL GROWTH FACTOR RECEPTOR FROM PRIMARY CULTURES OF BIOPSIED HUMAN GLIOMA.
S. Murphy and S. Thwin*. Dept. Pharmacology, College of Medicine, Univ. of Iowa, Iowa City, IA 52242.

Astrocytomas comprise the bulk of malignant brain neoplasms and carry a dismal prognosis. Gene amplification has been demonstrated in about 50% of these tumors, most consistently the gene coding for epidermal growth factor receptor (EGFr), suggesting involvement of EGFr-mediated growth regulation in the pathophysiological processes underlying malignancy. As the first step towards investigating the functional role of EGFr in neoplastic astrocytes, we have devised methods for deriving primary cultures from discarded human biopsies, and for selecting cells expressing EGFr and growing these on in culture.

Glioblastoma multiforme (0.1 g wet weight) were diced into cubes (0.4 mm) and seeded in small flasks. Within two days $GFAP^+$ processes, and then cells emerged from these explants, becoming confluent after 2-3 weeks. The majority of these cells were $GFAP^+$ and all EGFr-bearing cells were $GFAP^+$. The cultures were trypsinized, labelled with a monoclonal antibody against human EGFr (ICN ImmunoBiologicals) followed by FITC conjugated anti-mouse IgG, and then sorted by flow cytometry. Preliminary studies with A431 cells which express considerable amounts of EGFr revealed that trypsinization did not affect antibody labelling of EGFr. The glioma cells sorted on the basis of EGFr expression were harvested and replated. These cells were $GFAP^+$ and proliferated in culture.

This investigation was supported by Biomedical Research Support Grant RR 05572 from the NIH.

209.5

CHARACTERIZATION AND LOCALIZATION OF PERIPHERAL BENZODIAZEPINE RECEPTORS (PBR) IN HUMAN GLIOBLASTOMAS,
WC Broaddus[1], SR Vandenberg[2] and JP Bennett, Jr[3]
Depts. of Neurosurgery[1], Neuropathology[2], Neurology[3], Psychiatry[3], and Pharmacology[3], University of Virginia, Charlottesville VA 22908

Using radioligand binding techniques, six of six human glioblastoma (GBM) specimens had high concentrations of PBR ([^{3}H]-PK 11195 binding sites). The levels were significantly greater than in five normal human frontal cortex samples. The pharmacologic specificity of these sites differed significantly from PBR in human and rat kidney specimens.

Scatchard analysis revealed a small number of high affinity sites and a substantial number of sites of intermediate affinity. Under *in vitro* binding conditions the more numerous lower affinity site is the major contributor to specific binding measurements.

The ligand recognition site of the PBR in human GBM was photoaffinity labeled using [^{3}H]-PK 14105. SDS-PAGE revealed specific incorporation of label into a 17,300 molecular weight component. There was no specific incorporation into human frontal cortex, but a component of similar molecular weight was present in human kidney.

A seventh GBM was studied by *in situ* photoaffinity labelling and emulsion autoradiography of frozen/fixed sections. Light microscopy confirmed localization of PBR to malignant GBM cells.

We conclude that human GBMs consistently express PBR in greater density than in normal human brain. External imaging of these tumors with labeled analogues of PK 11195 thus appears feasible. Further characterization of the photoaffinity-labeled PBR should also provide useful information on the biology of glial tumors.

209.6

BENZODIAZEPINE (BZD) RECEPTOR IN CULTURED ASTROCYTES: PHOSPHORYLATION AND THE EFFECTS OF AMMONIA.
I. Ducis*, J.T. Neary and M.D. Norenberg (SPON: S. Erlich). Lab. Neuropath., Vet. Adm. Med. Ctr. & Univ. Miami Sch. Med., Miami, FL 33101

Previous studies have shown that ammonium chloride treatment increases the affinity of the peripheral-type BZD receptor (Brain Res., in press; Soc. Neurosci. Abstr. 14:1082, 1988) and alters protein phosphorylation in astrocytes (Brain Res 437:161, 1987). Since phosphorylation has been shown to affect the status of a number of membrane receptors, we determined a) whether the astrocyte BZD receptor might be affected by membrane phosphorylation and b) whether an altered state of phosphorylation might be a mechanism whereby ammonium chloride induces changes in receptor affinity. Primary astrocyte cultures were obtained from neonatal rat cortices. Phosphorylation of astrocyte homogenates by ATP and $MgCl_2$ was carried out for 5 min at 30°C in the presence of calcium, calmodulin and 8-Br-cAMP to activate calcium- and cAMP-dependent protein kinases. Particulate fractions were obtained by centrifugation at 20,000 x g for 15 min and receptor properties were assessed by using 3H-Ro5-4864 as the ligand. Scatchard analysis showed a 38% decrease ($p<0.01$) in Kd in fractions that had been phosphorylated. No significant change in receptor number was observed. Preliminary data suggest that no further reduction in Kd occurred when preparations from ammonium chloride-treated cells (10 mM, 22 hrs) were subjected to phosphorylation. These results indicate that phosphorylation affects the status of the astrocyte peripheral-type BZD receptor; furthermore, phosphorylation of this receptor or of closely associated membrane components may be responsible for the increase in affinity of the BZD receptor after exposure to ammonium chloride. (Supported by NIH grant DK38153 and the Veterans Administration)

ASTROCYTE ATP CONCENTRATIONS ARE REDUCED BY FACTORS CIRCULATING IN THE BLOOD OF REYE'S SYNDROME PATIENTS.
J.E. Olson. Department of Emergency Medicine, Wright State University School of Medicine, Dayton, Ohio, 45401.

Reye's Syndrome (RS) is characterized by the rapid onset and progression of neurological dysfunction caused by cerebral edema associated with astrocyte swelling. Plasma levels of free fatty acids and ammonia are significantly elevated. Use of salicylates during the prodromal illness may increase the likelihood of developing RS. We have demonstrated that astrocyte cell volume regulation following osmotic swelling is dependent upon cellular energy (J. Cell. Physiol. 128:209-217, 1986). In this study, we investigated the influence of fatty acids, ammonia, and salicylate on astrocyte energy state.

Astrocytes from primary culture were incubated for 30 min in hypoosmotic phosphate-buffered saline containing no additive (control cells) or 0.03-10 mM octanoate, dodecanoate, ammonia or salicylate. Protein and ATP contents then were determined in each sample.

Ammonia had no effect at any concentration tested. Relative to control cells, salicylate reduced the ATP content by 16% at 1.0 mM and by 92% 10 mM. Dodecanoic and octanoic acids reduced the ATP content by approximately 50% at 1.0 mM and 10 mM, respectively.

The results indicate that free fatty acids impair astrocyte energy metabolism at concentrations observed in RS. Salicylate also may contribute to the metabolic deficit. In contrast, ammonia does not appear to alter astrocyte energy metabolism. These effects may be important in the pathogenesis of cerebral edema in Reye's Syndrome.

Supported by the NIH (NS 23218).

209.8

INTERLEUKIN-1 (IL-1) IN ALZHEIMER'S: ALUMINUM AS A POTENTIAL INDUCER.
L.S. Kamaraju*, S.K. Sundar*, D.E. Schmechel*, M.A. Cierpial & J.M. Weiss (SPON: E. Ellinwood). Departments of Psychiatry and Medicine, Duke ADRC, Duke University Medical Center, Durham, NC 27710.

Some investigators believe that aluminum (AL) salts form the bulk of the inorganic material in the cores of senile plaques. Since Al is a potent inducer of IL-1 in macrophages, we investigated 1) IL-1 concentrations in brains of Alzheimer's disease (AD) patients, and 2) whether Al can induce production of IL-1 by astrocytes in vitro and in vivo.

Assay of glia-rich preparations from two AD brains showed, in fact, high levels of IL-1. In vivo treatment of C6 glioma cells with Al resulted in the secretion of copious amounts of IL-1 in contrast to undetectable levels in control cultures. Likewise, intraventricular infusion of Al into rats resulted in high levels of IL-1 in glial-rich cell fractions.

Although IL-1 has been recently detected in the brains of AD patients, its potential role has yet to be determined. In experimental animals, Al has been postulated to produce cognitive changes by decreasing glucose metabolism and IL-1 has been shown to inhibit glucose sensitive neurons; therefore, Al may exert effects on cognitive functioning via the induction of IL-1.

209.9

DELAYED SCHWANNIAN REMYELINATION OF CENTRAL AXONS AFTER INTRASPINAL ETHIDIUM BROMIDE + IRRADIATION
P.A. Felts[1]* & K.J. Smith[1,2], [1]Anatomy & Cell Biology, Eastern Virginia Medical Sch., Norfolk, 23501, & [2]Neurology, U.M.D.S., London, SE19RT.

Transcutaneous x-irradiation (40Gy) is known to prevent remyelination of central demyelinated lesions for 8 weeks (Blakemore & Patterson, '78), but long term examination has been prevented by radiation-induced skin and grey matter lesions. We have developed a technique which restricts the radiation to precise areas of the exposed spinal cord. Radiation occurs at 6.28 Gy/min, using a 10x20mm source of ^{90}Sr (0.1Ci) behind a shield of variable aperture. The ß particles are approximately 50% absorbed by 1mm of tissue, effectively restricting radiation to the superficial cord.

22 adult rats (Sprague Dawley) received dorsal column injections of ethidium bromide (0.6-1.2ul, 0.5mg/ml), with 40Gy of irradiation over a 3X5mm area. Glial and myelin dissolution were prominent by 7d, and by 21d the lesion consisted of naked, demyelinated axons. Remyelination was prevented for at least 1m (beginning in non-irradiated controls at 14d), but long term examination established that the vast majority of affected axons were eventually remyelinated by Schwann cells. Supported by NIH NS21670 to KJS.

209.10

PROLIFERATION OF SCHWANN CELLS OF UNMYELINATED FIBRES IN RAT SCIATIC NERVE DURING WALLERIAN DEGENERATION OF NEIGHBOURING NERVE FIBRES.
D.R. Archer* and J.W. Griffin. Department of Neurology, Johns Hopkins University Medical School, 600, N. Wolfe St., Baltimore, MD.

Following axotomy axons of the distal stump undergo Wallerian degeneration. Proliferation of Schwann cells whose axons are undergoing Wallerian degeneration is well known; in the rat Schwann cell division peaks 3 days after axotomy. The purpose of this study was to investigate the influence of Wallerian degeneration on neighbouring intact nerve fibres. We sectioned the L4 and L5 ventral roots in 4-week-old rats. At times up to 14 days after axotomy the rats were injected with ^{3}H-thymidine 2, 4 and 6 hours prior to sacrifice. Nerve segments from the sciatic nerve 2 cm distal to the L5 DRG were examined by electron microscopy and autoradiography. At both 3 and 4 days after labelling Schwann cells of intact, unmyelinated axons were seen in mitosis. Mitotic figures were rare in contralateral control nerves. These observations suggest that degenerating nerve fibres release a mitogenic factor capable of acting over a short distance to stimulate proliferation of nearby Schwann cells of unmyelinated fibres.

209.11

PATTERN OF GFAP IMMUNOSTAINING IN EARLY POSTNATAL RAT SPINAL CORD.
S. A. Gilmore and T. J. Sims. Dept. of Anatomy, Univ. of Arkansas for Medical Sciences, Little Rock, AR 72205-7199.

Immunoperoxidase stained, transverse sections of immature rat spinal cord were examined to determine the location and distribution of cells positive for glial fibrillary acidic protein (GFAP), an intermediate filament protein of astrocytes. The elucidation of these data is necessitated by the paucity of such information in normal rats to serve as a baseline for evaluation of astrocytic reactions in the injured spinal cord. The lumbosacral region (LSR) was studied in Charles River CD rats ranging in age from 3 to 21 days. At 3 days GFAP immunoreactivity was associated with punctate structures near the surface of white matter, suggestive of processes cut transversely. This was characteristic of the ventral and the ventrolateral funiculi. A few process bearing cells were noted in the dorsolateral white matter. The latter were noted throughout the LSR, whereas the punctiform distribution was limited to the more rostral sections. By 6 days GFAP immunoreactivity was present in the punctate pattern throughout the LSR. In addition, the dorsolateral white matter in caudal sections contained GFAP positive cells which appeared to have processes in a bipolar arrangement. More rostrally, at the gray/white interface in this region, many cells with multiple, thin, branching GFAP positive processes were noted. The intensity and the numbers of immunoreactive cells were markedly increased throughout the white matter by 9 days of age. With respect to the gray matter, a gradient still persisted at this age in that GFAP positive cells were present ventromedially in rostral sections but were not yet apparent in the caudal ones. Thereafter, GFAP immunoreactivity increased throughout the LSR with a tendency for a ventral to dorsal gradient. This pattern will be compared with that of vimentin immunoreactivity on contiguous or adjacent sections. Supported by NIH grant NS 04761.

DIFFERENTIAL REGULATION OF PROTEOGLYCAN BIOSYNTHESIS BY SOLUBLE MEDIATORS OF INFLAMMATION IN PRIMARY ASTROCYTE CULTURES.
P.C. Johnson-Green*, K.E. Dow and R.J. Riopelle. Queen's University, Depts. of Pediatrics and Medicine, Kingston, Canada K7L 3N6.

Proteoglycans on the cell surface and in the extracellular matrix have been implicated in cell adhesion and in the regulation of neurite outgrowth.

Primary astrocyte cultures from 3 day old rats were labelled with $^{35}SO_4$ and ^{3}H-glucosamine after pretreatment with Interleukin-1 (IL-1) (5 units/ml) or macrophage conditioned media (MCM) (5:1, DMEM/F12:MCM). Media and cell layers were extracted with guanidine-HCl and glycosaminoglycans (GAGs) were isolated by pronase digestion and ion exchange HPLC, and identified.

Untreated (control) cells released heparan sulphate (HS) (16% of total), chondroitin sulphate (CS) (46%), dermatan sulphate (DS) (13%) and hyaluronic acid (HA) (25%) into the media. The cell layer contained the same 4 GAGs, although in different proportions (53% HS, 33% CS, 5% DS and 9% HA). IL-1 treated cells released more GAGs into the media (140% HS, 167% CS, 167% DS and 168% HA of control), but the amount of GAGs in the cell layer was similar to the control. Conversely MCM treated cells released similar amounts of GAGs into the media as compared with control, whereas the cell layer contained 55% less HS.

The differential effects of MCM on cellular and released GAGs suggest that known proteolytic activity of MCM does not account for the observations, unless cell-associated proteoglycans are a preferred substrate for proteolysis. MCM may contain other factors that influence cellular production of GAGs and interfere with the IL-1 in the MCM. Our results also suggest that the effects of MCM on GAG content cannot be solely explained by IL-1.

These observations begin to address molecular mechanisms that influence axonal and oligodendroglial regenerative responses following insult to the CNS.

ESTRADIOL INCREASES GLIAL PEROXIDASE ACTIVITY IN THE HYPOTHALAMIC ARCUATE NUCLEUS.
H.M. Schipper*,R.M. Lechan and S. Reichlin. Lady Davis Inst. for Medical Research, Jewish General Hospital, Dept. of Neurology, McGill Univ., Montreal, Quebec and Tufts Univ. Sch. of Med., Dept. of Endocrinology, Boston, MA 02111 (SPON: P.Gloor)

In adult female rats, treatment with estradiol valerate (EV) produces anovulation and neuropathological changes in the hypothalamic arcuate nucleus (Brawer et al, Endocrinology 1978;103: 501). In the present study, a single intramuscular injection of 2 mg EV (n=4) resulted in a three fold increase in numbers of diaminobenzidine(peroxidase)-positive granules in the arcuate nuclei relative to vehicle treated controls (n=5,p<.01). The peroxidase activity was localized to astrocytes by double-label immunohistochemistry utilizing antiserum to glial fibrillary acidic protein. Diaminobenzidine staining occurred over a pH range of 4-10.5 and was resistant to the catalase inhibitor, aminotriazole, and to tissue pre-heating, indicating that a nonenzymatic pseudoperoxidation reaction has been induced in these cells by estrogen administration. Possible mediators of this reaction are metalloporphyrins known to be present in rodent hypothalamus. Enhanced peroxidase activity in arcuate astrocytes may play a role in estradiol-related hypothalamic damage by oxidizing estradiol to potentially toxic semiquinone radicals as occurs in peripheral estrogen target tissues.

MORPHOLOGY OF ASTROCYTES AND PRESUMED OLIGODENDROCYTES IN THE INTACT RAT OPTIC NERVE USING INTRACELLULAR INJECTION OF LUCIFER YELLOW (LY) AND HORSERADISH PEROXIDASE (HRP). Arthur M. Butt* and Bruce R. Ransom, Dept. Neurology, Yale Univ. Sch. Med., New Haven, CT 06510, *Biomedical Sciences Division, King's College London, Kensington, London, UK. (SPON: J. Ebersole)

Using intracellular injections of LY or HRP to visualize glial cells in the rat optic nerve(RON), two clearly distinct macroglial cell types were observed in over 500 cells examined from rats 1-30 days old. One cell type had the typical chacteristics of fibrous astrocytes. The other cells were presumed to be oligodendrocytes because their morpology corresponded well to the imagined picture of this cell type based on EM studies. Mature astrocytes had ~50-60 fine, radially directed processes 100-200μm in length which terminated in bulbous end-feet at the pial surface, at blood vessels, or within the nerve parenchyma (possibly paranodal end-feet). All astrocytes contributed to the subpial and perivascular glial limiting membranes and their morphology appeared to depend in part on their position within the nerve. Individual astrocytes often extended processes which spanned the entire transverse diameter of the RON(~500μm). Presumed oligodendrocytes, in RONs >2 weeks of age, had 20-30 processes ~150-200μm in length which ran exclusively along the long axis of the nerve parallel to the axons. The processes of these cells never branched or terminated at the pia or blood vessels, had no end-feet, and were connected to the cell body by fine, 10-15μm long, connecting processes. These longitudinal processes are most likely the external tongue processes of the myelin sheathes, and their length would correspond directly to internode distance (a parameter which has only been estimated to date). In many instances fine circular terminations could be detected on the longitudinal processes and these may represent paranodal loops. Each presumed oligodendrocyte would therefore myelinate 20-30 axons within 10-15μm of the cell body with an internodal distance of about 150-200μm. These studies on the 3-dimensional morphology of glial cells *in situ* should provide important new insights into the relationship between their form and their function. Supported by NIH grant NS 15589.

RADIAL GLIA GIVE RISE TO PERINODAL PROCESSES. T. J. Sims, S.A. Gilmore and S.G. Waxman, Dept. of Anatomy, University of Arkansas for Medical Sciences, Little Rock, AR 72205 and Dept. of Neurology, Yale Medical School, New Haven, CT 06510.

This study examined the associations between radial glia processes and the axolemma at nodes of Ranvier in the spinal cord of the mature axolotl salamander. Fixation of the spinal cord was accomplished by perfusion of the truncus arteriosus with a mixture containing 2% glutaraldehyde, 2% paraformaldehyde, 0.5 % acrolein in 0.9 M cacodylate buffer at pH 7.3. Spinal cords were cut into 2 mm segments and were embedded in Spurr plastic. Thick and thin sections were cut in sagittal or transverse planes and examined by light and electron microscopy. Radial glia represent a large proportion of the total glial population in the spinal cord of the mature axolotl. The radial glia in a location dorsal to the central canal project long processes to the dorsal surface of the spinal cord. These processes coalesce into large fascicles in the midline and form the dorsal median septum. As these processes pass through the white matter they give rise to branches that terminate by becoming apposed to the axolemma at nodes of Ranvier. Radial glia are present also in the midline ventral to the central canal. Processes from these cells extend a short distance to the glial limitans overlying the ventral medial septum. These processes give rise to short branches, as do their dorsal counterparts, and many of these branches terminate on nodal axolemma of myelinated axons in the anterior white commissure. Radial glia are thought to differentiate into astrocytes during development of the nervous system in mammals, and perinodal processes derived from astrocytes have been observed in a variety of species. The observations in this study support the view that radial glia, as well as astrocytes, give rise to perinodal processes. The origin of perinodal processes from radial glia in the salamander indicates that this axo-glial relationship is an important functional interaction preserved across a large portion of the phylogenetic scale. Supported by NIH grant NS-04761

210.3

THREE-DIMENSIONAL IMAGING OF SUBSTRUCTURAL FEATURES OF SELECTIVELY STAINED NODES OF RANVIER BY HIGH VOLTAGE EM AND COMPUTER-AIDED RECONSTRUCTION FROM SERIAL SECTIONS. M. H. Ellisman, T. J. Deerinck*, D. Hessler*, and S. J. Young, Lab. for Neurocytology, U.C.S.D., LaJolla, Ca. 92093

The node of Ranvier is the site of complex and rapid physiological events related to saltatory propagation of the action potential. In this region, myelinating cells and the axon form intimate associations via specializations of the cytoplasmic membrane systems, cytoskeleton, and plasma membrane. We have used selective staining and reconstructions from serial sections to study these specializations. Selectively stained thick sections were viewed at 1MeV with the aid of a High Voltage Electron Microscope (HVEM). ***Phosphotungstic Acid***, included in the primary fixative and followed by conventional osmium staining delineates the axolemma at the node and paranode, the ends of the paranodal loops, and the junctional feet of the glial-axonal-junction (GAJ). ***Lanthanum Nitrate***, in the secondary fixative, enhances the paranodal GAJ and provides negative staining of the junctional feet. ***Hatchett's Brown Reaction*** results in electron dense material associated with the nodal axolemma but not the paranodal region. This stain also delineates the paranodal loops. ***Tannic Acid*** in the primary fixative better defines the extracellular matrix associated with the nodal membrane and its relation to the Schwann cell microvilli and the nodal axolemma. ***Osmium Impregnation*** enhances contrast of differentiations of the axoplasmic reticulum which form subsurface cisternae adjacent to the GAJ's of the paranodal axolemma. 3-dimensional HVEM images reveal the distribution of each substructural feature in relation to other nodal components. We have also used computer-aided reconstructions from serial sections to follow axoplasmic intermediate filaments and found many to associate with the axolemma at the GAJ. These reconstructions have also allowed us to track the axoplasmic reticulum in this paranodal region. 3-D views of the node of Ranvier and selectively stained constituents provide a more complete structural framework for understanding the physiological processes occurring at this important site. CULTURED MAMMALIAN ASTROCYTES SYNTHESIZE COLLAGEN TYPE IV: EVIDENCE THAT ASTROCYTES MAY PARTICIPATE IN BASEMENT MEMBRANE FORMATION AT CNS BOUNDARIES. J.R. WUJEK, H. HALEEM-SMITH*, E. FREESE AND Y. YAMADA*. Lab. of Molec. Biol., NINDS, NIH and Lab. of Dev. Biol. and Anomalies, NIDR, NIH., Bethesda, MD 20892.

Basement membranes are formed at the interface between astrocytes of the central nervous system (CNS) and non-CNS structures, such as meninges and blood vessels. Meningeal cells and endothelial cells synthesize collagen type IV, a major component of basement membranes. Immunocytochemical studies have not shown the appearance of collagen type IV on cultured astrocyes (Rutka et al., J. Neuropath. Exp. Neurol., 1988, 45: 285) We have used RNA and protein analysis to investigate the ability of astrocytes to synthesize collagen type IV. Primary cultures of cerebral cortex astrocytes were established from neonatal rats. Northern blot analysis of astrocyte RNA, using a cDNA probe to alpha-1 collagen type IV (Oberbaumer et al., Eur. J. Biochem., 1985, 147: 217), revealed the presence of collagen type IV mRNA (similar in size to collagen type IV mRNA in differentiated F9 teratocarcinoma cells). The amount of collagen mRNA increased during extended growth of astrocytes from 2 weeks up to 10 weeks in culture, . Western blot analysis of astrocyte cell lysates showed a protein band at 190 kDa, corresponding to collagen type IV. These results show that astrocytes, *in vitro*, synthesize collagen type IV. We suggest that astrocytes, *in vivo*, may participate in the formation of basement membranes at the interface between CNS and non-CNS tissues (eg. meninges and blood vessels).

MONOCLONAL ANTIBODIES WHICH BIND SELECTIVELY TO ASTROCYTIC EPITOPES. Dennis M. D. Landis, Lori A. Weinstein*, Christine I. Skordeles*, and H. Ross Payne*. Department of Neurology and Center for Neurosciences, School of Medicine, Case Western Reserve University, Cleveland, OH 44106

We have been interested in obtaining monoclonal antibodies which bind selectively to astrocytic epitopes, and which would be useful in studies of astrocyte function, development, and lineage. Plasmalemmal fractions from primary cultures of neonatal rat forebrain astrocytes have been used as immunogens in ten fusions, and the resulting hybridomas have been screened by ELISA for binding to the immunogen and to live cultured astrocytes, and by immunocytochemical staining. Forty three clones have been selected, and we are in the process of characterizing each. Several antibodies bind to surface determinants on virtually all GFAP+ cells in culture. MAb 8C10 stains fixed and unfixed cultures and tissue; the tissue pattern suggests that it binds to an epitope distributed over most of the astrocytic surface. Comparison of staining patterns in cerebellum, hippocampus, and spinal cord suggests that this mAb may be a useful probe for identifying regional heterogeneity in the extent of astrocytic processes and for measuring astrocyte surface areas. Other antibodies bind to subpopulations of astrocytes in culture and in tissue. MAb 4C6 binds to scattered, flat GFAP+ cells in culture, but stains myelin in fixed tissue. Its pattern on Western blots appears to represent a hitherto undescribed epitope, and the mAb might represent a tool for studying oligodendrocyte lineage. Several mAb's stain intracellular epitopes in a sub-populations of cerebellar astrocytes, or are selective for astrocytic nuclei. MAb 5E6, for example, selectively stains astrocytes in white matter.

These antibodies may prove to be useful reagents in the analysis of astrocyte structure, function, lineage and development.

210.6

ISOLATION AND CHARACTERIZATION OF DOG GLIAL HYALURONATE-BINDING PROTEIN. G. Perides and A. Bignami. Harvard Medical School and VA Medical Center, Boston, MA 02132

Using antibodies raised against human glial hyaluronate-binding protein (GHAP), we identified its homologous in the dog central nervous system. The procedure to isolate the dog protein however, is considerably different. Instead of only one affinity chromatographic step which was used for human GHAP (Perides et al. J Biol Chem 264:5981, 1989), two ion exchange chromatography columns had to be introduced followed by the HA-Sepharose. Briefly, the protein was extracted from dog spinal cord with HCl at pH 2.2. Then it was enriched by binding to CM-Sepharose followed by a DEAE-Sepharose. Subsequently, the protein was affinity purified by binding onto a hyaluronic acid Sepharose column and eluted with 4M guanidine HCl. This brain-specific extracellular matrix glycoprotein consists of two isoelectric variants (pI 4.3-4.4) as the homologous human protein.

Enzymatic deglocosylation, peptide mapping with trypsin, V8 protease and Lys-C specific endoproteinase as well as hyaluronic acid binding experiments will be presented and the results will be compared to those obtained with human GHAP. Supported by NIH grant NS 13034 and by the Veterans Administration.

GLIAL HYALURONATE-BINDING PROTEIN (GHAP) IN TISSUE CULTURE. D. Dahl and A. Bignami. Harvard Medical School and VA Medical Center, Boston, MA 02132.

GHAP is a structural glycoprotein of brain extracellular matrix produced by white matter astrocytes. The in vitro expression of GHAP was studied in primary cultures prepared from mechanically dissociated postnatal rat cerebella. Cells stained with GHAP antibodies were first observed in 4-5 day cultures. The small and phase-dark cells were either isolated or collected in clusters. All cells were vimentin-positive and only few also stained with anti-GFAP. In 6-7 day cultures, the morphology of GHAP-positive astrocytes varied considerably from small cells similar to the vimentin-positive precursor to large cells with many processes. Flat, epithelioid, (type-1) astrocytes were GHAP-negative. The relation of GHAP-positive astrocytes with type-2 astrocytes remains to be determined, but type-2 astrocytes of stellate appearance (Aloisi et al. J Neurosci Res 21:188, 1988) were GHAP-negative. It is suggested that astrocytes form two distinct populations: GHAP-positive astrocytes mainly in white matter and GHAP-negative astrocytes mainly in gray matter, each group originating from a different precursor. Supported by NIH grant NS 13034 and the Veterans Administration.

IDENTIFICATION OF AN INTERFERON-γ RESPONSIVE ELEMENT IN THE HLA-DRA GENE BY TRANSFECTING CULTURED TYPE 1 ASTROCYTES. H. Moses* and J. Ting* (SPON: R. Rohwer). Curr. in Neurobiology and Dept. of Microbiology and Immunology, Univ. of North Carolina, Chapel Hill, NC 27599.

Previous studies have shown that Ia expression on type 1 astrocytes is induced with interferon-gamma(IFN-γ) treatment. This is of interest because class II major histocompatability complex(MHC) antigen expression has been detected in the brain during autoimmune and neurodegenerative disease processes. The purpose of this report is to use a molecular biological approach to identify the IFN-γ responsive DNA region of DRα in primary glial cells. Using a nested series of 5' deletion mutants, we have found that the IFN-γ responsive region in type 1 astrocytes is contained within basepairs -135 to -109. The deletion mutants contain the upstream promoter region of the DRα gene linked to a reporter gene, chloramphenicol acetyl transferase.

The deletion mutants all contain a putative CAAT box, a TATA box, and the transcriptional start site. The IFN-γ induction of DRα is not seen using deletion mutants that are less than 109 base pairs upstream from the start site. Furthermore, any additional region beyond -135 does not provide any greater induction with IFN-γ. With the deletion mutant containing the-109 to -135 base pair region, we have observed about a five fold increase of promoter function with IFN-γ treatment.

Preliminary experiments with a substitution mutant of the IFN-γ responsive element resulted in a loss of induction with IFN-γ treatment. Further experiments are in progress to determine if the IFN-γ induction of DRα is transcriptionally regulated, and finally site-specific mutagenesis studies should identify precisely the IFN-γ inducible sequences. As far as we know, this is the first report that delineates the IFN-γ responsive region in primary cells, specifically astrocytes.

ULTRASTRUCTURAL IDENTIFICATION OF ANTI-GFAP IMMUNO-REACTIVE CELLS IN THE REGION OF THE DEVELOPING AUDITORY DECUSSATION. Sherry Vinsant*, Constance Linville*, Darrell Agee* and Judy K. Brunso-Bechtold (SPON: Wayne Silver). Program in Cell Biology and Neuroscience, Department of Anatomy, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, NC 27103.

For some time we have been interested in mechanisms involved in the development of the hindbrain auditory decussation, the trapezoid body. During the early stages of the development of this decussation, light microscopy reveals the existence of a midline glial boundary (MGB) extending from the 4th ventricle to the base of the brain, as well as processes perpendicular to the boundary, both of which are immunoreactive to antibodies to glial fibrillary acidic protein (GFAP). Electron microscopy reveals a population of cells in the midline region which extend large processes through the MGB, often accompanied by bundles of axons. These cells contain glycogen granules and receive numerous synaptic contacts. In an effort to determine the identity of these cells we have used EM-immunocytochemistry to localize anti-GFAP immunoreactivity by the ABC-peroxidase method. Our results indicate that at least some of the cells with large processes and synaptic contacts are anti-GFAP immunoreactive. In addition, the processes of the MGB are immunoreactive at the EM level. (Supported by NS23092).

ASTROCYTE RESPONSES TO EGF AND CYTOKINE INTERACTIONS

K.R. Huff and L.L.V. Ibric*. Childrens Hospital of Los Angeles, University of Southern California School of Medicine, Los Angeles, CA 90027

We have studied changes in proliferation, Epidermal Growth Factor (EGF) binding, and major histocompatability (MHC) antigen expression of purified cells from neonatal rat or mouse cerebral cortices to treatments with EGF and cytokines. Astrocytes proliferate locally in immune mediated disease states, and the signals may come from growth factors released in injured nervous tissue alone or interacting with cytokines brought by immune cells crossing the vascular space.

We have found that astrocyte proliferation is markedly inhibited by gamma interferon (INF), is modestly increased by tumor necrosis factor (TNF), and is unchanged by interleukin-2 (IL-2) unless combined with INF which causes reduction. Immunofluorescence studies were performed on fixed GFAP containing cells, and fluorescence activated cell sorting (FACS) analysis was done of lightly trypsinized suspended unfixed cells using mAbs to class I and II MHC antigens, which demonstrated response to cytokines and EGF in immune mediation parameters as well. INF and TNF induced both class I and II expression, and EGF markedly induced class I expression; however, combined with INF or TNF reduced EGF induction of MHC. In addition, INF increased EGF binding despite the inhibition of astrocyte proliferation and EGF-induced class I MHC expression.

EGF may work as a concert member of local signals producing functional astrocyte changes in disease states, or it could be a coordinator of signals involving both changes in proliferation and changes in immune mediation in the absence of mitogenic effects.

210.11

TIME COURSE OF MITOGEN INDUCED ALTERATIONS IN THE CELL CYCLE OF CULTURED RAT ASTROCYTES.

D.L. Davies and R.B. Owens*. Depts. of Anatomy and Pathol., Univ. of Arkansas for Med. Sci., Little Rock, AR 72205-7199.

As part of an endeavor to analyze the proliferative and morphologic responses of astrocytes to endogenous mitogens, the cell-cycle of astrocyte enriched cultures was examined using flow cytometric techniques. An extract of homogenized adult rat brain was used as a mitogen to elicit a proliferative response in secondary cultures derived from neonatal rat cerebra. For flow cytometric cell-cycle analysis, cell nuclei were stained with propidium iodide after 6, 12, 18, 24 and 30 hrs of exposure to the brain extract. In control cultures, the proportion of cells in the quiescent/presynthetic (G_0/G_1), synthetic (S), and postsynthetic + mitotic (G_2+M) phases did not vary significantly during the 30 hr study interval. In contrast, in brain extract treated cultures, a decrease in the proportion of cells in G_0/G_1 was noted and a two fold increase in the number of cells in S phase was measured at 18 hrs. Furthermore, an increase in the proportion of cells in the G_2+M phases was observed at 24 and 30 hrs after introduction of the brain extract. These findings suggest that the brain extract increased astrocytic proliferation by recruitment of G_0/G_1 cells into the S phase, a finding compatible with studies of cultured chick neuroblasts and glia (Burakat, I. *et al.*, Cell Tissue Kinet. 18:45, 1985).

EXPRESSION AND DISTRIBUTION OF G-PROTEIN IN CEREBRAL CORTICAL CELLS. F.L. Jordan. Dept. of Oral Biology. College of Dentistry, The Ohio State University, Columbus, OH 43210.

There is much evidence that G-protein (Gp) functions as a transducer of external stimuli in mammalian cells; however, Gp function in brain has not been extensively studied. In an effort to develop a system in which to investigate this, the developmental expression and cellular distribution of Gp in rat cerebral cortex was determined. Gp was assessed in intact cerebral cortical tissue through gel electrophoresis and Western blot analysis, and the cellular localization was revealed through immunohistochemical staining in primary cultures of dissociated cells. Gp was detected in the intact tissue as early as E16 and increased through the neonatal and young adult stages. The protein could also be detected in cortical cultures, and localized via immunohistochemical staining as early as day 4 after plating of neonatal cells. In mature cultures Gp was detected in all cell types - neurons stained most intensely, some astrocytes (type 2) also exhibited significant staining, while most other cell types were detectably stained at lower levels. An overall pattern of developmental expression of higher levels in developing cells than in mature cells was observed. It can be concluded that Gp is expressed very early in cerebral cortical development, is expressed at higher levels in immature cells versus mature cells, and is present in essentially all mature cell types.

210.13

STUDIES OF THE DYNAMIC PROPERTIES OF MICROGLIAL CELLS BY TIME-LAPSE VIDEO MICROSCOPY. J. A. Glenn*, F.J. Jordan, P.L. Booth* and W.E. Thomas (SPON: M. Whitehead). Dept. Of Oral Biology, College of Dentistry, The Ohio State University, Columbus, OH 43210.

In continuing efforts to investigate the overall role of brain microglial cells, dynamic properties of these cells were studied. Utilizing a primary culture system of dissociated cerebral cortical cells from rat, viable cells equivalent to ramified microglia of intact brain tissue were identified and their activity monitored over time periods of 12-48 hr using time-lapse video recording. The most striking initial observation was the highly dynamic nature of these cells - microglia constantly rearranged their overall morphology by changes in the shape and size of the cell body and through the retraction and extension of processes. In addition, simultaneous with this activity the cells were mobile and exhibited apparently random migration usually over a spatial area several times the diameter of the cell body. In this dynamic state microglia were also observed to constantly ingest particles of cellular debris present in the cultures. Under certain conditions microglia displayed a cellular transformation in which they converted to a small sperical dark appearing cell form lacking processes. Similar cells in these cultures have previously been demonstrated to be predominately phagocytic. It is suggested that the ramified microglia possess the ability to convert into a highly phagocytic cell form.

210.14

CHARACTERIZATION OF CEREBRAL CORTICAL MACROPHAGES IN TISSUE CULTURE. W.E. THOMAS AND F.L. JORDAN. Dept. of Oral Biology, College of Dentistry, The Ohio State University, Columbus, OH 43210.

In an effort to establish an amenable preparation for the investigation of cerebral cortical macrophages, these cells have been characterized in tissue cultures of dissociated cells from rat. Previously determined unique morphological features were used to identify macrophages in living cultures where they were continuously monitored using time lapse video microscopy. Initially it was noted that the identified cell form usually exhibited mitosis. The resulting daughter cells displayed intense surface activity, including membrane bubbling and ruffling. The daughters then spread over the culture surface and assumed a very broad flat appearance, and remained in this state for extended time periods thereafter. Such flattened cells were observed to extend finger-like projections or processes up into the culture medium to entrap fragments of cellular debris which were then engulfed. This activity proceeded constantly. Individual flat cells apparently at random would pull up from the culture surface, round up to assume the originally identified cell form, and then undergo the pattern of mitosis described above. It was concluded that the characterized cortical macrophages are distinct from microglial cells, exhibit a specific pattern or cycle of cellular activity, and may be present in brain cell cultures in greater numbers than previously considered.

210.15

RAPID PROLIFERATION OF ASTROCYTIC PROCESSES IN CHICK COCHLEAR NUCLEUS FOLLOWING AFFERENT ACTIVITY BLOCKADE K. S. Canady* and E. W Rubel (SPON: N. Cant), Depts. of Physiology & Biophysics, Psychology and Otolaryngology, Univ. of Washington, Seattle, WA 98195

Cochlea removal in young chicks results in a rapid increase in astrocytic processes immunoreactive for glial fibrillary acidic protein (GFAP) in the cochlear nucleus, nucleus magnocellularis (NM). This increase is evident by 1 hour and reaches 80-100% by 6 hours after receptor removal (Rubel & MacDonald, *Soc. Neurosci. Abstr.*, 13:80; 1987). Analysis of Golgi impregnated glial cells has confirmed that the increase in GFAP reflects an increase in glial processes (MacDonald & Rubel, *Soc. Neurosci. Abstr.*, 15, 1989). The rapidity of this glial response suggests that growth of glial processes may be regulated by activity in NM neurons or 8th nerve axons. We tested this hypothesis by unilaterally blocking 8th nerve action potentials with perilymphatic injections of tetrodotoxin (TTX) in neonatal chicks. Immunocytochemistry was used to visualize GFAP within astrocytic processes in NM. The contralateral NM was used as a within-animal control. Far-field auditory evoked potentials were measured in a separate group of chicks before and after injecting TTX into the perilymph to confirm elimination of the auditory brain stem response.

Tissue sections taken from 6 chicks after 6 hours of unilateral 8th nerve activity blockade showed an increase in GFAP-positive processes in and around NM ipsilateral to afferent activity blockade. We conclude that astrocytes are sensitive to changes in neuronal activity, and that 6 hours of activity deprivation is sufficient to stimulate moderate growth of astrocytic processes. Supported by PHS grants NS24518 & GM07108.

NORMAL AND PROLIFERATING GLIAL PROCESSES OF N. MAGNOCELLULARIS IN NEONATAL CHICKS: A SILVER IMPREGNATION STUDY. G. H. MacDonald* and E. W Rubel, Hearing Development Laboratories, Univ. Washington Medical Center., Seattle, WA. 98195

Increased GFAP immunolabelling observed in Nucleus Magnocellularis (NM) after deafferentation by ipsilateral cochlea removal (CR) (Rubel and MacDonald, *Soc .Neurosci. Abs.*, 13:80, 1988) was further probed by silver impregnation methods. Chicks were perfused 4 hrs. after unilateral CR; brainstems were impregnated by del Hortega's silver nitrate method and embedded in celloidin. Computer stored 3-dimensional images were drawn of glial cells in and around NM. Distinct glial cell distribution patterns were found in control NM, with fibrous astrocytes and oligodendrocytes predominating. Other glial cells displayed microglial morphology, while distinctly protoplasmic astrocytes were rarely observed.

The impregnated glial cells in the deafferented NM doubled in number and displayed significant morphological changes. Presumptive fibrous astrocytes filled NM and the region between NM and N. Laminaris with primary processes of increased diameter and orientation parallel to NM axons. Although the number of primary glial processes was unchanged, the number of branch points nearly doubled and branches were much closer together on the processes, and process length increased approximately 80%. Some responding glial cells resembled protoplasmic astrocytes, or variants of other glial cell types. These findings support previous GFAP immunolabelling which indicated a rapid change in fibrous astrocyte processes after CR. We conclude that swelling and proliferation of processes are part of a glial response to decreases in synaptic activity. The results also suggest that glia types other than fibrous astrocytes may be involved in the response. Supported by NIH grant NS24518

PEPTIDE AMIDATING MONOOXYGENASE (PAM) IMMUNOREACTIVITY IN GLIA AS WELL AS NEURONS C.H. Rhodes and R.A. Angeletti, Univ. Pennsylvania and Albert Einstein Col. Med.

Anti-peptide antisera were raised against synthetic peptides corresponding to sequences near the N-terminus (NPAM), middle (MPAM), and C-terminus (CPAM) of PAM. Specificity of antiserum NPAM was demonstrated by biochemical and immunohistologic experiments. Protein purified from rat brain homogenate by elution from an NPAM-immunoaffinity column was enzymatically active and had an appropriate molecular weight on SDS-PAGE. Antiserum NPAM adsorbed by immobilized peptide produced no immunohistochemical staining. PAM is extensively processed, and pre-treatment of tissue with SDS or trypsin produced different patterns of staining, presumably because different forms of the enzyme are exposed by the treatments. In addition to staining neurons in most areas of the rat brain, NPAM produced staining of ependyma, intrafasicular glia (oligodendroglia), Bergmann glia, and subpial and subependymal fibers.

PHOSPHORYLATION OF VIMENTIN AND GFAP BY PROTEIN KINASE C AND CYCLIC AMP-DEPENDENT PROTEIN KINASE IN ASTROCYTES. B.C. Harrison and P.L. Mobley. *Univ. Texas Health Science Center, San Antonio, TX 78284*

Cultured rat astrocytes undergo changes in morphology in response to treatment with the protein kinase C (PK-C) activator phorbol 12-myristate 13-acetate (PMA). Exposure to PMA also produces changes in the phosphorylation of proteins including the cytoskeletal proteins glial fibrillary acidic protein (GFAP) and vimentin. The changes in morphology resemble that produced by treatment with 8-bromo cyclic AMP (an activator of cAMP-dependent protein kinase, PK-A), and this treatment also increases the phosphorylation of both GFAP and vimentin. Studies were then conducted to determine if PMA and 8-bromo cAMP treatments were phosphorylating similar sites on these proteins. After a 2 hour labeling period with ^{32}P-orthophosphate, cultures were exposed to 300 nM PMA, 2 mM 8-bromo cAMP or the vehicle (control) for 15 min and then subjected to two-dimension gel electrophoresis. GFAP and vimentin were cut from the gels and digested with trypsin. The peptide fragments were then subjected to 2-D tryptic mapping with electrophoresis in the first and chromatography in the second dimension. It was determined that PMA and 8-bromo cAMP treatments produced different tryptic maps for both GFAP and vimentin. Therefore, these studies suggest that PK-C and PK-A result in the phosphorylation of both GFAP and vimentin, but that the kinases differ as to their sites of phosphorylation of these proteins.

Head and Eye Movement Related Responses of Single Units in The Lateral Reticular Nucleus of Rhesus Monkey. J.O. Phillips* and A.F. Fuchs. (SPON: F.R. Robinson). Regional Primate Research Center and Depts. of Psychology and Physiology and Biophysics, University of Washington, Seattle, WA 98195.

The lateral reticular nucleus (LRN) is a major pre-cerebellar nucleus, which receives input from many regions of the CNS including the vestibular nuclei and several pre-oculomotor structures. To determine whether the LRN could transmit signals important for vestibular reflexes or voluntary eye movements, we recorded LRN unit activity in monkeys trained to fixate and track a point target while head fixed or during whole body sinusoidal rotation (.3 to 1.4Hz) about a vertical axis.

26 units have been subjected to a preliminary analysis. All showed a modulation of firing rate in response to whole body rotation. 3 units responded to smooth pursuit eye movements alone. 23 units responded to rotations during which eye movements were suppressed. Most of these showed an increase in average firing rate with peak head velocity, and were considered to be driven by vestibular stimuli. However, the signal relayed by the LRN is much less reliable and precise than that relayed by the vestibular nuclei under similar conditions.

THE EFFECT OF VESTIBULAR AND OPTOKINETIC STIMULATION ON FASTIGIAL NUCLEUS NEURONS IN THE ALERT MONKEY. U. Büttner, G. Markert-Schwab* and A.F. Fuchs. Dept of Neurology, Ludwig-Maximilian-University, Marchioninistr. 15, D 8000 München 70 (FRG)

The dorsal vermis of the cerebellum interacts via the fastigial nucleus with the vestibular nuclei. Both the dorsal vermis and the vestibular nuclei participate in visual-vestibular interaction. In this study the visual-vestibular interaction was investigated in the fastigial nucleus of alert monkeys (M. mulatta, fascicularis), chronically prepared for single unit and eye position (scleral search coil) recordings. Vestibular stimulation was achieved by rotating the monkey about a vertical axis in darkness at 0.2 Hz (± 40 deg/s). For optokinetic stimulation a surrounding cylinder was rotated in the horizontal plane at constant velocity (20 - 80 deg/s) for 60 s, or sinusoidally (0.2 Hz, ± 40 deg/s). The majority of neurons in the fastigial nucleus responding to vestibular stimulation were type II with an irregular firing pattern and no modulation with individual eye movements (Gardner and Fuchs, J Neurophysiol 38:627, 1975). Most of these irregular neurons also responded to constant velocity optokinetic stimulation. As in the vestibular nuclei, optokinetic and vestibular stiumuli had to be in opposite directions to elicit an activation (on-direction). Activity increased with stimulus velocity above 20 deg/s. No, or only little, modulation occurred during sinusoidal optokinetic stimulation. About 20 % of the neurons (both type I and II) had a regular firing pattern. All regular neurons responded to constant velocity (but not sinusoidal) optokinetic stimulation, with a higher sensitivity on average than the irregular neurons. The results show that 'vestibular' neurons in the fastigial nucleus respond to different modalities of stimulation. A comparison with dorsal vermis activity shows that the fastigial nucleus does not simply reflect the activity in the overlying cerebellar cortex.

MIDLINE SECTION OF COMMISSURAL CONNECTIONS BETWEEN THE VESTIBULAR NUCLEI IN THE MEDULLA DOES NOT AFFECT THE GAIN OF THE FAST COMPONENT OF THE VOR. E. Katz, B.Cohen, H.Cohen, J.Buettner*, Depts. of Neurol. & Physiol. Mt. Sinai School of Medicine New York,10029 & Dept. of Physiol. University of Munich.

Midline section of the medulla from the caudal border of the abducens nucleus to the obex, extending from 1 to 4 mm below the surface causes a partial or complete loss of the slow component of the VOR in the cynomolgus monkey (Katz, E. et. al., Soc. Neurosci. *14*: 173, 1988). In a typical animal, the time constant of the response to a step of constant velocity rotation in darkness fell to approximately 5-7 sec, and all functions attributable to velocity storage were lost or severely attenuated. The amplitude and maximum velocity of saccadic eye movements were unaffected. No significant changes were observed during a post-operative follow-up of one year, demonstrating the importance of the commissural connections for maintenance of velocity storage.

It has been postulated that vestibular commissural connections are utilized to adapt the gain of the fast component of the VOR in response to visual-vestibular conflict or after labyrinthectomy. In this study we adapted the VOR in a monkey with a midline commissural section and a consequent loss of velocity storage. The animal wore X0.5 reducing and X2.2 magnifying lenses for 6-9 hrs on separate days following base line testing. VOR gain adaptation was achieved through head and eye movements while the partially restrained monkey fed itself. Normal monkeys are able to alter the VOR step gain by about 30% in this paradigm during the same periods (Cohen, H. et. al., Soc. Neurosci. *13*: 1226, 1987). Similar changes in gain were recorded from the commissurectomized monkey when tested with steps of angular velocity (15-180 deg/s). On average the VOR gain increased 35% after 9 hrs. with magnifying lenses, and decreased 30% after 6 hrs. with reducing lenses. The data show that commissural connections caudal to the abducens nuclei, responsible for maintenance of velocity storage, are not essential for the animal's ability to adapt the gain of the fast component of the VOR.

SIMULATIONS OF A THREE-DIMENSIONAL VOR WITH STABLE GAZE. T. Vilis, D. Crawford*, and D. Tweed* (SPON J. Hore). Depts. of Physiology and Ophthalmology, University of Western Ontario, London, Canada, N6A 5C1.

The VOR data of the companion poster were compared to simulations of a model that incorporates the rotational kinematics of the eye (Tweed and Vilis, J. Neurophysiol. 58:832, 1987). Such a model is necessary to produce fixed slow phase axes, independent of eye position. The simulations show that the pattern observed in the slow phase eye position is a geometric consequence of rotation about a fixed axis. Actual and simulated eye position quaternions move along great circles in four-dimensional space with the vector components projecting to three-dimensional ellipses. These ellipses are tilted with respect to the axis of rotation, resulting in an eye position trajectory with a component perpendicular to the axis. The change in eye position depends on current position. For example rotations about a vertical axis produce a torsional change in eye position whose magnitude depends on vertical eye position. Such changes in eye position are required to produce the observed stable gaze direction in space.

Quick phases are targeted to a surface of desired eye positions that anticipates the action of slow phases by a mechanism in which primary position is shifted by the vestibular input.

211.5

QUICK PHASE PLANES ANTICIPATE VIOLATIONS OF LISTING'S LAW PRODUCED BY SLOW PHASES. D. Crawford*, T. Vilis,and W. Cadera*. Depts. of Physiology and Opthalmology, University of Western Ontario, London, Canada, N6A 5C1.

Three-dimensional eye positions were recorded in 4 monkeys during head rotations about various axes. Axes of eye rotation during slow phases of the VOR were independent of eye position and were either collinear with or deviated systematically from axes of head rotation. These deviations were accurately predicted by the 3 × 3 "gain" matrix computed from three orthogonal inputs at 0.5 Hz. The matrix was close to the negative identity but had a torsion to torsion component of -0.8 and small non-zero entries off the main diagonal. The gaze direction was usually stable in space. As expected, changes in eye position quaternions were mainly along the axes of eye rotation. However, when the initial eye position vector did not align with the eye rotation axis, the position vector rotated clockwise about the origin when viewed down the line of the eye velocity vector. Thus, surprisingly, even slow phase axes without torsional components produce violations of Listing's law. Quick phases not only corrected these violations, but directed the eye across the standard Listing's plane to the surface of position vectors that anticipated the violations, i.e. primary eye position rotated in the direction of head rotation. Quick phase axes are not just the reverse of slow phase axes. These results are modeled in a companion theoretical poster.

VESTIBULO-OCULAR REFLEX (VOR) DIRECTION ADAPTATION TO A PHASE SHIFTED OPTOKINETIC STIMULUS. K.D. Powell, S.A. Rude, K.J. Quinn*, B.W. Peterson, J.F. Baker. Dept. of Physiology, Norhwestern Univ., Chicago, IL 60611.

VOR gain and direction can adapt to reduce retinal slip. Can VOR *phase* also adapt to reduce retinal slip? To answer this question 5 alert cats were rotated horizontally for 2 hr. while viewing a phase shifted vertical optokinetic stimulus. In this paradigm the VOR must produce a vertical direction component which is phase shifted from the horizontal component to minimize retinal slip.

Vertical and horizontal VOR at .05 - 1.0Hz were measured with EOGs in the dark before and after adaptation. Horizontal whole body rotation at 0.25Hz was coupled to vertical rotation of a field of spots (a thousand points of light). The optokinetic sinusoid was 90° or 45° out of phase with the vestibular stimulus. The adaptive response was calculated as the difference between the pre and post adaptation vertical VOR during horizontal rotations. To determine if the horizontal VOR phase changed, the pre and post adaptation horizontal VOR were compared.

In all experiments, after 2 hr. adaptation, horizontal rotation produced a phase-shifted vertical VOR. In 90° phase shift experiments the vertical VOR to horizontal rotations adapted with an average gain of .09 and phase of 86° at .25Hz. An average vertical VOR gain and phase of .13 and -22° were measured at .25Hz after adaptation to a 45° phase lag. In no experiments did horizontal VOR phase change more than 6°. The phase shifted adaptive vertical VOR phases showed band-pass filter behavior, but gains are lower than in previous 0° phase direction adaptation, suggesting that phase shifted stimuli elicit a similar but less robust VOR adaptation. EFFECT OF LINEAR ACCELERATION ON THE VERTICAL VOR AND VISUAL SUPPRESSION. D.E.Angelaki, J.H.Anderson and B.Blakley. Depts. Otolaryngol. and Physiol., Univ. of Minn., Mpls., MN 55455.

It was shown in the cat (Blakley and Anderson, Soc. Neuro. Abst., 1986) that centripetal linear acceleration along the animal's vertical axis changes the VOR during vertical canal stimulation. The animals were positioned on or 45 cm. off the axis of rotation and ramp changes in angular velocity used. The eye velocity was approximated with a single exponential. Compared with on-axis, the response off-axis had a time constant and amplitude that were greater when the centripetal acceleration was directed ventrally and were less when the it was directed dorsally. Based on a model for the VOR with velocity storage (cf., Raphan et al., Exp. Brain Res., 35:229-248, 1979), these changes can be predicted if the feedback in the storage mechanism is modulated by the otolith input.

During the same rotations in the light and with the visual surround fixed to the animal, the dynamics of the VOR were different. A first order fit suggested that the time constants for both up and down eye movements were decreased by one to two seconds. For down eye movements, the time constant was about 2 sec or less and the centripetal acceleration changed the VOR to a greater extent in the dark compared to visual suppression. The model, with an optokinetic input and suppression, can account for this. (Supported by NS-12125 and NS-16567.)

CHANGES IN THE VESTIBULO-OCULAR REFLEX ASSOCIATED WITH SIMULATED STIMULUS CONDITIONS OF SPACEFLIGHT. L.Michaud*, D.E. Parker* and D.L. Harm* (SPON: D.J. Anderson). Neurophysiology Research Laboratory, NASA John son Space Center, Houston, TX 77058.

The Otolith Tilt-Translation Reinterpretation (OTTR) model of adaptation to weightlessness suggests that graviceptor tilt signals are reinterpreted by the brain as translation during prolonged exposure to microgravity. Exposure to a Tilt-Translation Device (TTD) that simulates the stimulus rearrangement present during spaceflight should facilitate the translation interpretation and suppress the tilt interpretation. Ten naive subjects participated in both a TTD and control (tilt in darkness) condition. Subjects were restrained on a one degree-of-freedom moving base. Linear vection was induced by a combination of Y-axis pitch tilt and X-axis linear translation of an optokinetic visual scene. Electrooculography recordings of compensatory vertical eye movements (VVOR) were obtained before, during, and immediately after each condition. Following TTD exposure subjects should exhibit diminished VVOR in response to pitch oscillation compared to VVOR before exposure. In 7 subjects, VVOR was significantly decreased after a 30 min. TTD profile, compared to no change in the control condition. Results indicate similarities between post-TTD VVOR and astronauts' postflight VVOR. Concepts for adapting astronauts to the stimulus rearrangements associated with microgravity prior to spaceflight is supported.

ADAPTIVE CHANGES IN VOR DIRECTION IN HUMANS. T. T. Khater*, B. W. Peterson, and J. F. Baker. Rehab. Institute of Chicago, and Northwestern Univ. Med. School, Chicago, IL 60611.

This study was designed to determine whether pairing vertical (vert.) image motion with horizontal (hor.) body rotation induces a plastic change in VOR direction in humans as it does in the cat, and to examine how behavioral state affects this change. Two normal subjects sat in a servo controlled rotating chair with the head held in a chair mounted restraint. Eye movements were recorded using d.c. EOG. After recording baseline hor. and vert. VOR data, the subject was adapted for two hours, by pairing ±12°, 0.25 Hz sinusoidal hor. chair rotation with ±18°, 0.25 Hz vert. optokinetic stimulation. Vert. and hor. VOR were recorded in total darkness every 15 minutes during adaptation and at the end of the two hour adaptation period.

Our subjects clearly acquired a vert. VOR component in response to 0.25 Hz hor. rotation in the dark. The gain of the acquired response was 0.14 in the first subject and 0.19 in the second, and the phases of both were ≈ 0°. The time constant of adaptation resembles the 30 minute time constant observed in the cat. Furthermore, as in the cat, deadaptation was clearly faster than adaptation, appearing to be complete in 15 min. in both subjects. There is also a correlation between VOR gain and state of consciousness. When one of the subjects tried to fixate on an imaginary object while in total darkness, her hor. and vert. VOR gains were 2.20x and 2.26x larger (respectively) than when she was not doing any mental exercises. Finally, there appears to be a component of the learned vert. response that could not be overcome by fixation, because when subjects were rotated while fixating a stationary LED, both reported that the LED appeared to move vertically in phase with the hor. chair rotation. Supported by EY05289, EY06485, and EY07342.

GRAVITOINERTIAL FORCE (G) LEVEL AFFECTS HORIZONTAL OPTOKINETIC AFTER-NYSTAGMUS P. Dizio and J.R. Lackner Ashton Graybiel Spatial Orientation Laboratory, Brandeis University, Waltham, MA 02254.

We have found that the decay time constant (T) of horizontal post-rotary nystagmus is lower in 0G and 1.8G than in 1G; T for vertical nystamus is attenuated only in 0G. Peak velocity of vestibular nystamus is unaffected by variations in G. To test whether an effect of G on velocity storage (Raphan & Cohen, 1977) is responsible for this we measured optokinetic after-nystagmus (OKAN) in 0, 1 and 1.8G in parabolic flight. Blindfolded subjects (n=4) were rotated about about a vertical axis at 60 °/s until vestibular nystagmus abated; then the eyes were alternately uncovered for 45 s to induce optokinetic nystagmus and covered (5 s after a transition to the desired G level) for 20 s to measure OKAN. There were at least three trials per subject, per G level, in each direction.

T for OKAN was 6.5, 9.9, and 8.2 s in 0, 1, and 1.8G. Only the 1G and 0G values are significantly different. G level did not affect the initial level of OKAN, the values being 19.8 , 16.7, and 18.7 °/s in 0, 1, and 1.8 G. There was no evidence of vertical eye movement during horizontal OKAN. We conclude 1)velocity storage activity in the plane of stimulation is attenuated in higher and lower than normal G levels, 2) the plane of velocity storage does not seem to change as a function G.

211.11

HEAD POSITION AND THE HUMAN VERTICAL VESTIBULO-OCULAR REFLEX (VOR). R.W.Baloh* and J.L.Demer.(SPON:R.C.Collins). Dept.of Neurology and Jules Stein Eye Institute, UCLA Sch.of Med.,Los Angeles,CA 90024-1769

Previous studies in cat found a decreased vertical VOR gain elicited by pitch with the animal on its side compared to pitch with the animal upright. These findings could have important implications in the pathogenesis of space motion sickness. We studied the vertical VOR and visual-vestibular interaction in 6 normal human subjects elicited by voluntary pitch in the upright and lateral positions (head-right and left). Subjects were trained to produce sinusoidal (0.4 - 2 Hz) and step pitch movements guided by a frequency modulated sound signal. Eye and head movements were recorded with a magnetic search coil.

There was no significant difference between average gain (eye vel./head vel.) of the VOR in the head upright and head lateral positions. Vertical VOR gain in any position could be more or less than 1. By contrast, gain during pitch in the light with an earth-fixed visual target was always near 1. Fixation suppression of the vertical VOR was highly correlated with the subjects' ability to perform vertical smooth pursuit. When asymmetric (in 3 subjects), upward pursuit was better than downward pursuit and the downward VOR was inhibited better than the upward VOR.

We conclude that combined otolith-canal stimulation is not sufficient for accurate vertical compensatory eye movements; vision is also required.

211.12

EFFECTS OF HEAD AND BODY POSITION ON TORSIONAL OPTOKINETIC AND VESTIBULAR EYE MOVEMENTS IN HUMANS. M.J. Morrow* and J.A. Sharpe. Division of Neurology, Playfair Neuroscience Unit, The Toronto Hospital, University of Toronto, Toronto, Ontario M5T 2S8

We studied torsional OKN and VOR in 5 normal subjects, aged 29 to 46, using magnetic search coil oculography. Patients were tested in three positions: sitting, head upright; sitting, head supine; and lying, head supine. OKN was elicited with a full-field drum rotating at constant velocity. VOR was measured to active roll plane head movements in all three positions, and to passive sinusoidal rotation in the two head-supine positions. VOR cancellation was measured during passive head movement.

OKN gains were low and OKAN was minimal. OKN and OKAN were unaffected by body or head position. Passive head-supine rotation produced higher VOR gains in lying than in sitting position. VOR gains were higher with an earth-fixed surround, and were slightly lower with a cancellation target. VOR gains during active head rotation were highest with the head upright.

Uniformly low OKN gain in each head position showed no effect of otolith or neck proprioceptive input. Higher passive VOR gains in the lying position may reflect an effect of neck proprioceptive input on the torsional VOR. Higher active VOR gains in the upright position indicate a dynamic otolith contribution. (Supported by NIH Grant EY-06040 and MRC of Canada Grant MT5404).

211.13

VESTIBULO-OCULAR REFLEX INITIATION IN INTERNUCLEAR OPHTHALMOPLEGIA. Janine L. Johnston* and James A. Sharpe (SPON: R.D.G. Blair) Playfair Neuroscience Unit and Departments of Medicine and Ophthalmology, The Toronto Hospital, University of Toronto, Toronto, Canada M5T 2S8

Horizontal vestibulo-ocular reflex (VOR) latency was recorded in 3 patients with unilateral internuclear ophthalmoplegia (INO) using a magnetic search coil technique and compared with 12 normal subjects. Patients were secured in a vestibular chair and accelerated at unpredictable timing and directions, achieving a mean head velocity of 30 deg/sec and acceleration of 320 deg/sec/sec. Trials were conducted in darkness without a target, and while fixating a stationary target. Mean VOR latency was 9 ms, and did not differ from VOR latencies for normal subjects (8 ± 5 ms). VOR gain in the first 40 ms after head motion was reduced (0.21; normal: 0.87 ± 0.13). After a latency of 71 ± 10 ms, VOR gain increased signficantly (0.67). In patients with INO, damage to direct VOR pathways resulted in low VOR gain, but did alter latency. Recovery of VOR gain after 70 ms may represent transmission through indirect, modifiable VOR pathways. This is significantly longer than the VOR latency of presumed indirect pathways in monkeys (Lisberger & Pavelko: J. Neurosci.1986) and may reflect abnormal conduction through the medial longitudinal fasciculus or neighbouring tegmental pathways. (Supported by the R.S.McLaughlin Foundation and MRC of Canada Grant MT5404)

211.14

Vestibulo-Ocular Reflex (VOR) and Adaptive Plasticity with Aging. G.D.Paige. Washington Univ, St Louis, MO 63110.

Vestibular deterioration with aging is known to occur anatomically. However, VOR changes with aging remain unclear. Further, nothing is known about potential deterioration in adaptive control which normally corrects VOR performance when visual-vestibular mismatches arise during head movements. The horizontal VOR was assessed (coil technique) in normal humans 18-89 years of age before and after 8 hr of adaptation to 2x lenses. Subjects were oscillated at 0.025-4.0 Hz, 50 o/s pk head velocity, and for 0.025 and 0.25 Hz, at 50-300 o/s pk velocity. For younger (Y, under 60) subjects, VOR gain was near 0.90 at 2.5-4.0 Hz, dropping to 0.55 as frequency decreased to 0.025 Hz. Phase showed a 3 deg lead at 4 Hz which disappeared as frequency dropped to 0.25 Hz, but returned to reach 14 deg at 0.025 Hz. The VOR in older (O, above 65) subjects was similar except for larger phase leads at 0.1-0.025 Hz. As head velocity rose from 50 to 300 o/s (0.025 and 0.25 Hz), gain in Y subjects was unchanged, but dropped in O subjects for 0.025 Hz. Phase lead rose with increasing head velocity at both frequencies, more so in Y subjects at 0.025 Hz but more so in O subjects at 0.25 Hz. After wearing 2x lenses, VOR gain rose by 45% at 0.025-0.5 Hz in the Y group, but only 30% in the O group. Gain change was less at higher frequencies; 22% for Y and only 2% for O subjects at 4 Hz. Gain change also declined with increasing head velocity. In conclusion, the VOR shows changes with aging as well as declining adaptive capabilities. (Supported by NIH grant AG06442.)

211.15

ADAPTIVE PLASTICITY OF THE SQUIRREL MONKEY VESTIBULO-OCULAR (VOR) REFLEX IN 3-D. S.L.Bello, G.Paige and S.M.Highstein, Dept. Otolaryngology., Washington Univ. Sch. Med., St. Louis, MO 63110.

Vertical, horizontal and torsional eye movements were recorded (3-D search coil tech.) in squirrel monkeys during earth horizontal head rotation in each of 3 head planes(yaw,pitch,and roll). The VOR was assessed over a broad frequency(0.025-4Hz) and amplitude(50-300deg/sec) range. Subjects were studied before and after 6Hrs. of multi freq. forced rotation while wearing 0.5x or 2x spectacles on alternate days both for head yaw and pitch. For head roll, a full field contrast disc was rotated in phase(0x) or 180 deg. out of phase(2x) relative to head. VOR gain and phase in all three planes were studied for all adaptation experiments. The pre-adapted Tor. and Vert. VORs showed greater low frequency phase leads than the Hor. VOR. The Tor. VOR showed roughly 1/2 the overall gain of the others. For each plane of head rotation, a robust coplanar change in VOR gain was observed, for both 0.5x(0x for roll) and 2x adaptation paradigms. However, the effect was less pronounced at high frequencies(>1Hz) and amplitudes (>100deg/sec).

211.16

CERVICO-OCULAR REFLEX IN HUMANS WITH NORMAL VESTIBULO-OCULAR REFLEX. S.E. Thurston[1,2], K.R. Becker*[3] and C.V. Ackley*[1]. Depts. of Neurology[1], Ophthalmology[2] and Otolaryngology-Head and Neck Surgery[3], Geisinger Medical Center, Danville, PA 17822.

Cervico-ocular reflex (COR) gain is low in normal humans but may increase to compensate for changes in the vestibulo-ocular reflex (VOR). Previous studies do not agree on the direction of normal COR eye movement re trunk movement. We measured gaze (eye in space), head, eye (gaze-head) and trunk position and velocity using magnetic search coils in 5 subjects as follows: 1) head and trunk rotated together (VOR), 2) trunk rotated with head stationary in space (COR) and 3) head rotated with trunk stationary (combined VOR+COR). Sinusoidal, horizontal rotations in the dark were at frequencies of 0.01-1.0 Hz with peak-to-peak amplitudes of 10-40 deg. VOR gain (eye velocity/head velocity) and phase were normal in all subjects. The COR was usually not measurable. COR gain (eye velocity/trunk velocity) never exceeded 0.07 and did not vary significantly with instructions to imagine a target stationary in space or moving with the trunk. Direction of COR eye movement was not consistently related to direction of trunk movement. Gains for combined VOR+ COR (eye velocity/head velocity) were higher at all frequencies than for the VOR alone and were greater than accounted for by adding the individual COR and VOR gains. These data confirm that the COR is negligible in humans with a normal VOR.

211.17

THE DIRECTION OF BALANCE INFLUENCES THE PERCEIVED UPRIGHT. Thomas A. Stoffregen, Gary E. Riccio*, and Eric J. Martin*. Dept. Psychology, University of Alabama, Tuscaloosa, AL 35487, and Dept. Kinesiology, University of Illinois, Urbana, IL 61801.

The perception of "upright" is thought to be based on detection of gravitoinertial force by the otolith organs. This kinetically defined direction can be contrasted with the kinematically defined direction of balance, the direction in which the torque acting on an inverted pendulum is zero. It can be argued that the direction of balance is more relevant to the control of orientation. In natural situations the direction of balance is determined by the direction of gravitoinertial force, but the two can be manipulated independently in the laboratory. We placed subjects in a whole body motion device that rotated around a fore-aft axis. The dynamics of the device were based on a simple inverted-pendulum model of human stance, such that the device was unstable: without control by the subject, its angular acceleration (rate of rotational falling) would be proportional to its angular position, or tilt, with respect to the direction of balance. We could vary the direction of balance with respect to the direction of gravitoinertial force. Subjects controlled the device so as to keep it "upright" across a pseudo-random disturbance. Subjects estimated their mean tilt from "upright" during each trial. These estimates were correlated with the direction of balance and with the direction of gravitoinertial force. Results showed that the perceived upright was significantly influenced by the direction of balance, and that the influence of balance was significantly greater than the influence of gravitoinertial force. These findings are at odds with classical approaches to the perception and control of spatial orientation, in which the perception of gravitoinertial force is deemed to play a fundamental role.

211.18

THE EFFECTS OF VARYING GRAVITATIONAL LOADS ON CUTANEOMUSCULAR TEST REFLEXES IN HUMAN LOWER LIMB MUSCULATURE (Q and H). *Szturm T., Jell R.M., *Kriellaars D. Dept. of Physiology, University of Manitoba.

It has been established from animal experiments that the coupling of otolith end organs and motoneurons subserving lower limb extensors/flexors involve a multi-link pathway which is shared by "Flexion Reflex Afferents". In previous human studies of the reflex effects of sural nerve stimulation during natural otolith stimulation using static tilt in pitch, a highly significant tilt-dependent modulation of the magnitude of the early component of the cutaneomuscular test reflex was demonstrated in lower limb flexors and extensors (Szturm et al Exp. Neurol. (1987) 97:529-541, (1988) 99:178-186). To seek further evidence in support of the otolith dependence of the cutaneomuscular reflex response we have examined its sensitivity to varying gravitational loads made possible by parabolic trajectory flight on the NASA operated KC-135 aircraft. Subjects, with head and body restrained, were placed in either; (1) a normal sitting position n=3, (2) rolled 90° R ear down, n=2. For each stimulus (pain threshold, delivered at 0.5 Hz) an epoch of 750 ms. of EMG was collected (150 ms. pre-stimulus and 600 ms. post-stimulus), rectified/low passed filtered (30 Hz). From the pool of EMG sweeps, those during elevated g. (1.8 g) and during microgravity period were averaged.

Mean EMG levels varied little between elevated g. and microgravity for all subjects expect one in position (1). For position (1) the magnitude of the early components of the test reflexes (calculated at peak and relative to mean EMG) varied slightly between G levels, but no significant or consistent changes were observed. This result is consistent with a utricle mediated tilt dependence of the reflex. In one subject, a late response developed in elevated g., consisting of an alternating sequence of excitation and inhibition (7-9 Hz). This late response, depending on the muscle, was not present, or was significantly reduced in microgravity. For position (2), although slight changes in the early components were observed between G levels, a larger sample size is needed to show significance. No differential effect of G level on the late component was observed. Sponsored by National Research Council of Canada

SOME VESTIBULOSPINAL NEURONS ALSO STAIN WITH ASPARTATE-LIKE IMMUNOREACTIVITY. G.A. Kevetter and A.R. Coffey*. Dept. Otolaryngology and Anatomy and Neuroscience. Univ. TX Med. Branch, Galveston, TX 77550.

In an effort to further characterize vestibulospinal pathways in the gerbil, immunocytochemistry was combined with retrograde identification of neurons. Small injections of 20% horseradish peroxidase (HRP) were made into the C5-C6 cord of anesthetized gerbils. Sections were reacted with nickel acetate-diaminobenzadine, giving a black reaction product. Sections were incubated in polyclonal antisera to aspartate (1:200 or 1:500, Chemicon) for 24 hours. They were then incubated in biotinylated anti-rabbit, followed by avidin-biotin-peroxidase complex, and finally reacted with diaminobenzidine to give a brown reaction product. Brown cells, stained with aspartate-like immunoreactivity (ASP-lir), were located in all four major vestibular nuclei. These included small and medium cells in the medial (MVN) and descending (DVN) vestibular nuclei and medium and large ASP-lir cells in the lateral (LVN) and ventromedial (VMVN) nuclei. In MVN, more cells were stained for ASP-lir caudally than rostrally. After the small injections of HRP into the cervical cord most cells were labeled in the caudal two-thirds of MVN and the adjacent DVN. Double-labeled cells (containing both the black particulate reaction product from retrogradely-transported HRP and also the diffuse brown reaction product from ASP-lir staining) were located in MVN, especially along the border with DVN. (Supported in part by BNS-NSF-84-18559).

CONTRIBUTION OF MEDIAL VESTIBULOSPINAL NEURONS (VSNs) TO SPATIAL TRANSFORMATION IN THE VESTIBULO-COLLIC REFLEX (VCR). S. I. Perlmutter, Y. Iwamoto, J. F. Baker, B. W. Peterson, Northwestern Univ. Med. School, Chicago, IL USA

We are investigating the neural substrates of spatial motor patterns of the VCR by recording VSN and neck muscle EMG activity. In 2 alert and 11 decerebrate cats (heads fixed), 2nd and higher order VSNs were identified by their responses to electrical stimulation of the labyrinth and descending MLF. The direction of rotation producing maximal activation (MAD) was determined from 0.5 Hz rotations in many vertical and horizontal planes. Connections of VSNs to neck motoneurons are being studied with spike-triggered averaging and cross-correlations.

Alert and decerebrate cat data were similar and combined (79 VSNs). Type II responses were more common in higher order than 2nd-order cells. Four VSNs exhibited complex behavior suggesting otolith input. Of 74 neurons with responses consistent with a linear sum of canal inputs, 25% had MADs aligned with the ipsilateral posterior (18), anterior (1) or horizontal (0) canal. Another 46% received convergent input from orthogonal canal(s) that shifted their MADs >10° from that of the primary ipsilateral input canal (9% vertical-vertical canal, 23% vertical-horizontal canal, 14% all 3 canals). 28% of VSNs responded as if their primary input were from contralateral canal(s). Low frequency responses of several cells suggested additional weak otolith input.

In alert cats, tonic eye position sensitivity was clear in 7/30 2nd-order VSNs. In 1 cat, 3/9 2nd- and 0/4 higher-order cells had axon collaterals identified by ascending MLF stimulation.

Significant spatial transformation of vestibular signals occurs on VSNs, even at the 2nd-order level. VSNs had more convergent input than VOR relay neurons reported last year. EY06485, EY07342

RESPONSE PROPERTIES OF VESTIBULAR NEURONS PROJECTING TO UPPER CERVICAL SPINAL CORD. S. Nonaka*, R.H. Schor, V.J. Wilson, Y. Yamagata*, B.J. Yates. Rockefeller Univ., New York, NY 10021 and Univ. Pittsburgh, Pittsburgh, PA 15213.

Different spatial tilts (e.g. roll vs pitch) evoke neck responses (vestibulocollic reflex) which have different temporal properties (Baker et al., 1985). Furthermore, the dynamics of the reflex suggest that it receives important input from irregular vestibular afferents (Bilotto et al., 1982). We examined the response properties of neurons in the lateral, medial, and descending vestibular nuclei of decerebrate cats which could be antidromically activated from mid-C1, but not from C5. The tilt direction evoking maximal modulation, and the response dynamics of these neck-projecting neurons, were examined using planar and rotating (wobble) sinusoidal tilts (0.02 to 2 Hz). The response properties of this neck population resemble those of vestibular neurons in an earlier study whose projection was not identified (Kasper et al., 1988); a larger fraction of the neck sub-population has advanced phase (> 90° at 1 Hz), suggesting a contribution from irregular afferents. Most neurons projecting to the neck exhibited the same temporal response to varying spatial stimuli. Some neurons exhibiting spatio-temporal convergence (Baker et al., 1984) were observed, but apparently too few to account for vestibulocollic reflex behavior; this behavior may be due to convergence of inputs with different spatial and temporal properties at other levels of the reflex pathway. (Supported by NIH grants NS02619, NS24930, NS08506).

211.22

OCULAR COUNTERROLLING IN PARABOLIC FLIGHT: PREDICTIVE TEST OF SPACE MOTION SICKNESS? S.G. Diamond and C.H. Markham, Dept Neurology, UCLA Sch Medicine, Los Angeles, CA 90024.

An earlier study examined 4 subjects who had symmetric ocular counterrolling (OCR) in ground-based 1G testing. During parabolas flown on a NASA KC-135 aircraft, 3 of the 4 had no eye torsion while upright in 0G or 1.8G. Tilted, they had no OCR at 0G, and more OCR at 1.8G than at 1G. None of these 3 became sick during flight.

The fourth subject had leftward eye torsion at 0G in upright and tilted positions. This bias was also seen at 1.8G, where he had less OCR than at 1G when tilted to the side inducing rightward OCR. He did become sick in flight.

These results suggested that asymmetry of the otolith system may be well compensated in the usual 1G environment on earth, but that exposure to unaccustomed gravitational states may unmask this compensation. The sudden asymmetric vestibular responses thus stimulated may be the cause of the unique motion sickness observed in space flight.

To test this hypothesis, 7 subjects with symmetric OCR in 1G underwent testing on the KC-135 for 20 parabolas to examine the correlation of asymmetric OCR in non-1G states with space motion sickness. Three subjects were former astronauts; some had been sick in space and others not. The OCR test attempted to ascertain blind which were which. Two subjects were prospective astronauts; the test attempted to predict their motion sickness in space. The remaining subjects were drawn from the NASA subject pool.

MOTION SICKNESS AND MOTOR STRATEGY. D.G.D. Watt, I. Nevo*, T. Yang* and A.V. Smith*. Aerospace Medical Research Unit, McGill University, Montreal, Canada H3G 1Y6.

Motion sickness occurs frequently in altered gravity environments such as orbital or parabolic flight. Under these conditions, coordination of eye, head and body movements is often unusual, with the eyes and head rotating with the torso when reorienting to a new target. Are these inappropriate motor strategies a cause of motion sickness?

10-17 subjects took part in each of 12 experiments over 24 weeks. Each session required a different pattern of eye, head and body coordination to be repeated for 30 minutes (e.g. sweep gaze back and forth between targets located 130 degrees to either side of straight ahead, at 0.7 Hz). A questionnaire and 5 vestibular tests were administered before and repeatedly after the rhythmical movement.

All experiments caused dizziness, postural instability and oscillopsia. Motion sickness could develop if the subject was distracted during the repetitive movement, but more often appeared when normal activity resumed. Vestibular responses were decreased, the greatest changes tending to occur in those subjects who became motion sick.

These results suggest that some (perhaps many) forms of motion sickness are associated with transiently altered vestibular function resulting from inappropriate motor strategies. The signs and symptoms may serve as a warning against these counter-productive strategies. Thus, "motion sickness" might be better labelled Dysadaptation Syndrome. (Supported by Medical Research Council of Canada)

211.24

ANALGESIC AND B-ENDORPHIN (BE) RESPONSES TO MOTION-SICKNESS IN MONOSODIUM GLUTAMATE-TREATED RATS. A.C. Scallet, S. Wilson*, R. L. Rountree*, W. Henry, Jr.*, A. Andrews*, and C.A. Walker[1], Natl. Ctr. for Toxicol. Res., Jefferson, AR 72079-9502 and [1]Univ. of Arkansas-Pine Bluff, Pine Bluff AR 71601.

Drugs, x-irradiation, and motion-sickness produce emetic responses and/or taste aversions. Area postrema (AP) lesions attenuate x-irradiation and drug-induced, but enhance motion-sickness-induced taste aversions in rats. To develop other indices of motion-sickness, we measured analgesia (55°C hotplate) before and after 30 minutes of cross-coupled acceleration as well as BE levels. We also evaluated animals with lesions of the AP (and other circumventricular organs, CVOs) produced by neonatal MSG treatment. Motion-sickness produced a brief (<30 min) increase in analgesic latency which was greater in MSG-treated than control rats (105% vs 51%, $p<0.01$). MSG-treated rats showed the expected decrease in hypothalamic BE (51%, $p<0.01$), but in correspondence to the analgesic effects, motion-sickness produced a further and larger relative drop of hypothalamic BE in MSG than control rats (52% vs 16%, $p<0.01$). These results identify analgesia as a useful endpoint for motion-sickness, suggest that BE may mediate certain motion-sickness responses, and confirm that CVO lesions enhance rather than block such responses. Supported by U.S.A. FDA and NASA Grant NAG 2-427.

212.1

SPATIAL PATTERNING OF HAIR CELLS IN THE VESTIBULAR AMPULLAE OF *Pseudemys scripta*. E.H. Peterson, L.L. DiCaprio* and A.M. Brichta. Department of Zoology, College of Arts & Sciences; Basic Science Unit, College of Osteopathic Medicine. Ohio University, Athens, OH 45701.

As part of a project aimed at understanding vestibular control of head movement in *P. scripta*, we are characterizing the spatial organization of ampullary hair cells using scanning electron microscopy of sonicated and unsonicated cristae, and differential interference contrast imaging of sectioned cristae. Complete reconstructions of hemi-cristae reveal that each bears 1800-2000 hair cells. Receptor somata and apical surfaces differ in size, shape, and density; their stereocilia vary in number, thickness, length, packing geometry, and position on the hair cell apical surface. These hair cell parameters covary to produce several spatial patterns across the surface of the crista, including (1) a central region in which receptors are large and sparsely packed, with very short stereocilia arranged in a distinctive geometric array, and (2) a peripheral ring where hair cells are small, with few, irregularly spaced stereocilia. Such hair cell spatial patterning parallels the morphological gradients exhibited by vestibular primaries in this species (Brichta and Peterson, 1989, Soc. Neurosci. Abs.), suggesting that mechanoelectric transformations occurring in the ampullary neuroepithelium may differ with spatial locus. Supported by NIH grant NS23498.

212.2

LOCATION SPECIFIC ARCHITECTURE OF PRIMARY AFFERENTS INNERVATING THE VESTIBULAR AMPULLAE OF *Pseudemys scripta*. A.M. Brichta and E.H. Peterson. Department of Zoology, College of Arts & Sciences; Basic Sciences Unit, College of Osteopathic Medicine. Ohio University, Athens, OH 45701.

To help understand vestibular control of head movements we are characterizing the functional architecture of vestibular primary afferents in a turtle, *P. scripta*. We have begun by assessing the morphology and spatial distribution of their peripheral processes using an in vitro horseradish peroxidase technique (Brichta & Peterson, 1987 Soc. Neurosci. Abs. 13:634). We traced each primary afferent to its cell soma in the vestibular ganglion, then reconstructed its peripheral terminal and characterized it in terms of morphological variables thought to have functional significance: axon diameter, soma area, number, size, and density of endings per terminal, and size and location of collecting territories.

There are three morphological classes of peripheral terminals: calyx, dimorphic, and bouton (Brichta & Peterson, 1988, Soc. Neurosci. Abs. 14:329). Calyceal terminals usually contact 3-5 hair cells and have small collecting territories (<660um²); terminals with single calyces are relatively rare. The terminals of dimorphic endings (calyces plus bouton sprays) also have small collecting areas (<1150 um²). Calyx and, probably, dimorphic endings are restricted to the central, 'flattened' portion of each hemicrista. Bouton terminals are found throughout the hemicrista, and their architecture varies with location. Bouton terminals with very large collecting areas (>2,500um²) are located toward the apex; some small (786um²) collecting areas are seen in the central region. Thus the center of each hemicrista bears all three terminal types, and central terminals tend to have the most restricted dendritic fields. At the far periphery there is an abrupt transition to bouton terminals with flattened collecting areas (<620 um²), characteristic 'spindly' architecture, and small varicosities.

This regional variation in primary architecture, taken together with parallel spatial patterns in *Pseudemys* vestibular hair cells (Peterson et. al., 1989, Soc. Neurosci. Abs.), suggests that there may be location specific differences in the transfer properties of the ampullary neuroepithelium. Supported by NIH grant 23498.

212.3

RESPONSE DYNAMICS OF BULLFROG HORIZONTAL CANAL AFFERENTS REFLECT THE LOCUS OF CRISTA INNERVATION. L. Hoffman* and V. Honrubia (SPON: M. McGinn), UCLA School of Medicine, Los Angeles, CA. 90024-1624.

The physiological characteristics of 142 afferents innervating the bullfrogs' horizontal semicircular canal cristae were studied. A subset of these neurons were labeled intraaxonally with horseradish peroxidase, and their axon diameters were measured and loci of innervation within the crista reconstructed. Morphophysiological data were evaluated in the context of the distribution within the crista of afferents of diverse axon diameters, determined in parallel experiments using extracellular labeling techniques.

The response dynamics of horizontal canal afferents were found to be continuously distributed across the range of values for the coefficient of variation of spontaneous firing (CV). Gains ranged from 0.2 to 6.7 $sp \cdot s^{-1}/^{\circ} \cdot s^{-1}$ and were positively correlated with CV for afferents with CV < 0.6. The gains of the more irregularly-firing afferents (CV≥0.6) exhibited broad variation (0.3 to 8.6 $sp \cdot s^{-1}/^{\circ} \cdot s^{-1}$), and were uncorrelated with CV. Response phases ranged between -1° and 76° (re: head velocity) and exhibited a similar association with CV as did gain. The afferents intraaxonally labeled exhibited a positive correlation between CV and axon diameter (r=0.61, n=15), indicating that the unlabeled afferents with the lowest CV values and smallest gains and phase leads corresponded to those with the smallest axon diameters. The smallest extracellularly-labeled afferents (<1 μm) were found to innervate the peripheral regions of the horizontal crista's bulbed portion. Intraaxonally-labeled neurons for which response dynamics were obtained had axon diameters that ranged between 1.2 and 8.3 μm, representative of the thickest 63% of the horizontal canal afferent population. In this sample of intraaxonally-labeled neurons, those with gains between 1.0 and 3.5 $sp \cdot s^{-1}/^{\circ} \cdot s^{-1}$ innervated the crista's bulbed end; of these, afferents with the smaller gains innervated the perimeter regions. These afferents exhibited the smallest phase leads (23° to 31°), and had axon diameters that ranged between 1.2 and 5.7 μm. Labeled afferents with gains between 4.4 and 7.1 $sp \cdot s^{-1}/^{\circ} \cdot s^{-1}$ innervated the crista's narrow end. The phase leads of these afferents were also larger, ranging between 45° and 65°, and ranged in axon diameter between 1.5 and 8.3 μm. This diversity in innervation loci of afferents with similar axon diameters was comparable to that observed in extracellularly-labeled specimens. (Support: NS 09823)

212.4

VERTICAL CANAL-RELATED VESTIBULAR NUCLEI NEURONS RESPOND TO TIME-VARYING LINEAR HORIZONTAL HEAD ACCELERATION. G. A. Bush[1] and A. A. Perachio[1,2]. Depts Otolaryngol.[1] and Physiol. & Biophysics[2], Univ. Texas Med. Branch, Galveston TX 77550.

Vertical canal-related neurons in decerebrated rats were identified by their responses to vertical angular head acceleration. They were then tested for their responses to sinusoidal linear head acceleration applied in the plane of the utricular maculae, across a frequency range of 0.2 to 1.4 Hz. The stimulus consisted of translational motion (peak acceleration of either ±0.08g or ±0.15g) along the sagittal head axis as well as vectors oriented ±90° to the midsagittal plane. Cells were also characterized according to their responses to ipsilateral electrical stimulation applied at the oval window. Most of the vertical canal-related neurons tested to date respond to linear acceleration. These cells generally show either large or modest response gain increases across frequencies while the response peaks (re: peak head acceleration) exhibit, respectively, an increasing phase lag or a modest phase lead as the stimulus frequency is increased. In cells with dynamic response characteristics, a response gain increase of 13 dB associated with a phase shift of as much as 120° occurred as the frequency was increased from 0.2 to 1.4 Hz. Both monosynaptically and polysynaptically driven neurons received convergent otolith/canal input. The responses of vertical canal-related neurons to translational linear acceleration resemble the dynamic tilt responses described previously (Schor et al. J. Neurophys., 53:1444, 1985) for lateral vestibular nuclei cells. (Supported by NASA grants NAG2-26, NTG 44-008-801; NIH grant NS24391)

212.5

GABA-LIKE IMMUNOREACTIVITY IN THE GUINEA PIG VESTIBULE:POST EMBEDDING LIGHT AND ELECTRON MICROSCOPY FINDINGS. [1]López,I.,*[2]Juiz,J.M.,*[3]Altschuler, R.A. and [1]Meza,G. Dept. Neurociencias, IFIC, UNAM[1] México, Dept. Histología, Alicante,[2]España and Kresge Institute, U. Michigan[3] Ann Arbor,USA.

Based on neurochemical, pharmacological and immunocytochemical evidence, a neurotransmitter role for GABA has been proposed at the synapse between vestibular hair cells and its afferent nerve endings. We have used postembedding immunocytochemical techniques to further explore the localization and distribution of GABA in the guinea pig vestibule.

Animals were perfused with a mixture of aldehydes. The vestibular organs were dissected, dehydrated and embedded in plastic. Semithin and ultrathin sections were incubated with GABA antiserum* and processed for postembedding immunoperoxidase and immunogold (IMG) staining, respectively.

By light microscopy (LM), immunoreactivity was found both in type I and type II hair cells and in some myelinated fibers in the subjacent connective stroma. With the E.M. as LM, GABA-like IMG reaction was located in hair cells (Type I and II), and it was also encountered in the afferent chalice contacting type I hair cell.

These results confirm the GABAergic nature of hair cells and suggest that a GABA-mediated interaction may exist between type I hair cell and its chaliceal afferent synapse.

4-Aminopyridine in the Semicircular Canal

Anthony J Ricci,BA*Charles H Norris,PhD,Paul S Guth,PhD

4-Aminopyridine (4-AP) is believed to block voltage sensitive potassium channels at millimolar concentrations. It is a novel blocker in that it binds to closed channels and can be released via depolarization. As such it would be expected to prolong depolarization and thus increase the firing rate. However, in the isolated semicircular canal of the frog (Rana Pipiens) 4-AP has quite different effects. In millimolar concentrations, this drug rapidly inhibits over 80% of spontaneous firing, while only blocking 20% of evoked firing. Carbachol, an acetylcholine agonist known to increase spontaneous firing in the canal, is almost totally inhibited by 4-AP. In micromolar concentrations the actions differ. Spontaneous activity is enhanced slightly while evoked is still inhibited, though to a lesser degree. The action of Carbachol is still inhibited. In some instances the 4-AP action is not apparent until the bolus of Carbachol is administered. 4-AP may aid in differentiating between spontaneous and evoked activity. It also may elucidate the stimulatory role of acetylcholine. This work was supported by grants from Southern Hearing & Speech & NIH Grant NS-22051.

212.7

COEXISTENCE OF CHOLINE ACETYLTRANSFERASE AND CALCITONIN GENE-RELATED PEPTIDE IN VESTIBULAR EFFERENTS OF THE GERBIL.

Perachio, A.A.[1,2] and Kevetter, G.A.[1,3], Depts. of Otolaryngology[1], Physiology and Biophysics[2], and Anatomy and Neurosciences[3], Univ. TX Medical Branch, Galveston, TX 77550.

In previous work, we identified the location of two groups of neurons whose cell bodies were retrogradely labeled following injections of horseradish peroxidase or fluorescent microspheres in the utricular maculae of the labyrinth in the gerbil. The larger of these two groups was labeled bilaterally following a unilateral injection and was located dorsolaterally to the facial genu. A smaller group was observed ventral to the genu and medial to the root of the facial nerve. The dorsal group of neurons were found to be acetylcholinesterase positive. In the present study, we demonstrated the coexistence of choline acetyltransferase (polyclonal antisera, Chemicon) and calcitonin gene-related peptide (polyclonal antisera, a gift from Dr. Cary Cooper) within retrogradely labeled efferent cell bodies. The smaller number of more ventrally located efferent neurons were not found to be immunoreactive to either set of antisera suggesting a functional subdivision among the vestibular efferents in this species. (supported by NASA NAG 2-26 and NIH 24391)

212.8

CENTRAL PROJECTIONS OF THE INDIVIDUAL VESTIBULAR SENSORY END-ORGANS OF THE CHINCHILLA.

A. Newman*, W. Lee*, C. Suarez*, V. Honrubia (SPON: J. Segundo). UCLA School of Medicine, Los Angeles, CA 90024

The central projections of afferent fibers from individual vestibular receptors were studied using horseradish peroxidase labelling in 42 ears from 32 chinchillas. The specificity of the labelling procedure was documented in the peripheral nerves and ganglion cells. Differences in the site of projection of fibers from each end-organ within the vestibular root, tract and each vestibular nuclei were demonstrated.

The superior vestibular nucleus (SN) was more profusely innervated by the end-organs than were the other nuclei (between ~500 to ~700 fibers from each end-organ). The lateral vestibular nucleus (LN) received a similar number of fibers from all the end-organs (~500 each) except from the utriculus (~700). The medial vestibular nucleus (MN) appeared to receive the least number of fibers of all the nuclei (~300 from each end-organ). The descending vestibular nucleus (DN) received uniform innervation from all the end-organs (~500 each) except from the utriculus (~300).

Fibers to the SN and the DN arrived as two different types of bundles. Bundles to the DN consisted of 10-20 medium size fibers, while those to the SN had one large fiber surrounded by others of smaller diameters. The LN received fibers of different diameters that projected singly, not in bundles, and made axosomatic contacts with the large cells (Deiters'). Some of these fibers were branches of the vestibular tract, while others were large primary afferents that directly innervated this nucleus. Innervation of the MN consisted of thin fibers arriving with a curvilinear trajectory through the LN and DN and forming a dense netlike pattern. There were no identifiable fiber projections in the ventromedial SN nor in the dorsomedial LN and DN. The MN was innervated throughout at the level of the rostral vestibular root. There were no projections in the caudal MN.

There were more projections to the cerebellum and interstitial nucleus (IN) from the maculae than from the cristae. The major projections to the restiform body were from the sacculus. The IN was the most densely innervated of all the nuclei. The utricular fibers were rostral to those of the sacculus in the IN.

212.9

CHANGES IN THE GLUTAMATE BINDING SITES IN THE RAT VESTIBULAR NUCLEI FOLLOWING HEMILABYRINTHECTOMY.

J. Raymond, J. Touati and D. Demêmes (SPON.ENA). U. INSERM 254, USTL 34060 Montpellier cedex France.

Neuronal mechanisms underlying functional recovery following hemilabyrinthectomy are still poorly understood. Recently it has been recognized that vestibular nerve terminals are glutamatergic (Raymond et al., Progress in Brain Res. 76, 1988) and glutamate binding sites have been characterized in the rat vestibular nuclei (Touati et al., Exp. Brain Res., 1989). It could be hypothesized that this transmitter system is involved in the recovery of the activity of deafferented vestibular nuclei.

In the rat, we investigated the synaptic loss and the glutamatergic deficit in the vestibular nuclei one week after unilateral vestibular nerve section. The synaptic density was quantified by measuring the immunoreactive surface of the whole population of terminals using an antibody against synaptophysin (p38)[1], a synaptic vesicle-specific protein. Our results indicate a loss of 35 % of the synaptic surface in the medial vestibular nucleus. At one-week after hemilabyrinthectomy, measurements of the high affinity glutamate uptake in the deafferented vestibular nuclei show a decrease of 31 %[2].

We investigated if this synaptic and glutamatergic deficit can be correlated with changes of the postsynaptic glutamatergic binding sites analysed by quantitative autoradiography.

Preliminary results do not indicate hypersensitivity of the glutamate receptors but are consistent with the involvement of glutamate in the regulation of the neuronal properties following vestibular compensation.

212.10

THE EFFECTS OF N-METHYL-D-ASPARTATE ANTAGONISTS ON GUINEA PIG VESTIBULAR NUCLEUS NEURONS IN VITRO FOLLOWING CHRONIC IPSILATERAL LABYRINTHECTOMY.

P.F. Smith*, C.L. Darlington* and J.I. Hubbard* (SPON: D. Menkes). Depts. of Psychology and Physiology, Univ. of Otago, Dunedin, New Zealand.

In order to determine whether N-methyl-D-aspartate (NMDA) receptors contribute to neuronal activity in the medial vestibular nucleus (MVN) following compensation for ipsilateral labyrinthectomy, we recorded extracellularly from MVN neurons in vitro, in brainstem slices from compensated guinea pigs, while perfusing with NMDA antagonists. Coronal slices of the rostral medulla including the MVN were incubated in a standard artificial cerebrospinal fluid. Slices were perfused with the selective NMDA receptor antagonists ((+)-5-methyl-10,11-dihydro-5H-dibenzo[a,d]-cyclohepten-5,10,-imine maleate) (MK801) or (3-((±)-2- carboxypiperazin-4-yl)-propyl-1-phosphonic acid) (CPP) (both 10^{-8}M). Of 10 neurons tested with MK801, 6 showed a decrease in firing rate, 1 showed an increase and 3 showed no change. Of 10 neurons tested with CPP, 4 showed a decrease in firing rate, 1 showed an increase and 5 showed no change. These results show that NMDA antagonists reduce the activity of some MVN neurons in vitro, following ipsilateral labyrinthectomy, suggest-that some component of the resting activity exhibited by these neurons may be mediated by NMDA receptors.

212.11

THE EFFECTS OF NEUROPEPTIDE HORMONES ON GUINEA PIG VESTIBULAR NUCLEUS NEURONS IN VITRO FOLLOWING CHRONIC UNILATERAL LABYRINTHECTOMY.

C.L. Darlington*, P.F. Smith*, and J.I. Hubbard* (SPON: T. Day). Depts. of Physiology and Psychology, Univ. of Otago, Dunedin, New Zealand.

In order to determine whether neuropeptide hormones may influence vestibular compensation for unilateral labyrinthectomy by acting on vestibular nucleus neurons, we examined the effect of adrenocorticotropic hormone, fragment 4-10 (ACTH4-10) and alpha-melanocyte stimulating hormone (alpha-MSH) (both 10^{-8}M) on medial vestibular nucleus (MVN) neurons in vitro, in brainstem slices from guinea pigs which had compensated for unilateral labyrinthectomy. Coronal slices of the medulla containing the MVN were incubated in a standard artificial cerebrospinal fluid. MVN neurons were recorded extracellularly before and after perfusion with ACTH4-10 and alpha- MSH. Neurons responsive to ACTH4-10 and alpha-MSH were found in the MVN ipsilateral and contralateral to the labyrinthectomy. Both increases and decreases in firing rate in response to these hormones were observed in different MVN neurons. These results suggest that neuropeptide hormones may influence compensation by acting directly or indirectly on MVN neurons.

212.12

EFFECTS OF VESTIBULAR NERVE TRANSECTION ON THE TANGENTIAL NUCLEUS OF THE HATCHLING CHICK.

E.M. Aldrich* and K.D. Peusner (SPON: J.M. Krum). George Washington Univ., Washington, DC 20037.

A previous quantitative electron microscope (EM) study described a normal developmental process of synaptic reorganization in the hatchling chick tangential nucleus (Peusner, 1984). Briefly, vestibular spoon endings retract from the principal cell bodies, while small terminals of uncertain origin proliferate. Total somatic surface covered by terminals is conserved. To identify the factors influencing synaptic reorganization, we have transected the entire vestibular nerve in hatchlings. Vestibular compensation was rapid: subjects were able to stand by 2½ days post-op, and by 7 days the righting reflex, head tilt, locomotion and balance were near normal. Subjects were prepared for EM at 1 day, 7 days and 8 weeks post-op. At 1 day, degenerative changes in vestibular fibers and axosomatic terminals were seen. However, some spoon endings with normal synaptic contacts were present. By 7 days degenerating terminals were not observed, and many terminals were present on principal cell bodies. At 8 weeks principal cells contacted by axosomatic terminals were seen. A quantitative EM study is underway. Supported by NIH grant RO1 NS18108.

CEREBELLAR MUTATIONS IN MICE AFFECT THE SIZE OF GABAergic TERMINALS IN THE NUCLEUS DEITERS. J. Bäurle*, U. Grüsser-Cornehls* and B. G. Grover*. (SPON: ENA). Dept of Physiology, Freie Universität Berlin, Arnimallee 22, D-1000 Berlin 33 (FRG)

The main source of GABAergic input to Nucleus Deiters are cerebellar Purkinje cells. In this study GABAergic terminals in Nucleus Deiters were investigated in two extreme types of cerebellar mutation in mice: the Weaver mice completely lacking granule cells and some Purkinje cells, the PCD mice displaying a total loss of Purkinje cells.

In material immunoreacted for GABA, camera lucida drawings of labelled terminal structures were made using plan-apo-oil-phase-contrast-optics (Zeiss). Quantitative evaluations of the cross-sectional area of terminals were performed with a computerized image analyzer (Kontron Mini-Mop, Zeiss).

Distinct differences in terminal sizes were revealed between the mutants and their controls. These differences were most pronounced between the two mutant types, whereas terminal sizes of the C57BL/6J-wildtype did not deviate from those of the B6CBA-wildtype. Terminal sizes in 6-month-old PCD mice vary from 0.2 - 2 μm^2, in controls from 0.2 - 3 μm^2 and in Weavers from 0.2 - 6 μm^2. The increase and subsequent decrease in terminal sizes with age found in Weavers and their controls was not as marked in PCD mice.

The increased number of large terminal structures in Weaver mutants is probably one of the plastic changes in cascade caused by the degeneration of granule cells, while the loss of such in PCD mice supports the assumption that the source of large terminals are cerebellar Purkinje cells.

Supported in part by DFG grant 276/19-5.

212.14

THE INTERCONNECTIONS OF THE PARIETO-INSULAR VESTIBULAR CORTEX (PIVC) IN THE SQUIRREL MONKEY. W. O. Guldin,* S. Akbarian* and O.-J. Grüsser. (SPON: ENA). Dept. of Physiol., Freie Universität Berlin, Arnimallee 22, 1000 Berlin 33, Germany.

The interconnections of the PIVC and the vestibular 3a area have been investigated with retrograde tracer techniques in Saimiri sciureus. By recording extracellular single units responsive to vestibular stimulation, the loci of injections were determined. Thereafter small amounts of various flourescence tracers as well as horseradish peroxidase were injected iontophoretically or by pressure via a capillary.

For the thalamic afferents we could not point out a specific nucleus of origin. Our data suggest that vestibular input to the thalamus is widespread over several nuclei: the ventral posterior inferior nucleus, the medial part of the ventral posterior nucleus, as well as parts of the oral and medial pulvinar nucleus.

For the cortico-cortical interconnections most outstanding was the finding of the extremely dense afferent and efferent connections of PIVC to the vestibular area 3a. Area 3a is also connected to those parts of area 7 known to contain a small amount of units responding to semicircular canal stimulation. We could also detect input to the PIVC from the frontal eye fields, the areas 8 and 6, as well as from the cingular cortex. Noteworthy is the fact that we never found any input from the visual cortical areas V1 - V4 and only sparse input from the temporal lobe.

IMMUNOHISTOCHEMICAL EVALUATION OF THE CONNECTIVE TISSUE SKELETON OF CHICKEN GOLGI TENDON ORGANS. A. Maier and R. Mayne. Department of Cell Biology and Anatomy, University of Alabama at Birmingham, Birmingham, AL 35294.

Tendon organs from leg and forearm muscles of White Leghorn chickens were examined with a library of monoclonal antibodies to determine the composition of their connective tissue skeleton. Their capsules were positive for constituents of basal lamina (collagen type IV, laminin, heparan sulfate proteoglycan), and for tenascin and collagen type VI. All intracapsular connective tissue bundles reacted with antibodies against collagen type I and chondroitin-4-sulfate. In addition, some also reacted with collagen types III and VI. At the tendinous end of the receptors the capsule and the collagenous bundles blended gradually with tendons. At the muscular end, terminating, in series muscle fibers that attached at receptors split to produce finger-like extensions that were separated by deep longitudinal fissures. Into these fissures extended tongues of connective tissue containing tenascin, collagen type I and fibronectin. Distally the connective tissues extended toward receptors, becoming continuous with the tenascin in the capsule and just internal to the capsule, fibronectin in the capsule, and collagen type I in the collagenous bundles. This arrangement of connective tissues suggests that muscle fibers that attach in series at the muscular ends of tendon organs exert a force during muscular contraction not only on the collagenous bundles, but also on the receptor capsule.

Supported by a grant from the Muscular Dystrophy Association.

REMODELING OF NEUROMUSCULAR JUNCTIONS IN MUSCLE OF THE C57Bl/KsJ-dbm DIABETIC MOUSE K.M. Klueber and L. Stahr* Dept. Anatomical Sciences & Neurobiology, University of Louisville, School of Medicine, Louisville, KY 40292

Diabetes adversely affects neuromuscular junctions (NMJ's). Ultrastructural evidence reveals degeneration of both the axons and myofibers resulting in denervation (Feczko and Klueber, Am.J.Anat 182:224-240, 1988). In partial denervation, axons sprout to form new synaptic contacts. The objective of this study was to determine if axonal sprouting with NMJ remodeling occurs in diabetic muscle. Extensor digitorum longus muscles (EDL) from 80 and 126 day old diabetic and control mice (n=5/group/age) were stained using a combined silver and cholinesterase stain (Slack and Pockett, Pflugers Arch 391:306-8, 1981). Examination of the whole mount diabetic EDL's revealed 2.2% of the axon terminals in 80 day and 3.0% of the axon terminals from 126 day (N= 322 and 228 NMJ's, respectively) had terminal sprouts. The sprouts either made synaptic contact with a myofiber near the original terminal or extended for a distance from the terminal without making contact. In diabetic muscles, very small NMJ's were observed which were absent in the controls. These small NMJ's may be synaptic contacts made by axonal sprouts which formed during degeneration of the parent axonal terminal. Thus, remodelling of NMJ's in diabetic muscle in response to degeneration of the axonal terminals and myofibers occurs during the progression of the disease. Funded by:USHS 1R29DK41553-01

213.3

ACETYLCHOLINESTERASE IN MUSCLES OF DIABETIC AND GALACTOSEMIC RATS. K.A. Skau. Div. Pharmacol. & Med.Chem., College of Pharmacy, University of Cincinnati, Cincinnati, OH 45267.

Experimental diabetes in animals produces abnormalities of motor nerves that might be expected to result in functional and biochemical changes in skeletal muscle. Galactosemia in rats produces similar neuronal abnormalities but does not have the complication of reduced insulin-stimulated glucose uptake. This study compared the acetylcholinesterase (AChE) molecular forms in skeletal muscle of diabetic (streptozotocin 65 mg/kg iv) and galactosemic (40% galactose diet) rats. At various times of diabetes and galactosemia the rats, with age-matched controls, were sacrificed and hemidiaphragm (HD), extensor digitorum longus (EDL) and soleus (SOL) muscles were homogenized. Solubilized AChE molecular forms were separated on sucrose density gradients and assayed with a radiometric assay. The predominantly red SOL exhibited an increase in all forms of AChE in both diabetes and galactosemia apparently independent of muscle weight differences. HD and EDL showed more variable results that might be related to changes in muscle mass. These results may represent differential regulation of AChE in different types of muscles.

213.4

EXPRESSION OF DEVELOPMENTAL AND MATURE MYOSIN ISOFORMS DURING DIAPHRAGM MATURATION. LaFramboise, W.A.*, Daood, M.J.*, Guthrie, R.D.*, Ontell, M. Univ. of Pittsburgh, Sch. of Med., Pittsburgh, PA 15261.

Rat diaphragm myosin heavy chain (MHC) composition was studied at embryonic (E) days 18 and 21, postnatal days (D) 4,21,30,60, and in the adult (>115 days) utilizing electrophoretic (6% SDS-PAGE) and immunocytochemical methods (n=4). Embryonic, neonatal and slow (Type I) MHC were present on E-18 through D-4 with either technique. A small percentage (14±5%) of E-21 myofibers reacted with a polyclonal antibody which in the adult rat diaphragm reacts with MHC-IIx and IIb fibers (Bulter-Browne and Whalen, Paris). At this stage, no fibers reacted with monoclonal antibodies specific for MHC-IIa or IIb (Schiaffino, Padova). An additional MHC band was present in D-4 gels. D-4 fibers reacted with the slow, neonatal and the IIx/IIb antibodies while the reaction with MHC-emb was reduced. Fibers also reacted with the antibody against MHC-IIa by D-4 (27±7%). By D-21, the embryonic band was not present, the neonatal band was diminished, and a second adult fast band appeared in the gels. A MHC-IIb band appeared by D-60. At this stage 34±8% of the fibers reacted with a monoclonal antibody specific for MHC-IIb. The adult pattern of MHC expression was established between 60 and 115 days postnatal. Mature diaphragms contained fibers of Types I, IIa, IIb or IIx MHCs (Type I:35±9%, IIa:31±3%, IIb:4±2%, IIx:30±6%). While it has previously been established that the adult rat diaphragm contains a high percentage of IIx fibers (Schiaffino et al., in press; Bar and Pette, 1988), this study establishes that the MHC-IIx appears prior to MHC-IIb and that MHC-IIb is transiently abundant in the diaphragm.

213.5

MODULATION OF SLOW MYOSIN EXPRESSION IN A MOUSE FAST-TWITCH MUSCLE. K. Condon and W.J. Thompson. Dept. of Zoology, University of Texas, Austin, TX 78712.

Previous investigations have noted the complete or nearly complete loss of slow muscle fibers in the extensor digitorum longus muscle of C57BL/6J mice during postnatal life. The basis of this loss and role of the nervous system in it are examined using monoclonal antibodies to myosin heavy chain isoforms. At postnatal day 3 (d3) there are approximately 175 slow fibers (12% of the total number of myofibers) distributed in a mosaic pattern through the deep region of the muscle. By d18 all myofibers express adult myosin isoforms and slow fibers still account for approximately 11% of the myofibers. However, in adults (10+ weeks) slow fibers account for only 0-3% of the myofibers. Moreover, many of the remaining slow fibers in these muscles co-express a IIA myosin isform suggesting the loss of slow fibers results from their transformation to a fast fiber type. To determine the role of innervation in this selective loss, sciatic neurectomy was performed in neonates at d2. Denervation results in a steady increase in the percentage of fibers expressing slow myosin (45% at d18, 83% at 5 weeks, and 98% at 33 weeks). Moreover, the increase progressively spreads from the deep to the superficial region of the muscles. Neonatal denervation also results in progressive atrophy of the myofibers such that in adults the cross-sectional area of the muscle is 10% of innervated muscles. Denervation of adult muscles by repeated evulsion of the common peroneal nerve produces markedly different results. No changes in myosin isoform expression are observed prior to 4 weeks. By 14 weeks the distribution and frequency of slow fibers (11-17%) resembles that seen at d3, suggesting re-expression of slow myosin in the original slow fibers. Atrophy of adult muscle is markedly less than in neonates with a reduction in cross-sectional area to 45% of innervated muscles. These results suggest that the loss of slow myosin during postnatal life is probably under neural control and that the expression of myosin heavy chain isoforms under aneural conditions is affected by the developmental history of the individual muscle fibers.

UNIFORM ENERGY CAPACITY OF FIBERS WITHIN MOTOR UNITS OF SNAKE MUSCLE. R. S. Wilkinson, B. W. C. Rosser, and P. M. Nemeth. Depts. of Cell Biology & Physiology, Neurology, and Anatomy & Neurobiology, Washington Univ. Sch. Med., St. Louis, MO 63110.

The thin transversus abdominis muscle of the garter snake contains ~100 fibers comprising 7-9 motor units of 3 types. We have measured homogeneity of enzyme content among the fibers of one motor unit in order to determine whether, and with what precision, a motor neuron controls gene expression in this muscle.

Terminals of one motor axon were labeled with the activity-dependent probe sulforhodamine 101. Fibers underlying the terminals were excised, as were control fibers identified as the same type (slower twitch) by physiological criteria. Fibers were assayed for key energy-related enzymes: β-hydroxyacyl-CoA dehydrogenase (βOAC); lactate dehydrogenase (LDH); and adenylokinase (AK). Homogeneity of enzyme activities (mol/kg dry weight/hr) was characterized by the coefficient of variation (CV = 100 x S.D./mean) among fibers. For each enzyme, the CV was smaller among fibers of a motor unit than among the control fibers of the same type (βOAC, 6.1% vs 17.7%; LDH, 7.4% vs 14.8%; AK, 11.8% vs 17.5%. Indeed, enzyme variation among fibers of a motor unit was no greater than that within one fiber at various points along its length (averages: βOAC, 8.4%; LDH, 9.8%; AK, 15.1%). These results demonstrate the precise biochemical alliance among muscle cells within one motor unit. Supported by NIH grants NS24752, DK38375 and the MDA.

213.7

METABOLIC HOMOGENEITY AMONG CAT TIBIALIS POSTERIOR MUSCLE UNIT FIBERS. C.E. Blanco*, M. Fournier and G.C. Sieck (SPON: M.A. Arbib). Dept. of Biomedical Engineering, USC, Los Angeles, CA 90089.

Metabolic variability among muscle unit (MU) fibers has been reported to be either higher than (Martin *et al., Am. J. Physiol.* 225:C43, 1988) or identical to (Nemeth *et al., J. Neurosci.* 6:892) that found along the length of individual fibers. These conflicting results may reflect differences in techniques used to quantify enzyme activity (quantitative histochemistry vs. microbiochemistry). Quantitative histochemistry was used to measure succinate dehydrogenase (SDH) activity in cat tibialis posterior (TP) muscle unit (MU) fibers identified by glycogen depletion. SDH variability along the length of fibers (~ 30 fibers/animal) was measured in 20 serial sections (10 μm thick) across a distance of 1000 μm. The mean coefficient of variation (CV) for SDH activity along the length of type II fibers was 12.4±4.0%. This compared to a mean CV of 15.6±5.7% for five MU (2 FF, 1 FInt, and 2 FR units; ~ 44 fibers/unit). Within a single section the CV for all type II fibers (~ 280/animal) was 57.1±10.4%. Thus, metabolic variability within a muscle unit was similar to that observed along the length of muscle fibers. We conclude that in the cat TP, the metabolic homogeneity among MU fibers reflects the predominance of neurogenic influences. (Supported by NIH grants HL34817 and HL37680.)

213.8

METABOLIC VARIABILITY ALONG DIAPHRAGM MUSCLE FIBER LENGTH. T.S. Cheung*, M. Fournier, C.E. Blanco*, and G.C. Sieck. (Spon: J.D. Schlag). Dept. Biomedical Engineering, USC, Los Angeles, CA 90089.

The coefficient of variation (CV) of succinate dehydrogenase (SDH) activity among muscle unit fibers in the cat diaphragm (DIA) is 20.1±6.7% for slow-twitch (type I) units and 26.6±6.9% for fast-twitch (type II) units. The purpose of this study was to determine whether this metabolic variability differed from that found along the length of individual DIA fibers. Muscle cross-sections (10 μm thick) were cut in the following sequence: 1 section stained for myofibrillar ATPase (used to classify fiber as type I or II); 4 sections reacted for SDH with substrate; and 2 sections reacted for SDH without substrate (tissue blanks). Five such sets were cut at 130 μm intervals across a total length of 870 μm. SDH variability was assessed for ~45 fibers in each of 5 DIA. The CV along fiber length was 13.4±2.1% for type I and 17.5±3.2% for type II. Within a single cross-section, the CV of fiber SDH activity was 21.5±5.4% for type I and 41.8±14.1% for type II. We conclude that SDH activity is not uniformly distributed along the length of DIA fibers and that this metabolic variability accounts for most of the differences in SDH activity among muscle unit fibers. (Supported by NIH grants HL34817 and HL37680).

213.9

VARIATION OF ENZYME ACTIVITIES IN RAT MUSCLE FIBERS WITH RESPECT TO THEIR LOCATION AND SIZE. B.W.C. Rosser, B.J. Norris* and P.M. Nemeth. Depts. of Neurology, and of Anatomy and Neurobiology, Washington Univ. Sch. Med., St. Louis, MO 63110.

We examined metabolic capacities of muscle fibers with different diameters and intramuscular locations, and from functionally distinct muscles in adult rats. Fibers were typed histochemically and dissected from adjacent lyophilized cross-sections for quantitative fluorometric assays of malate dehydrogenase (MDH, oxidative), lactate dehydrogenase (LDH, glycolytic) and adenylokinase (AK, high energy phosphate). Fibers from either type 1 or 2a populations were similar in diameter and in MDH, LDH and AK activities, from the deepest regions of the soleus muscle to their most superficial location in the overlying lateral gastrocnemius (LG). However, 2b fibers from the superficial regions of the LG were on average 1.65 times larger in diameter than the 2b fibers found deeper in the muscle. The larger 2b fibers had on average a fifth the MDH activity, but 1.25 and 1.41 fold greater LDH and AK activity than the smaller 2b fibers.

Type 2a fibers have a high capacity for both oxidative and glycolytic metabolism and, therefore, were studied from several functionally distinct muscles (psoas, LG, extensor digitorum longus, biceps brachii, superficial masseter, diaphragm and extraocular) of a single rat. Mean fiber diameters varied 2.46 fold, and enzyme activities varied 1.83, 2.57 and 1.69 fold for MDH, LDH and AK, respectively. While there was a strong inverse correlation (r=-0.94) between mean fiber diameters and MDH activities, fiber size was not related to either mean LDH or AK activities among the disparate muscles.

The results reveal distinct relationships between enzyme activities and fiber size, but they are limited to certain fiber types and enzymes. Thus, we conclude that other parameters related to muscle function are also involved in determining cellular metabolic capacity. Supported by NIH grant DK38375.

213.10

IMPAIRED Na^+ PUMP CAPACITY AND UPREGULATION OF PUMP NUMBER IN SKELETAL MUSCLES FROM SPONTANEOUSLY HYPERTENSIVE RATS (SHR). JG Pickar*, RC Carlsen, SD Gray*, Dept. Human Physiol., Univ. of Calif., Davis, CA 95616

Slow twitch oxidative soleus skeletal muscles from spontaneously hypertensive rats (SHR) with well established hypertension exhibit a deficit in Na^+-K^+ pump function. We have used electrophysiological and radioligand binding techniques to characterize this deficit in 24-28 week old animals. Muscle resting membrane potentials, determined in situ, were significantly more depolarized in SHR than in normotensive (WKY) rats (83.0 ± 0.5mV vs 88.2 ± 0.4mV). SHR membrane potentials were also significantly less hyperpolarized following a 4min period of repetitive stimulation (86.5 ± 1.0mV vs 94.3 ± 0.5mV). Addition of epinephrine (10^{-6}M) to soleus muscles in vitro generated a 8.6 ± 2.2mV hyperpolarization in WKY, but only a 1.2 ± 0.5mV hyperpolarization in SHR. Addition of insulin (4U/L) produced a 5.5mV hyperpolarization within 10min in WKY, but had no effect in SHR. SHR muscles were less depolarized by ouabain (10^{-3}M) than were WKY muscles, but neither the time course of depolarization nor the extent were significantly different. Despite these indications of an apparent reduction in Na^+ pump capacity in SHR skeletal muscles, ligand-binding studies using ^{3}H-ouabain indicated that SHR soleus contained 72% more high affinity binding sites than were found in age-matched WKY muscles. Binding affinities were similar in the two strains. The presence of an increased number of binding sites coupled with an apparent reduction in pump capacity suggests that hypertension may be associated with a defect in pump structure. (Supported by NIH HL37080).

213.11

CONFIGURATION OF THIN, INTERMEDIATE AND THICK FILAMENTS AT THE EQUATOR OF CHICKEN INTRAFUSAL FIBERS. R. Zak*, A. Maier, and R. Mayne* (SPON: B.J. Davis). Department of Medicine, University of Chicago, Chicago IL 60637, and Department of Cell Biology and Anatomy, University of Alabama at Birmingham, Birmingham, AL 35294.

The configuration and distribution of thin, intermediate and thick filaments at the equator of chicken intrafusal fibers were examined with immuno- fluorescence light microscopy, using monoclonal antibodies against actin, desmin and myosin heavy chains. Actin was localized within equatorial nuclei and in the spaces external to them; however, the fluorescence was much more intense within the nuclei than in the extranuclear spaces. Desmin and myosin heavy chains were only observed in the extranuclear spaces. Although all three filaments were present at the pole and at the equator, the fluorescent pattern produced after incubation with the various antibodies varied considerably between these two regions. Fluorescence at the pole was in the form of striations, while at the equator it was confluent. Incubation with an antibody against tropomyosin produced striations at the pole and confluent staining at the extranuclear portion of the equator, but failed to give any reaction within nuclei. This suggests that the extranuclear and intranuclear staining after incubation with anti-actin is due to different isoforms. The peculiar organization of filaments at the equator would be expected to result in mechanical properties that differ substantially from those of the pole.

Supported by a grant from the Muscular Dystrophy Association.

GEOMETRIC PATTERN OF TAPERING IN FAST MUSCLE FIBERS OF CAT TIBIALIS ANTERIOR. E. Eldred, M. Ounjian,* R.R. Roy, and R.V. Edgerton. Departments of Anatomy and Cell Biology, and Kinesiology, UCLA, Los Angeles, CA 90024.

Many fibers in the cat tibialis anterior muscle as seen through glycogen depletion of a motor unit and tracing through histological sections are seen to taper over a centimeter before ending (Ounjian et al., Soc. Neurosci. Absts 13:1213, 1988). Whether the diameter or the cross-sectional area varies linearly as length could give insight as to formation of the taper and relay of contractile force to the endomysium. For 12 endings in a fast motor unit comparison was made of correlation coefficients of linear regression curves for the relationships of length along the taper to: 1) fiber cross-sectional area as measured by an image-processing system, 2) the diameter, assuming the area to be a circle, and 3) measurements of the perimeter.

Coefficients were significantly higher for area/length suggesting that: 1) the taper cannot arise from a progressive loss of myofibrillae restricted to a peripheral zone of constant depth: 2) total force relayed to endomysium per unit of length is constant; and 3) the concentration of force per unit of circumference increases curvilinearly with approach toward the fiber tip. This suggests in turn a corresponding gradation in concentration of the endomysial envelope.

213.13

QUANTITATIVE ANALYSES OF MUSCLE FIBERS IN THE PRIMATE TONGUE. R. DePaul* (Spon: J. Abbs), Department of Speech, University of Wisconsin-Whitewater & Speech and Motor Control Laboratories, University of Wisconsin-Madison, 1018 Roseman Bldg., Whitewater, WI 53190

While primate intrinsic tongue muscles are of unquestionable importance for mastication, respiration, deglutation, and in humans, speech, there have been few advances beyond 19th century gross morphology. Distribution of muscle fiber types, their relative sizes, and variations in size and fiber type for different muscle sites appears critical for understanding tongue motor control.

Whole tongues were obtained from three young adult male macaca Fascicularis monkeys, blocked, sectioned, quick frozen in liquid nitrogen-cooled isopentane, and sectioned serially to provide cross-sectional views of superior longitudinal (SL), inferior longitudinal (IL), transverse (TV), and vertical (V) intrinsic muscles. Sections were processed by ATPase and reverse ATPase methods, and muscle fibers (n = 7758) in a select set of sections from each of the four intrinsic muscles were measured using an locally-developed computer program.

Overall, muscle fibers in these intrinsic tongue muscle fibers were smaller (Mean diameter 20.8 to 37.4 u) than in limb muscle, with Type II fibers only moderately larger than Type I. Type II fibers were strongly predominant, ranging from 70.3 to 84.8 %, which is a somewhat greater proportion of Type II fibers than most limb muscles. Importantly, from a functional view, all muscles manifested not only an striking increase in percentage of Type I to Type II fibers from anterior to posterior sites, but a parallel increase in fiber size. From anterior to posterior, fiber size increased from 8.9% for the transverse muscle to 64% for superior longitudinal. These data argue that the anterior and posterior portions of these muscles are distinct in their innervation and actions, with functional implications for differential movements of the tip and back of the tongue. Research supported by NIH Grants NS-13274, HD-03352, and NS-16373, and a grant from the University of Wisconsin-Whitewater.

213.14

PRELIMINARY MORPHOLOGICAL STUDIES EXAMINING COMPARTMENTS IN TWO-JOINT HUMAN MUSCLES. M.J. DeCamp,* M.T. Chopp,* S.L. Wolf, R.L. Segal, A.W. English (SPON: C.E. Coogler). Div. Phys. Ther., Dept. Rehab. Med. & Dept. Anat. & Cell Biol., Emory Univ. Sch. Med., Atlanta, GA 30322.

To acquire anatomical evidence of compartmentalization within human muscles, innervation patterns of lateral gastrocnemius (LG), extensor carpi radialis longus (ECRL), and flexor carpi radialis (FCR) muscles were examined in conjunction with muscle fiber architecture and attention paid to the distribution of muscle nerves. Consistent patterns of innervation were found within each of the three muscles. In LG, a single nerve enters the muscle proximally and contains 3 longitudinal and 2 recurrent branches, proximally. ECRL is innervated by 2 different branches of the radial nerve, each running roughly perpendicular to the muscle fascicles. Each branch is further divided into superficial and deep compartments. FCR was also clearly partitioned by its muscle nerve. Differentiation between motor and sensory axons was not possible. Thus, these muscles may not function as homogeneous units, but as aggregations of compartments.

213.15

MUSCLE FIBER LENGTHS, PINNATION ANGLES AND DEFORMATION OF APONEUROTIC SHEETS IN THE CAT MEDIAL GASTROCNEMIUS MUSCLE DURING NORMAL MOVEMENT. A.A. Caputi*, J.A. Hoffer and I.E. Pose*. Depts. of Clinical Neurosciences and Medical Physiology, University of Calgary, Faculty of Medicine, Calgary, Alberta T2N 4N1, Canada.

The ultrasound transit-time technique has revealed major differences between length changes in the medial gastrocnemius muscle (MG) and its muscle fibers during the cat step cycle (Griffiths & Hoffer, *SN Abstr 13:* 1214; Hoffer et al., *Progr Brain Res.*, in press). These discrepancies cannot be explained by a simple model where tendon compliance is in-series with the muscle fibers. We have used the ultrasound technique to investigate how three factors, *muscle fiber length, pinnation angle* and *deformation of aponeurotic sheets*, act in concert to determine the length of the muscle belly during the different phases of the step cycle (F->E3).

Twelve cylindrical piezoelectric crystals were implanted near the ends of muscle fibers at four levels of the MG muscle in the mid-saggital plane, to monitor fiber length, fiber pinnation angle and aponeurotic sheet deformation during level, up- and downhill locomotion, at speeds from 0.2 to 1.5 m/s. Fiber pinnation angles as function of time were computed by triangulation. Muscle length, tendon force and local EMG near crystals were also recorded. The following observations emerged:

1. Features of *muscle fiber* movement varied systematically depending on *location* within the muscle. The shorter *proximal* fibers worked over a wider range (100-150% of their length in early F) than the longer *distal* fibers (90-110%).
2. *Pinnation angles* changed over a wider range for proximal fibers (20-60°) than for distal fibers (10-30°). In general, pinnation angles were *steepest* when the fibers were at their *shortest;* however, this relationship was not obligatory.
3. The deep and superficial *aponeurotic sheets* had two lengthen/shorten episodes: in the *unloaded* phases (late F, E1) and during *stance* (E2-E3). The timecourse and extent of stretch in each episode varied with distance along each aponeurotic sheet.

Quantitative analysis of the relationship among these variables is being carried out taking into account architecture, task, speed, level of activation and external load.

NEUROMUSCULAR STRATEGIES UNDERLYING FAST MOVEMENT IN A TURTLE, *Pseudemys scripta*. R.J. Callister and E.H. Peterson. Department of Zoology and College of Osteopathic Medicine. Ohio University, Athens, OH 45701.

The head retractor muscle RCCQ in *P. scripta* comprises three fiber types (Callister et al., '89, J. Morph. 199:266-286). Fg fibers account for over 50% of total fibers and up to 80% of the muscle cross section. Some fibers of all types terminate in tapered endings within the muscle belly and are short (20-85% of total muscle length), but most Fg fibers and some FOG and SO types run the full muscle length (approx. 6cm). We have suggested that they may be specialized for producing rapid head displacements (Callister and Peterson, '88, Soc. Neurosci. Abs. 14: 1233). Examination of sudan black stained wholemounts and single fibers treated with NBT reveals that 3/4 RCCQ bellies are innervated by multiple segmental nerves whose intramuscular territories do not overlap. On single fibers, motor axons form focal MEPs that consist of 1-5 longitudinally arranged varicose strips. Single fibers bear 2-13 MEPs at 1-13mm intervals along their entire length; inter-terminal spacing is remarkably constant (approx. 5mm). Thus single fibers receive multiterminal and multisegmental innervation. Rapid head retraction would appear to require near simultaneous depolarization of MEPS along the fiber length, but we do not know how this synchrony is effected within the spinal cord. Supported by NIH grant NS23498.

214.1

IMMOBILIZATION DECREASES THE FATIGABILITY AND INCREASES THE FORCE PRODUCED BY CAT MOTOR UNITS. G.A. Robinson, R.M. Enoka and D. G. Stuart, Departments of Physiology and Exercise & Sport Sciences, University of Arizona, Tucson, AZ 85724.

Mechanical properties from individual tibialis posterior motor units were studied after a 3-week period of hindlimb immobilization in 11 adult cats and compared to those of units from 5 non-immobilized cats. All cats were preconditioned for 3 weeks in a communal environment. Immobilization of the maximally shortened test muscle using an external metal brace reduced its wet weight by an average of 17% compared to the contralateral control. Motor units were characterized into one of four types described previously for normal tibialis posterior muscle (FF, F(int), FR or S; McDonagh et al., J. Neurophysiol., 44: 696, 1980). Measurements of peak twitch force, time to peak twitch force, rate of twitch force development, peak tetanic force and fatigability were altered significantly in at least one motor unit type after immobilization, namely: 1) time to peak twitch force was lengthened in FF and F(int) units; 2) the rate of twitch force development increased in FF units; 3) the magnitude of peak twitch force increased in FF units, with a trend for increases among F(int) and FR units; 4) the magnitude of peak tetanic force increased in FF units, but decreased in S units, and 5) fatigability in FF, FR and S units was reduced. The changes in force production may reflect changes in muscle connective tissue whereas the decreased fatigability is probably related to the type of fatiguing stimulation used in the study. Supported by USPHS grants NS 20544, NS 25077, NS 20762, RR 05675, NS 07309 and HL 07249.

THE EFFECTS OF LIMB IMMOBILIZATION ON MUSCLE STRENGTH AND ENDURANCE. N.C. Rich. PHS Dept., Miami Univ., Oxford, OH 45056

The purpose of the investigation was to examine muscle strength, endurance, girth and fatfold changes of the upper arm following 14 days of immobilization. Five males and 5 female subjects were placed in two groups: (1) control and (2) isometric exercise. Measurements included: (1) forearm flexion and extension strength, (2) forearm flexion and extension endurance, (3) girths of arm, &(4) fatfolds. Each subject wore a fiberglass cast on the non-dominant arm from the deltoid to hand for 14 days. The exercise group performed 3 sets of 10-6 second contractions for both the flexors and extensors. Non-dominant strength decreased from 23.0 to 17.0 kg (26%) for flexion and from 15.0 to 12.9 kg (14%) for extension in the control group. The exercise group values decreased 16.2% and 13.5%, respectively. Flexion and extension endurance values decreased 22.4% and 17.9% in the control group and 13.7% and 16.1% in the exersize group. There were no differences in the girth or fatfold measurements. Thus, the data indicate that the performance of isometric exercise for both agonists and antagonists may prevent deleterious effects of immobilization.

DESIGN OF A MAGNETIC MUSCLE STIMULATIOR (TETANY) FOR CLINICAL USE. R.G. BICKFORD, D.BRITTAIN, P. FORTESCUE*, L. ALEXANDER*, EEG LABS, UCSD AND VA HOSPITAL, LA JOLLA, CA 92161.

Painless tetanic muscle stimulation has significant application in clinical rehabilitation. Magnetic stimulators, although painless, presently lack adequate repetition rate, frequency, power, and ability to operate without overheating. These problems can be solved using (1) high capacitor charging voltage (2) regenerative circuitry with transfer to a subsequent cycle of unused charge (4) appropriate trigger circuit for fast switching.

A stimulator of this kind yielding 400 joule, 100 sec pulses repeatable up to 30 per sec has been tested on the arm and leg muscles normal (6 subjects). Functional tetanus capable of raising the leg against gravity was produced using a 9 cm dia, 10 turn coil placed over the appropriate muscle. It runs on a duty cycle 100% without overheating. The stimulus is painless and thus provides an important clinical advantage over the comparable electric muscle stimulator (FES method).

MODIFICATION OF HUMAN MUSCLE PROPERTIES BY ELECTRICAL STIMULATION AFTER SPINAL CORD INJURY. R.B. Stein, J. Jefferson* and T. Gordon. Div. of Neurosci. and Dept. of Physiotherapy, Univ. of Alberta, Edmonton, Canada T6G 2S2.

The optimal method for training paralysed muscles for use in functional tasks remains unclear. Protocols involving from half an hour 2-3 times a week to 8 hours daily have been recommended. In this study tibialis anterior muscles of complete, spinal cord injured subjects were stimulated at 20 Hz and 50% duty cycle in successive 6 week periods for 15 min., 45 min., 2 hrs. and 6-8 hrs. daily. Fifteen min. of stimulation had little if any effect on the parameters measured: twitch and tetanic tensions, contraction and half-relaxation times, fatigue index (% of force produced after 2 or 3.5 minutes of stimulation, compared to control values) Forty-five min. of stimulation produced a substantial slowing of the muscle with increase in fatigue resistance. Longer periods of stimulation produced relatively small further changes. None of the patterns tested increased the force output of the muscles, but the increase in fatigue-resistance should be useful for tasks such as walking, produced by electrical stimulation. Supported by MRC and MDA of Canada.

ULTRASTRUCTURAL ANALYSIS OF ELECTRICALLY STIMULATED CANINE SKELETAL MUSCLE AFTER RESUMPTION OF NATIVE NEURAL IMPULSE ACTIVITY. B.C. Marts*, K.M. Klueber, J.W. Brown*, and J. Hoffpauir* (SPON:R. Gurd) Dept. Anat. Sci.& Neurobiology, U of Louisville, Sch of Med, Louisville, KY 40292 and Med Sciences Prog, Indiana U Sch of Med, Bloomington IN 47405

Do the ultrastructural and histochemical changes noted in skeletal muscle after electrical stimulation persist following cessation of stimulation? The objective of this study was to examine the cytoarchitecture of canine skeletal muscle after stimulation and following a period of normal neural impulse activity. The rectus abdominis muscles of 3 female dogs were stimulated electrically (2 Hz, 5.9V,.2 msec pulse duration; 97 days) after which neural impulse activity was resumed (155 days). Myosin ATPase activity demonstrated 44%, 100% and 98% Type I myofibers prior to, after stimulation (97 days) and normal neural activity (155 days), respectively. Following stimulation myofibers were characterized by disorganization of sarcomeres, target and ring fibers, focal degeneration, split fibers, abnormal mitochondria and myonuclear profiles which persisted after return of normal neural impulse activity. Among these fibers, evidence of regeneration (centrally placed nuclei, polyribosomes, activated satellite cells) was noted. The cytoarchitectural changes in muscle induced during stimulation persist 5 months after its cessation contrary to data reported by others. Funded by: Dept of Surgery, Indiana U. Sch. of Medicine.

EFFECT OF pH ON EMG MEDIAN FREQUENCY AND CONDUCTION VELOCITY IN THE HAMSTER DIAPHRAGM. L.Brody*, M.Pollock*†, S.H. Roy, C.J.DeLuca, and B.Celli*†, *NeuroMuscular Research Ctr, Pulmonary Ctr and Boston VA Medical Ctr†, Boston Univ., Boston, MA 02215.*

The physiological determinants of EMG fatigue parameters are uncertain. H^+ ion accumulation at the sarcolemma is believed to play a key role in determining the electro-physiological correlates of fatigue. To establish a causal relationship between muscle pH and EMG, studies must go beyond merely recording concurrent changes in these measures.

This paper describes an in-vitro method to externally manipulate muscle pH while measuring the resultant effect on surface-detected median frequency (MF) and conduction velocity (CV) parameters. Hamster muscle diaphragm strips (n=4) were isolated with the phrenic n. intact and placed in an oxygenated Krebs bath (26 °C). The muscle was clamped to a non-compliant load cell to measure isometric contractile tension. Tetanic contraction was developed via 40 Hz supermaximal stimulation of the phrenic n. Differential signals were recorded from 3 EMG detection surfaces for computation of CV (via the phase shift in the EMG signals) and MF. Repeated trials were conducted at bath pH's of 7.4, 7.0 and 6.6. Bath pH was altered by aerating pre-determined concentrations of O_2 and CO_2 into the bath.

Results indicated that the MF and CV decreased by an average of 15% and 13% respectively when the pH was changed from 7.0 to 6.6. Each increased by an average of 19% when the pH was changed from 6.6 to 7.0. No appreciable change in MF or CV occured when the bath pH was changed from 7.4 to 7.0 (or vice versa). This suggests that EMG changes are independent of extracellular pH because the muscle is effectively buffered at pH above 7.0. These results support the premise that MF and CV parameters are causally related to intracellular pH.

214.7

THE ELECTROMYOGRAMS MEDIAN FREQUENCY PREDICTS THE MOTOR UNITS RECRUITMENT STRATEGY. M. Solomonow, C. Baten*, J. Smith*, R. Baratta* & R. D'Ambrosia*. Bioengineering Laboratory, LSU Medical Center, New Orleans, LA 70112.

Since the median frequency (MF) of the EMG power density spectrum is linearly related to the average conduction velocity in the muscle (Stulen & DeLuca, IEEE-BME, 28:515-523, 1981), then the MF should increase only during the orderly recruitment phase of increasing force contraction but not during the final rate increase phase. Motor units of the isometric cat M. Gastrocnemius muscle were orderly recruited with concurrent rate increase at various control strategies with electrical nerve stimulation (Solomonow et al. IEEE-BME, 34:692-703, 1987). The MF of each M-wave picked with bipolar intramuscular electrodes was calculated and plotted vs. time. The MF increased only during the orderly recruitment phase of motor units but not during the final rate increase. Direct increase of the firing rate of all the motor units resulted in constant MF. It was concluded that the MF rise can predict the recruitment strategy of various muscles performing various functions.

CHANGES IN DIAPHRAGM CONTRACTILE PROPERTIES AFTER COMPENSATORY LOADING. W.Z. Zhan and G.C. Sieck. Dept. of Biomedical Engineering, USC, Los Angeles, CA 90089.

The influence of chronic compensatory loading (CL) on the contractile and fatigue properties of the diaphragm (DIA) was studied in adult hamsters. After paralysis of the right hemidiaphragm, EMG activity of the left side increased by 60% and inspiratory duration increased by 25%. The DIA forces generated during eupnea were 34% of maximum before paralysis and 56% after. After 2 weeks of CL, the isometric contractile and fatigue properties of the left hemidiaphragm were determined using an in vitro preparation and direct muscle stimulation. Tension measurements were normalized for muscle weight. Contraction time decreased by 13.4% and 1/2 relaxation time by 21.8% in the CL animals. Normalized maximum tetanic tensions were increased by 19.7% in the CL animals. The ratio of peak twitch tension to maximum tetanic tension decreased by 16%. No significant change in fatigue resistance was observed. These results suggest that after prolonged CL, there is an increased contribution of type II muscle fibers to the total force generating capacity of the DIA. (Supported by NIH grants HL34817 and HL37680).

214.9

EFFECT OF CHRONIC COMPENSATORY LOADING ON DIAPHRAGM MUSCLE FIBERS. G.C. Sieck and W.Z. Zhan. Dept. of Biomedical Engineering, USC, Los Angeles, CA 90089.

The influence of chronic compensatory loading (CL) on the metabolic and morphometric properties of diaphragm (DIA) muscle fibers was examined in adult hamsters. After paralysis of the right hemidiaphragm, EMG activity of the left side increased by 60% and inspiratory duration increased by 25%. Ventilatory forces generated by the DIA increased from 34% of maximum force generating capacity in controls to 56% in the CL animals. After 2 weeks of CL, the DIA was excised and rapidly frozen. Alternate serial sections were stained for ATPase (pH 9.0) and succinate dehydrogenase (SDH). Fibers were classified as type I or II based on the ATPase stain. Fiber SDH activity was quantified microphotometrically. After CL, the mean SDH activity of type I fibers increased by 30% and type II by 12%. The proportions of type I and II fibers were unchanged. However, the number of type II with higher SDH activity increased. The cross-sectional area of these higher oxidative type II fibers also increased. These results suggest that CL selectively affects the oxidative capacity of those DIA fibers that must increase their activation to sustain adequate ventilatory forces. (Supported by NIH grants HL34817 and HL37680).

MOTOR UNIT RECRUITMENT AND RATE CODING INFLUENCES ON MUSCLE TENSION AND EMG. A.J. Fuglevand*, D.A. Winter*, A.E. Patla, and D. Stashuk* (SPON:E. Cafarelli). Depts. of Kinesiology and Systems Design Engineer., University of Waterloo, Waterloo, Ont., CANADA N2L 3G1.

A motor unit (mu) pool model was employed to examine the relation between surface EMG and isometric tension. The model was comprised of three elements; a motoneuron, an isometric tension, and an EMG model. The size-principle based model predicted recruitment and firing patterns in 100 mus. EMG and tension were simulated for 11 levels of excitation from 5 to 100% maximum excitation (ME). ME was the excitation required to bring the last mu to saturation firing rate (SFR). Two recruitment ranges were tested, recruitment limit < 50% ME and recruitment limit > 70% ME. Five conditions of SFR were also tested. Linear EMG-tension relationships ($R^2 > .99$) were exhibited when recruitment operated over a large excitatory range. If the recruitment limit was less than 50% ME, the EMG-tension relation was nonlinear and nonphysiological. The selected range of SFRs had little effect on the shape of the EMG-tension relation. However, if no SFR limit was imposed, EMG increased as a fractional exponent of tension. If all mus were assigned similar SFR, and recruitment operated over a large range, a parabolic EMG-tension relation was demonstrated.

LONG TERM EFFECTS OF LOW FREQUENCY STIMULATION ON TENSION-FREQUENCY RELATIONS IN FAST-TWITCH MOTOR UNITS. R.K. Powers and M.D. Binder, Dept. of Physiol. & Biophys., Univ. of Washington, Seattle, WA 98195.

To investigate the long term effects of low frequency stimulation on tension-frequency (T-F) relations, single fast-twitch motor units from the flexor digitorum longus muscle were activated by stimulating ventral root filaments in barbiturate-anesthetized cats. T-F relations were determined by delivering trains of 25 pulses at frequencies of 10 to 80 Hz, first in ascending then in descending order. A series of 4 - 11 ten second 20 Hz trains was then delivered at 0.07 Hz, and T-F relations were determined at various times after this conditioning stimulation. T-F runs were generally followed by a 600 msec train at 200 Hz to specify the unit's maximum tension at that time. A standard fatigue test was applied at the end of the protocol in order to identify the unit as FR, FI or FF. The conditioning stimulation acted to shift the entire T-F relation along the frequency axis, and this shift could be quantified as a change in the activation frequency needed to produce 50% of the maximum tension (f50). Immediately after conditioning, f50 was reduced (-2.2±6.9 pps), but increased above control by 30 minutes (11.8±8.8 pps) and remained increased for several hours. The magnitude of these shifts was related to unit type - the initial decrease in f50 was seen primarily in FR units (-6.7±6.1 vs. 1.0±6.4 pps in FI + FF units), while the later increase was significantly greater in FI and FF units (17.1±6.6 vs. 4.4±5.5 pps in FR units). Preliminary analysis of unit EMG potentials indicates that these changes in tension production were often accompanied by long lasting decreases in muscle fiber conduction velocity.

EMG POWER SPECTRUM: A NON-INVASIVE MUSCULAR BIOPSY? M. Bilodeau*, A.B. Arsenault, D. Gravel*, D. Bourbonnais, F. Kemp*. School of Rehabilitation, University of Montreal and Research Centre, Montreal Rehabilitation Institute, Montreal, QC, Canada, H3S 2J4.

It has been proposed that the mean power frequency (MPF) of the EMG power spectrum increases gradually with force of contraction, this being more pronounced if the muscle investigated has a high proportion of fast twitch fibers. To validate this proposition, the Triceps Brachii (TB, 65% fast twitch fibers) was compared to the Anconeus (AN, 65% slow twitch fibers). Subjects (n=13) produced 10 isometric ramp elbow extensions from 0 to 100% of maximal voluntary contraction (MVC). EMG signals were recorded with miniature surface electrodes during these 5 sec. contractions. The MPF was obtained on 0.25 sec. windows taken at levels of 10, 20, 40, 60, 80 and 100% MVC. ANOVAs on the AN data showed that MPF increased ($p < .01$) up to 60% MVC. In contrast, the MPF for TB decreased ($p > .05$) down to 40% MVC. It thus seems that changes of the MPF with different force levels cannot be used directly to estimate the fiber type composition of two different muscles.

DISCHARGE VARIABILITY AND PHYSIOLOGICAL PROPERTIES OF HUMAN MASSETER MOTOR UNITS. M.A. Nordstrom* & T.S. Miles* (SPON: R. Tulsi). Department of Physiology, University of Adelaide, Adelaide 5000, Australia, and Department of Physiology, University of Arizona, Tucson AZ 85724.

Correlations were sought between motor unit discharge variability in the human masseter and physiological properties of the units which were determined using the spike-triggered averaging (STA) technique. Motor unit activity was recorded by an intramuscular electrode. Subjects bit on bars which measured the isometric biting force, and controlled the mean firing rate of a selected unit at 10 Hz for 15 minutes with the aid of feedback. The discharge variability was assessed from the normalized Standard Deviation (SD) for a mean interspike interval (ISI) of 100 ms. Variability measures were obtained for 37 units from 2-minute epochs at the beginning and end of the contraction. In 81% of units, ISI variability increased after 15 minutes of continuous activity. No significant correlations were found between initial ISI variability and recruitment threshold, twitch tension or TTP. However, there was a significant correlation between motor unit fatiguability and its initial discharge variability. This represents a previously unrecognized link between motoneurones and their muscle units. Supported by the NH & MRC of Australia. M. Nordstrom is a CJ Martin Fellow of the NH & MRC.

MEMBRANE POTENTIAL NOISE IN TONICALLY-CONTRACTING MOTOR NEURONS IN HUMANS. T.S. Miles*, K.S. Türker*, M.A. Nordstrom* and J.J. Seguin, Department of Physiology, The University of Adelaide, Adelaide S.A. 5000, Australia.

With the help of feedback, humans can run a single motor unit at a prescribed mean rate with only minor variations in the durations of the interspike intervals (ISIs). The relationship between the mean ISI and its Standard Deviation (SD) is linear over much of the unit's frequency. If the membrane potential of a tonically-firing motor neuron rises linearly towards the firing threshold during the ISI, with synaptic noise superimposed on this trajectory, the SD will be proportional to the ISI if the amplitude of the synaptic noise remained constant. The characteristics of the membrane noise could then be inferred from the variation in the ISIs. We determined the minimal variation of ISIs at various firing rates in masseter and limb motor neurons in order to estimate the minimal noise on their membranes. To ensure that the motor neuron was running at a constant rate, a computer program selected for analysis only the interval which followed 2 consecutive ISIs of specified duration. Our noise estimates are comparable to measurements made from intracellular recordings from CNS neurons in awake animals.

This project was supported by the Australian National Health and Medical Research Council.

TWITCHLIKE EMG-TORQUE MODEL IN HUMAN ANKLE FLEXORS. T. Sinkjær, E. Toft*, S. Andreassen*. Dept. of Medical Informatics and Image Analysis, Aalborg University, Badehusvej 23, DK-9000 Aalborg, Denmark.

The twitch of resting motor units changes with use and is a poor index for determining the contractile speed of active muscles (Dubose et al., Muscle & Nerve 10:744, 1987). In this study a twitchlike EMG-torque model of an active muscle was developed and compared to electrically elicited muscle twitches. The model was characterized by contraction time (CT), half relaxation time (HRT), maximal amplitude (AMP), and DC-gain. Eight subjects 22-30 years old were examined. The subject sat in a chair with the left foot strapped to a platform (Sinkjær et al, J. Neurophysiol., 60:1110,1988), and followed a tracking command around different percentages of Maximal Voluntary Contraction (MVC) in the ankle dorsiflexors. At the different %MVC a nonparametric model was calculated, describing the torque around the ankle joint from the rectified and filtered anterior tibialis EMG. CT and HRT: The best linear fit showed a CT of 89 ms at 0% MVC declining to 73 ms at 50% MVC. In the electrically elicited twitch CT was on average 71 ms. HRT was 115 ms at 0% MVC, declining to 95 ms at 50% MVC. HRT was on average 60 ms in the electrically elicited twitch. AMP and DC: An increase was observed from 0 to 20% MVC. Above 20% MVC both parameters declined at increasing contraction. A second order fit predicted the DC-gain to be suppressed to 0 Nm/μV at 90% MVC. The model proposes faster motor units to be recruited at increasing contraction levels, and the contractile properties in a muscle limit the maximal force developed (Toft et al., Exp. Brain Res., 74:213,1989).

CROSS-TALK BETWEEN PHOSPHOINOSITIDE- AND CYCLIC AMP -COUPLED RECEPTORS IN THE RAT HIPPOCAMPUS. M.Parenti, G.P.Ceresoli*, S.Consolo*, E.Palazzi* and A.Groppetti*. Dept.Pharmacology, Univ.Milan and "Mario Negri" Inst. Milan, Italy.

The stimulation of α-1 adrenergic receptors in rat hippocampal slices with phenylephrine (PHE) led to an enhanced phosphoinositide (PI) breakdown and an increased cAMP accumulation. This dual response could either be due to distinct subtypes of α-1 sites coupled to different second messenger-generating systems or, alternatively, a unique class of receptors linked to a common effector could generate a signal able to affect other cell receptor-coupled transduction mechanisms. Indeed cross-talk between hippocampal receptors was confirmed by the finding that diolein, a diacylglycerol (DAG) analogue that stimulates protein kinase C (PKC), enhanced cAMP formation, suggesting that PI-linked receptors, through DAG generation and activation of PKC, could positively influence adenylate cyclase (AC) activity. This is true for α-1 receptors since PHE-induced increase of cAMP was effectively antagonized by different PKC inhibitors, e.g. H-7 and staurosporine.

These observations support the view that hippocampal α-1 receptors coupled to PI breakdown "talk" to AC linked receptors. These, in turn, can communicate with the first since the elevation of cAMP by forskolin significantly decreased PHE stimulation of PI hydrolysis.

215.2

THE EFFECTS OF ETHANOL ON MEMBRANE PROPERTIES OF NEURONS OF THE VENTRAL TEGMENTAL AREA *IN VITRO*. M.S. Brodie and S.A. Shefner. Abbott Laboratories, Abbott Park, IL and University of Illinois College of Medicine, Chicago, IL.

Within the ventral tegmental area (VTA) are dopamine-containing neurons which have been studied electrophysiologically *in vitro* and *in vivo*. These neurons have been implicated in the central mechanisms which mediate the rewarding properties of drugs of abuse, including ethanol. Ethanol excites dopaminergic neurons of the VTA. We have made intracellular recordings from neurons of the VTA in order to characterize the excitatory effects of ethanol. Rat brain slices of the mesencephalon were prepared as described previously, and were maintained submerged in a superfused recording chamber. Neurons were selected which had electrophysiological characteristics similar to those previously established for dopamine-containing mesencephalic neurons recorded intracellularly *in vitro*. Concentrations of ethanol tested ranged from 80 to 160 mM. In our studies using extracellular recordings, 90% of the putative dopamine-containing VTA neurons were excited by ethanol; in our intracellular studies a larger percentage of neurons were either not affected by or were inhibited by ethanol. Those neurons which were excited by ethanol exhibited a slight depolarization (1-4 mV), with a decrease in slope resistance. Time-dependent anomalous rectification, a prominent characteristic of these neurons, was enhanced in neurons excited by ethanol. Furthermore, the action potential amplitude and the afterhyperpolarization amplitude were reduced during ethanol administration. These changes in the membrane properties of VTA neurons may be responsible for ethanol-induced excitation. Grant Support: PHS AA05846.

$GABA_A$ RECEPTORS MEDIATE MEDIAN PREOPTIC - EVOKED INHIBITION OF SUPRAOPTIC NEUROSECRETORY NEURONS IN RAT. R. Nissen and L.P. Renaud, Centre for Research in Neuroscience, Montreal General Hospital and McGill University. Montreal, Canada, H3G 1A4.

The hypothalamic supraoptic nucleus (SON) receives a projection from the median preoptic nucleus (MnPO). Extracellular recordings from the majority of SON neurons display a reduction in excitability following electrical and chemical stimulation of MnPO. In order to characterize the transmitter involved in this response, we utilized a transpharyngeal approach in urethane anesthetized male Long Evans rats to obtain further data from SON cells and the effects of locally applied inhibitory transmitter antagonists. Bicuculline methiodide (100μM) reversibly abolished the stimulus evoked inhibition of 17/18 vasopressin (VP) and 2/2 oxytocin neuron tested. Neither timolol (25μM), a β adrenergic antagonist, nor strychnine (100μM), a glycine receptor antagonist, had an effect on 5/5 VP neurons where the inhibition was abolished by bicuculline. These observations demonstrate that the MnPO projection to SON vasopressin and oxytocin neurons is predominantly inhibitory and is mediated by $GABA_A$ receptors. (Supported by MRC and FRSQ).

215.4

PHARMACOLOGY OF INHIBITORY RESPONSES RECORDED IN BASOLATERAL AND LATERAL AMYGDALOID NEURONS *IN VITRO*. H. C. Moises and M. S. Washburn (SPON: J. McReynolds). Dept. of Physiology, Univ. of Michigan , Ann Arbor, MI 48109.

Stimulation of forebrain afferents to the amygdala evokes a complex sequence of excitatory and inhibitory synaptic responses in basolateral and lateral amygdaloid neurons (Washburn and Moises, Neurosci. Abstr., this volume). In hippocampus and cortex a similar profile of inhibitory responses to synaptic stimulation occurs which involves the activation of $GABA_A$ and $GABA_B$ receptors. The purpose of this study was to determine the pharmacology of inhibitory events in the amygdala and to examine the ionic mechanisms involved.

Responses to stimulation of the external capsule or nucleus basalis were recorded intracellularly from neurons in the basolateral or lateral nuclei in horizontal and coronal slice preparations of the rat amygdala. Stimulation of either site evoked a short latency epsp followed by an early ipsp with maximal amplitude approximately 35 ms after the stimulus and a reversal potential close to -70 mV. This was typically followed by a late ipsp which peaked around 170 ms after the stimulus and reversed at approximately -90 mV. Bath application of the $GABA_A$ antagonist bicuculline methiodide (10 -40 μM) or the chloride channel blocker picrotoxin (20 μM) consistently blocked only the early ipsp. In contrast, the $GABA_B$ antagonist phaclofen (700 nM) selectively blocked the late ipsp. Pressure ejection of GABA (1-10 mM) produced inhibitory responses similar to those obtained with synaptic stimulation. This included a bicuculline- and picrotoxin-insensitive hyperpolarization which was associated with an increase in membrane conductance and which reversed around -90mV. A second hyperpolarization was observed that was also accompanied by an increase in membrane conductance, but had a reversal potential of -70 mV and was blocked by $GABA_A$ antagonists. In addition, GABA produced depolarizing responses that were not evoked by synaptic stimulation and which might have resulted from the activation of dendritic GABA receptors. Pressure ejection of the $GABA_B$ agonist baclofen (3 mM) consistently produced long-lasting hyperpolarizations which were insensitive to bicuculline, reversed near -90 mV and were associated with an increase in conductance.

These results suggest that amygdaloid neurons display inhibitory reponses to synaptically released GABA that are mediated by $GABA_A$ and $GABA_B$ receptors. These responses to GABA appear to involve an increase in chloride and potassium conductance, respectively. (Suported by NIDA grant DA-03365)

EXTRACELLULAR CYCLIC AMP (cAMP) DECREASES $GABA_A$ RECEPTOR-MEDIATED CHLORIDE CURRENT IN CULTURED RAT HIPPOCAMPAL NEURONS. N.A. Lambert‡ and N.L. Harrison. Laboratory of Neurophysiology, NINDS, NIH, Bethesda, MD 20892 and ‡Dept. of Neurobiology, Northeastern Ohio Universities College of Medicine, Rootstown, OH 44272.

We have studied the effects of cAMP and the membrane-permeant cAMP analogs 8-bromo-cAMP (8-Br-cAMP) and 8-(4-chlorophenylthio)-cAMP (CPT-cAMP) on the $GABA_A$ receptor-mediated chloride current (I_{GABA}) in E19 cultured rat hippocampal neurons. Whole-cell recordings were made using a pipette solution based on 145mM K gluconate and 5mM ATP. Outward currents were recorded in response to GABA from neurons held at -40mV in voltage-clamp. GABA was applied by pressure (1-2 p.s.i.; 20-100ms) from a micropipette containing 50μM GABA.

External perfusion with 8-Br-cAMP or CPT-cAMP caused a reversible, dose-dependent decrease in I_{GABA}; 8-bromo-cGMP was inactive. Peak I_{GABA} in the presence of 2mM 8-Br-cAMP was 52 ± 7% (mean ± S.E.M., n=5) of control; 1mM CPT-cAMP reduced I_{GABA} to 45 ± 5% (n=6) of control. However, 50 μM L858051, a water-soluble analog of the adenylate cyclase activator forskolin, did not decrease I_{GABA}, even in the presence of the phosphodiesterase inhibitor IBMX (100μM). CPT-cAMP also decreased I_{GABA} when the protein kinase A (PKA) inhibitor H-8 was present in the extracellular medium (50μM) or in the recording pipette (10μM).

External cAMP was also found to decrease I_{GABA}. The potency of cAMP was similar to the potency of the membrane-permeant analogs. Recording from cells with pipette solution containing 1mM cAMP did not cause a steady decline in I_{GABA}, while external perfusion with cAMP decreased I_{GABA} as before.

We conclude that the effects of membrane-permeant analogs of cAMP on I_{GABA} do not depend upon their ability to penetrate cells or activate PKA, and that effects of these analogs on receptors and ion channels should be interpreted with caution.

215.6

INCREASE IN THE EXTENT OF DYE COUPLING BETWEEN CA1 HIPPOCAMPAL PYRAMIDAL NEURONS BY RAISING EXTRACELLULAR BICARBONATE ION CONCENTRATION. J.Church, H. McLennan* and K.G. Baimbridge. Dept. Physiology, Univ. of British Columbia, Vancouver, B.C., Canada V6T 1W5.

Dye coupling between hippocampal neurons after intracellular injection of dyes such as Lucifer Yellow (LY) has been observed repeatedly. Reducing pH_i by raising P_{CO2} lowers its incidence suggesting that dye coupling is not artifactual. Cerebrospinal fluid pH is, however, determined by the active regulation of both CO_2 and HCO_3^-. We have therefore examined the possibility that changes in $[HCO_3^-]_o$, and thus pH_o, may modulate the extent of dye coupling between CA1 pyramidal neurons in the rat hippocampal slice.

In control conditions (26mM HCO_3^-, pH 7.4 after equilibration with 5% CO_2), 12 of 27 neurons (44%) injected with LY were dye coupled, usually to only one other neuron. In contrast, during perfusion with medium containing 72mM HCO_3^- (pH 7.9) for between 6 and 115 min, 30 of 34 neurons (88%) were dye coupled, often to two or three but occasionally to as many as eight others. This increase was reversed on reperfusion with control medium. The results suggest the possibility that raising $[HCO_3^-]_o$ increases pH_i, which in turn modulates the degree of dye coupling.

EXCITATORY AMINO ACID-STIMULATED PROTEIN PHOSPHORYLATION IN RAT HIPPOCAMPAL PYRAMIDAL NEURONS IN CULTURE. Wendy K. Scholz and H. Clive Palfrey* Dept. of Pharmacol. and Physiol. Sci. Univ. of Chicago, Chicago, IL. 60637.

Protein phosphorylation has been implicated in the transduction of glutamate stimulation leading to such phenomena as LTP and excitotoxicity. To investigate the biochemical mechanisms underlying glutamate receptor signaling, a neuronal culture system of predominantly hippocampal pyramidal neurons was used. These were prepared from 17d embryonic rat hippocampi by a modification of the procedure of Banker and Cowan (1977). Protein phosphorylation in pyramidal neurons cultured for 10-18 days was examined after labeling endogenous ATP by incubating cultures with $^{32}P_i$ and treating with glutamate or other agonists. Treatment with glutamate (100 uM), NMDA (100 uM plus 1 uM glycine in Mg2+-free media) or kainate (100 uM) resulted in phosphate incorporation into specific proteins that was 10-30% over basal (unstimulated) levels. In contrast to high K+ stimulation of pyramidal neurons, which caused a general increase in $^{32}P_i$ incorporation, glutamate stimulated incorporation into specific proteins of M_r 48, 64, 87, 135, and 200 kD, as assessed by polyacrylamide gel electrophoresis (PAGE). The 48 and 87 kD proteins were tentatively identified as GAP43/B50/neuromodulin and the brain 87 kD phosphoprotein of Wu et al. (1982). This incorporation was completely blocked by CNQX (a kainate/quisqualate antagonist) plus APV (an NMDA antagonist) added 5 min. before glutamate. Closer examination, using 2-dimensional PAGE, of the time course of phosphorylation following glutamate and NMDA treatment showed greatest incorporation into the most highly phosphorylated state of the 48 and 87 kD proteins at less than 5 sec. Incorporation into these proteins decreased at 1 and 2 min, showing greatest incorporation into the less highly phosphorylated forms. These two phosphoproteins are known to be protein kinase C (PKC) substrates. The involvement of PKC in glutamate stimulation is also supported by measurements of second messenger levels, specifically diacylglycerol (DAG) and $[Ca2+]_i$. DAG showed a 1.5 to 3-fold and $[Ca2+]_i$ an 8-fold transient increase following glutamate treatment.

CONVERGENCE OF THE EXCITATORY ACTIONS OF NEUROTRANSMITTERS IN RAT PREFRONTAL CORTEX. R.C. Araneda* and R. Andrade.(SPON: V. A. Chiappinelli). Dept. of Pharmacology, St. Louis Univ. School of Med., St. Louis, MO 63104

Many neurotransmitter receptors which inhibit adenylate cyclase couple to a common population of potassium channels in central neurons. While such convergence has implications for the mechanisms by which neurons integrate incoming receptor mediated signals, little is known about the extent to which receptors coupled to other transduction mechanisms converge upon common membrane mechanisms. To begin addressing this question we have used intracellular recording in in vitro slices from the rat prefrontal cortex to analyze the actions of serotonin (5-HT), noradrenaline and acetylcholine, three neurotransmitters coupled to the inositol phospholipids in this region.

Bath administration of 5-HT, norepinephrine and the cholinergic agonist carbachol elicited a qualitatively similar pattern of membrane effects. These included a slow depolarizations, an increase in the reactivity of the cells to depolarizing stimuli and the appearance of a slow depolarizing afterpotential following a burst of spikes. Pharmacological analysis revealed that these effects were mediated by $5\text{-}HT_2$, α-adrenergic and muscarinic cholinergic receptors, all receptor subtypes previously shown to increase the turnover of inositol phospholipids. In contrast to these results, activation of $5\text{-}HT_{1A}$ and $GABA_B$ receptors, two receptor subtypes not associated with the PI cycle, failed to elicit these membrane responses and instead resulted in a slow hyperpolarization.

These results indicate that neurotransmitter receptors which share the ability to increase the turnover of inositol phospholipids also converge upon a discrete set of membrane mechanisms to exert their actions. While these studies cannot resolve whether such convergence occurs at the level of the inositol phospholipid cascade, the similarity of electrophysiological actions of the neurotransmitter receptors examined suggest that the convergent regulation of cellular membrane properties might be a widespread phenomenon in central neurons. Supported by the PMA foundation and USPHS grant MH43985.

ELECTROPHYSIOLOGICAL EVIDENCE OF PROTEIN KINASE C (PKC) INVOLVEMENT IN EXCITATORY AMINO ACID RESPONSES. A. Baskys, N. K. Bernstein*, A. J. Mendonca*, N. W. Milgram and P. L. Carlen. Playfair Neurosci. Unit, Toronto Western Hosp., Addiction Res. Foundation, Div. of Life Sci. and Dept. of Physiology, Univ. Toronto, Toronto, Ont. M5T 2S8, Canada.

Excitatory amino acid (EAA) receptors are known to interact with the phosphoinositol second messenger system (Sladeczek F. et al., *Nature*, 317:717, 1985). To examine the role of this system in EAA-mediated responses, we perfused N-methyl-D-aspartate (NMDA) and quisqualate (Quis) at submicromolar concentrations (100-750 nM) on dentate granule neurons in hippocampal slices taken from 4-6 mos. old Fischer 344 rats. Both NMDA and Quis reduced the Ca^{2+}-dependent K^+ current (I_{ahp}) with respective IC_{50}s of 500 and 100 nM. NMDA but not Quis responses were blocked by the NMDA receptor blocker APV (50 uM). TTX did not block either response. Tetanic suprathreshold stimulation of the perforant pathway (400 Hz, eight 20 ms trains, 50-100 uA) reduced the I_{ahp}. This effect could be blocked by APV. The PKC inhibitor, isoquinolinesulphonyl - 2 - methyl - piperazine dihydrochloride (H-7, Sigma, 10 uM), abolished the NMDA- or Quis-induced suppression of the I_{ahp} suggesting that this reduction is mediated by a mechanism involving PKC. We further tested the effects of H-7 on the spatial learning behaviour of Long-Evans rats in the Morris water maze, showing that aquisition was not affected in the H-7 - treated rats. However, retention was better in animals which did not receive H-7. Supported by OMHF, MRC and NSERC.

LOCAL CIRCUIT EPSPS MEDIATED BY EXCITATORY AMINO ACIDS IN RAT NEOCORTEX. Alex M. Thomson *. Dept. Physiology Royal Free Hospital School of Medicine, Rowland Hill St., London NW3 2PF, UK (SPON: Brain Research Association)

Previous studies employing paired recordings and spike triggered averaging, in neocortical slices, indicated that excitatory postsynaptic potentials (epsps) evoked in layer II/III neurones by action potentials in layer III/IV cells were mediated by both NMDA (N-methyl-D-aspartate) and non-NMDA receptors, since only the later component was blocked by NMDA antagonists, while the entire epsp was reduced by broad spectrum excitatory amino acid (EAA) antagonists. CNQX (6-cyano-7-nitroquinoxaline-2,3-dione), which blocks non-NMDA EAA receptors and the NMDA-facilitating glycine receptor, reduced the entire epsp in the absence of added glycine, but more selectively blocked the early epsp component when glycine was applied. Responses to glutamate which are mediated predominantly by non-NMDA receptors under control conditions, were enhanced by added glycine. The enhanced response was blocked by NMDA antagonists and the naturally occurring glycine antagonist kynurenate. These results indicate that a single EAA transmitter can act at two receptor types on the post-synaptic cell and that the degree to which each receptor is activated depends on the endogenous levels of modulators such as glycine and kynurenate.

QUISQUALATE AND CARBACHOL: STIMULATION OF HIPPOCAMPAL CELL FIRING AND PHOSPHOINOSITIDE HYDROLYSIS. N.J. Pontzer and F.T. Crews. Dept. of Pharmacology, Univ. of Florida, Box J-267, Gainesville, FL 32610.

The relationship between agonist stimulated phosphoinositide (PI) hydrolysis and neuronal excitation in the CNS is not yet known. We have thus characterized quisqualate and carbachol stimulated PI hydrolysis in hippocampal slices from the rat. Lithium, which disrupts the phosphatidylinositol cycle, was used to further characterize the contribution of phosphoinositide metabolism to electrophysiological responses. Drug treatments were applied in artificial cerebral spinal fluid (ACSF) at 32°C, and firing rates from area CA1 were obtained 20-30 min after exposure when stable responses were usually obtained. For biochemical experiments, similar slices were labelled with [^{3}H]-inositol, and after washing out unincorporated label, stimulated in ACSF with agonist for 60 min at 32° C in the presence of 8 mM lithium. Both quisqualate and carbachol stimulated neuronal firing in a biphasic manner. Quisqualate had an EC_{50} of 3-4 μm for the stimulation of firing and above 10 μm responses rapidly desensitized. Carbachol stimulated firing with an EC_{50} of 1.4 μM and above 5 μM responses desensitized. Quisqualate stimulated PI hydrolysis with an EC_{50} of ≈2 μm and a maximum release of ≈10 % of total incorporated [^{3}H]-inositol. Carbachol stimulated PI hydrolysis was best fit (non-linear fit to 1 and 2 site models) by a two-site concentration-response curve with EC_{50}'s of 1.4 and 119 μm and a maximal response of 20.5%. These data demonstrated a possible relationship between PI hydrolysis and neuronal firing. Lithium (0.3-8 mM) reversed carbachol induced desensitization while having no effect on carbachol stimulated firing rate. In contrast, 2-8 mM lithium reduced quisqualate stimulated firing in a concentration-dependent manner. Our results are consistent with a model in which the PI second messenger system mediates quisqualate stimulated neuronal firing and carbachol mediated desensitization. Carbachol stimulated cell firing is caused by a non-PI mechanism, but results in PI hydrolysis, perhaps by calcium influx.

ANTIDEPRESSANTS MAY DIRECTLY AFFECT GTP BINDING SITES IN VITRO. H.Yamamoto*, M.Mikuni, A.Kagaya*, Y.Kuroda* and K.Takahashi* (SPON:T.Higuchi) Div. of Mental Disorder Res., National Institute of Neuroscience, NCNP, Kodaira, Tokyo 187, Japan.

Antidepressants(AD) in the CNS exhibit a variety of properties including amine uptake inhibition and the ability to induce β-down regulation. These observations may be insufficient to explain the therapeutic action of AD lacking the above properties. In an attempt to reveal the common profile of the AD, we studied the effects of AD on GTP binding sites of rat cortex clude membranes in vitro. In the presence of AD(final conc.300uM), in vitro GTP binding was shown to be transformed to a high Kd,high B_{max} state, but not in the presence of neuroleptic or anxiolytic agents. Ribosylation catalyzed by toxins affected selectively to the affinity of basal GTP binding with no effect on basal GTP binding capacity. A diminished increase in Kd value induced by AD was obtained following ribosylation of Gs, Gi or Go. Similarly the activity of GTPase with AD were inhibited in a dose-dependent manner. Inhibition of basal GTPase activity by AD probably reflected high Kd state of GTP binding sites sensitive to toxins. Our results indicate that AD may directly affect GTP binding sites, which can be G proteins. In view of the key role in the mood disorder and its therapeutic drugs, such direct interaction may represent an important mechanism.

SECOND MESSENGER MEDIATION OF SOMATOSTATIN (SS) ELECTROPHYSIOLOGICAL EFFECTS IN CA1 PYRAMIDAL NEURONS IN VITRO. P. Schweitzer*, S. Moore*, S. Madamba* and G.R. Siggins. Research Institute of Scripps Clinic, La Jolla, CA.

We previously found that SS augments the M-current (I_M), a voltage-dependent K^+ current blocked by muscarinic agonists, in hippocampal pyramidal neurons (HPNs) (Moore et al, Science 239:278, 1988). Several reports suggest that SS and muscarinic effects are mediated by second messengers such as G-proteins (see Mihara et al. J.Physiol. 390:335, 1987) or inositol triphosphate (Dutar and Nicoll, J. Neurosci, 8:4214, 1988). To test second messenger involvement in SS effects on I_M, we used single electrode voltage-clamp and computer averaging to measure membrane currents in rat hippocampal slices. In HPNs held at rest, SS superfusion (1 μM) often elicited a small outward current that was blocked by pertussis toxin (PTX) pretreatment in 4 of 6 cells. However, PTX did not affect the SS-induced increase in I_M at -40 mV holding potentials. The SS-induced I_M increase was blocked by the phospholipase A2 (PLA2) inhibitor quinacrine (5-8 μM; 10 of 10 cells) and by the cycloxygenase inhibitor indomethacin (10 μM; 4 of 4 cells), usually without recovery. However, neither PGE_2 nor $PGF_{2\alpha}$ altered I_M. These results suggest that the SS outward current at rest, but not SS I_M augmentation, is mediated by a PTX-sensitive G-protein. The SS-evoked I_M effect may involve some component of the PLA2 system, probably not PGE_2 or $PGF_{2\alpha}$. Supported by MH-44346, AA-06420, and AA-07456.

SOMATOSTATIN HYPERPOLARIZES NEURONS IN RAT DORSOLATERAL SEPTAL NUCLEUS BY A PERTUSSIS TOXIN-RESISTANT MECHANISM. M. J. Twery, L. A. Wong, and J. P. Gallagher. Dept. of Pharmacology and Toxicology, University of Texas Medical Branch, Galveston, TX 77550.

Somatostatin (SS) has been reported to have neuroendocrine and neurotransmitter-like actions which involve a guanine nucleotide regulatory (G-) protein sensitive to inactivation by pertussis toxin (PTX). The present study investigated whether a similar G-protein mediated the hyperpolarizing effects of SS on DLSN neurons using a submerged brain slice preparation and intracellular recording techniques. Rats (n=9) were administered PTX intracerebroventricularly (2.5 μg/5 μl) 2-5 days prior to testing. In tissue obtained from PTX treated rats, SS superfused (0.01-1 μM) or ejected from micropipettes (50-100 μM) produced membrane hyperpolarization (2-17 mV) and decreased the membrane resistance (15-40%) of DLSN neurons (n=15). Hyperpolarizing effects of SS persisted in the presence of tetrodotoxin. Current-voltage relations of the SS-induced, PTX-resistant, hyperpolarization indicated a reversal potential (-96.8 ± 4.2 mV, N=3) close to the potassium equilibrium potential. Membrane hyperpolarizations produced by SS in DLSN neurons from PTX treated tissue were similar to those recorded in tissue obtained from untreated rats. Potassium-mediated, hyperpolarizing responses to the selective $GABA_B$ agonist, baclofen, however, were selectively blocked by the PTX treatment used in the present study. Thus, direct hyperpolarizing effects of SS on postsynaptic DLSN neurons do not appear to involve a G-protein sensitive to inactivation by PTX. A PTX sensitive receptor transduction mechanism(s) however does mediate the actions of baclofen in these cells. (Research supported by USPHS MH-39162 to J.P.G.).

NICOTINIC RECEPTOR-MEDIATED INHIBITION OF RAT DORSOLATERAL SEPTAL NUCLEUS (DLSN) NEURONS IS CALCIUM-DEPENDENT. Linda A. Wong and Joel P. Gallagher. Dept. of Pharmacology and Toxicology, University of Texas Medical Branch at Galveston, Texas 77550.

Our previous studies using in vitro intracellular recording techniques revealed that nicotinic agonists such as nicotine, dimethylphenylpiperazinium (DMPP) and acetylcholine (in the presence of atropine) hyperpolarized postsynaptic DLSN neurons through an increase in a potassium conductance. To further characterize the K^+ conductance underlying this nicotinic-induced inhibition, brain slices were treated with media containing one of various classes of K^+ channel blockers, viz., Cs^+, 4-AP, Ba^{2+}, TEA, and apamin. Our preliminary data indicate that the agonist-induced response can be blocked by Ba^{2+} (2mM), TEA (20mM) and apamin (10μM). Since all three agents are known to block Ca-dependent K^+ channels in other neuronal preparations, it is likely that nicotinic agonists activate a Ca^{2+}-dependent K^+ conductance in DLSN neurons. Since this response persisted in media containing no added calcium and 6mM Mg^{2+}, it is possible that an intracellular calcium source is implicated. The ability to block the nicotinic receptor-mediated hyperpolarization via intracellular injection of EGTA or superfusion of divalent calcium channel antagonists, Ni^{2+}(400μM) or Cd^{2+}(200μM), lend further evidence implicating the role of calcium in the agonist-induced response. In summary, our present findings suggest that nicotinic agonists mobilize intracellular calcium which in turn activates a potassium channel. (Research supported by the National Tobacco Council, Inc.)

THE MUSCARINIC DEPOLARIZATION PRESENT IN RAT CORTEX IS POTENTIATED BY CELL STIMULATION. R.Andrade and R.C. Araneda. Dept of Pharmacology, St. Louis Univ. School of Med., St. Louis, MO 63104.

Functional studies in vivo have shown that cholinergic stimulation results in a marked facilitation of excitatory stimuli in mammalian cortex. In an attempt to better understand the cellular mechanisms which underlie this facilitation we have examined the cellular effects of cholinergic agonists in rat prefrontal cortex using intracellular recording techniques in in vitro rat brain slices.

Bath administration of carbachol (.3μM-30μM) was found to elicit a modest dose dependent depolarization which generally failed to directly excite cells in this region. Surprisingly however, when administration of this agonist was paired to low frequency stimulation, either brief depolarizing current pulses or evoked synaptic potentials, the ability of carbachol to depolarize these cells was found to be greatly potentiated. We have used current and single electrode voltage clamp to determine the membrane mechanisms underlying this potentiation. In these cells, in addition to its well establish effects on calcium and voltage activated potassium currents, carbachol induced the appearance of a slow calcium-dependent inward aftercurrent following a burst of spikes. This aftercurrent exhibited a slow decay lasting several seconds which allowed for its cumulative activation by low frequency stimulation. This resulted in an activity-dependent depolarization which could add to that directly elicited by carbachol. Low frequency stimulation failed to potentiate depolarizations elicited by current injection or bath applied glutamate suggesting that this potentiation is not simply an effect secondary to the carbachol induced depolarization. Since both atropine (1 μM) and pirenzepine (100 nM) both reduced or blocked the inward aftercurrent, this effect appears to be mediated by muscarinic cholinergic receptors of the M1 subtype.

These results suggest a novel mechanism by which the association of brief excitatory stimuli to cholinergic stimulation can lead to increased cell excitability. Supported by the PMA Foundation and USPHS grant MH43985.

M-CURRENTS IN PATCH-CLAMPED FROG PARASYMPATHETIC GANGLION NEURONES: EFFECTS OF MUSCARINE AND ADRENALINE. A.A. Selyanko*, J.A. Zidichouski and P.A. Smith (SPON: D.P.J. Boisvert). Bogomoletz Institute of Physiology, Kiev, U.S.S.R. and Dept. of Pharmacol., University of Alberta, Edmonton, Canada.

Whole-cell patch-clamp recording was used to study neurones which were enzymatically dissociated from Rana pipiens intra-atrial parasympathetic ganglia. Although muscarine produces inward current in sympathetic ganglion B-cells by depressing a slow non-inactivating K current (I(M)), this current is usually considered to be absent from parasympathetic ganglion neurones. Contrary to this, we found that under the conditions of our experiments, a Ba sensitive I(M) could be detected in frog cardiac ganglion neurones. This current had similar kinetics, magnitude and voltage-dependence to the I(M) recorded in sympathetic C-neurones and was clearly unaffected by agonists when ATP or cyclic AMP was included in the patch-pipette. Small inward currents were produced by 10μM muscarine or 10-100μM adrenaline in the absence of intracellular nucleotides. With intracellular cyclic AMP, both agonists produced (outward) K currents. Unlike the currents produced in sympathetic C-neurones, these currents failed to exhibit inward rectification. These results demonstrate the possible importance of phosphorylation and/or dephosphorylation in the production of agonist responses. Supported by MRC & AHFMR (Canada).

215.18

M-CURRENT POTENTIATION AND EFFECTS OF ADRENOCEPTOR AGONISTS ON FROG SYMPATHETIC NEURONES. P.A. Smith, H. Chen*, J.A. Zidichouski and A.A. Selyanko*. Dept. of Pharmacology, University of Alberta, Edmonton, Canada & Bogomoletz Institute of Physiology, Kiev, U.S.S.R.

When B-cells from Rana pipiens paravertebral sympathetic ganglia are studied with the whole-cell patch-clamp technique, muscarine always produces inward current as a result of M-current (I(M)) suppression (Selyanko et al., Soc. Neurosci. Abs. 14, 280, 1988). In about 40% of the B-cells, adrenaline produced inward current by suppressing I(M) whereas in about 9% of the cells an outward current occurred as a result of I(M) potentiation. Unpublished data using extracellular recording and precedents from other literature led us to suspect that I(M) inhibition may result from alpha-1-adrenoceptor stimulation whereas the potentiation might be mediated via a beta-adrenoceptor. Isoprenaline (10-25μM) produced a small outward current in 9/26 B-cells which appeard to involve I(M) potentiation yet produced inward current in 7 other cells. Phenylephrine (10-25μM) produced inward current in 6/11 B-cells and outward current in 1 cell. Although the predominant effect of adrenoceptor agonists seems to be I(M) inhibition, the results show that I(M) can occasionally be potentiated in neurones as it can in smooth muscle cells (Sims et al., Science, 239:190, 1988). However, there is only weak correlation between adrenoceptor subtype and type of response observed. Supported by MRC and AHFMR.

EFFECTS OF NPY ON B- AND C-CELLS IN FROG SYMPATHETIC GANGLIA. J.A. Zidichouski, H. Chen* and P.A. Smith. Dept. of Pharmacology, Univ. of Alberta, Edmonton, Alberta, Canada.

The whole-cell patch-clamp technique was used to study neurons isolated from Rana pipiens sympathetic ganglia. These ganglia contain two cell types which are identified on the basis of their response to muscarine; B-cells display an inward current (due to I(M) suppression) and C-cells exhibit an inwardly rectifying K^+ current (Selyanko et al., Soc. Neurosci. Abs. 14, 946, 1988). NPY immunoreactivity has been reported in C-cells but not in B-cells (Horn et al, J. Neurosc. 1987, 7, 1717). NPY has been shown to reduce Ca^{++} currents in C cells but not in B-cells (Schofield & Ikeda. Eur. J Phamacol. 1988, 151, 131). We futher examined the effects of NPY on both cell types to test whether it has other actions which are cell selective. In C-cells, 300nM NPY induced an outward current which inwardly rectified, reversed at E(K) and appeared similar to that induced by muscarine and adrenaline. However, in B-cells we observed two distinct effects on I(M). In 5 of 8 B cells a decrease in I(M) was observed. In the remaining 3 cells a small increase in I(M) was observed. Whilst the effect of NPY on C-cells may relate to the presence of autoreceptors, the significance of its effects on B-cells remains to be evaluated. I(M) is known to be modulated by a variety of peptides so that the effects of NPY may reflect a lack of absolute receptor specificity. Supported by MRC and AHFMR. We thank W.F. Colmers for the gift of NPY.

INTRACELLULAR DEMONSTRATION OF A NOVEL SLOW EPSP IN THE SYMPATHETIC B NEURONS OF THE FROG. Parviz Yavari* (SPON: T. E. Frumkes). Dept. Physiol. Cell Biophys., CPS of Columbia U., New York, NY 10032.

Last year at this meeting I presented evidence for the occurrence of a non-cholinergic slow EPSP in the bullfrog 9th and 10th paravertebral sympathetic ganglia recorded by the sucrose-gap technique. Here I describe intracellular experiments on the B neurons of the frog sympathetic ganglia demonstrating a cellular homolog for this EPSP. Recordings were made in vitro from 113 B cells in ganglia 9/10 of the frog (38 bullfrogs, 7 Rana pipiens). Tetanic stimulation of the sympathetic chain just below ganglion 6 (0.2-2V, 0.5 ms, 5-100 Hz for 1-2 sec) elicited a slow EPSP in 74 of 113 cells. In 55 cells the cholinergic nature of the slow EPSP was tested by determining the effect of high doses of atropine (10-100 μM) and d-tubocurarine (100 μM). In only 34 of these cells was a total blockade of the slow EPSP achieved. In the remaining 21 cells, the slow EPSP remained partially resistant to these antagonists indicting the non-cholinergic nature of these responses (amplitude 4.6 ± 0.7 mV; duration 3 ± 0.3 min, M ± SEM, n=21). The majority of these EPSPs were also resistant to pressure application of an LHRH antagonist (Jan & Jan, J. Physiol. 327:219, 1982). The novel slow EPSP could be further subdivided into (i) a very long latency response (latencies of 10-30 sec; M± SEM = 18 ± 2 sec, n= 8) with a slow rise to peak, and (ii) a shorter latency response (3 -6 sec) with a faster rise to peak. The novel EPSP(s) described here may reflect activation of preganglionic sympathetic B fibers containing CGRP (Horn & Stofer, Neurosci. Abs, 13:297, 1987) or sensory fibers containing SP/CGRP (Stofer & Horn, Neurosci. Abs. 14:355, 1988), both systems having been shown to make synaptic contact with B cells in frog ganglia.

216.1

EPSPs EVOKED BY VENTRAL ROOT AFFERENTS IN RAT MOTONEURONS: INVOLVEMENT OF NMDA AND NON-NMDA RECEPTORS. E. Shen*, M. Y. Wang* and N. J. Dun (SPON: D.D.Christ). Dept. of Pharmacol. Loyola Univ. Med. Ctr., Maywood, Il 60153

Intracellular recordings were made from antidromically identified motoneurons (MNs) in transverse spinal cord slices (500 μm) of neonatal (< 20 days) rats. Stimulation of ventral roots evoked an excitatory postsynaptic potential (EPSP) in over 30% of MNs tested. As the EPSPs were not abolished by dihydro-ß-erythrodine (1 μM) or d-tubocurarine (10 μM), the responses were not due to the activation of MNs by recurrent axon collaterals. Further, the EPSPs persisted in MNs when the dorsal half of the slice was transected from the ventral half. The EPSPs consisted of two components; an early EPSP of short latency (1.4 ± 0.4 ms) and/or a late EPSP whose latency (3 to 10 ms) showed some variability. The early and late EPSPs were reversibly antagonized by kynurenic acid. Further studies showed that the early EPSPs were abolished by the non-NMDA antagonist DNQX (0.5 -1 μM) and not affected by Mg-free solution. The late EPSPs were depressed by NMDA antagonists ketamine and APV (1-10 μM) and increased in Mg-free media. The results indicate that ventral root afferents make di-or poly-synaptic connections with the MNs which are confined within the ventral horn area and generate an EPSP mediated by an excitatory amino acid acting on NMDA and non-NMDA receptors. (Supported by NS24226)

216.2

PARTICIPATION OF NMDA AND NON-NMDA RECEPTORS IN THE SLOW EXCITATORY SYNAPTIC TRANSMISSION IN THE RAT SPINAL DORSAL HORN IN VITRO. M. Randic and G. Gerber* (SPON: N.A. O'CONNELL). Dept. of Vet. Physiol. and Pharmacol., Iowa State University, Ames, IA 50011, USA.

Using current-clamp and voltage-clamp techniques in spinal slices we have studied further the contribution of NMDA and non-NMDA receptors to the early and late components of the slow excitatory synaptic responses elicited in the rat (18-24 days) dorsal horn neurons by repetitive stimulation of dorsal roots (Kangrga et al., Neurosci. Abstr., 14:96, 1988). We distinguished early and late components of the slow excitatory synaptic currents (EPSCs) on the basis of their voltage-dependence and sensitivity to Mg^{2+}-ions and NMDA and non-NMDA receptors antagonists. In the presence of Mg^{2+}, the early component of the slow EPSC increased with membrane hyperpolarization with a linear I-V relationship, whereas the late component decreased. In a zero-Mg^{2+} medium, the early component was potentiated, but the late component was reduced or unaltered. SP-induced depolarization was also depressed in a zero-Mg^{2+} solution. Superfusion of slices with CNQX reduced (<25%) the early component of the slow synaptic response. This component was, however, more reduced (60%) by D-APV. In a zero-Mg^{2+} solution, or at membrane potentials positive to -55mV in 1mM Mg^{2+}, D-APV reduced or even abolished the early component. We propose that slow excitatory synaptic response has two components, an early transient component that requires activation of NMDA and non-NMDA receptors, and a late longer-lasting peptidergic component. Supported by NIH, NSF, and USDA.

216.3

FAST EXCITATORY SYNAPTIC TRANSMISSION IN THE RAT SPINAL DORSAL HORN IN VITRO IS MEDIATED BY NON-NMDA AND NMDA RECEPTORS. G. Gerber* and M. Randic, Dept. of Vet. Phys. and Pharmacol., Iowa State University, Ames, IA 50011, USA.

In the spinal cord 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX) selectively blocks responses to acidic amino acids acting at receptors of the non-NMDA type, whereas D-2-amino-5-phosphonovalerate (APV) is a selective NMDA-receptor antagonist. Using current-clamp and single electrode voltage-clamp techniques we found that in more than half of dorsal horn neurons superfusion of rat (18-23 days) spinal slices with CNQX ($5x10^{-6}$M in 1 mM Mg^{2+}-medium) completely and reversibly blocks fast excitatory synaptic responses evoked in dorsal horn neurons by stimulation of dorsal roots (2-6V for 0.02-0.2 ms). In the remaining cells, the synaptic responses were markedly reduced. Inward currents induced by α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) and quisqualate were reduced to a greater extent than those induced by kainate or NMDA. In 1 mM-Mg^{2+} medium, APV ($5x10^{-5}$-10^{-4}M) reduced the synaptic responses in most of examined cells but had little effect on their early rising phase. The effect of APV was more prominent in a zero-Mg^{2+} solution and at membrane potentials positive to rest. Under voltage-clamp, the excitatory postsynaptic currents also showed fast (CNQX-sensitive) and slow (APV-sensitive, Mg-sensitive) components, both of which had similar thresholds but differed in their latency and voltage-sensitivity. These results support the concept that both non-NMDA and NMDA receptor channels are simultaneously activated by transmitter released from stimulated primary afferents. Supported by NIH, NSF, and USDA.

INTRACELLULAR RECORDINGS FROM GUINEA PIG AUDITORY CORTICAL NEURONS MAINTAINED IN VITRO: ELECTROPHYSIOLOGICAL AND PHARMACOLOGICAL OBSERVATIONS. C.L. Cox, R. Metherate, N.M. Weinberger and J.H. Ashe Dept. of Psychology, Univ. of Calif., Riverside, CA 92521, Center for the Neurobiology of Learning and Memory, and Dept. of Psychobiology, Univ. of Calif., Irvine, CA 92717.

Intracellular recordings were obtained from 106 auditory cortical neurons (Vm= -65.5 ± 1.1 mV) in *in vitro* slices from guinea pig. Electrical stimulation to the underlying white matter or the pia elicited depolarizing or hyperpolarizing responses in 36 of 65 cells so tested. These responses varied as expected of synaptic potentials when the membrane potential was altered by intracellular injection of depolarizing or hyperpolarizing current. Most of these cells responded with an EPSP that could result in cell discharge when stimulation was of adequate strength. Several cells responded with an EPSP that was followed by an IPSP, and a few with only an IPSP.

Initial observations suggest that the quisqualate/kainate receptor antagonist, 6,7-dinitroquinoxaline-2,3-dione (DNQX) is capable of reducing and eventually blocking the EPSP. In 42 of 74 cells, the cholinergic agonists acetylcholine or methacholine produced a slow membrane depolarization that was usually accompanied by an increase in membrane resistance.

These findings set the stage for an intracellular analysis of the modulatory effects of ACh on auditory receptive fields that we have previously shown to occur in the auditory cortex *in vivo*.

PHENCYCLIDINE PRODUCES LONG-LASTING ELECTROPHYSIOLOGICAL CHANGES IN RAT STRIATAL NEURONS RECORDED IN VITRO. C.S. Bailey, S.G. Howard and M.S. Levine. MRRC, UCLA, CA 90024.

Effects of phencyclidine (PCP) on striatal neurons were examined using intracellular recordings in brain slices from 22 adult Sprague-Dawley rats. Baseline values were obtained for threshold currents that evoke excitatory postsynaptic potentials (EPSP) and action potentials (AP) when slices were bathed in Ringer's. Excitability in response to depolarizing current injection (EX) was also measured. Slices were then bathed with PCP (1, 10, 25, 50, 100 or 300 μM) and measurements were taken 15 min later. They were subsequently washed with Ringer's for up to 80 min. Measurements were taken at 15 min intervals during the wash. All concentrations of PCP produced increases in EPSP and AP threshold. These increases occurred more frequently with lower concentrations (1-25 μM). Recovery of both EPSP and AP threshold to baseline values occurred in <10% of the responding cells. EX increased in 76% of cells tested at 1-25 μM but in only 52% at 50-300 μM. Recovery of EX occurred in <20% of the cells tested. These findings indicate that PCP produced long-lasting decreases in synaptic transmission while increasing neuronal excitability. These effects may involve a mechanism common to the generation of both action potentials and excitatory postsynaptic potentials such as blockade of cation conductance. In addition, higher concentrations of PCP also produced more complex interactions, perhaps reflecting toxicity. Supported by USPHS Grants DA 3017 and HD 5958.

INTERACTION OF METAPHIT, AN ANALOG OF PHENCYCLIDINE, WITH THE RELEASE OF ^{3}H-DOPAMINE FROM RAT STRIATAL SLICES. I. Zimanyi*, A. Lajtha and M.E.A. Reith (SPON:I. Wajda). Center for Neurochemistry, N.S. Kline Institute, Ward's Island, New York, NY 10035

The effect of metaphit (MET), an isothiocyanate derivative of phencyclidine (PCP) was investigated on the release of ^{3}H-dopamine evoked by electrical (1 Hz, 60 shocks) stimulation (overflow), amphetamine (AMPH 0.1-10 uM), dopamine (DA 0.1-10 uM) or veratridine (VER 5 uM) from rat striatal slices. MET itself (10 and 25 uM) increased the basal release (outflow) of ^{3}H and decreased the overflow of ^{3}H at 25 uM concentration (S_2/S_1 was 1.0 and 0.4 in the absence and presence of MET, respectively). The AMPH and unlabeled (DA) induced outflow was inhibited by MET. The nomifensine (NOMI) induced outflow was further elevated additively by MET. The electrical stimulation evoked overflow of ^{3}H in the presence of AMPH and unlabeled DA was enhanced by MET, in the presence of NOMI MET additively enhanced the stimulation evoked release. The VER induced release was greatly decreased by MET. The above data shows the complexity of the effect of MET on the release of ^{3}H-DA: 1. it acts similarly to the DA uptake inhibitors on the outflow of ^{3}H-DA (additive effect with NOMI), 2. it inhibits the carrier mediated exchange of DA induced by AMPH or DA, 3. it inhibits the voltage-dependent sodium channels (VER induced release). This work was supported by an NIH grant DA 03025 and by a grant from BRSG.

IMMUNOHISTOCHEMICAL DISTRIBUTION OF *N*-ACETYL-ASPARTYLGLUTAMATE AND L-AP4-SENSITIVE SLOW SYNAPTIC TRANSMISSION IN TURTLE CEREBELLUM.
N.T. Slater, J.R. Moffett, L.J. Larson-Prior, and J.H. Neale. Dept. of Physiology, Northwestern University Medical School, Chicago, IL 60611 and Dept. of Biology, Georgetown University, Washington DC 20057 U.S.A.

A novel, slow excitatory postsynaptic potential (sEPSP) has recently been demonstrated to follow repetitive activation of parallel fibers (PFs) in the intact turtle cerebellum *in vitro* [1]. This PF-sEPSP is selectively blocked by L-2-amino-4-phosphonobutyrate (L-AP4, 20-100 μM), but not by L-serine-*O*-phosphate (200 μM), suggesting that the receptor mediating the PF-sEPSP differs from a "classical" AP4 receptor. Because L-AP4 also blocks EPSPs in mammalian piriform cortex which have been proposed to be mediated by the dipeptide *N*-acetylaspartylglutamate (NAAG), the potential role of NAAG in mediating the PF-sEPSP in turtle cerebellum was explored. We have used affinity-purified NAAG anti-sera to determine the histochemical localization of NAAG in turtle cerebellum. Purkinje cell somata and proximal dendrites, as well as somata of the deep cerebellar nuclei, showed dense NAAG-like immunoreactivity (NAAG-LI). The granular layer also exhibited heavy NAAG-LI. No distinct fibers were immunoreactive, either in the cerebellar peduncle, the granular layer, or the molecular layer. Although the molecular layer displayed NAAG-LI above background levels, label could not be localized to either fibers or terminals of the PFs. No label was seen in interneurons of either the granular or molecular layers. These data therefore do not support the conclusion that NAAG mediates the PF-sEPSP. The observation that PF-sEPSP is also blocked by the excitatory amino acid antagonists kynurenate (1-2 mM) and CNQX (10 μM)[1], suggests the following hypothesis: the PF-sEPSP is mediated via activation of postsynaptic non-NMDA receptors, and is selectively inhibited by presynaptic L-AP4 receptor activation. Excitatory Amino Acid (eaa) Antagonists Block Kindling Induced Synaptic Excitability in the Basolateral Amygdala (bla).
A.C. Anderson, E. Asprodini* and P. Shinnick-Gallagher. **Dept. of Pharmacology, Univ. of Texas Med. Branch, Galveston Tx 77550**

Synaptic transmission in amygdaloid kindled rats was examined using dl-2-amino-5-phosphonovaleric acid (dl-apv, 50uM), 7cl-kynurenic acid (7clkyn, 10uM), and 6-cyano-7-nitroquinoxaline-2,3-dione (cnqx, 5uM). Control intracellular recordings revealed an excitatory post synaptic potential (epsp) with a superimposed spike, a fast inhibitory post synaptic potential (f-ipsp) and a late hyperpolarizing potential in 50% of the cells. In some control neurons a burst could be evoked by suprathreshold stimuli. Kindled cells showed epileptiform bursting following threshold stimuli in 83% or an epsp with single spikes in 17% of the cells but no ipsp's were recorded. Dl-apv or 7clkyn blocked spikes and burst activity both evoked and spontaneous in 100% of control and 63% and 57% of kindled cells respectively. Resulting in a small residual epsp (75%) or completely blocked transmission (25%). These drugs had no effect on 12% and 25% of kindled cells respectively. The f-ipsp present in two control cells was reversibly decreased by dl-apv. Cnqx blocked burst activity and epsp in 100% of all neurons. The data suggest that bursting or spiking activity in bla neurons is mediated by the n-methyl-d-aspartate receptor, but that activation of the quisqualate receptor is also of primary importance. CATIONS ALTER THE ACTION OF CIS-2,3-PDA AS AN ANTAGONIST OF SPONTANEOUS ACTIVITY OF AFFERENT FIBERS IN THE LATERAL LINE OF XENOPUS LAEVIS.
S.C. Bledsoe, Jr. and S.J. Allen*. Kresge Hearing Research Institute, Univ. of Michigan Medical School, Ann Arbor, MI 48109.

This study evaluated the effects of different cations on the action of cis-2,3-piperidine dicarboxylic acid (cis-PDA), a glutamate receptor antagonist, on spontaneous activity at the hair cell/afferent nerve synapse in the lateral line of Xenopus laevis.

The in vitro methods for isolating and recording afferent nerve responses from a single lateral line organ and applying drugs dissolved in frog Ringer solution to the serosal surface of the skin were as previously described (Bledsoe and Bobbin, Neurosci. Lett. 32:315, 1982). In each experiment cis-PDA from 0.0625 to 5.0 mM was tested on spontaneous activity in standard Ringer solution and then again in Ringer solution which contained an additional 0.5 mM calcium or other cation.

Increasing concentrations of cis-PDA up to 2.0 mM progressively decreased the rate of spontaneous activity in a dose-dependent manner. Concentrations in excess of 2.0 mM, however, reversed this trend, perhaps due to agonist-like actions of the cis-PDA. An additional 0.5 mM calcium added to the Ringer solution enhanced the suppressive effects of cis-PDA, as did 0.5 mM manganese. Barium and strontium, which should substitute for calcium as charge carriers, actually partially blocked the effects of cis-PDA. Increasing the potassium concentration from 2.0 mM to 2.5 mM had a smaller, but similar effect. Cobalt (0.5 mM) completely blocked the decrease in spontaneous activity normally seen with cis-PDA. Magnesium (0.5mM) had no effect on the action of cis-PDA on spontaneous activity.

Although other interpretations are possible, these results are best explained by actions of the cations on pre- and post-synaptic elements with a predominant effect of charge screening by calcium on the post-synaptic nerve.

ACTIONS OF BACLOFEN AND KAINATE ON MONOSYNAPTIC GABA IPSPS IN RAT HIPPOCAMPAL SLICES
C.H.Davies* and G.L.Collingridge*. (SPON: Brain Research Association) Department of Pharmacology, University of Bristol, Bristol BS8 1TD, U.K.

In the presence of 40 μM D-2-amino-5-phosphonovalerate (APV) and 20 μM 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX) which block synaptic excitation, stimulation in stratum radiatum evokes a pure monosynaptic biphasic IPSP in nearby CA1 neurones. These IPSPs exhibit paired-pulse fatigue that may be due to neurotransmitter acting on presynaptic receptors. We have looked for some possible candidates.

(-)Baclofen (0.25-5 μM) depressed this IPSP (and IPSC) by 50-100 % and hyperpolarised cells, whereas (+)baclofen was inactive. Phaclofen (1 mM) reversed these effects of (-)baclofen and also depressed the late phase of the IPSP.

Kainate (1-10 μM) depressed both the early and late phases of the IPSP in parallel and tended to depolarise cells. In contrast α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA; 10 μM) depolarised cells but did not depress the IPSP.

The results can be explained by these drugs acting directly on presynaptic GABA terminals to inhibit GABA release, in addition to having postsynaptic actions.

216.11

BACLOFEN BINDING TO $GABA_b$ RECEPTORS CAN BE STIMULATED OR DISPLACED BY CALCIUM CHANNEL LIGANDS.
M.I. Al-Dahan* and R.H. Thalmann, Baylor College of Medicine, Houston, TX 77030.

Synaptic plasma membrane from adult male rat cerebrum was prepared and [^{3}H]-baclofen binding was assayed by filtration as described earlier (Al-Dahan and Thalmann, J. Neurochem. 1989, 52, p.313) with the major exception that saponin (0.5%) rather than Triton was used to permeabilize the membranes. The dihydropyridine (DHP) calcium channel antagonist nifedipine displaced up to 75% of the [^{3}H]-baclofen binding (IC50=16±5nM) while the DHP calcium channel agonist Bay K8644 stimulated binding up to 30% (EC50=115±48nM). The DHP agonist +202-791 also stimulated binding up to 30% (EC50=7.6±2.5nM) while its enantiomer had no consistent effect. These compounds did not compete for the $GABA_b$ site, since a Scatchard analysis revealed that nifedipine (10 nM) primarily affected $GABA_b$ receptor density rather than affinity (control Bmax = 935±48fmol/mg protein; Kd=54±8nM; while in the presence of 10nM nifedipine, Bmax was reduced to 638±49mg/k and Kd=49±7nM). The calcium channel antagonist D600 also displaced up to 30% baclofen binding (IC50=27±17nM), while the antagonist diltiazem stimulated binding up to 35% (EC50=75nM). Although these results could reflect the forward coupling of $GABA_b$ receptors with calcium channels in brain, they do not rule out other, possibly more direct interactions between $GABA_b$ receptors and calcium channel ligand binding sites. Supported by NINCDS grant NS21713.

EFFECTS OF BACLOFEN AND BICUCULLINE ON DENTATE GRANULE CELL EXCITABILITY SUGGEST A PRESYNAPTIC LOCUS FOR GABAb RECEPTORS.
S.C. Steffensen*, Y.M. Kim*, and S.J. Henriksen. (SPON: N. Ling) Department of Neuropharmacology, Research Institute of Scripps Clinic, La Jolla, CA 92037.

In vitro studies have suggested both pre- and post-synaptic actions for GABA receptors in the hippocampus (N. Harrison et al, Neurosci. Letts, 85(1988) 105-109). The purpose of our studies was to further characterize GABAergic mechanisms influencing dentate granule cell excitability in the anesthetized rat. Field potentials were elicited by perforant pathway stimulation and population spike (PS) amplitudes of 5-8mV (half-maximal stimulation) were obtained at recording depths where simultaneous granule cell single-unit recordings were encountered. Control curves of test vs. conditioning PS amplitudes using a paired-pulse (PP) paradigm revealed a triphasic function with absolute inhibition occurring between 10-40ms, potentiation (e.g. 220% of control at 80ms) between 40-160ms and partial inhibition between 160-560ms (e.g. 60% of control at 560ms). Microiontophoretically applied ±baclofen (0.1-1.0mM in saline, 50-200nA) had minimal effects on primary excitability (10% increase in test PS amplitude) but produced a dose-dependent antagonism of PP inhibition at both short and long interstimulus-intervals (ISIs). In fact, higher concentrations and/or ejection currents of baclofen *potentiated* PSs at short (10-40 ms) ISIs (eg 200% of control). These effects were competitively antagonized by concurrent microiontophoretic application of the putative GABAb antagonist, phaclofen (50-75mM in saline, 50-100nA). In contrast, microiontophoretic application of the the GABAa competitive antagonist bicuculline (0.7mM in saline, 50-100nA) produced an incomplete antagonism of PP inhibition at short ISIs and complete antagonism at long ISIs. Unlike baclofen, bicuculline produced a marked increase in primary excitability (up to 200% of control) and single-unit firing rate. Baclofen either slightly decreased or had no effect on firing rate. These results together with in-vitro studies suggest that baclofen, a GABAb agonist, produces this 'paradoxical' decrease in PP inhibition by actions on GABAb receptors located presynaptic to dentate granule cells. (Supported by AA07456 and KO2/DA00131 to S.J.H.)

Opioid peptides and GABA inhibit A-delta and C fiber-evoked epsps recorded from substantia gelatinosa neurons in an adult rat spinal cord slice.
M. Yoshimura and T. M. Jessell, Center for Neurobiology and Howard Hughes Medical Institute, Columbia University, New York, NY 10032

The actions of opioid peptides and GABA on A-delta and C fiber afferent evoked monosynaptic epsps have been analyzed by intracellular recording from substantia gelatinosa (s.g.) neurons in a transverse slice preparation of adult rat spinal cord.

Superfusion of slices with the mu opiate receptor agonist DAGO (100nM - 1 uM) hyperpolarized about 60 % of s.g. neurons that received A-delta and/or C fiber input and depressed afferent-evoked epsps by 40 - 100 %. The effect of DAGO was reversed by application of naloxone (100 nM). DAGO also suppressed A-delta and C fiber evoked epsps in s.g. neurons in which hyperpolarizing response to DAGO were not detected. The delta opiate receptor agonist DPDPE (100 nM - 1 uM) did not alter the membrane potential of s.g. neurons and did not suppress A-delta and C fiber epsps. The kappa receptor agonist dynorphine (1 uM) produced a small (~ 30 %) inhibition of afferent evoked epsps but did not affect the membrane potential of s.g. neurons.

GABA (1 - 2 mM) hyperpolarized 60 % of s.g. neurons and suppressed A-delta and C fiber evoked epsps in both GABA-sensitive and -insensitive neurons. The suppression of epsps in GABA-insensitive s.g. neurons was not reversed by the GABA-A receptor antagonist bicuculline (10 uM). The GABA-B receptor agonist baclofen (10 - 20 uM) hyperpolarized many s.g. neurons and suppressed afferent-evoked epsps. However, at lower concentrations (500 nM - 1 uM) baclofen suppressed epsps without affecting the membrane potential of s.g. neurons.

These results suggest that opioid peptides and GABA modify fine fiber-evoked input to some s.g. neurons, in part, by a direct post-synaptic action. However, our results are also consistent with a pre-synaptic inhibition of excitatory transmitter release from A-delta and C fiber afferents.

GADOLINIUM REDUCES NERVE-EVOKED, BUT NOT SPONTANEOUS RELEASE OF ACETYLCHOLINE (ACh) AT THE MOUSE NEUROMUSCULAR JUNCTION.
W.D. Atchison. Dept. Pharmacol./Toxicol., Michigan State Univ. E. Lansing, MI 48824.

The lanthanide gadolinium (Gd^{3+}) has been proposed to block a component of neuronal calcium currents preferentially. This component has been proposed by some to be the "N" component of I_{Ca}. A number of heavy metal polyvalent cations which are known to block neuronal Ca channels alter neurotransmitter release both at rest, and following nerve stimulation. Inasmuch as the type of Ca channel responsible for transmitter release from somatic motor axon terminals is unclear, it was of interest to determine whether Gd^{3+} would affect Ca-dependent release of ACh from motor axon terminals in response to nerve stimulation, or spontaneously. Mouse hemidiaphragms were cut to prevent contractions, and end-plate potentials (EPPs) and miniature end-plate potentials (MEPPs) were recorded. Gd^{3+} concentrations of 10-100 μM reduced the amplitude of nerve-evoked EPPs. At higher concentrations (50, 100 μm), Gd^{3+} ultimately blocked the EPP completely. At no concentration tested, did Gd^{3+} affect the frequency of occurrence of MEPPs. Thus, Gd^{3+} affects nerve-evoked, but not spontaneous release of ACh from mouse motor nerve terminals. In this regard, Gd^{3+} differs in its effects from several other heavy metal Ca channel blockers such as Pb^{2+}, La^{3+} and Hg^{2+}. (Supported by NIH grant ES03299.)

EFFECT OF ω-CONOTOXIN GVIA ON SYNAPTIC TRANSMISSION IN THE CA1 FIELD OF THE RAT HIPPOCAMPUS.
O. RASCOL*, P. DUTAR and Y. LAMOUR. *Physiopharmacologie du Système Nerveux, INSERM U 161, 2 rue d'Alésia, 75014 Paris, France.*

ω-Conotoxin GVIA (ω-CgTx),a peptide isolated from the venom of a marin mollusc, has been studied on CA1 pyramidal hippocampal neurons using intracellular recordings in the in vitro slice preparation. We observed that ω-CgTx applied in the superfusion medium (0.1-1μM) quickly (≃ 1min) and irreversibly blocked the EPSP and IPSPs elicited by stimulation of the Schaffer collaterals/commissural fibers (n=6). It also blocked the slow cholinergic EPSP induced by stimulation of the cholinergic afferents (n=3). These synaptic events being due to the postsynaptic action of neurotransmitters released from terminals, we studied the postsynaptic effects of GABAergic and cholinergic agents in the presence of ω-CgTx. These effects were unaffected by ω-CgTx. In addition, ω-CgTx had no effect on the membrane polarization or on the afterhyperpolarization which follows a train of spikes (n=9). These results suggest that ω-CgTx acts at a presynaptic level, blocking the synaptic transmission in the hippocampal slice. This effect probably results from the action of ω-CgTx on the N-type calcium channels which seem to be presynapticaly located in this structure.

FREQUENCY-DEPENDENT INHIBITION BY ω-CONOTOXIN GVIA (ω-CT) OF NEUROGENIC ENHANCEMENT OF THE ELECTRICALLY PACED GUINEA PIG LEFT ATRIA (GPLA).
R.A. Keith, D. LaMonte and A.I. Salama. Dept. of Pharmacology, ICI Pharmaceuticals Group, ICI Americas Inc., Wilmington, DE 19897.

A 5 sec field stimulation (FS, 1 mSec, 25 V, 0.5 - 40 Hz) of the electrically paced (punctate electrode, 2 Hz, 4 mSec, 4V) GPLA caused a delayed enhancement of the contractile response. Tetrodotoxin (3×10^{-7} M) or propranolol (3×10^{-6} M) inhibited FS enhancement by greater than 90% suggesting adrenergic neuronal mediation. ω-CT, an inhibitor of neuronal N- and L-type voltage-sensitive calcium channels (VSCC) has been shown to inhibit neurotransmitter release. ω-CT caused a concentration-dependent and irreversible inhibition of FS enhancement but had no effect on the paced response. The inhibition of FS enhancement by ω-CT was more pronounced at lower frequencies, e.g., 10^{-8} M ω-CT inhibited 4 Hz by 97 $\pm$ 2% and 40 Hz by 16 $\pm$ 2% (n=8). The frequency-dependent inhibition by ω-CT suggests that ω-CT sensitive (low frequencies) and ω-CT insensitive (high frequencies) VSCC mediate neurotransmitter release. Neomycin, an aminoglycoside antibiotic that displaces [^{125}I]ω-CT, reversibly inhibited both the paced response and the FS enhancement. Pre-exposure of GPLA to 10^{-2} M neomycin prevented the irreversible inhibition of FS enhancement caused by 10^{-8}M ω-CT, suggesting a common neuronal site of interaction for ω-CT and neomycin.

216.18

DEPOLARIZATION-DEPENDENT ACTIONS OF DIHYDROPYRIDINE CALCIUM CHANNEL LIGANDS IN THE IN VITRO RAT HIPPOCAMPUS.
M.H. O'Regan*, J.D. Kocsis, N.P. Poolos, and S.G. Waxman. Dept. of Neurology, Yale Univ. Sch. of Med. and VA Med. Ctr., West Haven, CT. 06516. Extracellular field potential analysis was utilized to examine the central nervous system (CNS) effects of dihydropyridines (DHP). In the absence of light, application of the DHP nimodipine or nifedipine (10-40μM), putative Ca^{++} channel antagonists, increased the excitability of CA_1 pyramidal cells as evidenced by an increase in the magnitude of the population EPSP and the appearance of multiple population spikes. Both actions were dependent upon membrane depolarization, achieved via elevated K^+(5 mM), low frequency (20 Hz stimulus trains, or high intensity (30-40 V) stimulation of the Schaffer collaterals. The effects of nifedipine were abolished upon exposure to high intensity light, while the effects of nimodipine were not. Application of the agonist DHP, Bay K 8644 (0.1-2 μM) in the dark, had similar excitant actions. Upon washout plus exposure to light, these effects were first abolished and then reversed, resulting in a persistent decrease in the EPSP although the postsynaptic membrane remained sensitive to glutamate. These results demonstrate that DHPs can directly alter synaptic transmission in the mammalian CNS, with implications for the neuroprotective activities of these agents.

216.19

FACILITATION OF HIPPOCAMPAL 5-HYDROXYTRYPTAMINE RELEASE BY L-TYPE VOLTAGE SENSITIVE CALCIUM CHANNEL AGONISTS: DEPENDENCY ON MAO INHIBITION.

T.J. Feuerstein*, K.I. Bär* and E. Neuschwander* (SPON: G. Campbell). Goedecke Research Institute and Neurologische Universitätsklinik, D-7800 Freiburg, F.R.G.

Bay K 8644, a dihydropyridine (DHP) agonist of L-type voltage-sensitive calcium channels (L-VSCC) has been reported to enhance 5-hydroxyptamine (5-HT) release from rat cortex slices (Middlemiss and Spedding, *Nature* 314: 94; 1985). This effect was observed in slices incubated and superfused with medium containing the monoamine oxidase (MAO) inhibitor pargyline. There is, however, other evidence suggesting that Bay K 8644 has no effect on neurotransmitter release (e.g., Dooley et al., *Eur. J. Pharmacol.* 148: 261, 1988). Since inhibition of MAO alters the balance between the cytoplasmic and vesicular transmitter pools, we investigated the effects of the DHP agonists Bay K 8644 and (+)-202-791 and of the DHP antagonist (-)-202-791 on 5-HT release evoked from rabbit hippocampal slices by K^+ (25 mM) in the presence and absence of pargyline (10 uM). The slices were pretreated, incubated with (^{3}H)-5-HT and superfused in medium with or without pargyline. They were stimulated twice and DHP ligands (1 uM) were added 15 min before the second stimulation. Bay K 8644 and (+)-202-791 significantly enhanced the evoked overflow of tritium only when pargyline was present. When MAO was not blocked, however, both DHP agonists were without effect on the evoked transmitter release. The L-VSCC antagonist, (-)202-791, either in the presence or in the absence of pargyline, did not affect the release of 5-HT.

These results indicate that the 5-HT-releasing actions of DHP agonists are critically dependent on MAO inhibition which provides a cytoplasmic 5-HT pool.

EXCITATORY AMINO ACIDS: RECEPTORS IV

217.1

USE OF (+)[^{3}H]-7-N$_3$-MK-801 FOR PHOTOAFFINITY LABELLING THE NMDA RECEPTOR. M.S. Sonders*, P. Barmettler†, J.F.W. Keana†* and E. Weber (SPON: M. Seger) Vollum Institute for Advanced Biomedical Research, Oregon Health Sciences University, Portland, OR 97201, and †Department of Chemistry, University of Oregon, Eugene, OR 97403

Relatively little is known about the structure of the NMDA receptor. In order to identify the constituent proteins of this ligand-gated ion channel we have synthesized a radioactive photoaffinity derivative of MK-801, a highly selective non-competitive NMDA antagonist which binds at the PCP site. This ligand, (+)[^{3}H]-7-N$_3$-MK-801, has a specific activity of 30 Ci/mmol, displays reversible binding characteristics and a pharmacological profile virtually identical to those of MK-801 itself (Keana et al., Soc. Neurosci. Abstr. 14:199.25, 1988). In guinea pig brain membranes (+)[^{3}H]-7-N$_3$-MK-801 binds to a single class of apparent sites with a K_D of 2.8 nM and a B_{max} of 1.2 pmol/mg protein. It also displays a binding maximum at pH 8 and a rank order of inhibitor potencies characteristic of the high affinity PCP binding site (MK-801> (-)MK-801>TCP>dexoxadrol>PCP>(-)cyclazocine >(+) cyclazocine≥(+)SKF 10,047> (-)SKF 10,047>D-ketamine>L-ketamine>levoxadrol).

Photoaffinity labelling was performed on crude guinea pig brain membranes in 5 mM Tris HCl buffer, pH 8, containing 0.1 mM PMSF, 1 mM EDTA and 50 µg/ml bacitracin. Membranes (0.2-0.4 mg/ml) were incubated in the dark for >4 hours with (+)[^{3}H]-7-N$_3$-MK-801 (<10 nM) in the absence or presence of 10 µM PCP and then rapidly filtered and washed on GF/C filter discs. The filters were then irradiated with long wave UV light, rewashed and the radioactivity was solubilized from them with 0.5% SDS. Samples were concentrated by either lyophilization or precipitation with ice-cold acetone and electrophoresed on SDS-polyacrylamide gels under reducing conditions. Fluorograms of stained gels indicate a single radioactive protein band which migrates with an apparent molecular mass of 115 kd. This band was absent from lanes of samples that had been incubated with PCP or that had not been irradiated.

HYBRID ARREST OF GABA AND NMDA RECEPTOR EXPRESSION IN XENOPUS OOCYTES INJECTED WITH RAT BRAIN mRNA. **S.J. Myers*, C.C. Joneckis*, R.A. Nicholas*, and R. Dingledine, (Spon. D.B. Hoch). Dept. of Pharmacology, University of North Carolina at Chapel Hill, Chapel Hill, NC 27599-7365.**

The ability of several oligodeoxynucleotides to block the translation of specific rat brain mRNAs was investigated in *Xenopus laevis* oocytes. Antisense oligonucleotides (30 mers) were mixed with whole rat brain poly A+ mRNA and injected into stage V oocytes (35 ng RNA and 6-26 ng oligo per cell). After 3 days oocytes were voltage clamped (-60 mV) and inward current responses to 100µM bath applications of γ-aminobutyric acid (GABA), kainate (KA), N-methyl-D-aspartic acid (NMDA), and carbachol were measured. Oocytes injected with mRNA alone evoked 16 ± 3, 54 ± 7, 46 ± 5, and 25 ± 5 (Mean ± SEM) nA responses to GABA, KA, NMDA, and carbachol, respectively. Oligo 840 selectively (0.06-2.7 pmols/cell) inhibited GABA and NMDA evoked currents over those of KA and carbachol. Four other oligos tested under similar conditions failed to produce similar results. In separate experiments RNAse H and DNAse were added 20 min apart to an oligo 840:mRNA mixture *in vitro* (37 C) prior to injection. Under these conditions GABA and NMDA currents were specifically inhibited by 96% and 67%, respectively, whereas KA and carbachol responses were unaffected. Northern analysis of whole rat brain mRNA probed with oligo 840 detected seven distinct bands with M_r sizes from 1.6 to 10.9 kb. Three of these bands have apparent M_r's similar to that of GABA$_A$ α-subunit mRNAs. These results together suggest that oligo 840 recognizes GABA and perhaps NMDA receptor mRNAs in a sequence specific manner.

PARTIAL PURIFICATION AND CHARACTERIZATION OF A [3H]CPP RECOGNIZING PROTEIN. M.D.Cunningham, M. Gurfinkiel*, P.S.Johnson*, K.Bushell*, and E.K.Michaelis. Depts of Biochemistry, Pharmacology, and the Center for Biomedical Research, University of Kansas, Lawrence, Kansas, 66045.

We have used a combination of CHAPS and polyoxyethylene-10-tridecyl ether, in the presence of glycerol and high concentrations of protease inhibitors, to solubilize [3H]CPP recognition sites from rat brain synaptic membranes. Ligand saturation analyses of intact membranes show a single binding site with a Kd and Bmax of 0.5uM and 3 pmol/mg which changes to 0.6uM and 6 pmol/mg upon solubilization.

[3H]CPP binding activity was purified by ibotenate affinity chromatography, and a fraction eluted with MgSO4 contains saturable binding with Kd and Bmax of 0.8uM and 11 nmol/mg. [3H]CPP displacement profiles by various acidic amino acids and amino acid analogs indicate the presence of recognition sites for NMDA antagonists but not agonists; binding also appears to be modulated by Mg+2 ions and glycine. This fraction displays no evidence of GAD enzyme activity nor [3H]GABA binding activity.

SDS-PAGE of the MgSO4-eluted fraction reveals strong enrichment of a 58kDa protein. Western blot analysis shows antibodies we have previously raised against rat brain glutamate binding protein (JBC 263:417) do not recognize the 58kDa protein. This protein may play an importanat role in NMDA receptor-ion channel regulation. [Supported by grants DAAL 03-88-K0017 from ARO and AA04732 from NIAAA].

217.4

SPIDER TOXIN (JSTX)-BINDING PROTEIN IN RAT HIPPOCAMPUS. K. Shimazaki*, T. Nakajima*, and N. Kawai* (SPON: Y. Sahara). Dept. Neurobiol., Tokyo Metropol. Inst. Neurosci., Tokyo 183, and Dept. Anal. Chem., Fact. Pharmaceut. Sci., Tokyo Univ., Tokyo 113, Japan.

In order to purify the glutamate receptor of the brain we have used synthesized spider toxin (JSTX-3), which specifically blocks glutamatergic synapses. After a crude synaptic membrane fraction was prepared from rat hippocampus, a JSTX-3 binding protein was solubilized by Triton X-100. Specific binding of [^{3}H]-biotinyl JSTX-3 to the solubilized fraction was saturable with a K_d of 5 µM and a B_{max} of 12 pmol/mg protein. Binding was inhibited by unmodified JSTX-3, but not reduced by Asp-Cad-Put, an inactive analog of JSTX-3. The JSTX-3 binding protein molecules migrated with M_r = 17,000 and M_r = 66,000 in FPLC analysis using a Superose 6 column. SDS-polyacrylamide gel electrophoresis of the affinity-purified JSTX-3 binding protein showed a single band with silver stain, migrating with M_r = 70,000-80,000. This is the first demonstration of JSTX-3 binding protein isolated from the mammalian brain and our findings should facilitate the molecular characterization of the glutamate receptor.

217.5

SOLUBILIZATION AND PARTIAL PURIFICATION OF AMPA BINDING SITES FROM RAT AND BOVINE BRAIN.
C.Hunter,K.Wheaton* and R.J.Wenthold. Laboratory of Molecular Otology, NIDCD, NIH, Bethesda, MD 20892.

Binding sites for AMPA, proposed as a selective agonist for the quisqualate excitatory amino acid receptor, were solubilized from rat or bovine brain using 1% Triton X-100 in 0.5M potassium phosphate buffer containing 20% glycerol. The solubilized binding site had an M_r on gel filtration of 425,000 and was stable for several days at 4°C. Binding and pharmacological analyses indicated that the solubilized binding sites were similar to the membrane bound sites in rat and bovine preparations. [3H]AMPA binding to soluble and membrane preparations was increased in the presence of potassium thiocyanate. Scatchard analyses showed that both preparations contained high and low affinity binding sites. Competition studies with both preparations displayed a similar rank order of potency. A 54 fold purification of the soluble preparation from the rat was achieved by ion exchange chromatography and gel filtration. The characterization and purification of these soluble binding sites is potentially useful for the molecular characterization of this putative amino acid receptor subtype.

217.6

ISOLATION AND CHARACTERIZATION OF A cDNA ENCODING A PUTATIVE KAINIC ACID RECEPTOR SUBUNIT IN FROG BRAIN.
K.Wada[1*],Y.Nakatani[2*],K.Kusano[3],C.Dechesne[1],D.Hampson[1], S.Shimasaki[4*],K.Wheaton[1*],C.Banner[2*] and R.Wenthold[1]. [1]Lab. of Molecular Otology, NIDCD, [2]Lab. of Molecular Biology, NINDS, [3]Lab. of Neurochemistry, NINDS, NIH, Bethesda, MD20892 and [4]Neuroendocrinology Lab., The Salk Institute, San Diego, CA92138.

A putative kainic acid receptor in frog brain(Rana pipiens berlandieri) has been purified by domoic acid affinity chromatography and shown to contain a subunit of 48KDa protein (Hampson and Wenthold, J. Biol. Chem. 263, 2500,1988). Micro amino acid sequence was determined from the major V8 protease fragments of the 48KDa protein, and used to make oligonucleotide probes. Several clones were isolated from frog brain cDNA library using the probes. The deduced amino acid sequence from the overlapping isolated clones revealed that the cDNA encodes the 48KDa protein composed of 466 amino acids. Northern hybridization showed that two major transcripts of ~6 and ~4 kb were expressed specifically in brain. A characteristic hydrophobic feature found in other ligand gated ion channel subunits was conserved in the 48KDa protein. Some weak amino acid sequence similarities were found against brain nicotinic receptor subunits in particular segments. In situ hybridization showed that localization of transcripts for the 48KDa protein was compatible with the data of immunohistochemistry and receptor autoradiography studies for kainic acid receptor in frog brain. cDNA expression studies in oocytes are currently under way to determine the function of the cDNA.

217.7

PURIFICATION AND RECONSTITUTION OF THE KAINATE RECEPTOR FROM GOLDFISH BRAIN.
C.J.Ziegra* and R.E.Oswald. (SPON: T.Podleski) Dept. of Pharmacology, New York State College of Veterinary Medicine, Cornell University, Ithaca NY 14853.

Goldfish brain membrane fragments provide a good source of kainate(KA) receptors (100 pmol/mg pr) as determined by [3H]KA saturation binding. Previous results demonstrate that 50% of binding sites are recovered when solubilized in *n*-octyl-β-D-glucopyranoside (OG); the pharmacological profiles of membrane bound and solubilized receptors are similar (Henley and Oswald BBA 937:103, 1988).

KA receptors from whole goldfish brain were solubilized in a Tris buffer containing 2% OG and subsequently purified in a two step chromatographic procedure: ion exchange (DEAE) followed by domoate affinity chromatography (Hampson and Wenthold, *JBC* 263:2500, 1988). [3H]KA binding studies of crude solubilized brain revealed a single class of binding sites with a K_d of 360 nM and a B_{max} of 50 pmol/mg pr. In contrast, KA receptors purified in 20 mM Tris containing 10% glycerol and 0.1% Triton-X had a K_d of 200 nM and these preparations contained 6500 pmol/mg pr thus yielding a 130 fold purification. Displacement of [3H]KA by competitive ligands was similar in both; the K_i values for crude solubilized and purified receptors respectively were kainate 53 nM and 52 nM; kynurenic acid 4.8 mM and 6 mM; L-glutamate 35 mM and 54 mM. Silver stained SDS gels run under reducing conditions revealed a major band which migrated with a molecular weight of 49 kDa. However, there was also a 43 kDa band which was usually much less intense.

Purified KA receptors reconstituted into artificial lipid vesicles by an OG dialysis procedure bound [3H]KA with a K_d of 208 nM, similar to the purified soluble receptor. However, the specific activity (19800 pmol/mg pr) was apparently 3x greater in the reconstituted preparation. Preliminary studies indicate that when the purification and reconstitution are done in 20 mM Hepes with 100 mM NaCl, 50 mM KCl, and 5 mM $MgCl_2$ there is greater recovery of total numbers of binding sites.

217.8

DEVELOPMENT OF METHODOLOGY FOR RAPID PURIFICATION AND PHYSICO-CHEMICAL CHARACTERIZATION OF GLUTAMATE-BINDING PROTEINS FROM SYNAPTIC MEMBRANES.
K. Kumar*, K. Eggeman*, Y. Cong*, and E. Michaelis. Depts. Pharmacol. & Biochem., and Cent. for Biomed. Res, Univ. of Kansas, Lawrence, KS 66045

We have previously reported on the purification of a 71 kDa glutamate-binding protein (GBP) from rat brain synaptic membranes [Chen et al., J. Biol. Chem. 263, 417-426, 1988]. This glycoprotein has ligand binding characteristics suggestive of a role as a glutamate receptor in synaptic membranes. The protein has neither enzymatic activity nor the characteristics of membrane carriers for glutamate. In order to complete the biochemical and physico-chemical characterization of this protein, including amino acid analyses and amino acid sequencing, we have developed a new method for rapid purification of the protein to near homogeneity and removal of associated detergents. The new methodology involves affinity column chromatography through an L-glutamate-derivatized Trisacryl column and selective elution by 5 mM L-glutamate or 5 mM NaN_3. This fraction is highly enriched in glutamate binding activity, ~1,000-fold enrichment, and consists primarily of two protein species, ~70 and ~60 kDa proteins. This preparation has been used to estimate the sedimentation coefficient by sucrose density centrifugation in the presence of 5-20% sucrose in H_2O and D_2O and the Stokes radius by chromatography on Sephacryl S400 HR. Detergent removal and selective elution of the ~70 kDa protein is accomplished through HPLC on a cyanopropyl-derivatized column. A homogeneous preparation of this protein that is useful for chemical studies is obtained by this procedure. [Supported by grants DAAL-03-88-K0017 from ARO and AA 04732 from NIAAA].

217.9

AFFINITY PURIFICATION OF A KAINIC ACID BINDING PROTEIN FROM *XENOPUS* CNS.
A. Ambrosini*, J.M. Henley* and E.A. Barnard*(SPON. B.R.A., UK).MRC, Mol. Neurobiol. Unit, MRC Centre, Hills Rd, CB2 2QH Cambridge UK.

Kainic acid (KA) is a potent agonist at a subtype of excitatory amino acid receptors in the vertebrate CNS. Recently, Hampson and Wenthold presented the purification, by affinity chromatography, of a 48 kDa protein identified as the putative KA receptor(1). We describe here the affinity purification of the [3H]KA binding site from a particularly rich source, the *Xenopus* CNS. In this tissue, [3H]KA binds with high affinity to a large population of binding sites (K_d=54 nM; B_{max}=28 pmol/mg protein). These membrane-bound sites have been solubilised in 1% n-octyl-β-D-glucopyranoside (OGP). In detergent extracts [3H]KA binds with a K_d of 46 nM and a B_{max} of 22 pmol/mg protein and both membrane-bound and solubilised binding sites have similar pharmacological characteristics (2). We employed the domoic acid-affinity chromatography (1) to purify these OGP-solubilized [3H]KA binding sites. All of them were retained by the affinity resin and [3H]KA binding activity could be recovered after specific elution with 60 μM unlabelled KA and dialysis. Several bands were consistently identified on silver stained SDS gels of the specific eluate. Radiation inactivation experiments performed on *Xenopus* CNS tissue (in collaboration with dr. M. Nielsen, Denmark) suggest the [3H]KA membrane binding site is an oligomeric protein of 240 kDa.

The pharmacological and biochemical properties of these purified proteins and their identity as part of the putative KA receptor will be described.

217.10

CHARACTERIZATION AND PARTIAL PURIFICATION OF A CHLORIDE- AND CALCIUM-DEPENDENT GLUTAMATE-BINDING PROTEIN FROM RAT BRAIN.
N. Brose*[1], S. Halpain[2], C. Suchanek*[1] and R. Jahn[1] (SPON: G. Neuweiler). [1]Dept. Neurochemistry, MPI for Psychiatry, D-8033 Martinsried, FRG and [2]Rockefeller University, New York, NY 10021.

A glutamate-binding protein was solubilized from rat brain synaptic plasma membranes using sodium cholate. Its properties were characterized after incorporation into proteoliposomes. Glutamate binding was dependent on calcium and chloride ions. The effects of the two ions were synergistic and maximal at concentrations of 10^{-5} M calcium and 10 mM chloride ions. Glutamate binding was not affected by inhibitors specific for NMDA and kainate receptor subtypes, but was inhibited by quisqualate and DL-APB. Furthermore, binding was abolished by DIDS and dithiothreitol. These properties resemble those of the chloride- and calcium-dependent binding site. Starting from the detergent extract, the glutamate-binding protein was purified 123-fold using fractionated ammonium sulfate precipitation, chromatography on hydroxyapatite and on DEAE-Sephacel as sequential purification steps. SDS-PAGE of the purified protein fraction showed two major bands migrating with M_r values of 51,000 and 105,000. Glutamate binding to the partially purified protein is not due to a sequestration process or product binding to N-acetylated α-linked acidic dipeptidase. A rabbit antiserum was generated by immunization with the partially purified binding protein. The antibodies react with a band of 51,000 Da. Small amounts of this antiserum lead to a significant inhibition of glutamate binding. Glutamate-binding activity was completely removed from solubilized synaptic plasma membranes by immunoprecipitation, indicating that the 51,000 Da protein is an essential component of the binding site.

218.1

ACTIVATION OF PERIPHERAL NOCICEPTORS BY GLUTAMATE.
D.L. Tanelian and M.B. MacIver. Dept. of Anesthesia, Stanford Univ. Sch. of Medicine, Stanford, CA 94305.

Glutamate has been shown to activate CNS, spinal cord and dorsal root ganglion neurons, but to date has not been shown to stimulate mammalian sensory afferents. Using the in vivo rabbit cornea model of nociception (Tanelian, D.L. and Beuerman R.W., Exp. Neurol.,84:165, 1984), a population of peripheral afferents has been identified which are activated by glutamate and selectively blocked by glutamate antagonists in a reversible fashion.

Corneal C-fiber afferents responded to topical application of glutamate (100 uM) in a tonic fashion which lasted for the duration of stimulus application and in some cases, slightly beyond. The addition of glycine (100nM) potentiated the effect of glutamate, but produced no effect on its own. N-methyl-D-aspartate (NMDA:100 uM) was as effective an agonist as glutamate (100uM). The antagonists 2-amino-5-phosphono-valerate (APV:100uM) and ketamine (100uM) completely abolished the responses to glutamate and NMDA in a reversible fashion. This evidence establishes the existence of glutamate receptors on the peripheral terminals of mammalian sensory afferent fibers. Preliminary data suggests that they may be an NMDA receptor subtype. However, further studies are needed to completely characterize the receptor subtype (s). Supported by the Parker B. Francis Investigatorship in Anesthesiology and the American Cancer Society.

NMDA RECEPTOR ACTIVATION REGULATES THE PHOSPHORYLATION STATE OF DARPP-32. Shelley Halpain, Jean-Antoine Girault, Stevin Zorn, and Paul Greengard. Laboratory of Molecular and Cellular Neuroscience. The Rockefeller University, New York, NY 10021.

Medium-sized spiny neurons of the striatum receive glutamatergic input from the neocortex. The excitatory response of these cells to glutamate may be inhibited in vivo by dopaminergic inputs from the substantia nigra. DARPP-32, a protein enriched in medium-sized spiny neurons, is phosphorylated by cAMP-dependent protein kinase on a threonyl residue. Previous studies indicated that dopamine and other activators of cAMP-dependent protein kinase could stimulate phosphorylation of DARPP-32 in striatal slices. We sought to examine the effect of glutamate agonists on DARPP-32 phosphorylation. Rat striatal slices were preincubated with ^{32}P-ortho-phosphate to label the cellular ATP pools. Addition of 50 μM forskolin for 5 min resulted in a 200% increase in threonine phosphorylation of DARPP-32. This forskolin stimulation was prevented by co-treatment with 100 μM N-methyl-D-aspartate (NMDA). The specific NMDA receptor antagonist D-aminophosphonopentanoic acid (D-AP5) blocked the effect of NMDA. These results indicate that, in the striatum, activation of NMDA receptors and activation of dopamine receptors have opposite effects on the state of phosphorylation of DARPP-32. When DARPP-32 is phosphorylated on a threonyl residue it acts as a potent inhibitor of protein phosphatase-1. Thus, the stimulation of DARPP-32 threonine phosphorylation by forskolin or dopamine in situ presumably results in the inhibition of protein phosphatase-1. Activation of NMDA receptors would remove this inhibition. We suggest that such a mechanism may be involved in the opposing effects exhibited by dopamine and glutamate on the excitability of medium-sized spiny neurons.

218.3

PHARMACOLOGICAL PROPERTIES OF THE NMDA RECEPTOR SYSTEM COUPLED TO THE EVOKED RELEASE OF [^{3}H]GABA FROM STRIATAL NEURONS IN PRIMARY CULTURE. D.E. Kemp and S. Weiss (SPON: W.J. Becker). Neuroscience Research Group, University of Calgary, Calgary, Alberta.

The actions of a series of endogenous excitatory amino acid (EAA) agonists and synthetic antagonists at the NMDA receptor system coupled to the evoked release of [^{3}H]GABA from striatal neurons in primary culture was examined. EAA agonists displayed the following rank order of potency in evoking [^{3}H]GABA release: glutamate > homocysteate > aspartate, NMDA > cysteine sulfinate. Glutamate, homocysteate and cysteate were equieffective, while at saturating concentrations, aspartate and NMDA reached 75 and 65%, respectively, of the maximum efficacy of the former three agonists. The release of [^{3}H]GABA evoked by 100μM NMDA was attenuated in a dose-dependent manner by the following antagonists (IC_{50}, μM): MK-801 (0.067), PCP (0.151), CGS-19755 (3.81), APV (18.8), kynurenate (100) and γ-DGG (100). The antagonist properties of MK-801 and PCP were not competitive with NMDA, while NMDA dose-response curves performed in the absence and presence of increasing concentrations of CGS-19755 resulted in parallel rightward shifts (pA_2 = 5.95). CGS-19755 produced similar rightward shifts of the homocysteate dose-response curve (pA_2 = 5.89). At glutamate concentrations < 100μM, CGS-19755 and APV were potent antagonists of glutamate-evoked release, however at glutamate concentrations > 100μM these agents were ineffective blockers. The blockade of NMDA-evoked release of [^{3}H]GABA by kynurenate was not competitive in nature. Glycine (ineffective alone) induced a dose-dependent (EC_{50}, 1.3μM) reversal of 100μM kynurenate blockade of the NMDA response; glycine did not reverse the effects of any of the other classes of antagonists. Although with increasing kynurenate a rightward shift of the glycine dose-response curve was observed, at 300μM kynurenate the reversal was incomplete. This study suggests that three distinct sites for antagonists exist on the NMDA receptor system mediating EAA-evoked release of [^{3}H]GABA from striatal neurons.

Supported by the Medical Research Council of Canada.

PHENCYCLIDINE ATTENUATION OF NMDA-INDUCED DOPAMINE RELEASE IN THE RAT STRIATUM. P. Marek and S. Howard, MRRC, Department of Pharmacology, UCLA, CA 90024

The effects of phencyclidine (PCP) and N-methyl-D-aspartic acid (NMDA) on striatal concentrations of dopamine and DOPAC were studied using in vitro microdialysis. Samples were collected from urethane anesthetized rats and analyzed using an HPLC-EC assay. NMDA and PCP were administered locally with microdialysis probe for a 30 sec period and their effects were measured in 10 minute samples collected for one hour period following drug administration. 1 mM NMDA produced a 2000% increase in extracellular dopamine concentration and a 20% decrease in extracellular DOPAC concentration.

Administration of 25 μM PCP prior to NMDA reduced the effect of NMDA by 50%. Administration of 1 mM APV for 30 sec prior to NMDA produced a complete block of the NMDA effect. PCP induced dose dependent increase in extracellular dopamine concentration without changing DOPAC level. This grant was supported by NIH grant DA 03156.

218.5

NMDA RECEPTOR AND METABOLIC PATHWAY INVOLVED IN GLUTAMATE-INDUCED SRIF RELEASE FROM CORTICAL NEURONS. L. TAPIA-ARANCIBIA and H. ASTIER. URA 1197 CNRS, University Montpellier II, France.

We have recently shown that glutamate (Glu) stimulates somatostatin (SRIF) release from rat cortical neurons in primary cultures presumably by activation of a NMDA receptor type (J. Neurochem. in press). The present experiments were designed 1/ to further characterize the related receptor. 2/ to examine the metabolic pathways involved in the Glu-stimulated SRIF release. SRIF was measured in the media by RIA after a 15 min incubation of glia-free cortical neurons with the agonists or antagonists in Mg^{2+}-free Locke medium. Under these conditions Mg^{2+} decreases the stimulatory effects of Glu. NMDA and Glu-induced SRIF release were blocked in a dose-related manner by DL-2-amino-5-phosphonovaleric acid (APV) and thienyl-phencyclidine (TCP), and potentiated by glycine or serine (10 μM) ; these potentiations were reversed by kynurenic acid (200 mM). Zn2+ (50 mM) was also able to significantly decrease the stimulatory effect of NMDA.

The metabolic pathways involved were studied by using : mepacrine an inhibitor of phospholipase A_2 (PLA_2) ; H7 a specific inhibitor of Prot Kinase C ; indomethacin (Ind) a blocker of the cyclooxygenase pathway and nordihydroguairetic acid (NDAG) , a lipoxygenase inhibitor. Mepacrine (0.5 mM) completely inhibited the stimulatory effect of Glu (10 μM), while H7 (100 μM) had no effect on SRIF release. Ind and NDAG (100 μM) significantly reduced the inhibitory effect of Glu and NMDA (10 μM). Furthermore, melittin, a PLA_2 stimulatory peptide, also increased SRIF release in a dose-dependent manner, this effect being blocked by mepacrine. Preliminary results show that Glu is also able to stimulate [^{3}H] arachidonic acid release from the cortical neurons.

These data suggest that 1/ a NMDA receptor-channel complex is involved in the stimulatory effect of Glu on SRIF release 2/ the activation of PLA_2 seems to participate in this response.

This work was supported by a grant from the INSERM (88-4002).

TTX AND STX INHIBIT RESPONSES OF SPINAL CORD NEURONS IN CELL CULTURE TO NMDA. M.J. McLean and A.W. Wamil* (SPON: W.D. Dettbarn). Dept. of Neurology, Vanderbilt Univ. Med. Ctr., Nashville, TN

We studied the effects of the marine toxins tetrodotoxin (TTX) and saxitoxin (STX) on the responses of mouse spinal cord neurons in monolayer cell culture to N-methyl-D-aspartate (NMDA) and glutamate (GLU). Neurons were superfused with phosphate buffer containing 7-10 mM Mg^{++} to suppress spontaneous activity. Pressure application of NMDA or GLU from a patch clamp pipette near a neuron impaled with a microelectrode for conventional transmembrane recording of potential produced a concentration dependent depolarization and firing of action potentials. Action potentials fired in response to application of NMDA or GLU or elicited by depolarizing current pulses applied through the recording microelectrode were abolished reversibly by TTX or STX. Responses to NMDA were diminished by TTX (IC_{50} 5 X 10^{-10}M) and by STX (IC_{50} 10^{-9}M). Half-maximal inhibition of GLU (10^{-5}M) responses by TTX occurred at about 10^{-8}M). Responses to NMDA were abolished by AP-7 and MK-801. About 60% of the GLU response was abolished by AP-7. These findings indicate that TTX and STX can reversibly block sodium influx through ion channels activated by NMDA and the excitatory amino acid neurotransmitter GLU. (Supported by a Mallinckrodt Scholarship and NIH Grant NS 01194 to MJM and a Cissy Patterson Fellowship to AWW.)

218.7

THE RELATIVE POTENCY OF LANTHANUM AS A BLOCKER OF VOLTAGE-GATED CALCIUM CURRENTS AND OF CURRENTS EVOKED BY EXCITATORY AMINO ACIDS. D.B. Reichling and A.B. MacDermott, Dept. Physiology and Center for Neurobiology and Behavior, Columbia Univ., NYC, NY 10032

Glutamate can promote voltage-depedent Ca^{2+} entry into neurons by directly activating Ca^{2+}-permeable NMDA receptors and indirectly activating voltage-gated Ca^{2+} channels (VGCC). La^{3+} blocks current through VGCC. To determine if La^{3+} selectively blocks VGCCs during EAA activation of non-voltage clamped neurons, we tested the effectiveness of different concentrations of La^{3+} on VGCC currents and currents evoked by excitatory amino acids (EAA). First, the potency of La^{3+} as a blocker of VGCCs was assessed. Cultured neurons from the dorsal horn of rat spinal cord were continuously perfused with bath (5 mM Ba^{2+} added) and inward currents were evoked by depolarizing voltage steps from −60 mV. Maximal blocking of VGCC was achieved with concentrations of La^{3+} between 1 and 10 uM. The second set of experiments tested if these concentrations of La^{3+} had any effect on EAA-gated currents. To minimize the activation of VGCC, the neurons were voltage clamped. 1 uM La^{3+} reversibly depressed the response to 50-100 uM NMDA by 51%; 10 uM La^{3+} caused 73% depression. In contrast, the responses to 50 uM kainate and 10 uM quisqualate were not depressed by either concentration of La^{3+}. In some cells, 10 uM La^{3+} increased the response to kainate and quisqualate. Thus, doses of La^{3+} which effectively blocked VGCCs did not reduce responses to kainate and quisqualate and only partially reduced responses to NMDA. Therefore, La^{3+} may be a useful tool to distinguish between direct effects of EAAs and indirect effects due to activation of VGCCs.

218.8

THE EFFECTS OF N-METHYL-D-ASPARTATE (NMDA) ON CALCIUM FLUX AND NEUROTRANSMITTER RELEASE FROM RAT BRAIN NEURONS. J.J. Woodward, R.A. Gonzales, J.E. Dildy*, S.M. Rezazadeh*, J.L. Morris*, and S.W. Leslie. Division of Pharmacology and Institute for Neuroscience, University of Texas at Austin, Austin, TX 78712.

The effects of the glutamate receptor agonist, N-methyl-D-aspartate (NMDA) on calcium flux and neurotransmitter release were investigated using several different preparations of brain neurons from Sprague-Dawley rats. Stimulation of freshly dissociated whole brain neurons from neonatal (0-1 days old) rats with NMDA (25-200 uM) rapidly increased intracellular free calcium concentrations ([Cai]) as measured by fura-2 spectroscopy. These increases were blocked or reversed by magnesium (1 mM) or the selective NMDA receptor antagonist 2-amino-5-phosphonovalerate (AP5, 100 uM). Similarly, brain slices prepared from the corpus striatum or the frontal cortex of adult Sprague-Dawley rats released significant amounts of endogenous dopamine (striatum) or preloaded tritiated norepinephrine (cortex) over a two minute stimulation with 50-1000 uM NMDA. Release of endogenous dopamine or tritiated norepinephrine was totally blocked by magnesium (1 mM). In contrast to these findings, calcium entry into whole brain neurons freshly dissociated from adult Sprague-Dawley rats was not stimulated by NMDA (25-1000 uM) as measured by fura-2 spectroscopy and $^{45}Ca^{2+}$ flux experiments. NMDA also did not stimulate the release of endogenous dopamine from these cells. However, stimulation of freshly dissociated adult brain neurons for thirty seconds with potassium (15-45 mM) significantly increased $^{45}Ca^{2+}$ uptake as well as [Cai] as measured by fura-2. In addition, these cells released significant amounts of endogenous dopamine upon potassium depolarization. These results suggest that the NMDA receptor-operated calcium channel may be sensitive to disruption by experimental manipulations during tissue isolation. EXCITATORY AMINO ACID-INDUCED SYNAPTIC ACTIVITY BETWEEN CULTURED RAT HIPPOCAMPAL PYRAMIDAL NEURONS ASSESSED USING FURA-2 MICROFLUORIMETRY. Richard J. Miller, Wendy K. Scholz and Kenneth P. Scholz (Spon L. Noronha-Blob). Dept. of Pharm. and Physiol., Univ. of Chicago, Chicago, IL 60637.

Fura-2 microfluorimetry was used to record spontaneous activity in cultures of rat hippocampal pyramidal neurons prepared by the methods of Banker and coworkers (1977) as modified by Scholz et al., (1988). These cells possess NMDA and quisqualate-kainate subclasses of excitatory amino acid receptors as well as receptors for many other neurotransmitters that are endogenous to the hippocampus. Intracellular recording demonstrated that these cells form primarily excitatory synapses when cultured from 17 day embryonic rats. Cell bodies had a basal $[Ca2+]_i$ of 75-150 nM. When the culture dish was perfused with Mg2+-free medium supplemented with 10-1000 nM glycine, neurons exhibited large spontaneous fluctuations in $[Ca2+]_i$ of 50-300 nM. These fluctuations could be blocked by 10 uM APV and 1 uM TTX, indicating that they may be due to enhanced spontaneous synaptic activity that is a consequence of removal of the Mg2+ blockade from the NMDA receptor. In addition, removal of Mg2+ may affect transmitter release or the threshold for generation of action potentials. Activation of receptors that produce presynaptic inhibition in the hippocampal slice preparation also reduce these spontaneous fluctuations of $[Ca2+]_i$. These include receptors for adenosine and neuropeptide Y as well as GABAb receptors. It is possible that the $[Ca2+]_i$ fluctuations observed under these conditions may serve as a useful model of epileptiform activity at hippocampal synapses.

NMDA RECEPTOR-MEDIATED INCREASES IN CYTOSOLIC CALCIUM IN CEREBELLAR GRANULE CELLS: MODULATION BY GLYCINE AND MAGNESIUM. E.F. Nemeth and T.N. Parks, Natural Products Sciences, Inc., Salt Lake City, UT 84108.

A method for measuring cytosolic free Ca^{2+} ($[Ca^{2+}]_i$) in large, homogeneous populations of normal CNS neurons was developed. Dissociated cerebellar granule cells from 8 day-old rats were prepared by enzymatic treatment and trituration, plated onto polylysine-coated plastic squares, and cultured in the presence of cytosine arabinoside for 7-9 days. Cells were loaded loaded with fura-2 by incubation with fura-2/AM, washed, and the plastic squares transferred to a cuvette containing Mg^{2+}-free buffer for fluorescence recording. The addition of glutamate, aspartate, NMDA or KCl caused rapid, dose-dependent increases in $[Ca^{2+}]_i$ whereas the addition of a variety of other CNS transmitters were without effect on $[Ca^{2+}]_i$. Maximal increases in $[Ca^{2+}]_i$ were obtained with 25 uM NMDA. The response to 40 mM K^+, but not that to 25 uM NMDA, was inhibited by 1 uM nifedipine. The addition of glycine (0.1-1 uM) caused no change in $[Ca^{2+}]_i$ but greatly potentiated the responses to NMDA and to aspartate. In contrast, increases in $[Ca^{2+}]_i$ elicited by NMDA were blocked by prior addition of Mg^{2+} (1 mM). Increases in $[Ca^{2+}]_i$ elicited by NMDA were also inhibited by MK-801 (IC_{50} = 35 nM) or AP-5 (IC_{50} = 20 uM). The effects of glycine, Mg^{2+}, and certain drugs on NMDA-induced increases in $[Ca^{2+}]_i$ in cerebellar granule cells thus parallels their effects on NMDA-induced changes in electrical activity as determined by electrophysiological methods. Measurements of $[Ca^{2+}]_i$ by this means thus provide a valid and simple assay for investigating NMDA receptors and for rapidly assessing the effects of various drugs on functional responses mediated by such receptors.

ZINC MAY ENTER CORTICAL NEURONS THROUGH NMDA CHANNELS. J. Koh and D.W.Choi. Dept. of Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

Zinc (Zn^{++}) is released at forebrain excitatory synapses with neuronal activity, where it may regulate the activation of glutamate receptors. We have been interested in the additional possibility that such Zn^{++} might enter postsynaptic neurons through open NMDA channels, where it could modulate intracellular processes, or in excess, cause neuronal injury. We examined Zn^{++} entry with a fluorescent chelator specific for Zn^{++} (toluene sulfonamide quinoline, TSQ) (Frederickson et al., J. Neurosci. Meth. 20: 91-103, 1987). Murine cortical cell cultures were exposed for 2 min to 100 μM Zn^{++} in a HEPES buffered salt solution lacking Ca^{++}. Neuronal perikarya and processes showed intense fluorescence after TSQ application. However, when the same Zn^{++} exposure was done in the presence of 30 μM MK-801 or 1 mM D-APV, the staining was markedly reduced. A voltage-dependent Ca^{++} channel blocker, nifedipine, did not attenuate the TSQ signal even at 100 μM. Furthermore, the less intense signal produced by exposure to 50 μM Zn^{++} for 1.5 min could be markedly increased by co-application of 1 mM NMDA. These data suggests that Zn^{++} may enter neurons at least in part through open NMDA channels. If Zn^{++} can be translocated from presynaptic to postsynaptic neurons, it could play a physiological role as a "trans-synaptic messenger."

MODULATION OF NMDA RESPONSE BY HALOPERIDOL AND *m*-NITRO-PCP. E.S. Rocha[1*], A. Ramoa[1], E.X. Albuquerque[1,2]. (SPON: E.P. Christian) [1]Lab. Mol. Pharmacol. II, UFRJ, Brazil and [2]Dept. Pharmacol., Univ. Md. Sch. Med., Baltimore, MD 21201.

Electrophysiological studies have shown that haloperidol potentiates the MK-801 antagonism of NMDA responses (Monnet *et al., Soc. Neurosci. Abst.*, 1988). We examined the effect of haloperidol on the response properties of single NMDA receptors. Application of NMDA (10-30 μM) to outside-out patches of membrane, excised from cultured fetal rat hippocampal neurons, elicited ion currents which were generally affected by haloperidol. Haloperidol (300 nM-1 μM) potentiated the NMDA response in about half of the patches studied by increasing the frequency of NMDA-induced openings. Potentiation by haloperidol was weaker than that observed with other NMDA receptor potentiating agents such as glycine (1-10 μM) and *m*-NITRO-PCP (5-10 μM) (Ramoa and Albuquerque, *FEBS Lett. 235*:156, 1988). Haloperidol and *m*-NITRO-PCP did not affect channel lifetime. At higher concentrations, however, both haloperidol (5-30 μM) and *m*-NITRO-PCP (5-10 μM), but not glycine (100 μM), markedly reduced the frequency of NMDA openings. This effect was reversed at positive potentials. Channel lifetime (intra-burst openings) was differently affected by both agents: it was reduced by *m*-NITRO-PCP but remained relatively unaltered with haloperidol. Thus, both agents modulated NMDA receptor function in a concentration-dependent manner. At low concentration, they may allosterically enhance the NMDA response. MODULATION OF NMDA CURRENTS BY INTRACELLULAR PHOSPHORYLATION. M.C. BARTLETT*, M.W. SALTER, & J.F. MACDONALD. Playfair Neurosci. Unit, The Toronto Hosp. & Dept. of Physiol., Univ. of Toronto, Toronto, Ont. M5T 2S8.

NMDA currents "wash out" to about 50% of their initial amplitude during whole-cell patch clamp recordings, an effect which is prevented or reversed by dialysing the neuron with an ATP regenerating solution (MacDonald et al, *J. Physiol.* 1989, in press). Cultured hippocampal neurons were patch-clamped using the whole-cell configuration. NMDA currents were evoked by pressure applications of 250 μM L-aspartate. The intracellular solution consisted of (in mM): 120 CsCl, 35 CsOH, 11 EGTA, 1 $CaCl_2$ (or 80 μM EGTA, 25 μM $CaCl_2$), 2 TEA, 2 $MgCl_2$, 10 HEPES. In addition, the ATP regenerating solutions contained: 4 K-ATP, 20 phosphocreatine, 50 U/ml creatine phosphokinase. Adenosine-5'-0-(3-thiotriphosphate ($ATP\gamma S$) thiophosphorylates proteins which are then resistant to hydrolysis by phosphatases. Replacement of ATP with $ATP\gamma S$ also prevented the wash out of NMDA currents but the non-hydrolyzable analogue β,γ-methylene ATP was unable to retard wash out. To test for the possible involvement of a specific protein kinase we examined the effects of the phorbol ester 12-0-tetradecanoyl phorbol-13 acetate (TPA), an activator of protein kinase C. TPA (10 nM or 3 μM) was applied by bath perfusion. When neurons were dialysed with the ATP regenerating solution TPA caused a reversible depression of NMDA currents. This depression was blocked when TPA was co-perfused with the protein kinase C inhibitor, H7 (20 μM). In contrast, NMDA currents recorded following wash out were not blocked by TPA. Thus, while phosphorylation is required to maintain NMDA currents activation of protein kinase C can, paradoxically, depress NMDA currents. Supported by the Savoy Foundation and the MRC of Canada.

PHORBOL ESTER ENHANCEMENT OF NMDA-INDUCED CURRENTS IN XENOPUS OOCYTES. John P. Leonard, and Stephen R. Kelso Department of Biological Sciences. University of Illinois at Chicago, Chicago, IL, 60680.

The N-methyl-D-aspartate (NMDA) subclass of receptors for glutamate, has recently drawn attention as a result of its involvement in a range of processes including associative forms of synaptic modification. We wished to determine whether the properties of this receptor could be modulated by C-kinase, which is implicated in LTP in hippocampus.

We have taken advantage of the Xenopus oocyte system for expressing functional channel proteins. Xenopus oocytes were injected with rat brain mRNA and currents were recorded using two-electrode voltage-clamp techniques. All cells (n>30) exhibited NMDA responses with several properties previously shown to be characteristic of the NMDA class of receptors. The response was reversibly inhibited by 0.1 to 1 mM Mg^{2+}, by 2 mM Cd^{2+}, and the specific NMDA antagonist, 2-amino-5-phosphonovaleric acid (APV, 10 μM). In addition, in 20 cells, application of the protein kinase C activator, 4-β-phorbol- 12,13-dibutyrate (PDBu) increased the NMDA-evoked current recorded at -80 mV to > 200% of control. Controls, often in same cell, used α-phorbol, a stereoisomer that does not activate C-kinase. This effect did not require external Ca^{2+}, as substitution for Ca^{2+} with Ba^{2+} yielded similar results.

218.15

"DESENSITIZATION" OF NMDA RESPONSES MAY INVOLVE CHLORIDE IN XENOPUS OOCYTES. Stephen R. Kelso and John P. Leonard. Department of Biological Sciences. University of Illinois at Chicago, Chicago, IL, 60680.

The N-methyl-D-aspartate (NMDA) subclass of glutamate receptors has recently been expressed and studied in oocytes injected with rat brain mRNA. The response to NMDA application typically shows a rapid early inward current that decays in several seconds to a relatively stable level. This decay is reportedly due to desensitization.

Xenopus oocytes were injected with rat brain mRNA and currents recorded using two-electrode voltage-clamp techniques. In some experiments, the transient current could be evoked more than once during a single application of NMDA, suggesting that the receptor did not actually desensitize. A transient inward current would occur immediately after removal of NMDA channel block by either 1 mM Mg^{2+} or 100 μM APV. DNDS, a stilbene derivative that blocks chloride channels, nearly eliminated the transient component. Replacement of extracellular Ca^{2+} with Ba^{2+}, which is a poor activator of $I_{Cl(Ca)}$, also abolished the transient component. In contrast to the case in normal saline, DNDS did not affect the NMDA response in Ba^{2+} saline. We suggest that a significant portion of the NMDA current typically seen in these oocytes is carried by an inward chloride current (as E_{Cl} = -25 mV) triggered by Ca influx through the NMDA receptor/ channel.

INTRACELLULAR CALCIUM INCREASES THE RATE OF RECOVERY FROM N-METHYL-D-ASPARTATE (NMDA) DESENSITIZATION. Gary D. Clark, David B. Clifford and Charles F. Zorumski; Washington University School of Medicine, St. Louis, MO 63119

Desensitization of NMDA evoked currents in postnatal rat hippocampal neurons is dependent on the presence of extracellular calcium. Using standard patch clamp techniques we have found that in the presence of 1μM glycine responses to NMDA (1mM) attenuate 17 $\pm$ 11% in 19μM calcium and 78 $\pm$ 15% in 3mM calcium. The site of action of calcium in this process is not certain. In the presence of intracellular calcium buffers, NMDA currents desensitize more prominently than when calcium chelators are omitted. Additionally, in the absence of calcium chelators many NMDA currents desensitize initially but exhibit a secondary increase in current during a prolonged NMDA application. The secondary increase is not seen in the presence of 1,2-bis(o-aminophenoxy)ethane -N,N,N',N'-tetraacetic acid (BAPTA) and is not the result of a calcium activated K^+ or Cl^- current. We have also found that in the presence of calcium chelators recovery from NMDA desensitization occurs as a monoexponential process with a time constant of about 60s. In the absence of calcium chelators the time constant of recovery is 12s. These results suggest that increases in intracellular calcium do not promote and actually diminish NMDA desensitization by increasing the rate of recovery.

Activation kinetics of NMDA, kainate and quisqualate receptors in mouse hippocampus. M.L. Mayer and L. Vyklicky Jr*. Unit of Neurophysiology and Biophysics, LDN, NICHD, NIH, Bethesda, MD 20892.

Excitatory synaptic currents in the CNS often have two components with distinct temporal and pharmacological properties. The epsc due to activation of quisqualate receptors shows fast activation, and decays with a time constant of 1-4 ms; the NMDA receptor mediated component of the epsc has a slower rise time, and a decay time constant of 50 - 150 ms.

We used a fast perfusion system to apply excitatory amino acids to embryonic hippocampal neurons in dissociated cell culture (e.g. PNAS 86, 1411-1415, 1989), and will describe experiments in which the equilibrium dose response relationship and the kinetics of activation and deactivation of NMDA, kainate and quisqualate receptors was studied following rapid application and removal of transmitter candidates.

The activation of NMDA receptors is relatively slow (minimum time constant 7-10 ms at 1 mM NMDA) compared to responses to kainate and quisqualate (minimum time constant ≈ 1.5 ms at 3 mM kainate), suggesting that the slow rise time of the epsc may reflect the gating process at NMDA receptors. However, since NMDA receptor responses deactivate with a time constant of 4-8 ms, the long duration of the epsc most likely reflects rebinding of transmitter in the synaptic cleft.

219.1

EFFECTS OF TTX AND AMILORIDE ON THE SODIUM CHANNEL GATING. M.Ichikawa* and G.Matsumoto* (SPON:K.Kawano). Electrotechnical Lab., Tsukuba, Ibaraki, 305, Japan.

Both TTX and amiloride are known as the sodium channel blocker. It has been understood that these reagents work as a plug into a channel pore and have no appreciable effect on gating current. We measured the sodium gating current of squid giant axons in the presence and absence of one of these reagents or both of them. External 300nM TTX blocked sodium ionic current completely and reduced the gating charge by about 20%. Internal 2mM amiloride exhibited the similar effect on sodium channels. Detailed comparative studies on the effects of TTX and amiloride show, however, that TTX was more influential on the gating current than amiloride was; the total charge more reduced and the falling phase more quickened. When both TTX and amiloride were applied at the same time, the gating current was completely blocked. This result suggests that these reagents have a cooperative effect on the sodium channel gating mechanism.

219.2

KINETIC EVIDENCE FOR TWO Na CHANNELS IN FROG SKELETAL MUSCLE. R. Hahin Biological Sciences Dept. Northern Illinois University, DeKalb, IL 60115

Sodium currents were studied using the vaseline gap voltage clamp method. Frog muscle Na currents activate and inactivate following an initial delay. Inactivation occurs via a double exponential decay for all voltages. Deactivation of Na currents exhibits two components and retains the components after eliminating inactivation with Chloramine-T treatment. These observations are interpreted as the activation, inactivation and deactivation of two subtypes of Na channels. Plots of the slow deactivation component magnitude vs the duration of the eliciting pulse provide a way to determine the kinetics of the putative slow Na channel in muscle. Ammonium substitution for Na in the Ringer produces a voltage dependent activation and inactivation of current which exhibits only one decay phase, suggesting that adjustments of the ionic environments of the channel can mask the presence of one of the channel subtypes so that the kinetically fast Na channel which is the majority carrier of the current can be seen in isolation.

219.3

SODIUM CURRENT EXPRESSED IN Y-79 HUMAN RETINOBLASTOMA CELLS AFTER IN VITRO DIFFERENTIATION. M. Gomez*, G. Waloga* and E. Nasi* (SPON: B. Schnapp). Dept. of Physiol. Boston Univ. Sch. of Med.: Boston, MA 02118.

Y-79, a cell line derived from human retinoblastoma, can be induced to differentiate by altering the culturing conditions, making it possible to investigate the ontogenesis of membrane conductances during the process of differentiation. We had previously reported that undifferentiated Y-79 cells under whole-cell voltage clamp exhibit a small inward current which is carried by both Ca and Na ions (probably sharing a common conduction pathway) and is only partially blocked by tetrodotoxin (TTX). We have recently induced neuron-like differentiation in Y-79 cells by culturing them on a poly-D-lysin and laminin substrate. Differentaited Y-79 cells express a large inward current which is abolished by removal of external Na and is blocked completely and reversibly by TTX. Its fast kinetics resemble the Na current that underlies the action potential in neurons. This could reflect a modification of the original population of channels or the expression of a novel sodium-selective channel.

219.4

PUMILIOTOXIN-B ACTIVATION OF SODIUM CURRENT IN GUINEA PIG HIPPOCAMPAL NEURONS. R.E.Sheridan, S.S.Deshpande*, F.J.Lebeda, J.P.Apland, D.J.Braitman* and M.Adler. Neurotoxicology Branch, U. S. Army Med. Res. Inst. of Chem. Def., APG, MD 21010.

The actions of Pumiliotoxin-B (PTX-B), extracted from the skin of the frog *Dendrobates pumilio*, were examined in hippocampal slices and in dissociated hippocampal neurons isolated from the adult guinea pig. Application of 0.5-1 μM PTX-B to hippocampal slices caused repetitive field discharges in response to orthodromic stimulation of the CA1 region. In the CA3 subfield, toxin application caused spontaneous epileptiform events. Prolonged toxin incubations reduced excitability in both regions. While washout of toxin transiently restored hyperexcitability, further washing (>30 min.) eliminated all toxin effects. In whole-cell patch clamp of isolated CA1 pyramidal cells, 1-2 μM PTX-B shifted the midpoint of Na^+ current activation 14 mV more negative than normal and increased the apparent voltage sensitivity threefold. PTX-B did not change the rate of Na^+ current inactivation and had no effect on the delayed K^+ current. These experiments suggest that PTX-B binds to the open state of the sodium channel and shifts the activation voltage of toxin-modified channels to more negative potentials.

219.5

EFFECT OF ALIPHATIC ALCOHOLS ON THE BINDING OF [^{3}H]BATRACHOTOXIN BENZOATE TO VOLTAGE-SENSITIVE SODIUM CHANNELS IN SYNAPTONEUROSOMES. C.R. Creveling and M.E. Bell*. Lab. of Bioorganic Chemistry, NIH, Bethesda, MD 20892.

Treatment of synaptoneurosomes from guinea pig cerebral cortex with straight chain alcohols (n-alkanols) from C 1 to C10 inhibited the specific binding of [^{3}H]batrachotoxin-A benzoate ([^{3}H]BTX-B) to voltage-sensitive sodium channels in a concentration-dependent manner. The potency of n-alkanols increased progressively from methanol (Ki=0.88M) to nonanol (Ki=4.5x10^{-5}M). No further increase in potency was observed with decanol. n-Alkanols from C11 to C23 were inactive. The correlation between Ki values and published anesthetic potencies of n-alkanols from C2-C10 approached unity. The inhibition was competitive. n-Alkanols increased the equilibrium dissociation constant without affecting the apparent maximum number of binding sites. The dissociation rate of the [^{3}H]BTX-B/sodium channel complex at equilibrium was accelerated by n-alkanols in a concentration-dependent manner. The apparent competitive inhibition of [^{3}H]BTX-B binding and the accelerated dissociation rate induced by n-alkanols are similar to that observed with other local anesthetics. These results are consistent with an indirect allosteric mechanism whereby the modification by an anesthetic agent of a site(s) closely associated with but distinct from the BTX binding site results in a decrease in the affinity of the BTX-site for BTX. It is suggested that this change in the BTX binding site results from a shift of the ion channel from a conducting to a non-conducting state following the modification of a specific protein(s) by the anesthetic agent. Similar effects of n-alkanols have been obtained with ligands for the central GABA-gated chloride channel suggesting a wider distribution of the protein(s) responsible for the allosteric effect.

219.6

PERMETHRIN ENHANCES DIVALENT CATION INFLUX THROUGH VOLTAGE SENSITIVE SODIUM CHANNELS IN THE POND SNAIL *L. stagnalis*. C.A. Ferguson* and G. Audesirk. Biology Dept. University of Colorado at Denver, 1200 Larimer St., Denver, CO 80204.

Permethrin, a synthetic pyrethroid, has been shown to exert its toxic effect by delaying the inactivation of voltage sensitive sodium channels, thus prolonging open time. Permethrin has also been shown to decrease neurite initiation and elongation in cultured neurons, both thought to be calcium dependent mechanisms.

Voltage clamp studies were done to determine the effect of permethrin on divalent cation influx in the RPD-1 neuron of *L. stagnalis* using barium as the charge carrier. 250uM permethrin causes a forty percent increase in inward barium current over controls, measured at the end of a 200 msec clamp step. TTX (1uM) alone does not affect barium current in control (non-permethrin exposed) neurons. However, upon addition of 1uM TTX to the permethrin, inward barium currents are reduced to control values. This would suggest that the observed increase in inward barium current seen with permethrin is a result of divalent cations flowing through voltage sensitive sodium channels whose open time has been prolonged by permethrin.

219.7

STEADY-STATE ACTIVATION PROPERTIES OF BATRACHOTOXIN-MODIFIED SODIUM CHANNELS IN LIPID BILAYERS. L.D. Chabala, B.W. Urban*, L.B. Weiss, W.N. Green and O.S. Andersen. Depts. of Physiology & Biophysics and Anesthesiology*, Cornell University Medical College, N.Y., N.Y. 10021.

Batrachotoxin-modified sodium channels from canine synaptosomes were incorporated into neutral lipid bilayers. The steady-state activation curve was a sigmoidal function of membrane potential with a midpoint potential (V_a) that varied as a function of symmetrical [NaCl] (-109 mV in 0.1 M NaCl to -75 mV in 1.0 M NaCl). The apparent gating charge (z_a=3.4-3.9 elementary charges) showed no systematic variation. The positive shifts in V_a along the voltage axis as [NaCl] increased were interpreted in terms of screening of negative charges (Gouy-Chapman theory) near the gating machinery. The external surface has the larger apparent charge density, which was quantified by experiments in asymmetrical NaCl. At constant [NaCl], V_a could vary by as much as 20 mV, and spontaneous shifts in gating were often observed that resulted in a shift of the activation curve along the voltage axis with little change in z_a. At low salt (0.1 M), symmetrical additions of 0.005 M Ba^{+2} caused a depolarizing shift in V_a, ~two-fold larger shifts were seen when Ba^{+2} was added only to the extracellular side. Ba^{+2} is screening negative charges, but, from the magnitude of the shift, it appears that Ba^{+2} may also bind to the gating machinery, since Ba^{+2} addition generally reduces z_a.

219.8

FURTHER CHARACTERIZATION OF SINGLE SODIUM CHANNELS FROM DIFFERENT HUMAN BRAIN TISSUES. C. Frenkel*, DS Duch*, and BW Urban. Anesth & Physiol Depts, Cornell U Med Coll, New York, NY 10021; Inst Anästh, Univ Bonn, 5300 Bonn, FRG.

Continuing previous work, sodium channels from diseased and non-diseased human brain were incorporated into planar lipid bilayers in the presence of 0.25 and 1 uM batrachotoxin (BTX). The following single channel properties were examined, serving as an indicator of whether the corresponding distinct functional domains of the channel protein remained similar or unchanged in the two tissues: single channel conductance and subconductance states (ion pathway), steady-state activation (voltage sensor), fractional open times outside the gating region (BTX-binding site), tetrodotoxin block (TTX-binding site) and pharmacologic interactions (hydrophobic protein domains). Effects of surface charge were tested by changing electrolyte concentrations. The single channel properties did not depend on BTX concentration (close to K_D) used. No statistically significant differences were noted comparing preparations from the different tissues. These results indicate either that sodium channels from a variety of brain tissues do not differ in fundamental characteristics or that the present technique is highly selective for a particular type of sodium channel. Single channel properties did not change over a time period of 20 months, demonstrating a viable and extremely stable sodium channel system suitable for structure-function and pharmacologic studies.

219.9

THE VOLTAGE-SENSITIVE SODIUM CHANNEL IN HUMAN BRAIN. C.M. Lu, R.E. Powers*, AND G.B. Brown. Neuropsychiat. Res. Prog., Dept. Psychiat. & Biochem., Univ. of AL. at B'ham, B'ham., AL. 35294.

The voltage-sensitive Na-channel has been extensively studied in animal models, but very little is known about human Na-channels. Therefore, we have undertaken to provide a pharmacological profile of human brain Na-channels by assessing the binding characteristics of several Na-channel specific neurotoxins.

In preparation for similar studies involving human brain tissue, we examined the post-mortem stability of Na-channel in rat. Rat brain tissue was left intact for 0,4,8, and 12 hrs post-mortem before preparing synaptoneurosomes as described[1]. The channel stability was determined by measuring total specific binding of ^{3}H-batrachotoxin A 20-α-benzoate (^{3}H-BTX-B) at different post-mortem times as mentioned. The channel protein was found to be quite stable even if the brain tissue was not dissected until 12 hrs post-mortem. For the effect of long-term storage time, tissue was stored in a -70°C freezer for up to 12 mo. before making the synaptoneurosomes. Data collection is still in progress at this point. Saxitoxin (STX) binding behavior has been examined in human brain tissue. Synaptoneurosomes were prepared from frontal pole of a normal human brain[2]. This brain was dissected 7 hrs post-mortem and had been stored at -70°C. Binding reactions were initiated by addition of 150 µl of 2 nM ^{3}H-STX to a mixture of 150 µl synaptoneurosome preparation plus varying concentrations of unlabeled STX. The K_d was found to be 3.9 nM with a B_{max} of 2.34 pmol/mg protein. Preliminary results with ^{3}H-BTX-B binding suggest a slightly lower binding affinity for human Na channels than for rat. These results demonstrate the feasibility of preparing synaptoneurosomes from post-mortem human brain and open the way to the development of a pharmacological profile for human brain Na-channel. 1. Brown, G.B. (1986) J. Neursci. 6(7): 2064. 2. All experimental procedures have been reviewed and approved by the Human Use Committee of UAB.

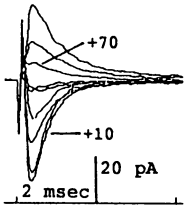
THE ROLE OF ALTERED SODIUM CURRENTS IN ACTION POTENTIAL ABNORMALITIES OF CULTURED DORSAL ROOT GANGLION NEURONS FROM TRISOMY 21 HUMAN FETUSES. P. Caviedes*, B. Ault* and S. I. Rapoport (SPON: A. NORONHA). Laboratory of Neurosciences, National Institutes on Aging, NIH, Bethesda, MD 20892, U.S.A.

Trisomy 21 (Down Syndrome) results in abnormalities in electrical membrane properties of cultured human fetal dorsal root ganglion (DRG) neurons. Action potentials show faster depolarization and repolarization rates, with decreased spike duration, compared to diploid neurons. To analyze the faster depolarization rate of trisomic neurons, we studied the sodium currents of cultured human fetal DRG neurons from trisomy 21 and control subjects, using the whole cell patch clamp technique. A fast, tetrodotoxin (TTX)-sensitive Na^+ current; and a slow, TTX-resistant component were identified. The inactivation curves of both current types in trisomic neurons showed a 10 mV shift towards more depolarized potentials compared to control neurons. Thus, whereas essentially all of the fast Na^+ channels were inactivated at normal resting potentials in control cells, approximately 10% of these channels were available for activation in trisomy 21 cells. Further, the fast current showed accelerated activation kinetics in trisomic neurons. The slow Na^+ current of trisomic neurons showed slower deactivation kinetics than control cells. No differences in maximal conductances were observed between trisomic and control neurons. The data indicates that acceleration of the depolarizing phase of the action potential in trisomy 21 neurons at resting potentials is primarily due to activation of residual fast Na^+ channels that have accelerated activation kinetics.

219.11



TTX-SENSITIVE AND -RESISTANT SODIUM CHANNELS IN A HUMAN NEUROBLASTOMA CELL LINE THAT DIFFERENTIATES IN RESPONSE TO RETINOIC ACID. R.E. Weiss* & N. Sidell*‡ (SPON: L. Kruger). Depts. of Pediatric Cardiology and *Pathology, UCLA School of Medicine, Los Angeles, CA 90024.

Na currents were recorded from human neuroblastoma cells (LA-N-5) before and after treatment with $4x10^{-6}$ M retinoic acid (RA) and 10^{-3} M dibutyrl cAMP with the whole-cell voltage clamp technique. Cells were bathed in a Tyrodes solution at 18° C. K currents were blocked with internal Cs. The holding potential was -80 mV. Peak Na currents were recorded at test potentials near 0 mV. The mid-point of steady state inactivation was between -40 and -50 mV. Dose-response experiments demonstrated that 10-20% of the Na current was TTX resistant, requiring >10 µM TTX for complete block. All Na currents were blocked by Co at a half-blocking concentration of 0.1-0.2 mM. After 10 days post RA treatment, the kinetic properties of the Na current appeared unchanged. Preliminary results suggest that the ratio of TTX-resistant to TTX-sensitive Na channels declines.

PATCH-CLAMP CHARACTERIZATION OF NATIVE Na CHANNELS FROM ELECTROCYTES OF THE ELECTRIC EEL *Electrophorus electricus*. S. Shenkel* (SPON: W.S. Agnew). Dept. of Cellular & Molecular Physiol., Yale Univ. School of Medicine, New Haven, CT 06510.

Macroscopic and single-channel currents were recorded from inside-out patches of innervated electrocyte membrane at 22-24°C. The figure shows currents in response to steps from -40 to +100 mV. Peak currents of 40 to 90 pA were obtained between 0 and +10 mV. Currents were characterized by an activation midpoint potential near -5 mV and an apparent gating charge of ~ 3e. The mean current was half inactivated at -87 mV. The single-exponential inactivation time-constants became shorter between -50 mV (~1 msec) and 0 mV (~0.3 msec) and gradually increased with stronger depolarizations to ~1 msec at +130 mV. Under biionic conditions the selectivity ratio P_{Na}/P_K was concentration dependent. The single-channel slope conductance was ~16 pS (mM: 200 Na_{pip}/200 K_{bath}) at -40 mV.

DEAE, A PROCAINE METABOLITE, RAISES FIRING THRESHOLD OF PYRAMIDAL CELLS. L.R. Cole*, and J.F. Butterworth IV. Dept. of Anesthesia, Wake Forest Univ. Medical Center, Winston-Salem, NC 27103

Procaine, a local anesthetic which is rapidly metabolized in serum to diethylaminoethanol (DEAE) and p-aminobenzoic acid, has been shown to produce long-lasting analgesia after intravenous infusion.[1,2] These findings could be explained if procaine metabolites had pharmacological activity. The present study was undertaken to determine whether DEAE alters excitability of brain cells similarly to procaine, its parent compound.

Microelectrode current clamping methods were used to measure threshold and spike amplitude before and after drug application to rat hippocampal slices.

Procaine greatly increased threshold (300-400%) at concentrations (0.5 & 1.0mM) which minimally reduced spike amplitude, and did not inhibit impulse conduction. Likewise, 5mM DEAE increased threshold (300-400%) but permitted impulse conduction.

Our findings demonstrate that DEAE, at a concentration obtainable after prolonged procaine administration, alters excitability of brain cells. Thus, persisting DEAE levels may underlie the prolonged effects of procaine infusions.

EFFECTS OF CYANIDE ON THE EXCITABILITY OF CULTURED NEUROBLASTOMA CELLS. S.S.Deshpande*,M.Adler,R.E.Sheridan and D.J.BRAITMAN*, Neurotoxicology Branch, U.S. Army Med. Res. Inst. of Chem. Def., Aberdeen Proving Ground, MD 21010

Mechanisms underlying alteration of excitability by sodium cyanide (CN) were investigated in hybrid NG108-15 neuroblastoma cells differentiated with 1mM dibutyryl cAMP. These cells exhibit action potentials as a result of a sequential increase in conductance to Na^+ (Na-spike) and Ca^{2+} (Ca-spike). After 15 minutes perfusion, CN (1-5mM) produced a selective inhibition of the Ca-spike elicited by anodal break stimulation. After 30-45 minutes CN exposure,Ca-spike threshold increased, the spike amplitude was depressed 20-30% and the time course was prolonged. This depression was further enhanced during repetitive stimulation as shown by a decline in amplitude of successive responses which led to a complete block. These effects were reversible; complete recovery was observed after 45-60 minutes of perfusion with CN-free medium. Higher CN concentration (10mM) produced depression of Na^+ as well as Ca^{2+} components of the action potential. Although the role of cellular anoxia in inducing these effects is not clear, the preferential action of CN in suppressing the Ca-spike suggests an alteration of Ca^{2+} conductance as shown earlier, in mouse dorsal root ganglion cells (Duchen, M.R. and Somjen, G.G., J. Physiol, 401, 61-P, 1988).

ANTITOXIN COMPONENTS OF SCORPION VENOM (LEIURUS QUINQUESTRIATUS) G.B. Brown, R. J. Bradley and J.E. Gaupp*. Neuropsych. Res. Prog. and Dept. of Psych., Univ. of AL at B'ham, Birmingham, AL 35294

Scorpion venoms from a variety of species are typically multicomponent mixtures of polypeptides, the individual components of which often share significant sequence homology with other constituents of both the same and other venoms. Thus, families of sodium channel scorpion polypeptide neurotoxins (α, β, γ toxins) have been classified on the basis of sequence homologies, immunological cross-reactivity, and common sodium channel effects (e.g. Kopeyan et al., FEBS Lett. 181: 211-217, 1985). Due to the presence of numerous homologs with varying activities, we hypothesized that there may be present in the venom components (albeit at low concentrations) that bind the Na channel receptor with high affinity, yet lack efficacy. Such components would represent natural experiments with relevance to structure-activity relationships of scorpion neurotoxins and might provide useful antitoxins. We now report the presence of such components in the venom of L. quinquestriatus with antitoxin activity apparently directed against scorpion α-toxins.

Whole venom (Sigma Chemical Co.) was dissolved in 0.1 M NH_4OAc, pH 6.9 (40 mg/ml) and fractionated on a Rainin Dynamax C18 column (1x25 cm) using a 2-step gradient between 15 and 80% isopropanol in ammonium acetate. Fractions eluting at 15% and at 80% isopropanol were identified in a screening assay as having an inhibitory effect on α-scorpion toxin-enhanced BTX-B binding to rat brain sodium channels. The latter fraction was the more potent and has been further studied. Pretreatment of isolated rat phrenic nerve with this fraction at a concentration corresponding to 0.2 mg whole venom/ml had no effect on the compound action potential (CAP), but did inhibit the effect of L. quinquestriatus toxin V (an α-toxin) on the CAP. Further purification of this component by gradient HPLC on a C4 reversed phase column has yielded an active fraction that is ≥ 80% pure by native and SDS PAGE. We are currently working to obtain sequence information for this interesting component.

CONDUCTION MEASURED IN SINGLE DEMYELINATED AND REMYELINATING AXONS USING OPTICAL TECHNIQUES. P. Shrager, C. Rubinstein* and E. Brunschweiger*. Dept. of Physiology, Univ. of Rochester Medical Center, Rochester, NY 14642.

In amphibian and mammalian peripheral axons sodium channels are present in demyelinated internodes, though at much lower densities than at nodes of Ranvier (Brain Res. 483: 149 (1989)). In the present study we have followed conduction in single fibers optically. *Xenopus* sciatic nerves demyelinated by lysolecithin were stained with the dye RH155. Light absorption measurements were made at 705±25 nm. In control nerves signals were confined to the nodal region (velocities, 7-24 m/s). At one week post-injection some axons were covered by loose, disrupted myelin while others had been completely demyelinated by macrophages. Optical records showed that action potentials could propagate >1 mm in these cells (at ~1 m/s), though successful conduction entirely through the lesion (~3 mm) was very rare. At 10-12 days post-injection proliferating Schwann cells begin to envelop the demyelinated fibers and at 14-15 days the first few lamellae of new myelin can be seen. Conduction through these zones remains at about 1 m/s, but increasing numbers of signals traverse the entire demyelinated region. Calculations allow an assessment of the relative importance of internodal sodium channels and of new, thin myelin in this process. Supported by the NIH (NS17965) and the National Multiple Sclerosis Society (RG-1774).

POTASSIUM CHANNELS III

The MBK1 mouse K^+ channel protein is encoded by a single uninterrupted exon. K. G. Chandy*, #C. Williams*, R. H. Spencer*, +B. Tempel, #G. A. Gutman* (SPON: M. Cahalan). Dept. of Med. & #Dept. of Microbiology & Molecular Genetics, Univ. of CA Irvine, CA 92717; +Geriatric Res , Education and Clin. Ctr, VA Med. Ctr, Seattle.

Several classes of K^+ channels have been identified in diverse cell types. The molecular mechanisms responsible for generating these physiologically diverse K^+ channels are best understood in *Drosophila*. Four different K^+ channel proteins arise from the *Shaker* locus through alternative splicing of a single primary transcript. Expression of cDNAs encoding these proteins in *Xenopus* oocytes gives rise to voltage-dependent K^+ currents with different physiological properties. In contrast, we report here that the voltage-dependent K^+ channel gene from mouse brain, MBK1, is encoded by a single, uninterrupted exon. Furthermore, two genes closely related to MBK1 are encoded at distinct genomic loci. Restriction map data suggest that one of these genes encodes the mouse homologue of the second rat brain K^+ channel (RBK2) cDNA, implying that it may also have an intronless coding region. If other mammalian K^+ channels have intronless coding regions, their genomic sequences may be readily expressible in *Xenopus* oocytes, thereby facilitating the experimental association of K^+ channel genes with the biophysical behavior of the proteins they encode. These data suggest that discrete genes may be responsible for K^+ channel diversity in mammalian cells.

220.2

MOUSE BRAIN GENE MBK1 CODES FOR A VOLTAGE-SENSITIVE K CHANNEL OF THE DELAYED RECTIFIER TYPE. K. M. Houamed*, B. L. Tempel and W. Almers, Depts. of Physiology & Biophysics and Pharmacology, Univ. of Washington, Seattle, WA 98195

Because MBK1 is highly homologous to the *Shaker* gene of *Drosophila*, MBK1 was suggested to code for a voltage-sensitive K channel (Tempel et al., Nature 332, 847). Indeed, mRNA transcribed from MBK1 in vitro caused the appearance of voltage-sensitive K channels (30 µA at 10 mV) in *Xenopus* oocytes. Cell-attached patch recordings were made from 4 cells with 5 µm tip pipettes filled with Ringer. In the Fig., 16 voltage pulses (arrows) to between -50 and 90 mV were applied from a holding potential of -100 mV. Channels opened with a delay. Activation was rapid, being half-maximal within 1.8 ± 0.1 ms at 50 mV. No inactivation is evident (< 3% in 1 s at 50 mV). The open probability was half maximal at -19 ± 6 mV. The reversal potential was 89 ± 8 mV, indicating a high selectivity of the channel for K over Na. These properties are characteristic for K channels of the delayed rectifier type, as found in squid giant axons. Supported by NIH grants NS-27206 and AR-17803.

220.3

A NON A-TYPE POTASSIUM CHANNEL WITH DELAYED RECTIFIER PROPERTIES: ISOLATION THROUGH EXPRESSION CLONING IN *XENOPUS* OOCYTES. G.C. Frech, A.M.J. VanDongen, G. Schuster, A.M. Brown and R.H. Joho. (SPON: D. Kunze). Department of Molecular Physiology and Biophysics, Baylor College of Medicine, Houston, TX 77030.

Voltage-activated potassium (K^+) channels are an exceptionally diverse and widely distributed class of ion channels. We have isolated from the rat brain and expressed in *Xenopus* oocytes a new type of K^+ channel genc (non A-type) with properties of a delayed rectifier. Size-fractionated rat brain poly(A)$^+$ RNA was microinjected into *Xenopus* oocytes to identify fractions expressing potassium channels. Oocytes injected with RNA enriched for sizes between 3.3-4.2 kb expressed a depolarization-induced outward potassium current (I_K). This RNA was used to construct, in a transcription-competent vector, a directional cDNA library enriched for full-length inserts (Frech, G. & Joho, R. *Gene Anal. Techn.* 6:33, 1989). DNA from pools of cDNA clones were used as templates for *in vitro* synthesis of mRNA. After microinjection of oocytes with transcripts, we detected I_K currents in several pools of 10,000 recombinants. Using the oocyte system as a screening assay and by selecting and subdividing "positive" pools containing 1000, 100, and 12 clones, a single functional clone drk1 (with a 3.4 kb insert) was isolated. The electrophysiological properties of this K^+ channel were reminiscent of the delayed rectifier. The expressed channels showed sigmoidal voltage-dependent activation, inactivated only partially with a time constant of several seconds, and were selective for K^+ over Na^+. The DNA sequence of drk1 was determined and showed a open reading frame encoding a protein of 853 amino acids. Comparison of drk1 to K^+ channel sequences from *Drosophila*, rat and mouse shows that drk1 is most closely related to Shab from *Drosophila* (70 % identity in the core region), whereas A-type channels from *Drosophila* and rat brain do not show a close relationship. The fact that A-type channel genes of rat and *Drosophila* are more related to one another than to our new K^+ channel indicates that A-type and non-A-type K^+ channels are evolutionarily older than the common ancestor of flies and mammals.

220.4

CHARACTERIZATION OF A CLONED DELAYED RECTIFIER POTASSIUM CHANNEL FROM RAT BRAIN EXPRESSED IN *Xenopus laevis* OOCYTES. A.M.J. VanDongen*, G.C. Frech*, R.H. Joho*, and A.M. Brown,
Dept of Molecular Physiology and Biophysics,
Baylor College of Medicine, Houston, Texas, TX77030.

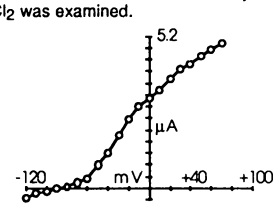
Voltage dependent K^+ channels are diverse and widespread. We have recently isolated a cDNA clone (*drk1*) encoding a K^+ channel from rat brain by expression cloning, using *Xenopus* oocytes (Frech *et al.*, this meeting). This channel was expressed in oocytes by injection of *in vitro* transcripts and functionally characterized using 2-electrode voltage clamp (2EVC) and patch clamp techniques. Depolarizing voltage steps from holding potentials between -80 and -30 mV produced large (> 10 μA) outward currents, which did not inactivate within 500 msec. In 2EVC experiments, threshold for activation was -20 mV, time to half maximal activation ranged from 100 to 10 msec, and activation kinetics were sigmoidal. Using 10 second voltage steps, partial inactivation did occur with a time constant of several seconds. Reversal potentials were estimated from instantaneous current-voltage relationships. Substituting external Na^+ for N-Methyl-D-Glucamine$^+$ had a negligible effect, while varying external K^+ concentration shifted the reversal potential with a slope of 48 mV per decade. K^+ currents were more sensitive to 4-AP (IC_{50}=0.5 mM) then TEA (IC_{50}=10 mM). The density of expressed channels was so large that in cell-attached patch experiments using pipettes of 1 Mohm, macroscopic K^+ currents (up to 500 pA) were recorded. Single channel current were recorded using small pipettes and oocytes injected with less RNA. The unitary current amplitude at +40 mV was 0.5 pA, the mean open time was 5 msec and the probability of opening versus time resembled macroscopic currents. Functionally, *drk1* expresses a channel that activates more slowly than any of the cloned K^+ channels expressed in oocytes thus far and more closely resembles a delayed rectifier than an A channel. Since *drk1* is also structurally distinct from reported K^+ channel cDNAs, we have identified a novel K^+ gene.

220.5

FUNCTIONAL CROSS-HYBRIDIZING CLONES OF A RAT BRAIN DELAYED OUTWARD RECTIFYING POTASSIUM CHANNEL. J.A. Drewe, G. Frech, T. VanDongen, A.M. Brown and R.H. Joho. (SPON: P. Rutecki). Dept. of Molecular Physiology and Biophysics, Baylor College of Medicine, Houston, TX 77030.

The cloning and expression of a rat brain delayed outward rectifying potassium channel by Frech *et al* is being presented at this meeting. Families of related gene products have been found for both the rat sodium channel and for the *Drosophila* transient potassium channel. Low-stringency cross-hybridization techniques were used to isolate related clones from other rat brain cDNA libraries. The potassium channel clone was nick translated and used to screen 500,000 cloning events. The hybridization conditions were 50% formamide at 30°C, washing with 290 mM NaCl, 18 mM PO_4 and 2 mM EDTA (2X SSPE) at 35°C. Thirteen positive clones were isolated, three of which with indications of low homology. RNA has been transcribed *in vitro* from ten of these clones and injected into *Xenopus* oocytes for expression. Variations have been found in the electrophysiological kinetics of the expressed currents. These are in the process of being correlated with differences in the primary sequences. These results are likely to provide information about the molecular bases for structure-function for this rat brain delayed outward potassium channel.

220.6



PROPERTIES OF A CLONED RAT BRAIN POTASSIUM CHANNEL EXPRESSED IN XENOPUS OOCYTES. M.J.Christie, J.P.Adelman,* J.Douglass* and R.A.North Vollum Institute, Oregon Health Sci. Univ. Portland, OR 97201.

A clone (RBK-1) which was isolated from a rat hippocampus cDNA library encodes a voltage activated potassium channel which is sensitive to blockade by 4-aminopyridine and tetraethylammonium, (Christie et al, Science 244:221, 1989). Therefore, the current expressed in Xenopus oocytes has features in common with both delayed rectifier and A-currents in hippocampal neurons. Further properties of the current were examined in the present study. Recordings of membrane current were made during depolarizing pulses using oocytes injected with RNA transcribed in vitro from RBK-1. The concentration of blockers producing a 50% reduction of the current was 5.5 ± 0.4 nM (n=3) for charybdotoxin and 6.1 ± 0.8 (n=6) for α-dendrotoxin. β-bungarotoxin (300 nM) did not block the current, or affect the inhibition produced by α-dendrotoxin (10 nM). The expressed current differs in toxin sensitivity from both delayed rectifier and A-currents in hippocampal neurons. The predicted amino acid sequence of RBK-1 contains a consensus sequence for phosphorylation by A-kinase. Application of forskolin (3 μM) or injection of cAMP (4 mM) into oocytes did not affect the outward current. When the phosphorylation site of RBK-1 was changed from serine (ser^{445}) to alanine by site directed mutagenesis, the induced currents were indistinguishable from the wild type.

220.7

EXPRESSION OF A POTASSIUM CHANNEL FROM RAT BRAIN cDNA IN *XENOPUS* OOCYTES. D.L. Lewis, D.E. Clapham* and E.G. Peralta*. Dept. Pharm., Mayo Clinic, Rochester, MN 55905 and Dept. Molecular Biology, Genentech, Inc., San Francisco, CA 94143.

An oligonucleotide probe encoding amino acids 72-98 of a putative mouse potassium channel protein was used to screen a rat forebrain cDNA library under high stringency conditions. A single clone was identified which encoded a 495 amino acid protein displaying >90% identity with the mouse protein sequence. In vitro transcripts encoding this putative rat forebrain potassium channel were synthesized following insertion of the cDNA into a plasmid vector containing an SP6 promoter sequence. *Xenopus* oocytes were injected with 25ng mRNA. Whole cell currents were recorded using a two microelectrode voltage clamp on day 3. A non-inactivating, voltage-dependent outward potassium current was recorded (Fig). This current activated at potentials ≥-60mV. Control oocytes never showed this outward current. The sensitivity of this current to TEA, 4-AP and $BaCl_2$ was examined.

220.8

CLONING AND EXPRESSION OF K^+ CHANNELS FROM RAT BRAIN R.Swanson, K. Folander, J. Antanavage, C. Bennett, J. Williams, *L. Kaczmarek, R.B. Stein, and J. Smith Merck Sharp and Dohme Research Labs, West Point,PA and *Dept. of Pharmacology, Yale Univ. Sch. Med., New Haven, CT

K41, a cDNA encoding the putative carboxy terminal half of a rat brain K^+ channel (Kaczmarek, 1988), was extended in the 5' direction by constructing a specifically primed cDNA library. Two classes of upstream sequences were isolated. One, represented by clone A, contains sequences identical to the 5' end of K41 while the other, represented by clone B, is homologous but nonidentical. Clone A, when ligated to K41, induces a delayed rectifier type I_K in Xenopus oocytes. It activates in a voltage-dependent manner with a midpoint of activation at +20mV. Time to peak current (at 40mV) is 38ms at room temp, and the currents show only partial inactivation during depolarizing pulses as long as 10s. Clone B, when ligated to K41, induces the expression of a more rapidly activating I_K with a time to peak (at 40mV) of 12ms at room temp. It activates at voltages more negative than does clone A, with a midpoint of activation near -25mV, and also shows little inactivation during prolonged depolarizing steps. Both currents are blocked completely by 1 mM 4AP and are relatively insensitive to block by TEA (IC_{50}=100 mM).

220.9

ISOLATION OF A cDNA CLONE CODING FOR A SECOND POTASSIUM CHANNEL EXPRESSED IN RAT BRAIN. D. McKinnon. Department of Pharmacology, Washington University Medical School, St. Louis, MO 63110.

A second potassium channel expressed in rat brain is identified by cloning and characterization of cDNA clones. Two cDNA clones, isolated from rat brain libraries, encode a 499 residue protein that is 80% identical with a previously described rat brain potassium channel and 68% identical with a *Drosophila* potassium channel. This new channel is called BK2 to distinguish it from the previously described potassium channel (BK1). The BK2 gene, unlike the *Drosophila* potassium channel gene complex, appears to produce a single, large RNA transcript. Southern analysis of rat genomic DNA indicates that the BK1 and BK2 transcripts are the products of independent genes. Analysis of the distribution of BK2 transcripts in rat brain by in situ hybridization histochemistry suggest that the BK2 gene is ubiquitously expressed by CNS neurons. Identification of this putative second mammalian potassium channel cDNA indicates the existence of a potassium channel gene family, confirming electrophysiological data on the diversity of potassium channels expressed in rat brain.

220.10

CLONING AND EXPRESSION OF A DELAYED RECTIFIER TYPE K^+ CHANNEL FROM NEONATAL RAT HEART AND DES-PRIMED RAT UTERUS K. Folander, J. Smith, J. Antanavage, C. Bennett, R.B.Stein and R. Swanson (SPON:R. Gould) Merck Sharp and Dohme Research Labs, West Point, Pennsylvania

Northern blot analysis of rat poly A^+ mRNAs, probed with oligonucleotides derived from the sequence of a K^+ channel from rat kidney (Takumi et al, 1988), identified bands of the same size (0.7kb) in the poly A^+ fractions of RNA from kidney, neonatal heart, and DES-primed uterus. No signal was observed in mRNA from brain, adult heart, or non-primed uterus. The polymerase chain reaction was used to clone the cDNAs encoding the channel from neonatal heart and DES-primed uterus. The nucleotide sequences of both clones are identical to that from kidney. Injection of RNA transcripts of the clones into Xenopus oocytes resulted in the expression of outward K^+ currents, measured using standard two microelectrode voltage clamp technique. The currents slowly activate over a time course of seconds in response to depolarizing potentials of $\geq$-20mV. Currents were K^+ selective as determined by tail current analysis in different K^+ concentrations. TEA (20mM) partially blocked the slow outward currents and the antiarrhythmic drug, clofilium, blocked the current with an IC_{50}=75uM. Antisense oligonucleotides derived from the clones specifically inhibit the expression of the slow outward current observed in oocytes injected with mRNA from the parent tissues (eg., kidney or uterus).

220.11

SIZE FRACTIONATED RAT BRAIN mRNA INDUCES VARIOUS VOLTAGE DEPENDENT POTASSIUM CHANNELS IN XENOPUS OOCYTES. J.H. Hoger*[1], B. Rudy[2], N. Davidson[1],& H. Lester[1]. Divs. of Biology & Chemistry, Caltech, Pasadena, CA 91125. and Dept. of Physiology & Biophysics, N.Y.U. Med. Ctr., N.Y., N.Y. 10016.

The great diversity of voltage dependent K channels encoded in rat brain mRNA was studied by two microelectrode voltage clamp experiments of Xenopus oocytes injected with unfractionated and sucrose gradient size fractionated poly(A) RNA. Our main conclusions are: (1) injection of the principal I_A current encoding fractions (5-7Kb) gives tetraethylammonium (TEA) sensitive channels unlike most of the I_A in unfractionated RNA. (2) The predominent delayed rectifier (I_k) currents are encoded in a (7-10 Kb) fraction. TEA (40mM) blocks only 50% of this I_k. This I_k does not inactivate during a 3sec depolarization at +30mV. (3) The I_k encoded in the (3 -7Kb) fractions contain components of different TEA sensitivity as compared to the unfractionated RNA. A component in these fractions undergoes inactivation at +30mV with a time constant of 2 sec.

Overall, these studies suggest a high degree of diversity in rat brain K channels. Supported by NIH GM-10991, GM-29836, GM-26976, Klingenstein Foundation, and an American Cancer Society Fellowship to JHH.

220.12

Cloning and characterization of human potassium channel genes. M. K. Mathew* §, M. Ramaswami* §, M. Gautam*§, C. A. Kamb* ‡, B. Rudy † & M. A. Tanouye §. § Division of Biology, California Institute of Technology, Pasadena, CA; ‡ Department of Biochemistry and Biophysics, University of California, San Francisco, CA; † Department of Physiology, New York University, New York, NY.

The polymerase chain reaction (PCR) can be used to amplify a region of DNA between two defined sequences. Using sequences conserved at the amino acid level between the *Shaker* potassium channel gene from *Drosophila* and a mouse homolog, six different sequences were amplified from human genomic DNA [Kamb *et al.* Proc. Natl. Acad. Sci., in press]. These amplified fragments were then used to probe several cDNA libraries prepared from human brain. cDNAs corresponding to five of the six amplified fragments were isolated and sequenced. All of the sequences are very similar to *Shaker* at the amino acid level and suggest similar structural organization for the encoded proteins. The nucleotide sequences, however, are quite dissimilar even among the various human clones indicating that they are derived from distinct genes. Amino acid sequence similarities are maximal in the putative voltage sensing element (S4) and in flanking hydrophobic segments that may define transmembrane helices. The connecting loops, on the other hand, are less conserved.

Correlation of the functional properties of these channels, as assayed after expression in Xenopus oocytes, with their sequences should allow the formulation of hypotheses regarding the structural basis of potassium channel function and diversity.

220.13

Molecular Cloning of a Rat Heart Potassium Channel cDNA. J. C-L. Tseng-Crank* and M. A. Tanouye. (SPON: W. D. Crank) Division of Biology, California Institute of Technology, Pasadena, CA 91125.

Cardiovascular-specific K channels are potential targets of anti-arrhythmia and anti-hypertensive drugs. We initiated investigation of rat heart K channels by using PCR method to amplify K channel-specific sequences from cDNA libraries. Amino acid sequences conserved among *Drosophila*, mouse, and rat K channels were selected to make degenerate oligonucleotide primers. A 220 bp fragment corresponding to transmembrane domains H4 to H6 was cloned and named RHKp. The amino acid sequence of RHKp is highly conserved compared to the corresponding region in a rat brain clone RCK1 (Baumann et al., EMBO J. 7:2457, 1988), with differences mainly in the loop connecting H4 and H5. One significant change from Tyr to Lys is found in H5. The DNA sequences are 77% homologous, with differences mostly in the third base position. Southern analysis suggests that in addition to the gene corresponding to RHKp there is another gene with substantial sequence homology. Using RHKp to screen heart library yielded 2 cDNAs of insert sizes 3.2 Kb and 1.8 Kb. *Xenopus* oocyte expression experiment may provide evidence correlating this gene to the known heart K channels.

220.14

THE SHAKER GENE SUPERFAMILY OF PUTATIVE POTASSIUM CHANNELS IN THE MAMMALIAN BRAIN. M. Pak*, A. Ratcliffe*, A. Wei, A. Butler*, D. Gottlieb and L. Salkoff. Dept. of Anat. & Neurobiol., Wash. U. Sch. Med., St. Louis, MO 63110

Previously we demonstrated in Drosophila the existence of a family of Shaker-like genes, Shab, Shaw, and Shal. We now report that similar genes exist in mammals and that each Drosophila gene may correspond to a separate subfamily of genes in mammals. In Drosophila the Shaker gene primary transcript is extensively alternatively spliced to produce a subfamily of highly similar potassium channel proteins (Papazian et al., Science, 1987). In mammals, however, there is no evidence that extensive alternative splicing exists. Instead, a Shaker subfamily of separate but highly similar genes may produce the minor variation of protein products (McKinnon, JBC, 1989). In mammals, similar subfamilies may exist representing perhaps all of the Drosophila genes. These subfamilies apparently produce proteins which vary only slightly in features relative to the differences seen between families. The diversification of the Shaker gene superfamily probably occurred prior to the separation of vertebrates and invertebrates.

220.15

CLONING OF *APLYSIA* POTASSIUM CHANNEL WITH HOMOLOGY TO *DROSOPHILA SHAKER*. P. Pfaffinger*, B. Zhao*, M. Knapp*, J. Brunet*, D. Dugan*, and E.R. Kandel. HHMI, Columbia Univ., N.Y., N.Y. 10032.

Modulation of K^+ channels contributes to various forms of synaptic plasticity in *Aplysia*. To begin to examine K^+ channel modulation on the molecular level, we have cloned a K^+ channel from *Aplysia* that has high homology to the *Drosophila Shaker*, mouse and rat K channels. Homology screening was performed using PCR on total nervous system RNA. To screen, we constructed oligonucleotide pools for all possible codings of two short stretches of conserved amino acid sequence (one sense and one antisense). Using these two pools as primers, PCR amplified a single DNA band of 180 bp, the predicted size based on other K channel clones. This fragment was sequenced, and showed >85% identity to other K channel clones. We have made specific oligonucleotides to this *Aplysia* K channel and are using PCR to clone the complete coding region out from this central sequence. Amplification in the 3' direction, using oligo dT plus restriction sites as the 3' primer, has identified five different 3' ends, one of which has a possible A kinase phosphorylation site. These 3' ends are apparently generated by alternative splicing since Southern Analysis suggests this is a single copy gene. In the 5' direction, we have cloned past the transmembrane spanning regions. The domain containing the transmembrane spanning regions has >70% identity to other channels. We are now completing the cloning of the 5' end and attempting expression in oocytes.

220.16

A NEW METHOD FOR RNA PHENOTYPING ALLOWS MAPPING OF POTASSIUM CHANNEL mRNA ISOFORMS IN IDENTIFIED *APLYSIA* NEURONS. B. Zhao*, E.R. Kandel, and P. Pfaffinger* (SPON: J. Goldman). HHMI, Columbia, N.Y., N.Y. 10032.

K^+ channels differ in their distribution, function, and modes of regulation in different identified cells. We are exploring how expression of different K channel mRNA's, cloned from *Aplysia* nervous system, contribute to differential channel function and modulation in identified cells. Toward this end we have developed a new technique to determine the level for these mRNA's in individual neurons. We prepare total RNA from identified neurons. Following oligo dT primed reverse transcription, the cDNA is amplified using primers for specific K^+ channel mRNA isoforms. By diluting the cDNA until the specific K channel can no longer be amplified, we can measure the levels of expression for that specific mRNA in individual cells using a Poissonian analysis. This method is more sensitive for the measurement of rare transcripts that code for channel proteins than *in situ* hybridization and more precise than conventional RNA phenotyping. Preliminary experiments on one K^+ channel isoform show it to be expressed in R2, sensory clusters and bag cells. Normalized to calmodulin this isoform is present in these cells at 100 times greater levels than in mRNA prepared from total nervous system. Extending this work to other K^+ channels mRNA's and other cells should provide insights into the relationship between the expression of different isoforms and the electrical properties of specific neurons.

AGE- AND TISSUE-RELATED EXPRESSION OF POTASSIUM ION CHANNEL mRNA LEVELS IN THE RAT. CJ Luneau*, JB Williams*, and RB Stein*, (SPON: D Pettibone), Merck, Sharp & Dohme Res. Labs, West Point, PA

To assist concurrent efforts towards molecular cloning of mammalian K+ ion channels, total polyadenylated RNA pools were prepared from heart and brain of various aged Sprague-Dawley rats, and from various tissues of adult rat, and other species. Partial cDNA's of 4 different putative rat brain K+ channels (E.Levitan and L.Kaczmarek, unpublished, and R.Swanson, et al, unpublished) and a cloned heart delayed rectifier type K+ channel (K.Folander, et al, unpublished) were used as probes on RNA blots. Specifically hybridizing bands unique to each clone were identified and range from 0.7 to 9.5 kb. Developmental regulation of specific mRNA is observed for 2 of the 5 channels. Two of the channels appear to be specific to brain; the other 3 are also observed in other tissues. Careful electrophysiological measurements from expression of whole mRNA pools and the cloned individual channels will be necessary to dissect the role of each in defining the electrical excitability of the rat heart and nerve cell at various developmental stages.

220.18

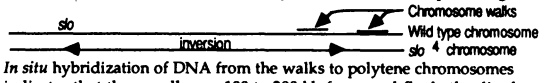
EXPRESSION OF TRUNCATED I_A CHANNEL SUBUNITS IN MUTANT OR TRANSGENIC DROSOPHILA. A. Mallart, G. Gisselman‡, S. Sewing‡, B.W. Madsen‡, C. Bourret‡, D. Angaut-Petit‡, F. Müller-Holtkamp‡, A. Ferrús‡ and O. Pongs‡. Ruhr Universität Bochum, F.R.G.; C.N.R.S., Gif/Yvette, France and Instituto Cajal, Madrid, Spain.

Shaker (*Sh*) mutants of *Drosophila melanogaster* lack or have abnormal transient K current (I_A) in muscle or nervous tissues. Some *Sh* mutants, like Sh^{102}, behave as antimorphs in gene dosage tests. Since the *Sh* locus encodes a transcription unit which expresses a family of I_A channel subunits, it was postulated that mutated *Sh* gene products give rise to abnormal I_A channel subunits. We found by cloning and sequencing the appropriate part of the Sh^{102} DNA that the mutation caused a base exchange giving a termination codon thereby generating truncated I_A subunits lacking the 6th presumed transmembrane helix and the entire carboxy terminus. To explain the dominant antimorphic behavior of Sh^+/Sh^{102} heterozygotes, we hypothesized that the truncated I_A channel subunits produced in Sh^{102} form multimeric assemblies with their normal counterparts to give inactive channels. This was tested by inserting similarly truncated cDNA in wild type flies using a heat shock expression vector which lead to the transformation of wild type into *Sh* flies as shown by a 30% reduction in larval muscle I_A, increased transmitter release in neuromuscular junctions and leg shaking behavior in adult flies.

220.19

DECREASED POTASSIUM CHANNEL CONDUCTANCE, ENCODED BY THE *SHAKER* LOCUS IN *DROSOPHILA*, INCREASES VOLATILE ANESTHETIC REQUIREMENTS M.Maze, J.Tinklenberg, I.S.Segal, R.W.Aldrich (SPON: K.L.Chow) Depts. of Anesthesia and Neurobiology, Stanford University, Stanford CA 94305 & PAVAMC CA 94304

Evidence is accumulating for the pivotal role of potassium (K^+) conductance for anesthetic action(FASEB J 3:A1202,'89). The K^+ channel encoded by the *Shaker* (*Sh*) locus on the X chromosome of *Drosophila melanogaster* (*D.m.*) may be similar to the one altered by volatile anesthetics. Alleles for the *Sh* locus which express different degrees of dysfunctional K^+ conductance ($Sh^{null} > Sh^{KS133} > Sh^5$) and the wild-type (WT) were tested for their sensitivity to the volatile anesthetic, forane. *D.m.* were equilibrated to a measured concentration of forane and a heat stimulus was applied to individual flies for a maximum of 6 sec. The flies were designated as nonresponders if no purposeful movement was noted. The concentration of forane was adjusted and after equilibration the testing procedure was repeated. After testing at a minimum of 4 concentrations, the IC_{50}'s (forane concentration at which 50% of the flies were nonresponsive) were derived for each cohort (n=150). Compared to the WT (0.50%), Sh^{null} (1.57%) had a 3-fold, Sh^{KS133} (1.30%) a 2.6-fold and Sh^5 (0.68%) a 1.3-fold increment in the IC_{50}. This rank order of insensitivity to forane correlates with the degree to which K^+ conductance is decreased and provides further evidence for the important role played by K^+ conductance in volatile anesthetic action.



Supported by NIGMS #30232 and the Veterans Administration.

MOLECULAR ANALYSIS OF THE *SLO* LOCUS: A GENE AFFECTING A CA^{2+}-ACTIVATED K^+ CURRENT. N. S. Atkinson*, G. A. Robertson and B. Ganetzky, Lab. of Genetics, Univ. of Wisc. Madison, WI 53706

The transient Ca^{2+}-activated K^+ current, I_{Cf}, is required for the normal repolarization of the action potential in the dorsal longitudinal flight muscles (DLM) of *D. melanogaster*. The slo^1 mutation eliminates I_{Cf} causing action potentials to be much broader than normal. A 37°C heat pulse immobilizes slo^1 homozygotes for extended periods. The *slo* gene may encode a protein that 1) is involved in regulation or assembly of the channel that conducts I_{Cf}, 2) conveys the Ca^{2+} signal to the channel or 3) is the channel itself. We are utilizing a mutational approach to clone *slo* because such an approach does not rely on assumptions concerning the nature of the gene product.

We have used behavioral screens to isolate a number of new mutant *slo* alleles and have demonstrated that the behavioral and physiological phenotypes result from a single mutational event. As a prerequisite to cloning, the gene was localized cytologically to the right arm of chromosome 3 with the use of five chromosome rearrangements. The slo^4 mutant allele is the result of an inversion, one end of which is in the *slo* locus and the other end of which is in the *E(spl)* region. Two chromosome walks from this region were furnished to us by E. Knust and J. Campos-Ortega.

In situ hybridization of DNA from the walks to polytene chromosomes indicates that these walks are 100 to 200 kb from, and flank, the distal end of the inversion. Extension of the existing chromosome walks to the distal endpoint of the inversion will provide us with an entry point into the *slo* gene. This approach will enable us to elucidate at a molecular level the nature of the *slo* product and its role in the production of I_{Cf}.

221.1

KAPPA OPIATE RECEPTORS: MAJOR NEUROENDOCRINE ROLE AND ATYPICAL RESPONSE TO CHRONIC STIMULATION IN ONTOGENY. C. Kuhn, W. Adamson* and R. Windh.* Dep't of Pharmacology, Duke University Medical Center, Durham, NC 27710.

The present study contrasts the normal ontogeny and development of tolerance at mu and kappa opiate receptors, and evaluates the contribution of these characteristics to the neuroendocrine adaptations which occur during perinatal opiate treatment. The ontogeny of growth hormone (GH) and corticosterone (CS) responses to the mu/delta agonist morphine (MOR) and the kappa agonist U50,488 were determined. Also, GH and CS responses to U were measured 48 hrs after 5 days of chronic U(.5 mg/kg/day up to 2.5 mg/kg/day) on days 5-9 or 20-25. For both hormones, U responses appeared earlier than MOR responses, but CS responses preceded GH (day 2 vs day 5). GH tolerance was not observed at any age, while CS tolerance was observedin weanling pups but not earlier. These results show that kappa responses reliably precede mu, as postulated earlier . The resistance to kappa tolerance contrasts with the marked and specific mu CS tolerance we have observed in neonatal or adult rats. These results show that adaptations of neural systems to chronic perinatal opiate treatment are not easily predicted by the timing of treatment relative to the first appearance of the response, but instead appears determined by the receptor subtype mediating the response and the particular response under investigation.

221.2

A COMPARISON BETWEEN THE ANTINOCICEPTIVE EFFECTS OF (S,S) AND (R,R) U-50, 488 FOLLOWING SYSTEMIC AND INTRAVENTRICULAR ADMINISTRATION. L.B. Estall*, P. de Costa*, K. Rice* and A. Pert (SPON: A. Gran da). BPB, NIMH and LC, NIDDK, Bethesda MD 20892.

Although kappa receptor-specific opiate agonists produce antinociceptive effects in a variety of tests, there is still confusion regarding the precise neural focus of their actions or pharmacological specificity. In these studies, we have evaluated and compared the antinociceptive properties of the active and inactive enantiomers of U-50, 488 (a selective kappa agonist) following either systemic or intraventricular injections. (S,S) U-50, 488 (the active enantiomer) increased reaction latencies in the hot-plate, paw-pressure and tail-flick tests. (R,R) U-50, 488 (the inactive enantiomer) did not alter the reaction times in any test. Surprisingly, however, the effects of the active enantiomer were relatively resistant to antagonism by either naloxone or MR-2266. Intraventricular injections of (S,S) U50, 488 (100 nmoles) also increased reaction latencies in the hot-plate and paw-pressure tests. The inactive enantiomer, however, was equally effective. Nor-BNI did not antagonize the effects of (S,S) U50, 488 in any test. These findings suggest that kappa agonist antinociception does not appear to involve supraspinal mechanisms, but is probably mediated either peripherally or at the spinal level.

221.3

SITES OF DOPAMINE RELEASE INHIBITION BY KAPPA AGONISTS: LACK OF LOCAL EFFECT IN THE NUCLEUS ACCUMBENS. B.A.Donzanti, M.A.Burian, J.S.Althaus and P.F.VonVoigtlander (SPON: E.C.Krimmer). NEOUCOM, Rootstown, Ohio 44272 and The Upjohn Company, Kalamazoo, Michigan 49001.

The selective kappa opioid agonist, U-50488H has been shown to reduce the release of dopamine in the striatum and nucleus accumbens (Dichiara et al., 1985). In the present experiments, microdialysis probes were inserted into the nucleus accumbens of freely moving rats. Perfusates were analyzed for dopamine, DOPAC, HVA and U-50488 by HPLC-EC. U-50488H (2.5-10mg/kg, s.c.) resulted in a dose related reduction of dopamine, DOPAC and HVA release. Overtly, the animals displayed an initial hyperactivity followed by hypomotility and excessive urination. In contrast, when U-50488H (up to 1mM) was perfused through the probe only a transient increase in dopamine release was noted. This coincided with a period of hypermotility. The effects of U-50488H on dopamine synthesis, levels and metabolism were assessed in aromatic amino acid decarboxylase (NSD 1015) treated rats. U-50488H did not cause the marked alterations of these parameters typical of the action of dopamine autoreceptor agonists. Together these results indicate that U-50488H acts at sites distant from the nucleus accumbens to inhibit dopamine release and that modulation of dopamine receptor mediated feedback is not involved.

221.4

REGULATION BY KAPPA OPIOID RECEPTORS OF TUBEROHYPOPHYSIAL DOPAMINERGIC (THDA) NEURONS AND THE SECRETION OF α-MELANOCYTE STIMULATING HORMONE (αMSH). J. Manzanares, K.J. Lookingland and K.E. Moore. Department of Pharmacology and Toxicology, Michigan State University, East Lansing, MI 48824.

The secretion of αMSH is tonically inhibited by THDA neurons projecting to the intermediate lobe of the pituitary. The purpose of the present study was to examine the role of kappa opioid receptors in regulating THDA neurons and the secretion of αMSH in male rats. The activity of THDA neurons was estimated by measuring in the dissected intermediate lobe of the pituitary: 1) the concentration of 3,4-dihydroxyphenylacetic acid (DOPAC) and 2) the accumulation of 3,4-dihydroxyphenlalanine (DOPA) after the administration of a decarboxylase inhibitor (NSD 1015). Systemic administration of U50,448, a kappa opioid agonist, caused a dose- and time-related increase in plasma levels of αMSH and a decrease in DOPAC concentrations and DOPA accumulation in the intermediate lobe. These actions of U50,488 were blocked by an intracerebroventricular injection of nor-binaltorphimine, a selective kappa opioid receptor antagonist, but not by naltrexone. These results suggest that the kappa agonist U50,488 increases αMSH secretion by decreasing the inhibitory tone of THDA neurons projecting to the intermediate lobe of the pituitary. (Supported by NIH grant NS15911).

SIGMA RECEPTORS REGULATE CONTRACTIONS IN GUINEA PIG ILEUM LONGITUDINAL MUSCLE/MYENTERIC PLEXUS. B.G. Campbell, M. Scherz*, J.F.W. Keana* and E. Weber. Vollum Institute, Oregon Health Sciences Univ., Portland, OR 97201 and Univ. of Oregon, Eugene, OR 97403.

Sigma receptors are specific, highly localized binding sites in limbic and sensorimotor structures of the brain as well as certain endocrine organs and peripheral structures. These sites interact with many psychotropic agents including the psychotomimetic benzomorphan opiates, the psychotomimetic drug phencyclidine (PCP) and its analogs, as well as numerous typical and atypical antipsychotic drugs such as haloperidol, chlorpromazine and the novel drugs BMY 14802, rimcazole and remoxiperide. Systematic investigations into the function of sigma receptors have been hampered by the lack of a wide spectrum of selective sigma receptor ligands and the lack of an in vitro bioassay system in which to study sigma receptor function.

We report here the characterization of 11 congeners of the selective sigma receptor ligand DTG (N,N'-di[o-tolyl]guanidine --see B. Tester, this meeting, for details of synthesis and structure-activity relationships) and the development of an in vitro bioassay demonstrating sigma receptor-mediated responses. DTG and 9 congeners with potent sigma receptor affinity dose-dependently and by a neuronal mechanism inhibit muscle contractions of the isolated guinea pig ileal longitudinal muscle/myenteric plexus preparation (LMMP) evoked by electrical stimulation or by exogenous serotonin acting via neuronal 5-HT3 receptors. Two additional DTG congeners with very low sigma recetpor affinity do not inhibit LMMP contractions evoked by either stimulus. The bioactivity of these and numerous other compounds strongly correlated with their binding affinity for CNS sigma receptors, suggesting the presence of functional sigma receptors in the LMMP. Supported by grants from NIMH (MH40303 and MH42068) and Cambridge NeuroScience Research.

1,3-DI(2-TOLYL)GUANIDINE AND PHENCYCLIDINE CAUSE SIGMA RECEPTOR MEDIATED INHIBITIONS OF SPONTANEOUS PURKINJE CELL FIRING RATE IN RAT CEREBELLUM. M. B. KIM*, P. C. BICKFORD-WIMER, R. FREEDMAN, AND B.J. HOFFER. (SPON: G.W. KINDT) V.A. Medical Center 1055 Clermont St. Denver, CO 80220; Department of Pharmacology UCHSC 4200 E. Ninth Ave. Denver, CO 80262

The relationship of sigma "opiate" and PCP receptors in the central nervous system has been the subject of much recent debate. In this study the physiological effects of the sigma agonist 1,3-di(2-tolyl)guanidine) (DTG) were investigated in the cerebellum using electrophysiological techniques. Local application of DTG via pressure micro-ejection from glass multibarreled micropipettes was compared with that of phencyclidine (PCP). Similar to PCP, local application of DTG caused a dose dependant and reversible inhibition of Purkinje cell firing rates. Dose response curves after local application of the two drugs demonstrated that they had equipotent ED50s of about 20 PSI-SEC. Previous investigations with PCP have demonstrated that it acts as an indirect noradrenergic (NE) agonist in the cerebellum. The possible interaction of DTG at NE synapses was investigated in animals pre-treated with 6-hydroxydopamine to destroy NE terminals. Paired animal experiments were performed to compare the potency of PCP and DTG between control and lesioned cerebella using the same multibarreled mircropipette. Cumulative population dose response curves to both DTG and PCP were significantly shifted to the right in 6OHDA treated rats ($p<0.02$ and 0.01 respectively, two tailed Kolmogorov-Smirnov test for two populations) suggesting that endogenous NE is important for the observed Purkinje cell responses to both PCP and DTG. Taken together, this data further supports the commonality of certain types of PCP and Sigma mediated effects in the cerebellum. Supported by USPHS grant .DA 02429 and the VAMRC

(+)-PENTAZOCINE ATTENUATES (-)-ETHYLKETOCYCLAZOCINE-INDUCED EEG AND EEG SPECTRAL POWER. N.C. Paquette, K.L. Marquis, N. Khazan and G.A. Young. Dept. of Pharmacol. & Toxicol., Univ. of Maryland Sch. of Pharm., Baltimore, MD 21201.

Benzomorphans have been shown to have both opioid and nonopioid components whose effects can be further delineated using enantiomers. We hypothesized that the nonopioid effects interact or suppress the opioid component in the racemates. Thus, an enantiomer with known nonopioid effects should suppress the opioid effects of a selective opioid enantiomer. I.v. administration of (-)-ethylketocyclazocine (EKC), a selective kappa opioid agonist, at 0.5 mg/kg produced high-voltage EEG bursts with peak frequencies in the 4-6 Hz band that were associated with exophthalmos and behavioral stupor. When (+)-pentazocine, (4.0 mg/kg), the nonopioid sigma enantiomer, was given, the EKC-induced high-voltage EEG bursts were attenuated and absolute spectral power in the 4-6 Hz band was decreased with a correlated decrease in behavioral stupor. These findings complement a previous study which demonstrated that haloperidol, a presumed sigma antagonist, unmasked opioid effects of U-50,488H, a kappa and sigma ligand, on EEG power spectra in rats (Young et al., FASEB J. 3:A421, 1989).

221.8

DESENSITIZATION AND SENSITIZATION TO THE BEHAVIORAL EFFECTS OF SUBSTANCE P AND EXCITATORY AMINO ACID (EAA) AGONISTS IN THE MOUSE SPINAL CORD: INVOLVEMENT OF OPIOID RECEPTORS. X. Sun* and A.A. Larson (SPON: D.H. Smullin). Dept. of Vet. Biol., Univ. of Minn., St. Paul, MN 55108.

We have previously demonstrated that repeated intrathecal (i.t.) injections of substance P (SP) in mice result in desensitization to the caudally directed biting and scratching behavior (CBS) elicited by SP. To determine whether desensitization develops selectively to this effect of SP, we tested various EAA agonists, which also produce CBS behavior when injected intrathecally, for their ability to evoke sustained CBS behavior after multiple challanges. Like SP, repeated i.t. injections of N-methyl-d-aspartate (NMDA) typically result in some desensitization but only after an initial potentiation. In contrast, repeated i.t. injections of kainic acid (KA) or quisqualic acid (Quis) result in marked sensitization. These results suggest that repeated i.t. injections of SP and EAA agonists result in behavioral profiles that are distinct in time course and intensity. SP-elicited desensitization is blocked by the opioid antagonists naloxone and beta-funaltrexamine (beta-FNA). To determine whether endogenous opioids are also involved in the sensitization or desensitization to EAA agonists, we evaluated the effect of opioid antagonists on these processes. Five nmol of 1,3-di-O-tolyguanidine (DTG), a sigma-selective antagonist, enhanced the development of SP desensitization but prevented NMDA desensitization. The delta antagonist ICI 174864, at a dose of 0.25 nmol, prevented NMDA desensitization but significantly inhibited sensitization to the effect of Quis. These data indicate that sigma opioid receptors may be involved in NMDA and SP desensitization whereas delta opioid activity antagonizes the development of Quis sensitization and NMDA desensitization. Supported by USPHS grants DA04090, DA04190 and DA00124.

221.9

GUINEA-PIG VAS DEFERENS CONTAINS *SIGMA* BINDING SITES BUT NOT PHENCYCLIDINE BINDING SITES. X.-Z. Wu* and T.-P. Su., Neuropharmacology Laboratory, Addiction Res. Ctr., NIDA , Baltimore, MD 21224.

The guinea-pig vas deferens was proposed to contain both *sigma* receptors and phencyclidine (PCP) receptors as *sigma* and PCP drugs potentiated electrically-induced twitches of the isolated tissue preparation (Vaupel, D.B. and Su, T.-P., Eur. J. Pharmacol. 139:125, 1987). This study examined the presence of these two receptors in the guinea-pig vas deferens using radioligand binding assay. [^{3}H]*d*-SKF-10047 bound saturably to a single class of binding sites in the homogenates of the guinea-pig vas deferens with a K_d of 311 nM and a Bmax of 1090 fmol/mg protein. IC50's of several representative *sigma* drugs in displacing [^{3}H]*d*-SKF-10047 from this binding site correlated well with the IC50's obtained from *sigma* binding in the brain (r = 0.96). However, attempts to label the PCP receptor in this tissue using [^{3}H]TCP (N-[1-(2-thienyl)cyclohexyl]piperidine) yielded negative results. The IC50's obtained from the *sigma* binding assay in the vas deferens did not correlate with the potentiating potencies observed in the previous study. Therefore, although the previously observed effects induced by *sigma* and PCP drugs in the vas deferens may be mediated in part through *sigma* receptors, the possibility exists that the responses are mediated through an as yet unknown mechanism.

221.10

LACK OF EVIDENCE FOR SIGMA RECEPTORS IN THE MOUSE VAS DEFERENS (MVD) PREPARATION. Susan J. Ward[1], Lee Hildebrand[1,*], Lorraine C. Fleissner[1,2] and Diane L. DeHaven-Hudkins[2]. Neurobiology, Sterling Research Group, [1]Rensselaer, NY 12144 and [2]Great Valley, PA 19355

It has been suggested previously (Weber et. al., Eur. J. Pharmacol. 138: 447, 1987, Neurosci.) that putative sigma agonists potentiate electrically stimulated twitch contractions (ESTC) of the MVD preparation, but only in concentrations 100 - 10,000 times greater than their Ki's in sigma binding assays. Thus, the purpose of the present study was to evaluate lower, potentially more relevant, concentrations of ligands for possible sigma receptor effects in the MVD.

Putative sigma agonists and antagonists all inhibited 0.1 Hz ESTC in nM concentrations. Inhibitory activity plateaued between 20 and 60% for all compounds except DTG, which had a shallow dose response curve. Subsequent to the plateau, higher concentrations (30 uM) of rimcazole and BMY-14802 fully inhibited ESTC.

	Sigma Binding	MVD			
Compound	Ki (uM)	IC_{50} ± s.e. (nM)	Emax	Slope	n
Haloperidol	8.5	172 ± 82	68 ± 11	1.5 ± 0.6	4
DTG	86.1	1944 ± 1300	100 ± 0	0.7 ± 0.1	4
BMY 14802	173	50.6 ± 11.3	39 ± 8	4.1 ± 1.5	4
Rimcazole	249	51.8 ± 31.2	38 ± 9	2.6 ± 0.9	4
(+)3-PPP	319	179 ± 59	44 ± 5	2.9 ± 0.4	8
(+)Pentazocine	871	16.9 ± 1.3	22 ± 3	2.4 ± 0.3	4

There was no correlation between inhibitory potency or maximal effect in the MVD and binding potency at sigma sites in guinea pig brain (r = -0.36 and -0.69 respectively). The inhibitory effects of (+)3-PPP on ESTC were not antagonized by the putative sigma antagonists DTG (10 uM), haloperidol (1 uM), rimcazole (3 uM) or BMY 14802 (3 uM), nor by yohimbine, (+)SCH-23390, (-)sulpiride, or naloxone. It is concluded that the inhibitory effects of sigma ligands in the MVD are not mediated by sigma receptors. Although the mechanism of sigma ligand effects in the MVD has not been established, the data caution against a presumption that effects of low concentrations of sigma ligands are sigma-receptor mediated.

We thank Drs. D.P. Taylor (Bristol-Myers) and R.M. Ferris (Burroughs-Wellcome) for the supplies of BMY-14802 and rimcazole.

221.11

AGE-RELATED DIFFERENCES IN SIGMA BINDING PARAMETERS AND BEHAVIORAL RESPONSES TO A SELECTIVE SIGMA LIGAND. M.K. Hemstreet*, R.R. Matsumoto, W.D. Bowen and J.M. Walker. (SPON: T.O. Bruhn). Brown University, Department of Psychology and Section of Biochemistry, Providence, RI 02912.

Sigma receptors were assayed using [^{3}H]-di-o-tolylguanidine in whole brain minus cerebellum of young adult rats (2-3 months old) and middle aged rats (5-6 months old). These binding studies showed that the older rats had poorer sigma binding parameters (Bmax=368 ± 34; Kd=53 ± 7) than the younger animals (Bmax= 557 ± 43; Kd=26 ± 2). The older animals also exhibited a decreased behavioral response to the selective sigma ligand, di-o-tolylguanidine (DTG). Unilateral microinjection of DTG into the substantia nigra pars reticulata of rats produced fewer contralateral turns in middle aged animals, compared to younger rats (t=2.83; P<0.02). Likewise, the postural changes produced by unilateral microinjection of DTG into the red nucleus were much weaker in the older animals (t=2.75; P<0.02). These data suggest that changes in the number and affinity of sigma binding sites that occur during development have subsequent effects on movement.

221.12

SIGMA DRUGS CAN BLOCK CARBACHOL-STIMULATED PHOSPHOINOSITIDE TURNOVER IN NCB-20 CELLS. J. Adams* and E. Weber. Vollum Institute for Advanced Biomedical Research, Oregon Health Sciences University, Portland, OR 97201.

The neurohybrid NCB-20 cells should provide an appropriate model for investigating the functional role of the haloperidol-sensitive sigma site (Largent, et al., EJP 124, 183, 1986; Adams et al., manuscript in preparation). It has recently been shown that sigma drugs block agonist-stimulated phosphoinositide (PI) turnover in rat brain synaptosomes (Bowen, et al., EJP, 149, 399, 1988). We here conducted studies to further characterize the nature of this effect in NCB-20 cells. Cells were pre-labeled with [3H]myo-inositol and the accumulation of [3H]inositol-1-phosphate ([3H]-IP1) was assayed in the presence of LiCl (Berridge, et al., Nature, 312, 315, 1984). Di-ortho-tolyl-guanidine (DTG), at 100 uM, completely attenuated the response elicited by 1mM carbachol (the effects of carbachol were mediated strictly through muscarinic receptors in these cells). There was no effect of 100 uM DTG on basal levels of [3H]-IP1. The inhibition by DTG was dose-dependent with an ED50 value of approximately 20 uM. The reduction of carbachol-stimulated [3H]IP1 accumulation by DTG was reversible, did not require a pre-incubation period, and was immediate. Carbachol dose-response curves performed in the presence of 50 uM DTG or haloperidol show a decrease in maximum response indicating that the inhibition by these two sigma ligands is noncompetitive in nature. DTG, however, did not antagonize PI hydrolysis stimulated by bradykinin in NCB-20 cells. The DTG congener, dimethyl-guanidine, which is inactive in sigma binding assays, was without effect at 1 mM, while the potent DTG congener, diadamantylguanidine, was as effective as DTG at inhibiting the carbachol response. These data suggest that sigma ligands can negatively modulate some component(s) of the PI signalling pathway. Supported by NIMH grants MH40303 and MH42608 and a grant from Cambridge NeuroScience Inc.

221.13

DETERMINATION OF EFFICACIES AT THE μ-OPIATE RECEPTOR IN A NEUROBLASTOMA CELL LINE. L. Toll, Life Sciences Division, SRI International, Menlo Park, CA 94025.

The μ-opioid receptor is the site mediating the analgesic activity of morphine and the majority of fused ring and peptide opiates. Some fused-ring opiates, so-called "mixed agonist/antagonists" such as nalorphine, are thought to be κ-agonists and μ-antagonists. It is unclear, with these compounds, which site mediates analgesic activits and, in fact, what their activity or efficacy is at the μ receptor. The neuroblastoma cell line SH-SY5Y has both μ and δ receptors and a μ receptor mediated inhibition of adenylate cyclase activity has been demonstrated. We have confirmed this, finding a maximum of 50 to 70% inhibition of forskolin-stimulated cAMP accumulation by morphine and other μ-agonists. The mixed agonist/antagonist nalorphine was less effective, causing only 25% inhibition at 100 μM. The morphine-induced inhibition was inhibited by naloxone but not by the selective δ-antagonist ICI 174,864. To determine efficacies of various opioid compounds at the μ receptor, we have determined potency in the inhibition of cAMP accumulation in intact cells, and under the same conditions, determined binding affinities at the μ receptor using the μ-selective peptide antagonist [^{3}H]CTOP. Relative efficacies, based on the relationship between potencies and binding affinities for selected compounds, will be discussed.

221.14

A NALTRINDOLE ISOTHIOCYANATE (NTI-NCS), A SELECTIVE NONEQUILIBRIUM DELTA OPIOID RECEPTOR ANTAGONIST. M. Sultana*, A.E. Takemori*+, P.S. Portoghese. Department of Medicinal Chemistry, College of Pharmacy, and Department of Pharmacology+, Medical School, University of Minnesota, Minneapolis, MN 55455.

Naltrindole (NTI) is a recently developed nonpeptide opioid antagonist that is highly selective for δ opioid receptors (Eur. J. Pharmacol. 146:185, 1988). In an effort to convert NTI into a selective, nonequilibrium δ opioid receptor antagonist we have synthesized its 5'-isothiocyanate (NCS) substituted analogue (NTI-NCS). Incubation of NTI-NCS (100 nM) with the mouse vas deferens preparation (MVD) for 30 min followed by thorough washing afforded an 18-fold shift (IC_{50} ratio) of the concentration-response curve for the δ-selective agonist, [D-Ala^2, D-Leu^5]-enkephalin (DADLE). On the other hand, the IC_{50} ratios of morphine (μ-selective) and ethylketazocine (κ-selective) did not differ significantly from unity in the guinea pig ileum preparation (GPI) after exposure to NTI-NCS. When administered i.c.v. (10 nmol) in mice 24 hours prior to antinociceptive testing (abdominal stretch) with the δ agonist, [D-Ser^2,Leu^5,Thr^6]enkephalin (DSLET), NTI-NCS shifted the dose-response curve by a factor of 50 (ED_{50} ratio). In contrast, NTI-NCS failed to shift the response of morphine and produced only a small shift (ED_{50} ratio = 3) with the U50488H. These experiments demonstrate the nonequilibrium, selective blockage of δ opioid receptors by NTI-NCS.

THE AFFINITY LIGAND "UPHIT" ACYLATES THE κ OPIOID RECEPTOR *IN VIVO*: RECEPTOR BINDING AND PHARMACOLOGICAL EVIDENCE. L. Band,*† B.R. de Costa,*§ V. Bykov,*† A. Pert,*†† S. Iyengar,§§ P.L. Wood,§§ K.C. Rice,§ R.B. Rothman† (SPON: C.J. Smith). † Unit on Receptor Studies, LCS, and †† BPB, NIMH, Bethesda, MD 20892; § Laboratory of Medicinal Chemistry, NIDDK, Bethesda, MD 20892; §§ G. D. Searle & Co., St. Louis, MO 63198.

An isothiocyanate analog, (1S,2S*trans*-2-Isothiocyanato-4,5-dichloro-N-methyl-N-[2-(1-pyrrolidinyl)cyclohexyl]-benzeneacetamide), of U50,488, designated "UPHIT," has been developed for site-directed acylation of κ opioid receptors. The (S,S) isomer displaced [^{3}H]U69,593 binding *in vitro* with IC_{50} values of 25.92 ± 1.74 nM, whereas IC_{50} values obtained for the (R,R) isomer and racemate were 827.42 ± 4.80 and 115.10 ± 1.22 nM, respectively. Twenty-four hours after i.c.v. injection of the racemate (0-100 μg/10 μl dimethyl sulfoxide), guinea pig brain membranes were prepared and pretreated with the site-directed acylators BIT and FIT, depleting membranes of μ and δ binding sites, respectively. Binding assays revealed that the 100 μg dose eliminated 98% of [^{3}H]U69,593 and 40% of [^{3}H]bremazocine sites without reducing [^{3}H]FOXY or [^{3}H]DADL sites. Injection of (-)-U50,488 and the (R,R) isomer of UPHIT produced no change in binding parameters. Pretreatment with 50 and 75 μg of the (S,S) isomer (i.c.v.) attenuated an increase in ACTH release induced by sytemic injection of 8 mg/kg of U50488H in rats. These results indicate that UPHIT binds selectively and irreversibly to κ sites and acts as an irreversible κ receptor antagonist.

221.16

CHRONIC HALOPERIDOL TREATMENT DIFFERENTIALLY REGULATES DOPAMINE AND SIGMA RECEPTORS. R. R. Matsumoto, W. D. Bowen and J. M. Walker. Department of Psychology and Section of Biochemistry, Brown University, Providence, RI 02912.

Haloperidol is a neuroleptic with equal affinity for dopamine and sigma receptors. A recent study in our laboratory showed that microinjection of haloperidol in the red nucleus of rats produces dystonic reactions through sigma receptors. We now report that chronic haloperidol treatment differentially regulates dopamine and sigma receptors. In this study, rats received daily s.c. injections of haloperidol (5 mg/kg) or an equal volume of saline for up to 20 days. The striata from these animals were assayed for dopamine receptors using [^{3}H]-sulpiride as the radioligand while the rest of the brain (minus cerebellum) was assayed for sigma receptors with [^{3}H]-di-o-tolylguanidine. This drug regimen down-regulated sigma receptors at 10 and 20 days and produced the expected up-regulation of striatal dopamine receptors in the same animals. The simultaneous up-regulation of dopamine receptors and down-regulation of sigma receptors by haloperidol suggests that the compound acts as a dopamine receptor antagonist and a sigma receptor agonist. This finding suggests that haloperidol and other similarly acting sigma ligands act as agonists at sigma receptors.

221.17

INTERACTION OF UMESPIRONE (KC 9172), A NOVEL ANTIPSYCHOTIC/ANXIOLYTIC AGENT, WITH SIGMA RECEPTORS. H. KRAHLING*, M. RUHLAND*, Y. ITZHAK* (SPON: A. FISHER), Kali-Chemie Pharmaceutical Division, D - 3000 Hannover 1, W. Germany and Dept. of Biochemistry & Mol. Biology, REPSCEND Labs, University of Miami School of Medicine, Miami, FL, 33101 USA.

Umespirone (KC 9172) is a potent atypical antipsychotic with anxiolytic properties derived from: 3,7-diazabicyclo[3.3.1]nonan-2,4,6,8-tetraons. In the present study we examined the interaction of umespirone with the sigma and PCP receptors postulated to be involved in psychotomimetic activity. Sigma receptors in rat brain membranes were labelled with (+)[3H]-3-PPP and (+)[3H]-SKF 10047, and PCP receptors with [3H]PCP-3-OH and [3H]TCP. Umespirone competes for the binding of the sigma ligands in a biphasic manner: IC50's 0.75 and 330 nM (vs.(+)[3H]-3-PPP). Inclusion of umespirone in the saturation binding assays of (+)[3H]-3-PPP indicated a noncompetitive type of interaction: i.e., control binding: Kd = 27 nM; Bmax = 53 pmol/g tissue. In the presence of umespirone (50 nM) Kd = 28 nM; Bmax = 33 pmol/g tissue. Umespirone (10 μM) does not inhibit the binding of the PCP ligands. The high selectivity of umespirone for the "sigma/haloperidol" receptor site, compared to other antipsychotic/anxiolytics, may attribute not only to its therapeutic effects but also to the reduced side effects liability of this compound.

221.18

PRENATAL INFLUENCE OF MORPHINE AND NALTREXONE ON THE EXPRESSION OF OPIATE AND MUSCARINIC CHOLINERGIC RECEPTORS R.Simantov, S.Amir and J.Dymshitz* Dept. of Neurobiology and Genetics, Weizmann Inst. of Sci., Rehovot, Israel

Prenatal exposure to opiate agonists and antagonists may retard or accelerate, respectively, the early development of the brain. We sought to investigate whether application of morphine or naltrexone alters the expression of opiate and muscarinic cholinergic receptors in several regions of fetal rat brain, and in striatal neuronal cultures. When injected at early stages of embryonic development (E5-E14), both opioids had no effect on opiate binding levels in any brain region. However, naltrexone applied during the period of rapid opiate receptor expression (E14-E18) increased the number of opiate binding sites. Similar effect was observed in neuron-enriched striatal cultures. Morphine injected on days E14-E18 or applied in culture had an opposite but more moderate effect. The kinetics of morphine-induced receptor down-regulation indicated that this process requires several days. However, exposure of the cultures to 10 μM of morphine for 30 mins or 2 hrs increased the opiate binding levels by 20-40%, whereas naltrexone had no such effect. In addition, both opioids did not change the expression of muscarinic cholinergic receptors, monitored with ^{3}H-QNB. The study indicates that during the early period of brain development opiate receptors may be affected by morphine and naltrexone directly through the receptors and not via a general hormonal system of the pregnant mother.

221.19

STRESS-INDUCED TOLERANCE TO DELTA RECEPTOR AGONIST DPDPE AND SELECTIVITY OF THE IRREVERSIBLE DELTA LIGAND, DALCE. Daniel J. Calcagnetti*, Wayne D. Bowen and Stephen G. Holtzman. Dept. of Pharmacology, Emory University, Atlanta, GA 30322 and Brown University, Section of Biochemistry, Providence, RI 02912.

Experiments were conducted to 1) provide evidence of the selectivity of [D-Ala2, Leu5, Cys6] enkephalin (DALCE) as an antagonist of delta receptor ligands and 2) use DALCE as a tool to explore the role of delta receptors in restraint stress(RS). Dose- and time-response curves were generated for the respective delta and mu selective opioid agonists DPDPE (3-30μg) and DAGO (0.03-0.3μg) to increase paw-lick latency (PLL) in the hot-plate test in rats after ventricular (ICV) injection. ICV injected DALCE (0.4-10 μg, 24 hr) did not alter baseline pain sensitivity. DALCE dose-dependently blocked the increase in PLL produced by DPDPE (30μg) but not that induced by an equivalent analgesic dose of DAGO (0.3 μg). Lastly, we determined whether 1 hr of RS would a) alter delta receptor sensitivity as indexed by DPDPE-induced analgesia and b) attenuate the ability of DALCE to functionally antagonize DPDPE-induced analgesia. Rats were tested for analgesia induced by DPDPE (30-120μg) 24 hr after one of four treatments: vehicle + no RS; vehicle + RS; DALCE (10μg) + no RS; DALCE + RS. Exposure to RS alone produced tolerance to DPDPE-induced analgesia. DALCE antagonized DPDPE similarly regardless of RS condition. The effects of both RS and DALCE were surmounted by the highest dose of DPDPE. We conclude that DALCE is a selective delta antagonist and that RS can induce tolerance to the analgesic effect of DPDPE. [Supported by NIDA grants DA00541(SGH) and DA03776(WDB) and RSA DA00008 (SGH)].

SENSITIVITY TO OPIOIDS IN INBRED MICE: NALTREXONE PRECIPITATED WITHDRAWAL JUMPING. J.C. Chow*, I. B. Finn*, J. M. Carney* and T. W. Seale (SPON: R. Gilmore). Dept. of Pharmacology, Univ. of Kentucky Coll. of Med., Lexington, KY 40536, and Dept. of Pediatrics, Univ. of Oklahoma Hlth Sci. Ctr., Oklahoma City, OK 73104

C57Bl/6ByJ, C57Bl/6J, C57Bl/10SnJ, DBA/2J, BALB/cByJ, A/J, AKR, SWR, CBA/J and C3H/HeJ mice were pre-treated (i.p.) with morphine (32mg/Kg), normorphine (32mg/Kg), etonitazine (0.01mg/Kg), levorphanol (3.2mg/Kg) and fentanyl (0.5mg/Kg) and injected 30 min later with naltrexone (NTX). Nine of the ten strains responded (+) to morphine (M). Levorphanol (L) and fentanyl(F) responsiveness was similar to morphine in the nine strains, with the exception of C57Bl/10SnJ. DBA was consistently hyporesponsive (-) to the five opioid agonists studied. Etonitazine(E) and normorphine(N) failed to produce NTX-precipitated withdrawal jumping in three and five of the nine strains respectively.

	6ByJ	6J	10SnJ	DBA	BALB	A/J	AKR	SWR	CBA	C3H
M	+	+	+	-	+	+	+	+	+	+
N	+	-	+	-	+	+	-	-	-	-
E	+	+	+	-	+	+	-	+	-	-
L	+	+	-	-	+	+	+	+	+	+
F	+	+	+	-	+	+	+	+	+	+

The data indicate that the genetic determinants of precipitated jumping are complex and consistent with the existence of multiple mu-receptor subtypes. (Supported in part by DA04028 and NIDA contract 271-87-8133).

PAIN MODULATION: BIOGENIC AMINES I

222.1

EVOKED RELEASE CHANGES IN SEROTONIN AND NOREPINEPHRINE: IN VIVO DIALYSIS OF RAT DORSAL HORN. R. M. Bowker, Dept. Anat., Mich. State Univ., E. Lansing, MI 48824 and R. H. Abhold, Dept. VCAPP, Wash. State Univ., Pullman, WA 99164.

Employing an in vivo dialysis technique basal levels of serotonin (5HT) and norepinephrine (NE) were collected by in vivo dialysis of the rat dorsal horn during chemical and electrical stimulation. In anesthetized rats a dialysis probe was placed in the lumbar spinal cord and 20-minute samples were collected from the dorsal horn and measured during direct chemical stimulation and electrical stimulation of nucleus raphe magnus (NRM) (100 μA, 100 μsec pulses, 10 Hz for 10 min). Chemical infusions of 100 mM KCl and 100 mM glutamate resulted in an increased release of NE (321.4 ± 41.2% and 488.9 ± 79.2%, respectively). On the other hand, 5HT levels decreased (49.6 ± 4% and 76.1%, respectively). Electrical stimulation of the NRM produced an increased release of both NE (66.5 ± 3.2%) and 5HT (451.4 ± 20.4%). These changes were significantly different ($P > 0.01$ level) from baseline levels. These findings suggest differences in the released regulation of NE and 5HT nerve terminals of the dorsal horn in their modulation of nociceptive neurotransmission.

222.2

THE ANTINOCICEPTIVE EFFECT OF NUCLEUS RAPHE MAGNUS (NRM) STIMULATION ARE MEDIATED THROUGH A 5-HT_1-LIKE RECEPTOR. N. El-Yassir* and S.M. Fleetwood-Walker* (SPON: W.A.MacKay) Dept. of Physiology, Univ. of Toronto, Canada and Dept. of Preclinical Vet. Sciences, R(D)SVS, Univ. of Edinburgh, U.K.

Serotonin (5-HT) is one of several endogenous compounds implicated to play a role in analgesia. The medullary NRM is thought to be the major source of the descending 5-HT-containing terminals in the spinal dorsal horn and stimulating NRM has been reported to result in antinociception. Recent studies have established the existence of several types of 5-HT receptors. Our aim was to investigate the type of 5-HT receptor which mediates the antinociceptive effect of NRM stimulation in the dorsal horn. Experiments were carried out on rats anaesthetized with a mixture of chlorolose and urethane. Extracellular recordings were made from multireceptive dorsal horn neurones through the central barrel of a 7-barreled electrode which was also used for ionophoresis of compounds. The effect of NRM stimulation (0.4 ms, 33-100 Hz) on both nociceptive and non-nociceptive responses was assessed. Stimulation of the NRM and adjacent reticular formation resulted in selective inhibition of the nociceptive responses of 14/20 cells, but caused non-selective inhibition of both nociceptive and non-nociceptive responses in 6/20 cases. Cyanopindolol, a selective 5-HT_1 receptor antagonist, reversed the effects of brainstem stimulation on 6/6 cells. Ketanserin, a selective 5-HT_2 antagonist on the other hand, failed to antagonize the effects of brainstem stimulation in 4/4 cases. The results of this study strongly suggest that the antinociceptive effect of 5-HT at the level of the dorsal horn is mediated through a 5-HT_1-like receptor.

222.3

N-ACETYLSEROTONIN INDUCES ANALGESIA ON THE HOT PLATE TEST. G.M. Brown, M.C. Brown* and D. Grossi*. McMaster University, Hamilton, Ontario L8N 3Z5

In a previous study (Psarak, S., et al, Life Sci., 42:1109, 1988.) we reported that 10 nM N-acetylserotonin (NAS) infused in the lateral ventricle (IVC) elicited an analgesic response in the rat tail flick test. This response was not elicited by equivalent doses of serotonin or melatonin.

In order to determine whether this was not simply due to an effect on nonresponsive spinal reflexes we have examined effects of IVC NAS on the hot plate test using paw licking as an end point. An analgesic effect was seen 3 hours after NAS administration (NAS: 37.45 ± 12.6 seconds vs VEHICLE: 20.7 ± 11.4; Mean ± SD). No animals displayed gross sensory or motor disturbances, catalepsy or sedation. These findings provide further evidence that NAS has an analgesic effect on pain induced by thermal stimuli. Taken together with previous findings employing IVC antiserum to NAS this study supports the concept that endogenous NAS plays a role in pain regulation.

222.4

PATTERNS OF ANALGESIA PRODUCED BY THE NOVEL ANXIOLYTIC BUSPIRONE IN THREE PAIN TESTS IN RATS. L.Rogers* and J.Giordano*(SPON:P.LACY) Drake Univ.Coll.Pharm.Health Sci. Des Moines IA 50311

The novel anxiolytic buspirone is an agonist at serotonin 5-HT1a receptors. Other 5-HT1a agonists have been shown to produce analgesia. Therefore, the present study examined temporal and dose-related patterns of analgesia produced by buspirone in tests of acute thermal,mechanical and formalin-induced chemical inflammatory pain. Long Evans rats were injected with 1,3,5 mg/kg buspirone i.p.; controls received saline injections. Analgesia was assessed at 15-30 min. intervals post-injection to 240 min. Buspirone produced time- and dose-dependent analgesia in all nociceptive tests, with greatest effect against chemical and mechanical pain; buspirone was less potent in the thermal pain test. At maximal dose, peak analgesia occurred at 30 min. post-injection, with significant effects persisting to 60-90min., dependent upon the test. Locomotor ability and overt activity (eg-grooming,rearing) were unaffected at any dose. These data demonstrate differential analgesic efficacy of buspirone against specific types of pain. Ongoing studies in our laboratory are characterizing the neuropharmacologic substrates mediating these effects.

222.5

PERIPHERALLY ADMINISTERED SEROTONIN 5-HT3 RECEPTOR ANTAGONISTS PRODUCE ANALGESIA AGAINST ACUTE AND CHRONIC INFLAMMATORY PAIN. J.Giordano* and L.Rogers*(SPON:T.SOWA) Drake Univ.Coll.Pharm.Health Sci., Des Moines IA 50311

Systemic, but not centrally administered serotonin 5-HT3 receptor antagonists attenuated acute chemical-inflammatory pain (Giordano & Dyche, Neuropharmacol.28, 1989). In light of the mechanisms of the inflammatory pain response and the localization of 5-HT3 sites on C-fiber afferents, these findings suggested a role for peripheral 5-HT3 sites in inflammatory pain. The present study examined analgesic effects of peripherally administered 5-HT3 antagonists against acute and chronic inflammatory pain in rats.

ICS-205-930 or MDL-72222(1-100 µg/50µl) were intraplantarly injected; acute inflammatory pain was assessed by the formalin test. Chronic inflammation was produced by hindpaw inoculation with Freunds complete adjuvant; analgesia was assessed by drug-induced changes in pressure sensitivity in the affected paw. ICS-205-930 and MDL-72222 produced dose-related analgesia against acute and chronic inflammatory pain. 5-HT3 antagonists had greater effect in the acute pain test than in the chronic paradigm. In both tests, ICS-205-930 was more potent than MDL-72222. These data further support the involvement of peripheral 5-HT3 sites in inflammatory pain, and suggest the utility of specific 5-HT3 receptor antagonists as peripheral analgesics.

222.6

L-TRYPTOPHAN POTENTIATES ANALGESIC EFFECT OF LOW CURRENT TRANSCRANIAL ELECTROSTIMULATION (TE). M.H. Skolnick, R.F. Hamilton*, J.R. Lake* and D.H. Malin. Univ. of Texas Grad. School of Biomedical Sciences, Houston, TX 77030 and Univ. of Houston - Clear Lake, Houston, TX 77058.

TE involves ultralow amplitude, charge-balanced current pulses applied across the head through low impedance sites in the external ears. TE produces analgesic effects which are blocked by pretreatment with the 5-HT synthesis inhibtor pCPA, suggesting serotonergic mediation. Forty rats were pretested for latency with a 50°C wet tail-flick test and injected with either 5-HT precursor L-tryptophan (200 mg/kg i.p.) or with vehicle alone. Forty minutes after injection, half of each group received TE (10µA, 10Hz, 2msec pulse width), while the other group received "sham stimulation". After 30 minutes of stimulation, each rat was retested for tail flick latency. Analgesia scores were the % increase in latency from pretest to posttest. Anova revealed significant stimulation and drug effects. Post-hoc analysis revealed that rats receiving both TE and L-tryptophan (* in table) had higher analgesic scores, $p<.05$, than any other group.

ANALGESIA SCORES (% Change Pretest To Posttest) M± SEM	TE	SHAM STIMULATION
L-TRYPTOPHAN	65.4 ± 16.6*	-2.1 ± 4.2
VEHICLE	33.2 ± 9.8	-5.9 ± 7.5

222.7

THE EFFECT OF CHRONIC TRYPTOPHAN TREATMENT ON AUTOTOMY INDUCED BY NERVE LESIONS. F.V. Abbott, and S.N. Young. Dept. of Psychiatry, and School of Nursing, McGill Univ., Montreal, Canada H3A 1A1.

Serotonin is one of the neurotransmitters in the spinal cord that gates nociceptive afferents, and its precursor, tryptophan (TRP), has been tested in clinical pain. However, a serotonin system in the brain can also antagonize morphine analgesia. Thus, it is important to determine which types of pain might be helped or exacerbated by TRP. We have now tested the effect of chronic tryptophan treatment on autotomy induced by nerve lesions in the rat, a potential model of phantom limb pain. Rats underwent unilateral sciatic and saphenous neurotomy and were placed on diets containing either 0.15% or 0.75% TRP. Animals were observed for autotomy of the paw on the lesioned side and were killed when the digits were removed. The high TRP diet caused a significant decrease in autotomy and significant elevations in brain and spinal cord serotonin even during the daytime, when food intake is at its lowest. Chronic tryptophan did not alter the response to noxious heat or formalin. Our data suggest that tryptophan will be a useful treatment of phantom limb pain. (Supported by the MRC of Canada).

222.8

AUTORADIOGRAPHIC MAPPING OF SEROTONIN RECEPTORS IN RAT SPINAL CORD. R.M. Murphy, A.M. Zieleniewski and F.P. Zemlan. Dept. of Psychiatry, Univ. of Cincinnati College of Medicine, Cincinnati, OH 45267-0559.

In vitro autoradiography was used to study the distribution and types of serotonin (5-HT) receptors in rat spinal cord. Tissue sections (8 uM) from cervical, thoracic and lumbar spinal cord were cut at -15°C with a cryostat and thaw-mounted onto gelatin-coated slides. Following preincubation, sections were incubated for 60 min with 2 nM ^{3}H-5-HT in a 0.17M Tris-HCl buffer (pH 7.6), in the presence and absence of 10 uM cold 5-HT, washed twice with ice-cold (4°C) buffer, and dried with cool air. To identify serotonin receptor subtypes, competition studies were performed with several ligands (100pM-1uM) including 8-OHDPAT, RU24969 and mesulergine. Slides were opposed against ^{3}H-Ultrofilm, exposed for 2 months, and analyzed by micro-densitometry.

Across all three spinal cord levels, the total number of 5-HT receptors was 2-3 times higher in the dorsal horn than in the ventral horn, with the highest densities in laminae 1-4 and the lowest densities in laminae 7 and 8. Receptors characteristic of the 5-HT$_{1A}$ binding site were distributed throughout all layers of the dorsal horn. Receptors characteristic of the 5-HT$_{1B}$ site were distributed with nearly equal densities throughout layers 4-10 of the cord. The presence of 5-HT$_{1C}$ binding (^{3}H-mesulergine) was marginally detected in layers 1-4 of the cord. The remaining receptors appear to be a novel 5-HT$_1$ binding site similar to the one recently identified in spinal cord synaptosomes.

222.9

DOMINANT SPINAL CORD 5-HT RECEPTOR, 5-HT$_{1F}$: RELATION TO PAIN. E.F. Schwab, F.P. Zemlan and R.M. Murphy. Dept. of Psychiatry, Univ. of Cincinnati College of Medicine, Cincinnati, OH 45267-0559.

We have previously described that in spinal cord synaptosomes about 25% of ^{3}H-5-HT labeled receptors are 5-HT$_{1A}$ receptors, while 26% are 5-HT$_{1B}$. The remaining 49%, the dominant spinal cord 5-HT receptor subtype, is a novel binding site, the 5-HT$_{1F}$ site. The pharmacology of the 5-HT$_{1F}$ receptor has been defined in ^{3}H-5-HT (2nM) competition studies ([competitor] = 0.1 nM to 1 mM) employing a 100 nM 8-OH-DPAT and 10 nM RU24969 mask for 5-HT$_{1A}$ and 5-HT$_{1B}$ receptors. The 5-HT$_{1F}$ receptor had >10,000 nM affinity for 5-HT$_{1C}$ (mesulergine), 5-HT$_{1D}$ and 5-HT$_{1E}$ (methysergide), 5-HT$_2$ (ketanserin) and 5-HT$_3$ (MDL7222, ICS205-930) selective drugs, demonstrating a unique pharmacology. The 5-HT agonist, 5-MeO-DMT demonstrated a high affinity for 5-HT$_{1F}$ receptors (K_i=27 nM) while methysergide demonstrated low affinity for 5-HT$_{1F}$ receptors (>10,000 nM) but high affinity for other 5-HT spinal cord receptors (K_i 10 to 100 nM). Therefore, behavioral pain studies employing the 5-HT agonist 5-MeO-DMT in the presence of a methysergide mask for non-5-HT$_{1F}$ receptors were conducted indicating a potent 5-MeO-DMT induced increase in tail-flick latency. The present study pharmacologically characterizes the 5-HT$_{1F}$ receptor and demonstrates its involvement in spinal pain processing.

222.10

BEHAVIORAL EFFECTS OF 5-HT$_1$ AGONIST ADMINISTRATION ON SPINAL REFLEXES. A.M. Zieleniewski, R.M. Murphy and F.P.Zemlan. Dept. of Psychiatry, Univ. of Cincinnati College of Medicine, Cincinnati, OH 45267-0559.

The purpose of the present study was to determine if 5-HT$_1$ receptor subtypes differentially mediate the spinal processing of nociceptive input. Specifically, the effect of drugs selective for the 5-HT$_{1A}$ and 5-HT$_{1B}$ receptor subtypes were examined in the spinal animal on tail flick latencies (TFLs) and on three spinal withdrawal reflexes.

Three days after spinal transection at T_{10}, animals were injected i.p. at 20 min. intervals with increasing equimolar doses of either a 5-HT$_{1A}$ selective agonist (8-OH-DPAT, ipsapirone) or a 5-HT$_{1B}$ selective agonist (mCPP, TFMPP). The nociceptive sensitivity of the ventroflexion, dorsiflexion, and lateral flexion reflexes was quantified as size of the receptive field (RF) area of the reflex in cm^2. Tail flick latencies were determined ten days post-transection.

Significant dose-dependent increases in the sensitivity of all three spinal reflexes were observed following administration of the 5-HT$_{1A}$ agonists. A corresponding increase in sensitivity on TFL's was also observed. The predominant effect of 5-HT$_{1B}$ agonist administration was a dose-dependent decrease in RF area. A decrease in sensitivity was also observed in the tail flick test, with TFL's increased by 35% from baseline.

The results of the present study support the heterogeneous effects of 5-HT at the spinal level. Specifically, 5-HT$_{1A}$ agonist administration results in increased nociceptive sensitivity, while the 5-HT$_{1B}$ receptor subtype mediates an opposite effect.

223.1

THE PROJECTION OF LOCUS COERULEUS NEURONS TO THE SPINAL CORD IN THE RAT. FM Clark and HK Proudfit (SPON:H Hamm). Dept. of Pharmacol., Univ. of Ill. at Chicago, Chicago, Il 60680.

Although locus coeruleus (LC) neurons project to the spinal cord, the specific terminations of these neurons is not clear. The following studies were done to more clearly determine these projections. In the first experiment a unilateral iontophoretic injection of the anterograde tracer, phaseolus vulgaris leucoagglutinin (PHA-L), was made into the LC. A strong ipsilateral projection to the ventral horn and lamina X was seen in cervical, thoracic, and lumbar spinal cord segments. Very few axon terminals were seen in the ipsilateral dorsal horn or contralateral spinal cord. Over 90% of these axon terminals contained dopamine beta hydroxylase-like immunoreactivity (DBH) and were, therefore, assumed to contain catecholamines. In the second experiment, unilateral electrolytic lesions of the LC were made. Lesions produced a marked depletion of DBH positive axon terminals in the ventral horn and lamina X. These results indicate that LC neurons have a strong ipsilateral projection to ventral horn and lamina X and only a minor projection to the ipsilateral dorsal horn. The contralateral spinal projection was very minor. (Supported by USPHS Grant DA 03980.)

ST-91 MICROINJECTED INTO THE MEDULLARY DORSAL HORN ALTERS A MONKEY'S PERCEIVED INTENSITY OF NOXIOUS THERMAL STIMULATION. D.A. Thomas*, R. Dubner, F. Anton*, and D.R. Kenshalo, Jr. NAB, NIDR, NIH, Bethesda, MD 20892

We examined the effect of the α-2 adrenergic receptor agonist ST-91 microinjected into the medullary dorsal horn (MDH) of a monkey trained in a psychophysical task. The task required the monkey to detect temperature changes of 0.4, 0.6 or 1.0°C (T2) from a 3-9 sec noxious heat level of 46°C. We have previously shown that T2 detection latency is a measure of the perceived intensity of stimulation. ST-91 (0, 1, 3, 10, and 30 μg/0.2μl) dissolved in saline produced a dose-dependent and stimulus intensity-dependent increase in T2 detection latency. The α-2 receptor specificity of this effect was assessed by the injection of the α-2 receptor antagonist idazoxan during ST-91's peak effect on detection latencies. Idazoxan (2 mg/0.1 ml/kg of body weight; i.m.) in comparison to saline, significantly attenuated (p <0.01) the effects of ST-91 on detection latencies of the 0.4 and 1.0°C stimulus changes for a period of approximately 10 minutes. The effect of ST-91 on attentional, motivational and motoric aspects of the monkey's behavior was assessed by having the animal detect innocuous cooling and visual stimuli of similar difficulty. ST-91 had no effect on the detection of cooling or visual stimuli. These data suggest a role for α-2 adrenergic receptors in altering the perceived intensity of noxious heat stimuli at the level of the MDH, the earliest central relay pathway transmitting noxious information.

223.3

Effects of the alpha-2 agonists Dexmedetomidine and ST-91 on the Tail-Flick and Cardiovascular Responses to a Noxious Thermal Stimulus *H. Nagasaka, and T.L. Yaksh. Dept of Anesthes., Univ. of Calif., San Diego, La Jolla, CA 92093

The effects of intrathecally (IT) administered alpha-2 adrenoceptor agonists on the nociceptive threshold as measured by tail-flick (TF) latency and cardiovascular changes as measured by blood pressure (BP), and heart rate (HR) were investigated in 0.75% halothane-anesthetized and artificially ventilated male rats prepared with chronic spinal catheters. The TF and autonomic response BP and HR were evoked by the immersion of the tail for a maximum of 15 sec. in a 53° C waterbath. IT administration of Dexmedetomidine (DMET: 3.3ug, 0.33ug, and 0.033ug) and ST-91 (30ug, 3ug), and intravenous administration (IV) of DMET (0.33ug) was carried out with each dose being given in 3 or more rats. Administration of IT DMET or ST-91 produced a dose dependent block of the TF response and reduction in the BP and HR response evoked by the thermal stimulus. Maximum effects after DMET were observed in 5 min. and within 30 min. after ST-91. While IT alpha-2 agonist yielded a fall in resting BP and HR, the effect on these measures were more profound after IV administration, though IV agent had little effect on TF latency nor blocked completely the thermally evoked autonomic responses. These effects of IT DMET (3.3 ug) and ST-91(30ug) were dose dependently antagonized by the alpha-2 adrenoceptor antagonist Idazoxan IT (100 - 300 ug) pretreatment. These data suggest a potent spinal alpha-2 modulation of somatosensory and autonomic response to pain. (Grant: DA02110: T.Y.)

223.4

SPINAL ALPHA-TWO NORADRENERGIC RECEPTORS MEDIATE THE ANTINOCICEPTION PRODUCED BY MICROINJECTION OF PHYSOSTIGMINE INTO THE NUCLEUS RAPHE MAGNUS. **M.A. McCartney and H.K. Proudfit, Dept. Pharmacology, University of IL Coll. Med., Chicago, IL 60612.**

Activation of nucleus raphe magnus (NRM) neurons by local injection of carbachol produces antinociception which appears to be mediated by bulbospinal noradrenergic neurons, but not by raphe-spinal serotonergic neurons. The present study was designed to determine whether the antinociception induced by the microinjection of the cholinesterase inhibitor, physostigmine into the NRM of rats is mediated by serotonergic or noradrenergic bulbospinal neurons, and to determine the noradrenergic receptor subtypes involved.

Microinjection of physostigmine into the NRM produced antinociception that was reversed by intrathecal injection of the non-selective noradrenergic antagonist (ANT) phentolamine (30 ug), or yohimbine (alpha-two ANT-38 ug) using the tail flick test. Methysergide (serotonergic ANT-30 ug) had no effect, while intrathecal administration of the alpha-one ANT WB4101 (37 ug) enhanced the antinociceptive action of physostigmine. These antagonists had no effect on hot plate values, indicating the possible involvement of supraspinal sites in the mediation of physostigmine-induced antinociception.

These data provide further evidence that the antinociception induced by microinjection of cholinergic agonists in the NRM is produced by activation of bulbospinal noradrenergic neurons and is independent of raphe-spinal serotonergic involvement. (Supported by USPHS Grant DA03980).

ADENOSINE MEDIATES CALCIUM-INDUCED ANTINOCICEPTION AND POTENTIATION OF NORADRENERGIC ANTINOCICEPTION IN THE SPINAL CORD. J. Sawynok, A. Reid* and R. Isbrucker*, Dept. Pharmacol., Dalhousie Univ., Halifax N.S. B3H 4H7

Spinal administration of Ca^{2+} produces antinociception and potentiates spinal antinociception by morphine (J.P.E.T. 246: 500, 1988), but the mechanism of these actions is not known. Recently, we have demonstrated that adenosine release may mediate spinal antinociception by morphine (J.P.E.T. 243: 657, 1987). In this study, we have examined the action of Ca^{2+} on spinal antinociception by adenosine analogs, noradrenaline (NA) and 5-hydroxytryptamine (5-HT), and of methylxanthine adenosine receptor antagonists on Ca^{2+}-induced antinociception. Intrathecal coadministration of Ca^{2+} 50μg, which has no effect alone, potentiates the spinal action of morphine but not the analogs of adenosine CHA or NECA, using the rat tail flick test. This dose also potentiates the action of NA but not 5-HT. At higher doses (100-350μg), Ca^{2+} produces antinociception which is eliminated by pretreatment with theophylline 50μg or 8-phenyltheophylline (8-PT) 3μg. 8-PT also eliminates potentiation of the action of NA by the lower dose of Ca^{2+}. These observations suggest that Ca^{2+} can release adenosine from the spinal cord, and this both mediates antinociception and the interaction with NA and possibly morphine. CHRONIC CAFFEINE AFFECTS MONOAMINE SYSTEMS SUBSERVING TRICYCLIC ANTIDEPRESSANT-INDUCED ANALGESIA IN RATS. S. Brock*,[1], J. Blajek[3], C. J. Drebing*,[1], G.A. Gerhardt[1,2] and J. Giordano[3] (SPON: E.P. Finnerty). Depts. of Psychiatry[1] and Pharmacology[2], Univ. of Colorado Health Sci. Ctr., Denver, CO 80262 and Coll. of Pharmacy and Health Sci.[3], Drake Univ., Des Moines, Iowa 50311.

The present study examined the effects of chronic caffeine administration on patterns of amitriptyline (AMI)- and desipramine (DMI)-induced analgesia, and CNS monoamine levels in Long-Evans rats. Animals were injected with caffeine (10-30 mg/kg i.p.) for 28 days; control animals were injected with saline. Twenty-four hours following the final injections, animals were injected with AMI or DMI (5-20 mg/kg i.p.). Thermal and mechanical analgesic tests were performed according to the methods of Giordano and Barr (Devel. Brain Res. 32: 1987). Twelve hours following analgesic tests, rats were sacrificed and their brains and spinal cords were rapidly removed and frozen at -70°C. Tissue levels of monoamines and monoamine metabolites were determined using HPLC-EC. Chronic caffeine administration produced dose-dependent decreases in AMI- and DMI-induced analgesia in both thermal and mechanical tests. Significant neurochemical changes in the serotonin systems of the spinal cord, brain stem and cortex of the rats were also observed. In addition, caffeine produced dose-related hyperanalgesia as reflected by decreased baseline responses.

223.7

DESIPRAMINE AND ZIMELIDINE INCREASE TAIL FLICK LATENCIES MAINLY BY REDUCING SKIN TEMPERATURE.
A. Tjølsen*, A. Lund* and K. Hole.
Dept. of Physiology, University of Bergen, Bergen, N-5009 Norway.

A constant, reproducable negative correlation between tail skin temperature and tail flick latency to radiant heat has been demonstrated in rats and mice. Experiments involving manipulations of serotonergic systems have shown that changes of tail flick latency due to alterations of skin temperature may be misinterpreted as changes in nociception. On this basis, we have concluded that effects on temperature regulation must be taken into consideration when performing tests of nociception involving thermal stimuli.

The effect of the antidepressant drugs desipramine (5, 15 and 25 mg/kg intraperitoneally (i.p.)) and zimelidine (5, 20 and 30 mg/kg i.p.) in the tail flick test was investigated. A dose-dependent increase in the tail flick latency was found for both drugs, with maximal effect after 2-3 h. The tail skin temperature showed a similar dose-dependent reduction compared to control animals. This explained most of the increase of tail flick latency (ANCOVA), and only the highest dose of desipramine showed antinociceptive effect. In the increasing temperature hot plate test, however, low doses (2 and 5 mg/kg) of desipramine showed a dose-dependent antinociceptive effect.

223.8

EFFECT OF AMITRIPTYLINE ON INHIBITORY MECHANISMS IN THE TRIGEMINAL COMPLEX. G.H. Fromm, M. Nakata*, and T. Kondo*. Dept. of Neurology, Univ. of Pittsburgh Sch. of Med. Pittsburgh, PA 15261

Neuropathic pain is relieved by amitriptyline (AMI) in about half the patients. The antineuralgic action of AMI has been confirmed by several controlled trials, but AMI's mechanism of action has not been established. In previous experiments we found that AMI enhances the segmental inhibition and periventricular inhibition of some wide dynamic range (WDR) and nociceptive specific (NS) neurons but not low threshold mechanoceptive (LTM) neurons.

We have now further investigated the effect of AMI on inhibitory mechanisms in the trigeminal complex of cats anesthetized with alpha-chloralose. The i.v. administration of 1.0-4.0 mg/kg AMI facilitated diffuse noxious inhibitory control (DNIC) of WDR neurons in half the experiments. On the other hand, AMI usually depressed nucleus raphe magnus inhibition of these neurons.

Opioid analgesics are ineffective against neuropathic pain and have been reported to depress DNIC. The fact that AMI enhanced the action of this inhibitory mechanism therefore suggests that AMI's effect on neuralgic pain may be due to its ability to facilitate the action of DNIC on WDR neurons. SUPRASPINAL MEDIATION OF COCAINE ANALGESIA IN THE RAT. C.R. Belczynski Jr., Y. Lin., S. Neumann, T.J. Morrow and K.L. Casey. VA Medical Center and Depts. of Neurology, Physiology and Neuroscience Program, University of Michigan, Ann Arbor, MI 48105.

We have shown that cocaine (25 mg/Kg, i.p.) is a potent, centrally acting analgesic in the rat as measured using the formalin and hot-plate tests (Brain Res., 479:306, 1989). The study examines whether cocaine analgesia is due to direct spinal action or the result of descending supraspinal control. Twenty-six adult male rats were anaesthetized with chloral hydrate (300mg/Kg, i.p.) and allowed to recover spinal reflexes. The animals were then given cocaine (25 mg/Kg, i.p.) or saline and tested for analgesia using the tail flick test. Significant increases ($p<.01,.05$) in response latencies were observed within 10 minutes, and lasting beyond 60 minutes, as compared to control. Seven of these animals were spinally transected at thoracic levels (T4-T8) and tail flick was allowed 24 hours to recover. Surgical transection of the spinal cord at thoracic levels eliminated cocaine dependent increases in response latency. These results suggest that cocaine's analgesic effect in the rat is supraspinally mediated and not the result of direct action on spinal neurons. To determine possible locale for this descending control, localized R/F lesions were made and rats were tested with cocaine using the formalin test. 75% (6/8) of rats with lesions in Nucleus Raphe Magnus (NRM) and 100% (4/4) of rats lesioned in the Nucleus Accumbens (N.Acc) showed no reduction in cocaine analgesia. In addition, 100% (11/11) of rats microinjected with lidocaine(2%) into NRM showed no attenuation of cocaine analgesia. 90% (9/10) of rats with lesions in Locus Coeruleus (LC) and 100% (7/7) of rats with combined lesions in Ventral Tegmental Area (VTA) and N.Acc demonstrated a marked reduction in cocaine analgesia. **These results suggest that descending supraspinal mechanisms originating in the brainstem are necessary for cocaine analgesia in the rat. Further experimentation is necessary to determine whether these nuclei are sufficient for cocaine analgesia.**

223.10

THE ROLE OF SPINAL NORADRENERGIC, SEROTONERGIC AND OPIOID RECEPTORS IN DESCENDING MODULATION FROM THE A5 CELL GROUP. A. Burnett and G.F. Gebhart. Department of Pharmacology, College of Medicine, The University of Iowa, Iowa City, Iowa, 52242.

Previous studies have shown that the A5 noradrenergic cell group plays a role in both descending modulation of nociception and regulation of cardiovascular and other autonomic functions. The objective of the present study was to determine to what extent noradrenergic, serotonergic and opioid pathways are involved in mediating descending inhibition and changes in blood pressure and heart rate.

Experiments were conducted in lightly pentobarbital-anesthetized rats using the tail-flick reflex as a model of nociception. A5 cells were electrically stimulated and the effects of intrathecal injections of adrenergic, serotonergic and opioid antagonists were evaluated. Changes in blood presure and heart rate were recorded via a femoral arterial catheter.

Phentolamine produced a dose-dependent increase in the stimulation threshold for inhibition of the tail-flick reflex in the rostral A5, but did not produce significant increases in threshold in the caudal A5. Methysergide and naloxone produced no significant increases in threshold. Stimulation-produced pressor effects and increases/decreases in heart rate were not affected by the administration of these antagonists. These experiments suggest that spinal noradrenergic, but not serotonergic or opioid, receptors are involved in descending modulation of nociception from the A5.

223.11

THE INVOLVEMENT OF NOREPINEPHRINE (NE) AND SEROTONIN (5-HT) IN MORPHINE AND FENTANYL-INDUCED SPINAL ANALGESIA. T. Crisp, J.L. Stafinsky*, M. Uram* and V.C. Perni*. Dept. of Pharmacology, N.E. Ohio Universities College of Medicine, Rootstown, OH 44272.

Male Sprague-Dawley rats were injected intrathecally (i.t.) with morphine sulfate (MS) or fentanyl. Both drugs dose-dependently elevated tail-flick latency in a naltrexone-reversible manner. To determine if MS or fentanyl interact with spinopetal monoaminergic nerves to produce spinal antinociception, NE or 5-HT receptor antagonists were co-administered with the two μ agonists and tested for an ability to alter opiate-induced analgesia. The α-adrenoceptor antagonist phentolamine attenuated the effects of fentanyl, but did not alter MS-induced analgesia. Conversely, the 5-HT receptor antagonists spiroxatrine (5-HT_1), ritanserin (5-HT_2) and ICS 205-930 (5-HT_3) diminished the spinal effects of MS, but did not alter fentanyl-induced analgesia. Apparently, endogenous NE contributes to the analgesic effects of fentanyl, whereas 5-HT is involved in MS-induced spinal analgesia.

223.12

PAIN MODULATION PRODUCED BY GLUTAMINERGIC INTERACTION BETWEEN N. CUNEIFORMIS AND N. RAPHE MAGNUS . R.C. Richter and M.M. Behbehani. Dept. of Physiology and Biophysics, U. Cincinnati College of Med. Cincinnati, OH 45267-0576.

We examined the role of glutamic acid in the interaction between n. cuneiformis and the n. raphe magnus (NRM) in light of Fields' et.al. classification system of NRM neurons (as on-cells, off-cells, and neutral cells).

In the lightly anesthetized rat model, the response properties of 112 NRM neurons to electrical stimulation of NCF at 1 Hz demonstrated that 53% were excited, 20% were inhibited, and 28% were unaffected. Almost all excitatory responses exhibited very short latencies of 2-4 msec. In contrast, examination of the responses of 92 NRM neurons to NCF electrical stimulation at 100 Hz showed that 41% were inhibited while only 22% were excited and 37% were unaffected. No significant difference in response pattern was seen among the 3 classes of NRM neurons at either stimulation frequency. The response of 36% of NRM cells to electrical stimulation and microinjection of glutamic acid into the NCF could be blocked by microinjection of kynurenic acid into the NRM.

Thus the differential responses of NRM cells to NCF electrical stimulation do not appear to be attributable to their physiological classification. The short latency excitatory responses seen at 1 Hz are suggestive of a fast excitatory amino acid transmitter while the inhibitory responses seen with train stimulation would be consistent with a slower acting, possibly peptidergic, transmitter, or with a local inhibitory collateral network within NRM. Supported by PHS Grant #NS20643.

223.13

AN INTRACELLULAR STUDY OF THE EFFECT OF EPINEPHRINE ON PAG NEURONS AND ITS ROLE IN PAIN MODULATION. M. Jiang, S.D. Chandler and M.M. Behbehani. Dept. of Physiology and Biophysics. Univ. of Cincinnati College of Medicine. Cincinnati OH, 45267-0576.

The basic electrical and membrane properties of 16 PAG neurons and their response to epinephrine (EPI) were studied in an in vitro slice preparation. Neurons were recorded throughout the PAG, but due to size and density, the majority were located in dorsolateral PAG. The majority of cells were spontaneously active, but some were not. In 60% of the neurons epinephrine caused an inhibitory effect that was associated with hyperpolarization of the membrane. This effect of EPI was dose dependent and had a duration of action that varied from 3 to more than 20 minutes. In 6% of cells EPI did not produce any effect. In the remaining cells EPI caused depolarization of the membrane and an increase in the firing rate. In 75% of neurons that were depolarized by EPI, no change in the membrane resistance was detected. On the other hand, in neurons that were hyperpolarized, EPI consistently caused a decrease in membrane resistance. There was no correlation between resting membrane potential or the location of the neurons and their response to EPI.

Our observation that the inhibitory effect of EPI is associated with a decrease in the membrane resistance suggests that this effect of EPI is mediated by a post synaptic mechanism possibly by an increase in potassium conductance. On the other hand, lack of consistent change in the membrane resistance in neurons excited by EPI suggests that this effect of EPI may be due to a presynaptic mechanism. Supported by PHS grant NS20643.

223.14

RELEASE OF ASPARTATE AND GLUTAMATE IN THE DORSAL HORN OF THE CAT LUMBAR SPINAL CORD IN RESPONSE TO INTRADERMAL CAPSAICIN INJECTION. D. Liu*, L.S. Sorkin, M.G. Hughes* and D.J. McAdoo Marine Biomedical Institute, University of Texas Medical Branch, Galveston, Texas 77550.

Glutamate and aspartate are putative neurotransmitters found in a significant percentage of myelinated and unmyelinated primary afferent fibers. Intrinsic spinal cord neurons immunoreactive to glutamate and aspartate have also been observed. To explore the role of excitatory amino acids in pain transmission, we stimulated cutaneous unmyelinated fibers by intradermal capsaicin (0.5 cc, 3%) injection and measured release of amino acids within the spinal cord of anesthetized cats. Perfusates were collected following placement of a microdialysis probe in the dorsal horn and the perfusates analyzed by HPLC with fluorimetric detection. Surprisingly, as much or more aspartate was released when capsaicin was injected into the contralateral leg as when injection was in the ipsilateral leg. Glutamate was also released in response to contralateral stimulation. This suggests that, after noxious peripheral stimulation, excitatory amino acids may be released by intrinsic spinal neurons as well as primary afferent fibers. (Supported by NIH NS11255, the Spinal Cord Research Foundation and Bristol Myers.)

223.15

BILATERAL RELEASE OF 5HT INTO THE DORSAL HORN OF THE CAT LUMBAR SPINAL CORD ELICITED BY INTRADERMAL CAPSAICIN(CAP) INJECTION. L.S. Sorkin and M.G. Hughes*. Marine Biomed. Inst., Univ. Texas Medical Branch, Galveston, Tx. 77550.

Activation of the raphe spinal system should produce bilateral release of 5HT in the spinal cord. This study measures 5HT levels on one side of the dorsal horn after noxious stimulation of either the ipsi- or contralateral hindlimb.

Cats were anesthetized with α-chloralose and a dialysis probe was inserted through the lumbosacral enlargement of the spinal cord. The dialysis zone was confined to one side of the dorsal horn. CSF was perfused (4 µl/min) through the probe and samples collected for consecutive 20 min periods. Samples were injected without pretreatment into an HPLC with EC detection. After stable levels of 5HT were achieved, 3% CAP was injected intradermally at several sites on either the ipsilateral or contralateral leg at the start of a collection period. Some animals were pretreated with 8-OH DPAT, a $5HT_1$ agonist.

Ipsilateral CAP produced a significant increase in 5HT levels for 1 or 2 sampling periods. Contralateral injections also increased 5HT levels; both were totally blocked by the prior administration of 8-OH DPAT.

These results suggest that ipsilateral activation of C-fibers induces a bilateral release of 5HT and presumably a bilateral hypoalgesia. (Supported by the Forman Research Foundation and Bristol Myers Co.)

223.16

RELEASE OF CALCITONIN GENE-RELATED PEPTIDE (CGRP) FROM RAT SPINAL CORD IN VITRO. R.E. Solomon, L.D. Aimone, T.L. Yaksh and G.F. Gebhart. Dept. Pharmacol., Univ. Iowa, Iowa City, IA and Dept. Anesth., Univ. Calif., La Jolla, CA.

The release of CGRP from superfusates of rat spinal cord slices in vitro was studied using methods described for studying substance P (sP) release (Soc. Neurosci. Abs. 14: 562, 1988). CGRP was measured in perfusates and post-perfusion tissue extracts by radioimmunoassay. Elevation of the potassium concentration from 2 to 50 mM or addition of 10.0 µM capsaicin evoked release of CGRP from dorsal, but not from ventral, spinal cord at rates 4.9- and 22.3-fold, respectively, above the basal rate of CGRP release. The effects of potassium and capsaicin were concentration-dependent and were abolished by depletion of calcium from the perfusion buffer. CGRP release evoked by potassium or capsaicin was inhibited by clonidine or morphine (10 - 100 µM), but not by serotonin (1 mM). Tissue content of CGRP was 4307 ± 442 and 317 ± 45 pg/mg in dorsal and ventral spinal cord, respectively. These results indicate that CGRP is released from primary afferent nociceptive nerve terminals in the rat dorsal spinal cord and that the modulation of such release may mediate the spinal actions of certain analgesic drugs. Comparison of these results with those that we reported on the release of sP suggests that CGRP and sP may be co-released from primary afferent neurons, and that CGRP is present in the spinal cord and released by capsaicin in amounts much greater than is sP. Supported by T32 GM 07069, DA 05329, NS 16541 and DA 02879.

223.17

NORADRENERGIC REGULATION OF CALCITONIN GENE-RELATED PEPTIDE (CGRP) AND SUBSTANCE P (SP) RELEASE FROM RAT DORSAL HORN SLICES. L.D.Aimone,C.L.Hagaman* and T.L. Yaksh, Dept. of Anesthesiology, Univ. of Calif., San Diego, La Jolla, CA

Noradrenergic terminals from bulbospinal pathways are thought to modulate spinal nociceptive processing in part by a reduction of neurotransmitter release from primary afferent neurons. Using an *in vitro* model described previously (Soc. Neurosci. Abst. 14: 562, 1988), the present study examined the effect of increasing endogenous norepinephrine (NE) levels on the K^+-evoked release of CGRP and SP. NE was measured by HPLC with electrical chemical detection; SP and CGRP were measured by radioimmunoassay. The release of all three neurotransmitters was evoked in a dose-dependent manner by the addition of K^+. Basal levels of NE (0.06 ng/ml) were dose-dependently increased by the addition of desipramine (1-100 µM) or pargyline (100 µM). The addition of both compounds produced an additive effect, resulting in basal NE levels of 490 ng/ml. Desipramine had no effect on basal peptide secretion, but produced a dose-dependent decrease in the amount of CGRP and SP evoked by the addition of 70 mM K^+. The evoked release of these peptides was also inhibited by the addition of pargyline. Thus, the increase in NE secretion was correlated with a decrease in the release of CGRP and SP. These data indicate that NE can act presynaptically to inhibit the release of CGRP and SP from primary afferent neurons. This mechanism could account for the antinociceptive actions of spinally administered noradrenergic agonists.

224.1

EFFECTS OF ETHANOL ON EXTRACELLULAR DOPAMINE AND ITS CALCIUM DEPENDENCY AS MEASURED BY IN VIVO MICRODIALYSIS. K.M. Wozniak*, A. Mele*, A. Pert and M. Linnoila. (Spon: T. Nakajima). LCS/NIAAA, and BPB/NIMH, Bethesda, MD 20892.

Dopaminergic systems are thought to play a major role in the stimulant and reinforcing properties of drugs of abuse, including ethanol. The present study describes the effects of direct local infusion of ethanol on extracellular dopamine levels using the microdialysis technique. Animals were anesthetized with chloral hydrate, stereotaxically positioned and a 3mm microdialysis probe inserted into the corpus striatum. Following the establishment of basal dopamine extracellular levels (2-3h), various concentrations of ethanol in artificial csf (0.01-10% v/v) were slowly infused through the probe. Ethanol was found to increase dopamine levels at each dose used. This increase appeared to be dose-related at the higher concentrations (1-10%). The inclusion of 12.5 mM magnesium in the perfusion medium was found to significantly lower basal dopamine levels and also prevented, or significantly attenuated, the ethanol-induced dopamine release. This provides evidence that the release of dopamine by ethanol may involve calcium dependent processes.

224.2

BINDING OF [^{3}H]MUSCIMOL AND [^{3}H]RO 15-4513 IN THE CEREBELLUM OF RAT LINES WITH DIFFERING ALCOHOL SENSITIVITIES. E.R. Korpi and M. Uusi-Oukari*. Res. Labs, Alko Ltd, POB 350, SF-00101 Helsinki, Finland.

The binding of a $GABA_A$ agonist muscimol and of a benzodiazepine partial inverse agonist Ro 15-4513 was studied in brain membranes of two rat lines developed for high (ANT) and low (AT) sensitivity to moderate doses of alcohol.

The binding of [^{3}H]muscimol in cerebral cortical and hippocampal membranes was similar in both lines, whereas the B_{max} in cerebellar membranes was greater in the AT's than ANT's. The total binding of [^{3}H]Ro 15-4513 was fairly similar in both lines in all these brain areas. However, micromolar diazepam displaced all the specific cerebellar binding defined by 10 µM Ro 15-1788 in most ANT rats, while leaving about 25% non-displaced in most AT rats.

Since the sites for both the muscimol and the diazepam-insensitive Ro 15-4513 binding are localized in the cerebellar granular layer, the present results suggest a possible target of genetic modulation in the granule cells or in the cerebellar circuitry affecting them in the rat lines with differing alcohol sensitivities.

224.3

GABA TURNOVER IN THE BRAIN OF RAT LINES SELECTED FOR DIFFERENTIAL SENSITIVITY TO ETHANOL. K. Kiianmaa* and K. Hellevuo* (SPON: K.Nieminen). Res. Labs, Alko Ltd., 00101 Helsinki, Finland.

The effect of ethanol on GABA turnover was studied in different regions of the brain in the AT (Alcohol Tolerant) and ANT (Alcohol Nontolerant) rat lines developed for low and high degree of motor impairment from ethanol. The rate of GABA turnover was estimated from the accumulation of GABA after inhibition of GABA-T with aminooxyacetic acid (AOAA, 50 mg/kg, IP) given 10 min after administration of ethanol (2 or 4 g/kg, IP). The rats were killed two hours after the AOAA treatment with focused microwaves. GABA was analyzed by HPLC with fluorescence detection. The saline-treated ANT rats had a higher concentration of GABA in the striatum and a higher rate of GABA accumulation in the cerebellum than the AT rats. Ethanol suppressed the accumulation of GABA in both lines, but the suppression was significantly greater in the AT rats than in the ANT rats. In specific regions, this line difference was significant in the cerebral cortex and cerebellum with the higher ethanol dose. The results suggest that GABAergic mechanisms are involved in the differential sensitivity to the motor impairing effects of ethanol between the AT and ANT rats.

224.4

IN VITRO EFFECTS OF ETHANOL ON THE BRAIN ß-ENDORPHIN SYSTEM OF MICE WITH VARIABLE PREFERENCE FOR ETHANOL SOLUTION. J.-P. De Waele and C. Gianoulakis, Douglas Hospital Research Center and Department of Physiology, McGill University, Montréal, Québec.

Genetic factors may modify the effects of ethanol on neuronal and endocrine systems and, as a result, may influence the sensitivity of animals to ethanol as well as their consumption of ethanol solutions. The objective of this study is to examine the response to ethanol of the brain ß-endorphin system in two inbred strains of mice (C57BL/6 and DBA/2) by investigating the release of ß-endorphin by the hypothalamus following the In Vitro exposure to various doses of ethanol. This type of stimulation induced an increase in the release of ß-endorphin-like-peptides (ß-EPLPs) of both strains of mice. However, it was observed that both the spontaneous release and the ethanol stimulated release of ß-EPLPs was more pronounced by the hypothalamus of the C57BL/6 strain (voluntary drinker) than by that of the DBA/2 strain (showing aversion to ethanol). Furthermore, analysis by Sephadex G-75 chromatography indicated the release of ß-endorphin sized peptides by the hypothalamus at basal conditions as well as following ethanol exposure.

224.5

ETHANOL EFFECTS ON LIPID- AND PROTEIN-BOUND SIALIC ACID IN MICE OF DIFFERENT AGES. L. Cherian* and W. R. Klemm. Dept. Veterinary Anatomy, Texas A&M Univ., College Station, TX. 77843.

Mice of different ages were tested for changes in brain lipid- and protein-bound sialic acid (SA) two hours after ethanol (2 gm/kg, IP), either as a single dose or after five repeated doses of ethanol spaced 2 hours apart.

Ethanol generally decreased both gangliosidic and glycoprotein SA, but the effect varied with number of doses and age. Single-dose ethanol decreased both lipid- and protein-bound SA in young adults and aged mice, but there was no effect on lipid-bound SA in weanlings. With repeated injections, the 23% decrease in SA seen with young adults did not occur. Repeated injections did decrease both lipid- and protein-bound SA in aged mice, by 49% and 48%. Ethanol increased free SA in singly-dosed young adults and in multiply-dosed aged adults, while causing a distinct decrease in singly-dosed weanlings.

Comparison of single, repeated, or no saline injection in young adult controls indicated that the injection handling procedures themselves also affected both gangliosidic and glycoprotein SA. Supported by grant AA 06920, NIAAA.

ALCOHOL INDUCED ALTERATIONS IN ADENYLATE CYCLASE ACTIVITY IN CULTURED ASTROCYTES. T. Ritchie and E.P. Noble*. Neuropsychiatric Institute and Brain Research Institute, University of California, Los Angeles, CA 90024.

Primary astrocyte cultures prepared from neonatal rat brains were used to study the effects of ethanol (EtOH) on adenylate cyclase (AC) activity. Cultures grown in 24-well plates were prelabeled with ^{3}H-adenine followed by stimulation of AC activity in the presence of acute doses of EtOH (25-500 mM). A dose-dependent enhancement of 10^{-5} M norepinephrine (NE)-stimulated AC activity was observed with significant enhancement occurring at EtOH doses as low as 50 mM. Virtually identical dose-dependent enhancements were seen with stimulation by 10^{-5} M isoproterenol and 10^{-5} M adenosine suggesting that EtOH may be exerting its effects through these two receptor systems via a common mechanism. Similar EC_{50} values for stimulation of AC in the presence and absence of 100 mM EtOH by both NE and isoproterenol indicate that EtOH has little effect on the sensitivity to these agonists. When astrocytes were maintained in serum free medium, EtOH enhancement of NE-stimulated AC activity was sharply attenuated as opposed to cells maintained in serum supplemented medium. These findings suggest that acute exposure of astrocytes to EtOH may enhance AC activity by producing alterations at a site distal to the receptor, and that these alterations may be subject to hormonal influence. (Supported in part by USPHS grant AA07653.)

DIFFERENTIAL EFFECTS OF PRENATAL ETHANOL EXPOSURE ON CORTICOSTERONE RESPONSES TO RESTRAINT STRESS IN MALE AND FEMALE RATS. J. Weinberg. Dept. of Anatomy, Faculty of Medicine, The University of British Columbia, Vancouver, B.C. V6T 1W5, Canada.

Hyperresponsiveness to stress (enhanced pituitary-adrenal activation and/or delayed recovery) has been reported to occur primarily in fetal ethanol exposed (FEE) females and not in FEE males. However, the stressors studied have typically been acute and/or of short duration. The present study examined the corticosterone time course to prolonged (4 hr) restraint in adult males and females from prenatal ethanol (E), pair-fed (PF) and ad libitum-fed (C) treatment groups.

All animals showed a significant corticoid increase over the first hr of testing and a gradual return toward basal levels over the next 3 hr, although corticoids never completely returned to basal levels during the 4 hr test. In addition, in contrast to previous studies, E females were found to be similar to PF and C females in their pattern of corticoid responsiveness; E males, however, were similar to PF and C males in their initial response to stress, but showed a prolonged corticoid activation over the 4 hr test period. These data suggest that under conditions of prolonged rather than short duration stress, adrenocortical hyperresponsiveness may be demonstrated in E males, but not females.

CHRONIC ETHANOL EFFECTS ON THE ACIDIC PHOSPHOLIPIDS IN MOUSE BRAIN REGIONS. M. Navidi*, F.G. Yao* and G.Y. Sun (SPON: D. O'Brien). Sinclair Research Farm and Biochemistry Department, University of Missouri, Columbia, MO 65203.

We have reported previously that chronic ethanol administration resulted in an increase in the level of acidic phospholipids in brain. The increases in levels of phosphatidylserines (PS) as well as phosphoinositides (PI, PIP and PIP_2) are best shown in the synaptosomal membrane fraction, reflecting that these alterations are associated with synaptic mechanisms. Recently, the response of brain acidic phospholipids towards chronic ethanol treatment can be more effectively probed by prelabeling the phospholipids with ^{32}Pi through intracerebral ventricular injections. In this study, C57b16J mice were pair-fed a Sustacal (chocolate flavor) liquid diet containing 5% ethanol or a control diet containing an equal amount of glucose for 8 weeks. ^{32}Pi (20 uCi per brain) was injected to each brain 4 hr prior to killing and subsequent dissection of brain regions on ice. Cerebral cortex, hypothalamus, hippocampus as well as a synaptosome fraction from the cerebral cortex were obtained for analysis. the procedure for lipid analysis (Sun and Lin, Life Sci. 44: 689, 1989) allowed separation of all phospholipids including the poly-PI and PA in one single high performance thin-layer plate. Results from this study indicated an increase in labeling of poly-PI in cortex and hippocampus but not in hypothalamus. Among these brain regions, hippocampus from ethanol-treated group (n=8) exhibited most dramatic increases in labeling of the acidic phospholipids (PA, PS and poly-PI) as compared to the pair-fed controls (n=8). These results confirm other studies indicating that the hippocampus is more sensitive to the effects of ethanol and further emphasize the importance of this brain region in manifestation of the physiological effects of chronic ethanol administration. INTERACTIONS WITH ADENOSINE (ADO) AND ETHANOL (ET) OF ENDOGENOUS GLUTAMATE (GLU) RELEASED FROM RAT CEREBELLAR SYNAPTOSOMES. M. Clark* and M. S. Dar. BPB, NIMH, Bldg 10, Rm 3N212, Bethesda, MD 20892 and Department of Pharmacology, School of Medicine, East Carolina University, Greenville, NC 27858.

Effects of ET and ADO receptor agonist R-PIA and antagonist theophylline (TH) on release of endogenous GLU were tested in rat cerebellar synaptosomes. GLU release for 5-60 s was followed by its separation by rapid filtration. Released GLU was measured by an enzyme-linked fluorometric assay. Basal GLU release was 3.7±0.3 nmol/mg protein/5 s and was stimulated by high K^+. GLU release consisted of an initial rapid phase for the first 10 s followed by a relatively slower phase. Observation of Ca^{2+}-dependent and -independent GLU release suggested the role of neuronal and glial constituents of the synaptosomal preparation, respectively. ET (25-100 mM) caused a trend toward a dose-dependent inhibition of GLU release. R-PIA and TH inhibited and stimulated, respectively, basal release of GLU and R-PIA-inhibited release was blocked by TH. ET (25 mM) blocked the stimulatory effect of TH and the data with ADO deaminase suggested ADO role in this effect of ET. Results suggest ET inhibits GLU release in the cerebellar cortex via an ADO-sensitive mechanism and support our findings of cerebellar ADO modulation of ET-induced motor disturbances. [Funded in part by NC Alcoholism Res. Authority Grant #8605].

TEMPERATURE-RELATED CHANGES IN SENSITIVITY TO ETHANOL-INDUCED FLUIDIZATION OF C57 MOUSE BRAIN SYNAPTOSOMAL* PLASMA MEMBRANES (SPMs). R.L. Alkana, K. von Hungen*, C.F. Baxter, P.J. Syapin, and M. Bejanian. Alcohol and Brain Research Laboratory, School of Pharmacy, Univ. of Southern Calif., Los Angeles, CA 90033.

The present study tested the hypothesis that temperature-related changes in ethanol's fluidizing effects on brain membranes might underlie the effects of temperature on brain sensitivity to ethanol in C57 mice. SPMs were prepared from the pooled forebrains of 10 C57BL/6 mice. Fluidity measurements were made at 25, 32, and 37°C using 1,6-diphenyl-1,3,5-hexatriene (DPH). As previously reported, baseline fluidity increased significantly with increases in temperature. Further, increasing the temperature from 25 to 37°C significantly increased the fluidizing effect (% change in polarization) of ethanol on SPMs. Increasing the temperature from 32 to 37°C caused a nonsignificant increase in the fluidizing effect of ethanol. The minimum concentration of ethanol required to cause a significant increase in SPM fluidity was higher at 25°C (170.7 mM) than at 32 and 37°C (85.3 mM). Taken with previous behavioral studies, these results indicate that sensitivity to the fluidizing and behavioral effects of ethanol both increase with temperature. (Supported by NIAAA grants AA05234 & AA03972 & VA Medical Res. Serv.).

GANGLIOSIDES AND CHOLESTEROL DIFFERENTIALLY AFFECT MEMBRANE SELECTIVITY AND SENSITIVITY. R. Hitzemann, J. Lin* and K. Dains*. Psychiatry Service-VAMC Northport, NY 11768; Dept. Psychiatry, SUNY: Stony Brook, NY 11794

The selectivity and sensitivity of two different membranes (x and y) to perturbation (P) by non-electrolyte anesthetics (i), such as the n-alcohols, are related by $\log P_{i,y} = \log P_{i,x} * S_{x,y} + R_{x,y}$, where S is the selectivity constant and R is a measure of the difference in membrane sensitivity (Hitzemann, 1988). When $S_{x,y}$ is > 1, membrane "x" will show differentially greater perturbation by more hydrophobic molecules. We have examined, using fluorescence polarization techniques, the effects of ganglioside GM1 and cholesterol to alter the selectivity and sensitivity of DMPC liposomes to perturbation by n-alcohols (C1 to C8). The incorporation of GM1 (30 mole %) increases (> x 2) membrane sensitivity to perturbation (DPH as probe) without affecting membrane selectivity. In contrast, the incorporation of cholesterol (50 mole %) increases both membrane selectivity and sensitivity (> x 4). Because of the increase in selectivity (S = 1.30) the C-1 to C-3 alcohols are less potent to perturb structure in the presence of cholesterol. The addition of GM1 to the cholesterol containing liposomes has no effect on selectivity but markedly attenuates (> 50%) the increase in sensitivity. The data will be discussed in terms of the structure of anesthetic sensitive domains.

224.12

AFFERENT FIBER DISTRIBUTION IN RAT HIPPOCAMPUS AFTER CHRONIC ETHANOL EXPOSURE. C.T. Smothers and B.E. Hunter. Dept. of Neuroscience, University of Florida, Gainesville, FL 32610.

Chronic ethanol treatment (CET) has been shown to increase the amplitude of hippocampal population spike responses in the ventral hippocampus. These studies were designed to determine whether this regional variation results from underlying changes in afferent fiber distribution. Ethanol-treated (E) and control (S) groups were fed a liquid diet containing either ethanol or sucrose for 20 weeks followed by an 8 week abstinence period. Hippocampal slices were prepared from septal and temporal poles and maintained in a slice chamber. Stimulating electrodes were placed in stratum radiatum (SR) and a recording micropipette was placed in SR (afferent volley; dendritic EPSP) or in stratum pyramidale (population spike) of CA1. Spatial mapping studies were performed by generating input/output functions with stimulating/recording electrode distances of 100,250 and 500 microns.

CET resulted in significantly greater population spike responses in slices from the ventral pole as compared to the dorsal hippocampus. Population spike amplitude tended to decrease with increasing inter-electrode distance in S as compared to E animals in the ventral hippocampus. When population spike amplitude was plotted as a function of dendritic EPSP amplitude, a sigmoid function was obtained which exhibited a greater rate of rise with increasing electrode separation. Such results suggest that local circuit inhibitory interneurons are more effectively activated with decreasing distance between stimulating and recording electrodes. Together with previous studies, these results indicate that CET increases excitability in the ventral hippocampus by producing an enduring reduction in inhibitory synaptic transmission.

ETHANOL-RESPONSIVE PROMOTER ELEMENTS. M. F. Miles and J. Sturdivant*. Dept. of Neurology and The Ernest Gallo Research Center, Univ. Calif. San Fran., San Francisco, CA 94110.

We have recently shown that chronic ethanol exposure induces a specific pattern of changes in mRNA abundance in the NG108-15 neuroblastoma-glioma hybrid cell line. Included in those genes that are induced by ethanol is the constitutive member of the 70 kDa stress protein family, Hsc70. This protein is thought to play an important role in membrane protein trafficking and thus could mediate many of the pleiotropic effects of ethanol.

We have investigated the mechanism of ethanol regulation of Hsc70 by using transfection analyses with a Hsc70 promoter region fused to the coding region for bacterial chloramphenicol acctyltransferase (CAT). Ethanol causes a dose dependent increase in CAT activity in NG108-15 cells transfected with this construct. Control cultures (using viral promoters) show no change or decreased CAT activity.

These results suggest that ethanol regulates Hsc70 at the transcriptional level and that ethanol-responsive cis-acting sequences are present in the Hsc70 promoter. Further characterization of these will be presented.

LIVER DISEASE WITH OR WITHOUT VITAMINS A AND E DEFICIENCY AND BRAIN FUNCTION. A.M. Arria*, M.A. Kabene*, R.E. Tarter*, V. Warty*, D.H. Van Thiel* (SPON: J.R. JENNINGS). Dept. of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA 15213.

Vitamin A and E deficiency are a common consequence of cirrhotic liver disease. A deficiency of vitamin E has been postulated to produce a specific neurologic syndrome characterized primarily by disturbances in motor function. The purpose of the study was to assess the combined effect of vitamin A and E deficiency in adults with chronic liver disease who were not acutely encephalopathic. The association between vitamins A and E deficiency and neurologic status related to liver disease was assessed using a battery of neurocognitive tests. Controlling for liver injury status, it was found that vitamin A and E deficient patients (N=70) performed more poorly on tests of psychomotor capacity than vitamin A and E sufficient patients (N=51). The results suggest that nutritional deficiency may underlie, in part, the neurologic syndrome of hepatic encephalopathy.

COMPUTER ANALYSIS AND THREE-DIMENSIONAL RECONSTRUCTION OF SERIAL-SECTIONED BRAINS FOLLOWING CHRONIC ALCOHOL ADMINISTRATION: TOPOGRAPHIC DISTRIBUTION OF VASOPRESSIN- AND OXYTOCIN-CONTAINING NEURONS. GP Kozlowski, NC Smith*, WK Smith, JH deSchweinitz* and DJ Woodward. Departments of Physiology and Cell Biology, University of Texas Southwestern Medical Center, Dallas, TX 75235-9040 and Biographics Inc, 1950 Stemmons Freeway, Dallas, TX 75207.

The aim of this study was to determine the effects of chronic ethanol (ETOH) on the numbers and distributions of vasopressin (VP) and oxytocin (OT) neurons in the rat hypothalamus. The CARP/386 (Computer Aided Reconstruction Package for 80386 microcomputers) System was used to plot, quantitate and visualize cell population data. Male, Long-Evans rats were simultaneously pair-fed either a control liquid diet or one containing 5% ETOH for 15 da. They were perfuse-fixed and 40 μm serial-sections of their brains were processed for immunocytochemistry using either anti-VP or anti-OT sera. The positions of VP and OT neurons in traced outlines of sections were plotted using a computer/microscope. Neurons within particular areas of interest, e.g. the paraventricular nucleus (PVN), were color-coded for comparison with neurons in other areas of the reconstructed brains. The images can be rotated and viewed from multiple directions. Chronic ETOH appears to diminish the population of VP neurons in the PVN, but to augment OT neuronal number in the PVN. Supported by NIAAA AA-06014 and NINDS NS-25321.

PENTOBARBITAL RESPONSE IN MALE VS. FEMALE WLE SEGREGATING INBRED STRAIN RATS: MUTANT ALBINO VS. PIGMENTED LITTER-MATES. J.R.Taylor* and I.S.Westenberg (SPON: D.F.Wooley-Mc-Kay). Psychology Dep't., Glendale Com.Col., Glendale, AZ 85302.

With repeated pentobarbital (PB) dosing albino rat strains have been more PB-sensitive than pigmented strains, but within a strain albino (c/c) and pigmented (c/+) rats of the same strain have not differed in PB sensitivity. We made a within-strain comparison of c/c-vs.-c/+ PB sensitivity to single PB doses. Littermate quadruplets (c/c male, c/+ male, c/c female, c/+ female) of Westenberg-Long-Evans (WLE) segregating inbred strain rats were c/c or c/+ but otherwise genetically nearly identical. 80 mg/kg ip PB killed 5/10 females (2 c/c, 3 c/+) and 1/10 males (1 c/+). The lethal-dose-to-50% (LD50) for the females was 80 mg/kg, which was significantly below the LD50 for the males (sign test, $p < 0.05$). There were no significant c/c-vs.-c/+ differences in mortality for males or females. Of the surviving rats males slept 4-7 h and females slept 17-47 h. Male-vs.-female differences in sleeptimes were statistically significant ($U=0$, $p < 0.01$); c/c-vs.-c/+ differences in sleeptimes were not significant for males or females. These results parallel those of the within-strain, repeated-dosing study. They reinforce the conclusion that the PB-sensitivity difference between albino rat strains and pigmented strains is due to genetic factors other than just the albino mutation. Analysis of the between-strain difference may elucidate factors in PB's mode(s) of action.

MK-801 ENHANCES THE EFFECTIVENESS OF GENERAL ANESTHETICS. L. C. Daniell. Dept. Pharmacol. and Toxicol., Med. Coll. of Ga., Augusta, GA. 30912-2300.

The effect of MK-801 on potency or duration of anesthesia was tested for anesthetics from several chemical classes. Male ICR mice were pretreated with various doses of MK-801 ((+)-isomer, 0.3 to 3.0 mg/kg, i.p.) 30 min before administration of ethanol (4.2 g/kg, i.p.) or pentobarbital (50 mg/kg, i.p.) or 15 min before adminstration of various concentrations of halothane or diethyl ether. MK-801 alone did not produce anesthesia at any of the doses used in this study. The duration of loss of righting reflex induced by ethanol and pentobarbital administration was increased by MK-801 in a dose dependent manner. The concentration of halothane or diethyl ether required to produce non-responsiveness in 50% of subjects (the minimum alveolar concentration) was reduced by pretreatment with MK-801. These results show that MK-801 increases the effectiveness of general anesthetics and may provide information about neurochemical mechanisms of anesthesia.

DRUG DISCRIMINATION LEARNING: EFFECTS OF REPEATED DOSE-RESPONSE ASSESSMENTS.
S. Pournaghash, D. Owens*, R. Jeffreys and A. Riley. Psychopharmacology Laboratory, The American University, Washington, D.C. 20016.

Recently, Riley and his colleagues (Riley et al., Drug Dev. Res., 16:229, 1989) reported rapid drug discrimination learning within a conditioned taste aversion paradigm. Specifically, rats avoided a taste paired with a toxin when the taste was preceded by pentobarbital and drank the solution when preceded by distilled water. Because of this sensitivity, a confound may arise when different (nonpoisoned) doses of the training drug are given as probes to assess generalization. Specifically, the animals may rapidly learn that probes are not poisoned. Repeated assessments may result in the learning of another discrimination (training vs. probe dose). This possibility was addressed in the present experiment in which following the acquisition of a pentobarbital drug discrimination (10 mg/kg) a dose generalization was repeatedly determined. Although 3.2 and 5.6 mg/kg initially produced dose-related decreases in consumption, with repeated assessments consumption gradually increased following these doses. These data suggest that repeated dose-response assessments can affect dose-response functions within the conditioned taste aversion procedure.

225.1

SEROTONIN 5-HT_{1C} RECEPTOR MEDIATES CYCLIC GMP FORMATION VIA ARACHIDONIC ACID METABOLITES. M.J. Kaufman[1], F. Hirata[1]*, P.R. Hartig[1,2] and B.J. Hoffman[1,3]. [1]The Johns Hopkins Medical Institutions, Balto., MD, 21205, [2]Neurogenetic Corp., Paramus, NJ, 07652, and [3]Lab of Cell Biology, NIMH, Bethesda, MD, 20892.

The serotonin 5-HT_{1C} receptor mediates both phosphoinositide (PI) hydrolysis and formation of cGMP in choroid plexus. The pathway of cGMP formation is not known; however we have demonstrated that cGMP formation requires extracellular calcium. Cytosolic calcium elevation induced by PI turnover might stimulate calcium dependent enzymes such as phospholipase A_2 (PLA_2) to produce arachidonate. Then arachidonate metabolites could promote increases in cGMP. Therefore we have examined the role of PLA_2, cyclooxygenase and lipoxygenase in 5-HT stimulated cGMP formation.

Inhibition of PLA_2 with p-bromophenacyl bromide (10uM) reduced 1uM 5-HT stimulated cGMP formation by 40%. Inhibition of the cyclooxygenase pathway with 10uM indomethacin enhanced 1uM 5-HT stimulated cGMP formation by nearly 50%. Blockade of the lipoxygenase pathway with BW 755C (100uM) abolishes serotonin stimulated cGMP formation. Thus it appears that 5-HT_{1C} receptor stimulation leads to increases in arachidonic acid, and metabolites of the cyclooxygenase pathway inhibit while those of the lipoxygenase pathway stimulate cGMP formation.

225.2

SEROTONERGIC MODULATION OF LOCAL INHIBITION IN THE HIPPOCAMPAL SLICE IS MEDIATED BY cAMP. S. SPRINGFIELD, E. NEIL*, M. TILLMAN*. Dept. of Biology, City College of CUNY, New York, N.Y. 10031

Previous studies from our laboratory have demonstrated that serotonin (5-HT) attenuates local inhibition in the hippocampus and this modulatory action occurs through the 5-HT_{1A} receptor. This receptor subtype was previously established to be coupled to the adenylate cyclase/cAMP system. The present experiments address the hypothesis that cAMP may be the second messenger in 5-HT's modulatory action.

Hippocampal slices (350-450 µm) were obtained from adult male Sprague-Dawley rats and constantly superfused with a bicarbonate-buffered balanced salt solution. Slices were allowed to equilibrate at 32° C and aerated with 95%O_2/5%CO_2. Evoked population spikes were recorded with a single glass micropipette (2-10MOhms) filled with 3M NaCl. Twin stimuli (200-1000 µsec; 1-10V; 1/35-1/60 Hz) of interstimulus intervals of between 5 and 20 msec were presented to the stratum radiatum at the border of the CA1-CA2 region. Local inhibition occurred when the amplitude of the test (second) population spike is smaller than the conditioning (first) spike. The reduction has been attributed to the action of GABA-mediated inhibition superimposed upon orthodromic excitation.

Application of cAMP (10^{-9}-10^{-8}M) resulted in an increase in the amplitude of the test spike. In addition adenine (10^{-9}M), a metabolite of cAMP, attenuated local inhibition. The similarity of actions of these agents suggest that 5-HT's modulatory action in the hippocampus may involve cAMP as a second messenger. (NSF grant BNS 8606419, PSC-CUNY award and MBRS program).

225.3

NEUROCHEMICAL, ELECTROPHYSIOLOGICAL AND BEHAVIOURAL EVIDENCE THAT 8-OH-DPAT STIMULATES CENTRAL DOPAMINE SYSTEMS. M. Davies*, B.D. Sloley* and P.J.Fletcher* (SPON: A.A. Boulton). Neuropsychiatric Research Unit, Medical Research Bldg, University of Saskatchewan, Saskatoon, Sask., Canada.

We have used neurochemical, electrophysiological and behavioural techniques to investigate a potential interaction between the 5-HT receptor agonist 8-OH-DPAT and central DA systems. Striatal concentrations of DA and DOPAC were obtained from aliquots of homogenized rat striata using HPLC-ED techniques. Peripheral administration of 8-OH-DPAT (15 to 240 µg/kg IP) or the administration of 8-OH-DPAT (1µg) into the dorsal raphé nucleus (DRN) 30 mins prior to sacrifice increased the ratio of DOPAC:DA in the striatum. Electrophysiological studies in anaesthetized rats showed that IV administration of 8-OH-DPAT (0.3 to 10 µg/kg) increased the spontaneous activity of striatal neurones. This effect was completely reversed by haloperidol (0.1 mg/kg IV). Food intakes in free-feeding rats were measured over 1 hour following the microinjection of 8-OH-DPAT (1µg) into the DRN. 8-OH-DPAT consistently elicited an increase in food intake which was completely blocked by pretreatment with haloperidol (0.1 mg/kg SC) or spiperone (0.05 mg/kg SC). Spiperone (20 µg) was ineffective, however, when microinjected into the DRN suggesting that DA is involved downstream from the DRN. Taken together these results provide strong evidence that 8-OH-DPAT stimulates central DA systems which is probably due, at least in part, to a reduction of the inhibitory influence which 5-HT systems exert over central DA transmission. (Supported by Sask Health & Sask Health Res. Board).

225.4

ROLE OF SOMATODENDRITIC AUTORECEPTORS IN THE REGULATION OF SEROTONERGIC NEURONAL ACTIVITY IN BEHAVING CATS. C.A. Fornal, W.J. Litto, L.E. Ribeiro-do-Valle, and B.L. Jacobs. Prog. Neurosci., Dept. of Psychol., Princeton Univ., Princeton, NJ 08544.

Somatodendritic autoreceptors (presumably $5HT_{1A}$) may play an important role in regulating the firing rate of central serotonergic neurons. The present study examined the effects of spiperone, a presumed $5HT_{1A}$ antagonist, on a) the spontaneous firing rate of serotonergic dorsal raphe nucleus (DRN) neurons, and b) the suppression of serotonergic DRN neuronal activity produced by $5HT_{1A}$ agonists. Serotonergic neurons were recorded and identified using methods previously described (Fornal et al., Exp. Neurol. 98:388-403, 1987). Drugs were administered remotely via an indwelling jugular catheter. The spontaneous activity of serotonergic DRN neurons varied in association with behavioral state. Spiperone (1 mg/kg) increased unit activity when cats were aroused or alert, but not when cats were drowsy or asleep, as indicated by polygraphic criteria. Spiperone pretreatment (1 mg/kg) blocked the effects of 8-OH-DPAT (5 µg/kg), buspirone (20 µg/kg), and 5-MeODMT (20 µg/kg), for 2-3 hrs. Similar effects were not observed following haloperidol (1 mg/kg). We conclude that serotonin autoreceptors exert a tonic inhibitory influence on the firing rate of serotonergic DRN neurons during periods associated with high activity, such as active waking, and not during periods associated with low activity, such as sleep.

225.5

NERVE TERMINAL AUTORECEPTOR REGULATION OF SEROTONIN RELEASE. J.J. RUTTER* and S.B. AUERBACH. Dept. of Biol. Sci., Rutgers Univ., New Brunswick, NJ 08903.

Stimulated serotonin (5-HT) release from synaptosomes is enhanced by the 5-HT_1 antagonist methiothepin. This suggests the presence of 5-HT nerve terminal autoreceptors. We have used microdialysis in unanesthetized rats to further test the possibility that terminal autoreceptors regulate 5-HT release *in vivo*. Concentric-type dialysis probes were implanted in the ventromedial hypothalamus. Serotonin in the dialysate was measured by HPLC-EC. The synaptic origin of 5-HT was verified by 50% or greater inhibition with local administration of TTX or systemic administration of the somatodendritic autoreceptor agonist, 8-OH-DPAT.

Methiothepin, 20 µM, was locally perfused for two h in the dialysate, with or without pre-perfusion with fluoxetine, 10 µM, a selective 5-HT reuptake inhibitor. Fluoxetine pre-perfusion alone produced a fivefold increase above baseline; with the addition of methiothepin, 5-HT release was significantly increased at 30 min to 219 ± 51.4% of fluoxetine baseline levels (n=14). In contrast, without fluoxetine pre-perfusion, 5-HT was slightly, but non-significantly increased at 30 min to 39 ± 31% above baseline levels (mean ± s.e.m., n=6). This suggests that the nerve terminal autoreceptor is preferentially activated at supraphysiological levels of synaptic 5-HT. Preliminary data suggest that methiothepin also preferentially enhances 5-HT release during 2 h of restraint stress as compared to 2 h of undisturbed behavior.

Supported by NSF grant BNS-8708014.

225.6

EFFECTS OF ELECTRICAL STIMULATION OF THE DORSAL RAPHE NUCLEUS ON 5-HYDROXYTRYPTAMINE (5-HT) IN MEDIAL PREFRONTAL CORTEX (MPC) AND DORSAL HIPPOCAMPUS (DH) BY IN VIVO MICRODIALYSIS D.J. Mokler and J.H. Johnson. Dept. of Pharmacol., Univ. New England, Biddeford ME 04005 and Dept. Anatomy, Vir. Comm. Univ., Richmond VA 23298.

Previous experiments have shown that electrical stimulation (ES) of the dorsal raphe nucleus results in an increase in the levels of the major metabolite of 5-HT, 5-hydroxyindoleacetic acid (5-HIAA) in forebrain areas. The purpose of the present experiment was to examine the effects of ES of the dorsal raphe on the levels of 5-HT and 5-HIAA simultaneously in the DH and MPC by in vivo microdialysis. Male Sprague-Dawley rats were implanted with a bipolar electrode into the dorsal raphe nucleus and guide cannulae into the DH and MPC. After one week for recovery, microdialysis probes were placed into the DH and MPC under light ether anesthesia. Microdialysis was started immediately at a rate of 5 µl/min for 10 min periods. Samples were collected for one hour for baseline determinations. ES (200 µA, bipolar, 100 µsec duration, 20 Hz) produced an increase in 5-HIAA in the DH and MPC to a maximum of 120% of control after 20 min. The 5-HT_{1a} agonist 8-OH-DPAT, infused in the microdialysis fluid into the DH, produced a slight decrease in levels of 5-HIAA in the DH. Therefore, in vivo microdialysis can be used to detect changes in 5-HT activity following ES of the dorsal raphe. (Supported by NIH grant HD-12165)

225.7

REGULATION OF SEROTONIN RELEASE IN RAT STRIATUM: 5-HT$_1$ RECEPTOR AGONISTS INTERACT WITH THE 5-HT UPTAKE CARRIER. S.L. Garber and M.H. Makman *. Albert Einstein College of Medicine, Bronx, NY 10461.

The possible roles for serotonin (5-HT) release, receptor activation and intraneuronal 5-HT levels in mediating autoinhibition of 5-HT synthesis were studied in rat striatal synaptosomes. 5-HT itself inhibited basal formation of 5-HT from ^{14}C-tryptophan. Zimelidine, which inhibits 5-HT uptake, diminished the effect of 5-HT. 5-HT also blocked the stimulatory effect of forskolin, an activator of adenylate cyclase shown previously to stimulate 5-HT synthesis (Molec. Brain Res. 3:1-11,1987). Basal formation of 5-HT was not inhibited by the 5-HT$_1$ receptor agonists 5-methoxy-3(1,2,3,6-tetrahydropyridin-4-yl)1-H-indole (RU-24969), trimethylphenylpiperazine (TFMPP) or 8-hydroxy-2-(di-n-propylamino) tetralin (DPAT). However, efflux of prelabeled ^{3}H-5-HT was enhanced not only by 5-HT but also by TFMPP, DPAT and RU-24969; chlorimipramine, an uptake carrier blocker, reversed these effects on efflux. Specific uptake of ^{3}H-5-HT (Km=143nM) was inhibited by DPAT (Ki=345nM) or RU-24969 (Ki=1040nM), as well as by chlorimipramine. However, specific uptake of ^{3}H-DPAT itself did not occur. It is proposed that the 5-HT$_1$ agonists RU-24969, DPAT and TFMPP bind to the outer surface of the uptake carrier to promote exchange or release of 5-HT as well as to block uptake. Thus, certain 5-HT$_1$ agonists may act to regulate 5-HT release and uptake, independent of 5-HT synthesis, similar to the action of tricyclic and related antidepressants.

ACTIVATION OF 5-HT-2 RECEPTORS ALTERS UNIT ACTIVITY OF CORTICAL NEURONES. R.S. Neuman and G. Zebrowski*. Faculty of Medicine, Memorial University, St. John's, Nfld., Canada A1B 3V6

Noxious stimulation induces cortical desynchronization which is mediated by serotonin (Neuman, EEG and Clin Neurophysiol, 64: 546-555, 1986). In the present study we investigated the site of serotonin's action.

Unit activity recorded from layer IV neurones in the frontal-parietal cortex, in urethane anaesthetized rats, consisted of bursts separated by long interburst intervals which were synchronous with slow wave activity recorded from the same electrode. Noxious stimulation reversibly abolished the long interburst intervals resulting in continuous firing of the unit during and often outlasting the stimulus. This corresponded with cortical desynchronization. Systemic administration of ketanserin, cinanserin and cyproheptadine, but not vehicle, reversibly blocked the alteration of unit activity and accompanying desynchronization induced by noxious stimulation. The effects of low iontophoretic currents (10-20 nA) of ketanserin and cinanserin applied from adjacent electrode barrels mimicked the systemic administration of these agents, i.e. the burst-pause activity persisted despite the application of noxious stimulation.

Layer IV of the cortex contains a high concentration of 5-HT-2 receptors along with a dense plexus of 5-HT immunoreactive fibres which originate from the dorsal raphe. We conclude that noxious stimulation activates serotonergic neurones of the dorsal raphe which in turn enhance the firing rate of cortical neurones. Supported by the Canadian MRC.

SEROTONIN-DEPENDENT HIPPOCAMPAL ELECTRICAL ACTIVITY IN FREELY MOVING ANIMALS: A METHOD FOR EVALUATING SEROTONERGIC ANTAGONISTS. N.V. Watson*, E.L. Hargreaves and C.H. Vanderwolf (SPON: D.J. Stewart). Dept. of Psychology, Univ. of Western Ontario, London, Ontario. CANADA N6A 5C2.

The hippocampal Rhythmical Slow Activity (RSA) that persists following a large dose of scopolamine and that correlates with Type I motor activity (walking, struggling), appears to be dependent on central serotonergic transmission (Vanderwolf, 1988). Possible blockade of this activity by putative serotonergic antagonists was assessed in freely moving rats, pretreated with scopolamine (5 mg/kg s.c.). RSA was quantified by integrating 6-12 Hz activity during waking immobility and struggling.

Mianserin (1-50 mg/kg i.p.), and pizotifen (1-50 mg/kg i.p.) were without effect, but methiothepin (0.2-5 mg/kg i.p.) produced a dose-related suppression of scopolamine-resistant RSA. As a control for the cataleptogenic effect of methiothepin, it was shown that haloperidol (0.2-5 mg/kg i.p.) did not suppress scopolamine-resistant RSA.

Study of scopolamine-resistant electrocortical activity may provide a convenient assay of central serotonergic activity with a known relation to behavior. Supported by grants from NSERC to C.H.V.

SEROTONERGIC MODULATION IN THE HAMSTER HIPPOCAMPAL SLICE DIFFERENT THAN IN THE RAT HIPPOCAMPUS. D. J. Horrigan* and J. M. Horowitz. Dept. of Animal Physiology, Univ. of Calif., Davis, CA 95616.

The effects of serotonin on hippocampal population spikes at 34°C in the rat, a nonhibernator, have previously been described. To determine if similar effects could be observed in the hamster, a hibernator, hippocampal pyramidal cell activity was monitored in hamsters and rats following Schaffer collateral stimulation using methods described by Thomas *et. al.*, J. therm. Biol. 11:213, 1986. Population spike amplitude was measured before, during and after bath administration of 10 μM serotonin at a bath temperature of 20°C. The response consisted of a depression of the population spike during serotonin application and a recovery and overshoot of the spike amplitude following drug removal. At 20°C the average depression in the hamster was 52.4±10.1% and in the rat was 76.4±5.5% (mean ± SE). (In the hamster the depression was measured over a large temperature range and shown to persist for temperatures from 15°C to 35°C). The average overshoot in the hamster was 33.7±9.3% and was significantly ($p < 0.05$) larger than 7.4±4.8%, the overshoot seen in the rat. (In the hamster the enhancement was a minimum at 25°C and had a greater amplitude at 35°C and at 15°C). In summary, the overshoot is more pronounced in the hamster than in the rat indicating a difference between species. [Supported by NASA grant NAGW-1458].

226.1

RECOVERY OF BIOCHEMICAL RESPONSES MEDIATED BY MUSCARINIC RECEPTORS FOLLOWING ADMINISTRATION OF AN IRREVERSIBLE CHOLINERGIC AGONIST (BM 123). V.H.Sethy, D.K.Hyslop, and T.P.Boyle. CNS Diseases Research, The Upjohn Company, Kalamazoo, MI 49001.

The irreversible cholinergic agonist BM 123 was injected to rats to investigate the role of subtypes of muscarinic receptors in the regulation of (3H)-acetylcholine [(3H)-Ach] release and phosphatidylinositol hydrolysis (PIH) which may be mediated by M2 and M1 receptors, respectively. Treatment with BM 123 significantly reduced the inhibitory effect of oxotremorine (10 uM) on presynaptic release of (3H)-Ach and oxotremorine-M (300 uM)-induced PIH at 12 hr ($p<0.002$, <0.001, respectively). Time-dependent recovery of both muscarinic receptor-mediated (3H)-Ach release and PIH was observed, and the responses returned to normal levels by 144 hr. There was a linear relationship between the recovery of (3H)-Ach release response and (3H)-oxotremorine-M (3H)-Oxt) binding sites, but the relationship was non-linear with respect to the recovery of PIH response and (3H)-Oxt binding sites. These results indicate that the presynaptic muscarinic receptor system of the hippocampus involved in the regulation of (3H)-Ach release may lack spare receptors. On the other hand, there may be a receptor reserve in the muscarinic receptor system which mediates PIH.

226.2

PHARMACOLOGICAL CHARACTERIZATION OF PD 129409: A NOVEL MUSCARINIC RECEPTOR AGONIST. R.D. Schwarz, L.L. Coughenour, R.E. Davis, D.T. Dudley, W.H. Moos, and H. Tecle*. Parke-Davis Pharm. Res. Div., Warner-Lambert Co., Ann Arbor, MI. 48105.

Muscarinic receptor agonists may alleviate some of the symptoms associated with Alzheimer's disease. Present results characterize 1,2,5,6-tetrahydro-1-methyl-3-pyridinecarboxaldehyde, O-methyloxime, HCl (PD 129409), an orally active muscarinic agonist. In vitro, PD 129409 like other known agonists, binds with high affinity to muscarinic receptors (with no binding at a number of other receptors), shows a concentration-dependent and atropine-sensitive increase in phosphatidylinositol turnover (SK-N-SH cells) and a decrease in the release of [^{3}H]-ACh from rat cortical slices, as well as having no effect on brain AChE activity. Dose-dependent effects were observed upon oral and subcutaneous administration in both rodents (0.1-2mg/kg) and non-human primates (0.03mg/kg) using models of central (EEG, body temperature, and cerebral blood flow) and peripheral (heart rate and GI motility) cholinergic activity. Thus, PD 129409 is a novel, orally active muscarinic receptor agonist which may be useful in the treatment of Alzheimer's disease.

226.3

INTERACTION OF HOE 427, A SYNTHETIC ACTH(4-9)-ANALOGUE WITH MUSCARINIC M1-RECEPTORS IN RAT BRAIN. H.J. Gerhards*, B. Jablonka*, M. Leven*, G. Wiemer*, F.J. Hock and R. Geiger* (SPON: E.T.W. Liske). HOECHST AG, P.O.B. 80 03 20, D-6230 Frankfurt/M. 80, FRG.

In a previous publication, we described that the synthetic ACTH-analogue Hoe 427 improves cognitive functions and enhances central cholinergic transmission in rodents (F.J. Hock et al., Peptides, 9: 575, 1988; G. Wiemer et al., Peptides, 9: 1081, 1988).

We now report, that Hoe 427 displaces ^{3}H-Pirenzepine, a ligand that specifically labels the M1-subtype of muscarinic receptors in neural tissues. In vitro binding studies with brain homogenates and quantitative receptor-autoradiography revealed an affinity of Hoe 427 to this site in cortex, hippocampus and striatum of the rat brain.

Although the affinity of Hoe 427 to the ^{3}H-Pirenzepine labelled M1-site is rather low (IC50: 4.7 x 10^{-6} M, the possibility, that the observed effects of this peptide on central acetylcholine metabolism are mediated by an interaction with a M1-muscarinic site has to be discussed.

226.4

DIFFERENTIAL UPREGULATION OF HIPPOCAMPAL M-1 AND M-2 MUSCARINIC RECEPTORS AFTER CHOLINOTOXIN (AF64A) LESION OF THE MEDIAL SEPTUM OR DIAGONAL BAND. V.L. Dawson and J.K. Wamsley. Dept. Psych. and Pharm., West. Inst. Neuropsych., Univ. of Utah, SLC, UT

Cholinergic cell bodies in the medial septum (MS) and vertical nucleus of the diagonal band (VDB) project axons through the fimbria-fornix to terminate in a laminated pattern in the hippocampal formation. Inorder to investigate the cellular localization of muscarinic receptors, a selective cholinergic neurotoxin, AF64A, was stereotaxically injected into MS or VDB and changes in M-1 and M-2 muscarinic receptors and choline uptake (SDHACU) sites in the hippocampus, as well as, the MS and VDB were examined.

AF64A MS and VDB lesions resulted in the significant loss of M-1 receptors labeled with [^{3}H]pirenzepine (PZ), M-2 receptors labeled with [^{3}H]QNB+100nM PZ, and SDHACU site with [^{3}H]hemicholinium-3 (HC-3) in the MS or VDB. In the hippocampus of the MS lesion [^{3}H]HC-3 binding was significantly reduced in all lamina and M-2 receptors were significantly increased in the stratum oriens (Or) of areas CA2-4. In the hippocampus of AF64A VDB lesions, [^{3}H]HC-3 binding was only significantly reduced in the stratum radiatum (Rad). In these animals M-1 receptors were significantly increased in the Rad of areas CA2-4, and M-2 receptors were significantly increased only in the Or of area CA4. These data provide evidence that the hippocampus may be differentially innervated by the MS and VDB and the MS regulates postsynaptic Or M-2 receptors and the VDB mediates activity at the Rad M-1 receptor.

226.5

SECTOR-DEPENDENT NEUROTOXICITY OF ETHYLCHOLINE AZIRIDINIUM (AF64A) IN THE RAT HIPPOCAMPUS (H). S.Laganiere*, M. Marinko*, J.Corey*, E.Wulfert*, & I.Hanin. Dept. Pharmacol., Loyola U. Chgo. Sch. Med., Maywood, IL., & UCB sa, Brussels.

ICV administration of AF64A results in an irreversible hypofunction of the hippocampal cholinergic network (Fisher and Hanin, Ann. Rev. Pharmacol. Toxicol. 1986). If this effect is due to a direct action at the site of contact with AF64A, the H adjacent to the ventricular space should show the largest effect. Our results indicate that this is not the case. Whole H from Sprague-Dawley rats [225-300 g; 6 days after bilateral ICV saline or AF64A (1, 2 or 3 nmol/ventricle); N= 6 rats/group] were vibratome-sectioned along their long axis and divided into 5 equal sectors from the ventral, to the cortical surface of H. In saline treated animals choline acetyltransferase (ChAT) activity showed a linear gradient of decreasing activity away from the ventral surface (31%; $p<0.001$). Conversely, the effect in the AF64A-treated rats was curvilinear, and dose dependent at all AF64A concentration used. For example, in 1 nmol AF64A-treated rats ChAT activity was significantly ($p<0.005$) reduced by 33% and 41% in the first sectors adjacent to the ventricle; was maximally reduced (45%) in the third sector; and attained only a 37% and a 23% decrease, respectively, in the fourth and fifth (most cortical) sectors. The neurotoxicity of ICV administered AF64A in vivo is thus dependent upon both: 1) diffusion of the compound within the ventricle; and 2) the intrinsic susceptibility of selective cholinergic terminals to AF64A.

226.6

DARK RESIN, ANGELATES (ANG), FROM PEREZIA ROOTS ACTION ON RAT INTESTINE IN VITRO. X. García, E. Gijón and G. Alcántara*. Dept. of Physiol. and Dept. of Pharmacol. Sch. of Med. Universidad Nacional Autónoma de México, Ap. P. 70-250, México, D.F. 04510. MEXICO.

The isomeric mixture of hidroxiperezone angelates, a dark viscous compound, is one of the active principles obtained from Perezia roots, known by its laxative properties as a prehispanic remedy (Alcántara, G. Res. Congr. Nacl. Farmacol. Reu. Reg. Asoc. Latinoam. Farmacol. 10:52, 1986). The purpose of this study was to know if the ANG share some of the perezone properties on Wistar male rat intestine by isometric recording in vitro (García, X., Alcántara, G. y Gijón, E. Res. Congr. Nacl. Cienc. Fisiol. 31:C220, 1988). The ANG, like perezone, interrupt spontaneous intestinal activity, they relax intestinal smooth muscle and diminish muscle tonus, they block the contractile response induced by acetylcholine (ACh) in a reversible form. The exposure to a high ACh dose prolongs the recuperation time in spite of showing no ACh response at all after the ANG, whereas small ACh doses recover their response completely. The ANG also relax the ACh-induced contraction. The ANG induced a contraction followed by a rélaxation and a later slow contraction. These results show that the ANG behave like perezone, they probably affect the smooth muscle by interfering with the calcium movement and also suggest their interaction with the ACh receptor.

226.7

PEREZONE (PZN) ANTICHOLINERGIC ACTION FROM THE MUCOSAL TO THE SEROSAL SURFACE OF EVERTED AND NON-EVERTED RAT INTESTINE. E. Gijón, X. García and G. Alcántara*. Dept. of Physiol. and Dept. of Pharmacol. Sch. of Med. Universidad Nacional Autónoma de México, Ap. P. 70-250, México, D.F. 04510. MEXICO.

Perezone is one of the active principles isolated from Perezia roots, known by its laxative properties as a prehispanic remedy (Alcántara, G. Res. Congr. Nacl. Farmacol. Reu. Reg. Asoc. Latinoam. Farmacol. 10:52, 1986). Perezone shows anticholinergic actions when applied to the serosal surface of rat intestine in vitro (García, X., Alcántara, G. y Gijón E. Res. Congr. Nacl. Cienc. Fisiol. 31:C220, 1988). It is important to know if these PZN actions are also observed when applied on the mucosal surface, since in humans it is used orally. We found negative results with the in vitro method of everted intestine (Crane, R.K. and Wilson T.H. J. Appl. Physiol. 12:145-146, 1958), due to the need of isometric recordings of Wistar male rat intestine. A later development was the use of non-everted small intestine tied to a small piece of polyethylene tube 4mm O.D. The tube is a cantilever during the isometric recording. PZN applied to the mucosal surface through the tube, by a polyethylene cateter 1.5mm O.D., shows its characteristic anticholinergic properties with a latency of 20 minutes. This suggests a slow transference of PZN from the mucosal to the serosal surface.

226.8

REACTIVATION BY 2-PAM, ICD 467, MMB-4 and HI-6 OF SOMAN-INHIBITED ACETYLCHOLINESTERASE (AChE) IN RABBITS. L.W. Harris*, D.R. Anderson*, C.L. Woodard* and W.J. Lennox* (SPON: S.B. McMaster). USAMRICD, Aberdeen Proving Ground, MD 21010-5425.

This study determined whether pralidoxime Cl (2-PAM), 2-hydroxyiminomethyl-3-methyl-1-(2-(3-methyl-3-nitrobutyl-oxymethyl))-imidazolium Cl (ICD 467), 1-1'-methylenebis[4-(hydroxyiminomethyl) pyridinium] di-Cl (MMB-4) and 1-(2-hydroxyimino methyl-1-pyridinio-3-(4-carbamoyl-1-pyridinio)-2-oxapropane di-Cl (HI-6) would reactivate soman-inhibited AChE in vivo. Rabbits were atropinized (8 mg/kg, im) and given soman (13 ug/kg, iv; 1.2 x LD_{50}) 5 min later. Three min after soman, animals received oxime (50, 100 or 150 umol/kg, im). Whole blood was collected just before soman, at 2 min after soman and at 2, 5, 10, 15, 30, and 60 min after oxime or vehicle for determination of AChE activity. After anesthetizing and perfusing the rabbits, tissues were removed for AChE assay on the cortex, medulla-pons and diaphragm. HI-6 and MMB-4 (50 umol/kg, im) reactivated ($p < 0.05$) inhibited whole blood AChE and diaphragm ChE, but not brain AChE. 2-PAM and ICD 467 were ineffective. HI-6 was better ($p < 0.05$) than MMB-4 in reactivating blood AChE. These data suggest that HI-6 or MMB-4, but not ICD 467, would be effective with atropine as therapy against soman.

226.9

ATTEMPTS TO IMPROVE AN ANIMAL MODEL FOR THE STUDY OF SOMAN TOXICITY AND ITS TREATMENT. V.R. Jimmerson, T.-M. Shih, D.M. Maxwell* and R.B. Mailman. USAMRICD, APG, MD 21010 and Curric. Toxicol., UNC, Chapel Hill, NC 27599.

Cresylbenzodioxaphosphorin oxide (CBDP) was used to preferentially block sites on carboxylesterase (CaE) that bind soman (GD) irreversibly and to increase GD availability to more critical sites of action. After sc treatment with CBDP alone or followed by selected GD doses we examined plasma and lung CaE, brain cholinesterase (ChE) and acetylcholine (ACh), and severity of intoxication in the rat. CBDP treatment (1, 2, or 16 mg/kg) inhibited ChE (by 5-12%, 15-25% and 30-40% respectively) in selected brain regions with no effect on ACh, and inhibited plasma and lung CaE completely. CBDP pretreatment (1.0 mg/kg) reduced the minimal sign-producing dose of GD from 70.8 to 10.3 ug/kg and potentiated the ED50 for GD-induced inhibition of ChE activity by 9- to 14-fold in brain regions. ChE inhibition of 90% (18.5 ug/kg GD) was accompanied by approximately 2-fold elevations of ACh in brain regions independent of the CBDP pretreatment dose. Following CBDP pretreatment, the presence and severity of toxic signs did not vary widely from animal to animal as has been reported for rats treated with GD alone [Jimmerson et al, Toxicology, in press]. These data suggest that CBDP pretreatment may increase GD availability to critical ChE sites, and offer an improved animal model for examination of GD toxicity and its treatment.

226.10

PIRENZEPINE ATTENUATES THE STIMULUS PROPERTIES OF PHYSOSTIGMINE BUT DOES NOT GENERALIZE TO THE STIMULUS PROPERTIES OF SCOPOLAMINE. R.F. Genovese, T.F. Elsmore* and C.H. Rose* Department of Medical Neurosciences, Walter Reed Army Institute of Research, Washington, DC 20307.

Two groups of rats were trained to discriminate the effects of S.C. injections of scopolamine (SCO) (0.237 mg/kg, n=12) or physostigmine (PHY) (0.237 mg/kg, n=5) from vehicle, using a two-lever, variable interval 18 sec schedule of food presentation. Scopolamine (0.013-0.750 mg/kg) produced dose-dependent generalization (i.e. responding on the scopolamine appropriate lever) in SCO rats. Physostigmine (0.024-0.422 mg/kg) produced dose-dependent generalization in PHY rats. Pirenzepine (1.78-17.80 mg/kg) attenuated the physostigmine discriminative stimulus in PHY rats, but did not generalize to the scopolamine discriminative stimulus in SCO rats. These results suggest that the physostigmine stimulus is produced by both M_1 and M_2 muscarinic receptor activity and also suggest that the drug discrimination paradigm may be valuable for assessing the behavioral effects of M_1 and M_2 muscarinic receptor activity.

226.11

CENTRALLY-ACTIVE ANTIMUSCARINIC ANALOGS OF OXOTREMORINE (Oxo) BLOCK EXPERIMENTAL HYPERTENSION. H.M. Vargas* and B. Ringdahl*(SPON: P. Lomax). Dept. of Pharmacology, UCLA-School of Medicine, Los Angeles, CA 90024

The Oxo analogs BM-5 (N-methyl-N-(1-methyl-4-pyrrolidino-2-butynyl)acetamide) and Bok-1 (4-pyrrolidino-2-butynyl)5-methyl-2-pyrrolidone) are potent tremorolytic agents in vivo. We compared these compounds to atropine (ATR; reference agent) and assessed their ability to inhibit physostigmine(PHY)-induced hypertension. In urethane anesthetized Sprague-Dawley rats, intravenous (iv) Phy (77 nmol/kg) increased AP, 40 ± 5 mmHg. After 1 hour, each rat received a single dose of antagonist, then a second bolus of Phy ten minutes later. Antagonist dose-percent inhibition curves were constructed and 50% inhibitory doses calculated (ID_{50}). The results indicate that BM-5 and Bok-1 were equipotent with ATR, all having ID_{50} values in the 1.6-1.8 umol/kg range. The Oxo analogs did differ in two ways from ATR. First, BM-5 and Bok-1 produced selective antagonism of brain muscarinic function at doses which did not inhibit the peripheral muscarinic depressor response to acetylcholine (21 nmol/kg, iv), yet ATR produced 100% inhibition of the peripheral response at its ID_{50} for Phy. Second, ATR and BM-5, but not Bok-1, produced tachycardia via the blockade of cardiac muscarinic receptors. In conclusion, BM-5 and Bok-1 may be useful probes to study cardiovascular regulation by brain cholinergic neurons. (Supported by USPHS grant GM37816 to B.R.)

226.12

CHOLINERGIC MODULATION OF STARTLE AND FIGURE-8 MAZE ACTIVITY IN FEMALE MICE. J. Buelke-Sam, J.A. Johnson*, H.E. Shannon*, J. Tizzano and J.F. White*. Lilly Research Laboratories, Eli Lilly & Co., Greenfield, IN 46140.

The role of acetylcholine in modulating startle is not clearly understood. This study evaluated the dose-response curves produced by scopolamine (SCO, 0.3, 1, 3 mg/kg), oxotremorine (OXO, 0.03, 0.1, 0.3 mg/kg), physostigmine (PHY, 0.03, 0.1, 0.3 mg/kg) and pilocarpine (PIL, 3, 10, 30 mg/kg) on auditory and tactile startle and locomotor activity. Female CD-1 mice (8/group) were injected ip immediately prior to testing. Locomotor activity was measured for 1 hr in SDI figure-8 mazes; startle was measured in automated SDI chambers. Each 50-trial startle session was initiated with a 5-min adaptation period at a background noise level of 70 dBA followed by alternating 5-trial blocks of auditory (120 dBA noise) and tactile (20 psi air puff) stimuli presented at 8-sec intervals. SCO produced a dose-related increase in activity and auditory startle amplitude, but no change in either tactile startle amplitude or rate of startle habituation. OXO and PIL produced dose-related decreases in activity and decreased auditory and tactile startle; PHY decreased activity but increased startle. The ability of each agent to reverse the hyperactivity produced by 1 mg/kg SCO, or reverse the increase in auditory startle produced by 3 mg/kg SCO was evaluated. Only PIL was effective in reversing hyperactivity; OXO and PIL reversed enhanced auditory startle produced by SCO. PHY+SCO increased both auditory and tactile startle compared to the control or SCO-only groups.

226.13

INTERACTIVE EFFECTS OF PHYSOSTIGMINE, ACUTE AND TRAINED EXERCISE ON AChE ACTIVITY IN BRAIN AND MUSCLE OF RAT. SN Dube and SM Somani (SPON: D Desaiah) Dept of Pharmacol Southern IL Univ Sch of Med Springfield, IL 62708.

Physostigmine (Phy) is considered to be a potential pre-pretreatment agent against organophosphate intoxication. The effect of Phy on the time course of AChE following an acute bout of exercise (80% VO_2max) was investigated in endurance-trained rats. Male Sprague-Dawley rats (160-200 g) were exercised for 6 weeks (5 days/week) at progressively intensive levels on a motor-driven treadmill. Immediately following the acute bout of exercise, both groups (trained and untrained) rats were administered Phy (70 μg/kg,i.m. and were sacrificed at 2, 5, 10, 15, 30, 45 and 60 min. post-exercise. Blood, brain, thigh muscle, heart, and diaphragm were collected for AChE by radiometric method. Phy produced AChE activity 60 and 67% of control in brain and muscle, respectively at 15 min., was recovered to 80-85% of control within 60 min. Acute exercise plus Phy increased AChE activity to 69 and 74% of control in brain and muscle at 15 min. respectively. Trained rats showed AChE activity 93 and 86% of control in brain and muscle, respectively at 15 min. Trained exercise plus Phy further decreases the AChE activity to 48 and 62% of control in brain and muscle at 15 min. respectively. Similar pattern of AChE activity was also seen in RBC, heart, and diaphragm. It seems that acute exercise plus Phy increases and training plus Phy decreases the AChE activity in RBC brain, muscle, heart and diaphragm as compared to Phy alone. (Supported by U.S. Army contract No. DAMD 88-C-8024.)

CNS EFFECTS OF NEW ANTICHOLINESTERASES. P. DeSarno*, E. Giacobini, X.C. Tang*, M. Pomponi* and K. Sugaya* (SPON: B. Clark). Dept. Pharmacology, Southern Ill. Univ. Sch. Med., Springfield, IL 62794

For the experimental therapy of Alzheimer disease (AD), there is a need to develop new cholinesterase inhibitors (ChEI) that produce fewer side effects and have greater therapeutic action than presently tested drugs such as physostigmine (Phy) and THA (tacrine). We have examined the effect of two new reversible ChEI on the central cholinergic system of the rat and compared it with that of Phy, THA and metrifonate. Heptyl-physostigmine [(heptyl-Phy), MF-201, Mediolanum] is a carbamate derivative of Phy, Huperzine A (HUP-A) is a natural substance isolated from a Lycopodium plant. Our results show that both drugs can produce long-term inhibition (6 hrs) of ChE activity and a substantial increase of acetylcholine (ACh) levels in brain (up to 125%) following single dose i.m. administration. Side effects are mild for both drugs. Release of ACh from cortical slices is inhibited (19-26%) only at the highest concentration (10^{-5}-10^{-4}M). Our results demonstrate that both heptyl-Phy and HUP-A compare favorably to other reversible ChEI, in particular to Phy, as far as producing a more long-lasting inhibition of ChE activity and a more prolonged increase in ACh levels in brain with less severe side effects. Both drugs are interesting candidates for a cholinomimetic therapy directed to reverse cognitive deficits in AD patients. (Supported by NIA AG05416 and State of Ill. Dept. Pub. Health to E.G.)

HEMICHOLINIUM MUSTARD: AN IRREVERSIBLE INHIBITOR OF CHOLINE TRANSPORT IN RAT BRAIN SYNAPTOSOMES. K.H.Gylys, B.Ringdahl* and D.J.Jenden. Dept. of Pharmacology and BRI, UCLA School of Medicine, Los Angeles, CA 90024.

Hemicholinium mustard (2,2'-(4,4'-biphenylene)bis[2-hydroxy-4-(2-bromoethyl)-morpholine]),(HCM), is a mustard analog of hemicholinium 3 (HC3); like other mustard compounds, HCM cyclizes in aqueous solution to form a reactive aziridinium ion with intrinsic alkylating ability. The potency, reversibility, and time course of HCM effects in synaptosomes were examined and compared with HC3 effects. HCM inhibits 50% of high affinity choline transport (HAChT) at concentrations of 7nM (incub.7 min., 37°C); this activity is completely abolished by pre-incubation of the cyclized HCM with 0.1 mM Na thiosulphate(20 min., 20°C). However, thiosulphate added after a 12 min. incubation with HCM (50nM) failed to reverse HCM effects: 70% inhibition of HAChT remains even after up to 24 min. in the presence of thiosulphate (0.1mM). This suggestion of irreversibility is reinforced by experiments in which HCM preincubation (1-8 min) was followed by two thorough washes in fresh Krebs before the initiation of choline uptake measurement. In these experiments, choline transport remained inhibited by up to 40% following HCM incubation; transport in synaptosomes preincubated in HC3 returned to control values following the washes. HCM effects are rapid: if thiosulphate is added to synaptosomes 2 min. before HCM is added a 76% inhibition of choline transport still occurs; moreover, a 1 min. preincubation with HCM followed by 2 washes still results in a 17% inhibition. These results indicate that HCM is a potent and irreversible inhibitor of HAChT. (Supported by MH 17691)

ACTIVATION AND ION CHANNEL BLOCKADE BY THE NICOTINIC AGONIST (+)ANATOXIN AND DERIVATIVES. P. Kofuji[1,2*], Y. Aracava[1,2*], K.L. Swanson[1] and E.X. Albuquerque[1,2] (SPON: E.M. Glaser). [1]Dept. Pharmacol. Exp. Ther., U. Md Sch. Med., Baltimore, MD 21201 & [2]Lab. Mol. Pharm. II, UFRJ, Brazil.

(+)Anatoxin-a [(+)AnTX] is a potent agonist for the nicotinic acetylcholine receptor (AChR) and is toxic at the peripheral and central nervous system (CNS)(Spivak *et al.*, *Mol. Pharmacol.* 18: 384, 1980; Aracava *et al.*, *Neurotox'88*, Ed. G.G. Lunt, Elsevier Publ., 1988). In CNS, using micromolar concentrations of (+)AnTX (1-2 μM), some effects consistent with channel block have been observed. Previous data have not shown blocking effects of up to 200 nM (+)AnTX at peripheral nicotinic receptors. We have examined the effects of higher concentrations of the drug using the patch-clamp technique (cell-attached configuration) in dissociated muscle fibers. Channel activation was apparent with (+)AnTX in the nanomolar range; lengthening of the open state as a function of membrane potential hyperpolarization without an increase in number of brief closures was as expected for a pure agonist. By contrast, with further increases in drug concentration in the micromolar range there was a gradual loss of voltage dependence of the open state in association with a marked decrease in the duration of single channel currents. These blocking effects did not display stereoselectivity, as the blocking and unblocking rates were very similar for (+)AnTX and its enantiomer (-)AnTX. Methylation of (+)AnTX's amine moiety evoked a large decrease of agonist potency without disturbing the blocking effects. In summary, the nicotinic receptor blocking site recognized by (+)AnTX and some of its derivatives is much less structurally selective than the agonist binding site. NICOTINIC POTENCY OF ANATOXIN ANALOGUES WITH MODIFICATIONS OF THE ACETYL MOIETY. K.L. Swanson[1], R.S. Aronstam[2], S. Wonnacott[3*], H. Rapoport[4*], and E.X. Albuquerque[1,5]. Depts. of [1]Pharmacol. & Exp. Therap., Univ. MD Sch. Med., Baltimore, MD 21201; [2]Pharmacol. & Toxicol., Med. Coll. GA, Augusta, GA 30912; [3]Biochem., Univ. Bath, Bath BA2 7AY U.K.; [4]Chemistry, Univ. CA, Berkeley CA 94720; and [5]Lab. Mol. Pharmacol. II, UFRJ, Brazil.

The high stereoselectivity and potency of (+)-anatoxin-a (AnTX) at nicotinic acetylcholine receptors (AChR) of the neuromuscular junction (Spivak *et al.*, *Mol. Pharmacol.* 18:384, 1980; Swanson *et al.*, *Mol. Pharmacol.* 29:250, 1986) and of CNS synapses (Aracava *et al.*, *Neurotox '88*, Ed. G.G. Lunt, Elsevier Publ., 1988) makes this semirigid agonist an ideal focal compound for structure-activity studies. In earlier studies, N-methylation(s) caused a reduction in potency and revealed ion channel blocking activity. The present study includes and interrelates high affinity binding studies of the AChR sites for [^{125}I]α-bungarotoxin and [^{3}H]per-hydrohistrionicotoxin in *Torpedo* electroplaque and [^{125}I]αBGT binding, contracture and patch clamp studies in *Rana pipiens* skeletal muscle. (For binding to neuronal sites, see Wonnacott *et al.*, this meeting). In this series, the blocking activity was relatively weak in most cases and was unrelated to agonist potency. Modification of the acetyl moiety by reduction to an alcohol, alteration in the number of methyl groups, or a combination of these reduced the agonist binding affinity and the nicotinic efficacy of AnTX. The loss of potency in AnTXal, ahydroxyAnTX and AnTX-dimethylamide and the difference in potency between 10S and 10R AnTXols suggest that the methyl group has a specific role in definition of the pharmacophore. COMPARATIVE EFFECTS OF ANTHELMINTICS ON POSTJUNCTIONAL MEMBRANE POTENTIAL OF RATS AND NEMATODES. D.P. Thompson and W.D. Atchison. Parasitol. Res./Devel. Labs, The Upjohn Co., Kalamazoo, MI 49001 and Dept. Pharmacol./Toxicol., Mich. State Univ., E. Lansing, MI 48824.

The anthelmintics, levamisole, pyrantel, and several of their structural analogs block neuromuscular transmission of the rat hemidiaphragm preparation and isolated axial muscle of the parasite Haemonchus contortus. Intracellular recordings of postjunctional membrane potential (E_M) were made during application of these drugs to ascertain whether the agents caused depolarizing neuromuscular block in mammals or nematodes. In H. contortus, application of levamisole and pyrantel caused depolarization of the axial muscle to 58% and 68% of control, respectively. In contrast, only pyrantel depolarized the end-plate membrane at the rat diaphragm, and neither levamisole nor pyrantel affected muscle E_M in non-endplate regions. At a concentration of 100 μM pyrantel depolarized E_M to 75% of control. Preadministration of 2 μM d-tubocurarine (d-TC) prevented the depolarizing action of pyrantel at the rat neuromuscular junction. While levamisole did not depolarize the rat end-plate region, 3-NH_3-levamisole depolarized E_M by approximately 20% after 15 min exposure at 100 μM. This effect was blocked by prior application of d-TC. Thus, a differential pattern of neuromuscular blocking action is produced by these anthelmintics at mammalian and nematode neuromuscular junctions. (Supported by a collaborative research grant from the Upjohn Co. to Michigan State Univ.)

MONOAMINES AND BEHAVIOR II

NEUROCHEMICAL CORRELATES OF PUNISHMENT. J.E. Barrett, S.N. Olmstead* M.A. Nader* and S. Gleeson* (SPON: G.T. BOLGER). Department of Psychiatry, Uniformed Services University of the Health Sciences, Bethesda, MD 20814.

A number of drugs such as the benzodiazepines and barbiturates have specific effects on punished behavior. These drugs increase punished responding at doses that do not increase or increase to a lesser extent low rates of responding that is not punished. This study examined neurochemical correlates of punished and non-punished responding of pigeons through the use of cerebrospinal fluid (CSF) analyses collected from lateral ventricular guide cannulae. Pigeons' key pecks were reinforced under a fixed-interval 3-min schedule (FI) of food presentation. When the keylight was blue, pecks were not punished; when the keylight was red, however, every 30th peck during the FI produced shock. Keylight colors alternated irregularly on a daily or weekly basis. CSF was collected after certain sessions during which responding was punished and after other sessions when it was not. Control procedures included response-independent food and response-independent shock delivery. CSF was analyzed using HPLC-EC techniques. Punishment increased levels of dopamine and serotonin metabolites compared metabolite levels of the same pigeons under non-punishment or control conditions. Environmental consequences that control behavior are reflected specifically and dynamically in distinctive neurochemical changes. Supported by DA-02873.

227.2

DOPAMINE TRANSMISSION IN THE RAT STRIATUM, NUCLEUS ACCUMBENS AND PRE-FRONTAL CORTEX IS DIFFERENTLY AFFECTED BY FEEDING, TAIL PINCH, AND IMMOBILIZATION. G.Damsma, M.Yoshida*, D.Wenkstern*, G.G.Nomikos, A.G.Phillips@, and H.C.Fibiger, Div. of Neurol. Sci., Depts. of Psychiatry and @Psychology, Univ. of British Columbia, Vancouver, Canada, V6T 2A1.

Dopaminergic (DA) neurons in the midbrain are the origin of discrete projections to the forebrain. To examine the functional properties of some of these projections, microdialysis probes were implanted in the striatum (STR; 4mm exposed membrane), nucleus accumbens (NAC; 2mm) or prefrontal cortex (PFC; 4.7mm) of male Wistar rats (n=3, for each brain area). The day following probe implantation DA and metabolites were recordered on-line (Westerink et al., *Life Sci.*, 41:1763; 1987) at 20 minute intervals. All rats were deprived of food 36 hours prior to three conditions: feeding for 20 minutes, mild tail pinch for 10 minutes and immobilization for 10 minutes; each procedure was followed by the collection of six samples. Baseline values were: STR 6.9+2.2 fmol/min (mean+S.E.M), NAC 2.0+0.5, and for PFC 0.7+0.2. Feeding increased extracellular DA markedly in NAC and PFC while a minor increase in the STR was observed. Tail pinch induced a small increase of extracellular DA in the NAC and STR and a marked increase in the PFC. Immobilization stress increased DA profoundly in the PFC but did not change extracellular DA in NAC or STR. The changes in acid DA metabolites were similar, although less pronounced, supporting the conclusion that DA transmission differs regionally in reponse to various stimuli.

STRESS-INDUCED DOPAMINE RELEASE AND MOTOR IMPAIRMENTS IN 6-HYDROXYDOPAMINE-TREATED RATS.
K.A. Keefe, E.M. Stricker, M.J. Zigmond, E.D. Abercrombie. *Department of Behavioral Neuroscience and Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.*

Using *in vivo* microdialysis, we examined the relation between stress-induced dopamine (DA) release in striatum and the appearance of stress-induced akinesia in recovered 6-hydroxydopamine- (6-HDA) treated rats. DOPAC, HVA, and 5-HIAA levels in extracellular fluid (ECF) also were measured. The striatal tissue DA content was reduced by 98% in these animals, whereas basal DA in ECF (13.9 pg / 20 ul) was reduced by only 57% relative to untreated rats. Intermittent tail-shock stress increased DA in the ECF of the DA-depleted striatum by 10.9 pg / 20 ul (79%), while DOPAC and HVA concentrations both increased by 52% and 5-HIAA levels remained relatively constant (116%). The stress-induced increase in DA efflux was observed despite the presence of akinesia and catalepsy 15 min after the termination of the stress. We recently have shown that striatal DA in dialysates is increased by 9.5 pg/20 ul during stress in intact rats (Abercrombie et al., J. Neurochem, 1989). We propose that the relatively normal absolute increase in ECF-DA in the DA-depleted striatum after stress reflects the decreased density of innervation and consequent decrease in high affinity DA re-uptake sites in 6-HDA treated rats. Thus, it seems that the residual presynaptic dopaminergic function of 6-HDA-treated rats does not fail in response to stress and thereby underlie the induced akinesia, as has been hypothesized. ASSESSMENT OF AMPHETAMINE- AND HALOPERIDOL-INDUCED CHANGES IN DOPAMINE NEUROTRANSMISSION IN THE PRESENCE OF NOVEL AND FAMILIAR STIMULUS ENVIRONMENTS.
M. T. Bardo, S. A. Bowling*, R. C. Pierce* and R. B. Ennis*. Dept. of Psychology, Univ. Kentucky, Lexington, KY 40506.

Rats were administered amphetamine (0, 0.5 or 2.0 mg/kg) or haloperidol (0, 0.05 or 0.2 mg/kg) in the presence of either novel or familiar environmental stimuli. An inhibitor of the enzyme dihydroxyphenalanine (DOPA) decarboxylase, NSD-1015 (100 mg/kg), was also administered in order estimate synthesis of dopamine (DA) within these environments. Following injections, behavioral measures of both horizontal and vertical activity were obtainecd within each environment. Animals were then sacrificed for assaying brain DOPA, dihyroxyphenylacetic acid (DOPAC) and DA by high-pressure liquid chromatography.

As expected, the behavioral measures indicated that amphetamine increased and haloperidol decreased locomotor activity. Locomotor activity was also enhanced in the novel environment relative to the familiar environment. The neurochemical measures revealed that amphetamine produced a dose-dependent increase in DOPA accumulation in the striatum and dose-dependent decrease in DOPAC levels in the striatum and nucleus accumbens. Exposure to novelty had no significant effect on these amphetamine-induced neurochemical changes. In contrast to amphetamine, administration of haloperidol produced a dose-dependent increase in DOPA accumulation in the striatum, nucleus accumbens, and olfactory tubercle, as well as a dose-dependent increase in DOPAC in the striatum, nucleus accumbens and olfactory tubercle. More important, haloperidol-treated animals exposed to the novel environment had significantly higher levels of DOPAC in the striatum and nucleus accumbens relative to haloperidol-treated animals exposed to the familiar environment, thus indicating that novel stimulation alters DA metabolism. (Supported by USPHS grant DA05312.)

MEASUREMENT OF FOOTSHOCK-INDUCED CHANGES IN DOPAMINE AND METABOLITES BY IN VIVO DIALYSIS IN RAT PREFRONTAL CORTEX.
B.A. Sorg* and P.W. Kalivas (SPON: A.T. Campagnoni). Dept. of VCAPP, Washington State University, Pullman, WA 99164-6520.

We used in vivo dialysis to measure the effect of a 20 min intermittent footshock (0.35 mA) on DA levels and its metabolites in regions of the medial prefrontal cortex of male Sprague-Dawley rats. Samples were collected every 20 min and the levels of DA, DOPAC, and HVA were quantified by HPLC-EC. We assigned placement of cannulae into one of three rostro-caudal subareas of the prefrontal cortex: caudal = 2.2 - 3.1 mm, central = 3.2 - 4.1 mm, and rostral $\geq$ 4.2 mm from bregma (Paxinos and Watson, 1986), and into two medio-lateral regions: 0.1-0.9 mm, and $\geq$ 1.0 mm from the midline. While no consistent changes in DA levels were found after footshock, DOPAC levels increased after the 20 min shock in all regions and were maximal 20 min after the shock ended. In the medial portion of each rostro-caudal subdivision, the DOPAC increase was most pronounced in the central region (72% above baseline), and lower in the rostral (28%) and caudal (38%) regions. In the lateral portion, DOPAC increases were 38% in the central and 11% in the caudal regions. HVA levels paralleled DOPAC increases in all brain regions, although maximal levels were obtained 20 min later and were approximately 20% lower.

BRAIN DOPAMINE CONTENT AND THE INDUCTION OF SEXUAL BEHAVIOR IN THE FEMALE MUSK SHREW.
E.F. Rissman*, K.J. Darney*, A.L. Clendenon* and J.G. Vandenbergh* (SPON: D.J. Hudson). Depts. Psychol. and Biol., Univ. of Virginia, Charlottesville, VA 22903 and Dept. of Zoology, N.C. State Univ., Raleigh, N.C. 27695.

The female musk shrew (Suncus murinus), in striking contrast to other laboratory mammals, does not have a behavioral estrous cycle. Females are continually sexual receptive. When virgins are paired with males an initial period of aggressive contact, typically lasting for 45 minutes, ends when the female demonstrates receptive behavior. When females are paired with another female, for one hour prior to introduction to a male, receptive behavior occurs more rapidly than under control conditions. To explore the role of neurotransmitters in this rapid shift from aggressive to sexual behavior we sacrificed females at this transitional time and dissected chunks of brain tissue for HPLC analysis of catecholamine content. Higher DA content was found in MOB and MBH when females were paired either with a male or another female as compared with DA levels in females allowed to explore a novel cage for an equivalent length of time. In addition, DA activity was higher in AOB in females paired with males than in isolated controls. Taken together these data suggest a relationship between aggressive behavior, DA and the induction of receptivity. Supported by NSF 8706770, USPHS MH18411 and HD21632.

227.7

ELECTROCHEMICAL DETECTION OF CENTRAL DOPAMINE EFFLUX DURING SEXUAL ACTIVITY IN MALE RATS.
J.G. Pfaus[1], T.N. Newton*[1], C.D. Blaha[1,2], H.C. Fibiger[2], and A.G. Phillips[1]. Depts. of Psychology[1] and Psychiatry[2], Univ. British Columbia, Vancouver, BC, Canada, V6T 1Y7.

Pharmacological evidence suggests that central dopamine (DA) systems facilitate sexual behavior in male rats. Ex vivo studies confirm an increase in DA synthesis and release within mesotelencephalic and hypothalamic DA terminal regions following periods of copulation. However, this approach does not permit a detailed analysis of DA activity during sexual behavior.

In the present study, sexually active male rats were implanted with stearate-modified electrodes aimed at the nucleus accumbens. Chronoamperometry was used to examine extracellular DA concentrations before, during, and after 30-min tests of copulation. DA signals increased in each male when the female was placed into the chamber and this rise preceded the initiation of mounts and intromissions. Most ejaculations were followed by a sharp decline in the DA signal. DA levels began to rise before reinitiation of copulation. The DA signal remained elevated for at least 40 min after the female was removed from the chamber. These data indicate that mesolimbic DA levels increase before and during bouts of copulatory behavior. Studies are currently underway to examine DA efflux in other regions, (e.g. MPOA and caudate) and to define the precise stimulus that leads to the initial increase in DA levels.

227.8

IN VIVO VOLTAMMETRY IN THE NEOSTRIATUM OF FREELY MOVING RATS: MONITORING EXTRACELLULAR ASCORBATE AND DOPAC DURING ACUTE AND CHRONIC AMPHETAMINE.
G.V. Rebec, M.E. Kraft*, P.E. Langley*, and M.T. Ciancone*. Prog. Neural Science, Dept. Psychology, Indiana Univ., Bloomington, IN 47405.

Amphetamine, a well-known dopamine agonist, increases neostriatal ascorbate (AA) release, which may modulate both neostriatal function and the behavioral response to this drug. To study this issue further, we monitored extracellular AA and DOPAC, a dopamine metabolite, in the neostriatum of freely moving animals that received amphetamine at doses and treatment schedules known to produce different behavioral effects. Rats received single, daily injections of saline or D-amphetamine (1.0 or 5.0 mg/kg) for up to 15 days. Voltammetric recordings and corresponding behavioral measures were obtained at the beginning (Day 1), middle (Days 6-8), and end (Days 13-15) of treatment. On each recording day, an electrochemically modified, carbon-fiber electrode, which provides distinct waves for AA and DOPAC, was lowered into the neostriatum and, following the drug response, was removed and tested in a post-calibration step. Although acute amphetamine increased extracellular AA by up to 200 uM, this effect was not dose-dependent despite clear dose-dependent differences in the behavioral response. Multiple amphetamine injections produced biphasic changes in AA release: treatment for 6-8 days enhanced the amphetamine-induced rise in extracellular AA, but this effect declined as treatment continued for 13-15 days. Simultaneous behavioral measures indicated a uniform sensitization throughout the treatment period. DOPAC showed a monophasic decline with repeated amphetamine. Thus, amphetamine-induced changes in neostriatal AA release do not bear a simple relationship to the corresponding behavioral changes produced by this drug. Voltammetric recordings from other AA-rich forebrain sites, including the nucleus accumbens, may shed light on the role of AA in the amphetamine-induced behavioral response.

Supported by NSF (BNS 87-11240) and NIDA (DA 02451).

227.9

CHANGES IN EXTRACELLULAR DOPAMINE CONCENTRATIONS MEASURED BY IN VIVO INTRACEREBRAL MICRODIALYSIS AFTER DOPAMINE DEPLETION. E. Castaneda, I. Q. Whishaw and T. E. Robinson, Depts. of Psychology, Univ. Lethbridge, Lethbridge, Alberta, Canada T1K 3M4 & Univ. Michigan, Ann Arbor, Michigan, 48109.

Intracerebral microdialysis was used to measure extracellular dopamine (DA) from the corpus of striatum in rats depleted of DA. Rats received 6-hydroxydopamine (6-OHDA) in bilateral intraventricular infusions as 3-day old neonates or in bilateral infusions into the substantia nigra pars compacta as adults. After recovery, dialysate samples were collected from awake subjects during resting conditions and after 1.5 mg/kg amphetamine (AMPH), s.c. At least 3 days later tissue DA concentrations were determined. All samples were assayed by HPLC-EC. In adult-depleted rats extracellular DA concentrations decreased only when tissue DA levels were extremely low (<10%). Similarly, extracellular levels of DA were decreased to 12-54% in neonatally-depleted rats, all of which sustained greater than 99% tissue DA depletions. The response to an AMPH challenge was attenuated but all animals were able to increase extracellular catecholamines. Surviving mesostriatal DA cells may contribute towards normalizing extracellular DA levels following DA depletion. This in turn may contribute to recovery of behavioral function.

227.10

DOPAMINE RELEASE IS REDUCED IN THE NUCLEUS ACCUMBENS OF UNDERWEIGHT RATS. E. Pothos*, G.P. Mark and B.G. Hoebel, Department of Psychology, Princeton University, Princeton, NJ 08544-1010

Prior microdialysis experiments showed that feeding can increase extracellular dopamine (DA) in the nucleus accumbens (NAC) of freely moving, food deprived rats. In the present study, we tested the hypothesis that food deprivation leading to reduced body weight would alter basal DA or serotonin release in the nucleus accumbens. *In vivo* microdialysis and high performance liquid chromatography coupled with electrochemical detection (HPLC-EC) were used at 1-hour intervals for 3 hrs during the dark cycle on 3 test days each 10 days apart. Nine male rats were reduced to 80% body weight for the second of the three tests. Results showed that mean basal extracellular DA decreased 40-50% in the NAC of male rats reduced to 80% body weight ($p<.05$). A similar trend was observed in DOPAC levels, but not in HVA or 5HIAA output. DA release was restored by returning the animals to their pre-test body weight. Extracellular serotonin levels did not appear to change with weight reduction. As a control, DA and serotonin output remained unaltered over a 3-week period in non-deprived subjects. These results indicate that DA release in the nucleus accumbens is reduced in underweight rats.

Supported by USPHS grant DA-03597.

227.11

A METHOD FOR REPEATED INTRACEREBRAL MICRODIALYSIS. Dianne M. Camp* and Terry E. Robinson. (SPON. E.S. Valenstein). Department of Psychology and Neuroscience Program, The University of Michigan, Ann Arbor, MI, 48109.

High performance liquid chromatography (HPLC) coupled to series oxidative-reductive electrochemical detection with three flow-through coulometric electrodes was used to assay dopamine (DA), dihydroxyphenylacetic acid (DOPAC), homovanillic acid (HVA) and 5-hydroxyindoleacetic acid (5-HIAA) in dialysate. The purity of DA in dialysate was analytically verified by series reduction at two different points on DA's current/voltage curve. Using this HPLC method a new removeable concentric style (250 µm O.D.) dialysis probe was characterized over two days following insertion of the probe into the striatum of freely moving rats, and again following a second insertion into the same rats two weeks later. It was found that: (1) the basal concentration of DA was stable by the second 20 min sample obtained after insertion of the probe and declined only slightly 24 hrs later; (2) in contrast, the basal metabolite concentrations increased dramatically over the first 3 hrs after probe insertion and declined markedly 24 hrs later; (3) tetrodotoxin (TTX, 0.5 µM) administered via the probe decreased DA concentrations to a much greater extent 24 hrs than 3-6 hrs after probe insertion; (4) the basal concentration of DA following the second probe insertion was similar to that seen after the first insertion; (5) in contrast, the metabolite concentrations were lower following the second insertion; and (6) the sensitivity of DA to TTX following the second probe insertion was comparable to that seen following the first insertion.

227.12

LONG TERM BEHAVIORAL EFFECTS OF CHRONIC AMPHETAMINE USE. P. E. Paulson*, D. M. Camp* and T.E. Robinson (SPON: D. Green). Dept. Psychology & Neuroscience Program, University of Michigan, Ann Arbor, MI 48109.

This experiment characterized the behavioral response to an amphetamine (AMPH) challenge (2.6 mg/kg) given at various times (3, 7, 14, 30, 90 or 180 days) following pretreatment with saline or escalating doses (1→10 mg/kg over 6 weeks) of *d*-AMPH. The more rapid onset of stereotypy typical of sensitized animals, and measured by a marked decrease in locomotion about 40 min after the challenge, was not present at 3 or 7 days after the cessation of AMPH pretreatment, was present by 14 days, and then persisted undiminished for at least 180 days. In contrast, post-stereotypy hyperactivity was not seen until 30 days after the discontinuation of AMPH pretreatment and disappeared by 90-180 days. In summary: 1) Sensitization of stereotypy showed a delayed onset after the cessation of AMPH pretreatment, but persisted indefinitely thereafter. 2) Sensitization of post-stereotypy hyperactivity showed an even more delayed onset, but did not persist. These data suggest that the neural systems responsible for behavioral sensitization undergo dynamic changes for a prolonged period of time following the cessation of repeated AMPH treatment. Furthermore, different behaviors sensitized by AMPH (eg., onset of stereotypy vs post-stereotypy hyperactivity) must be mediated by different neural systems, and each of these neural systems is changed somewhat differently by AMPH pretreatment. Studies are in progress to identify neural correlates of these behavioral phenomena.

227.13

DOES AMPHETAMINE PREFERENTIALLY INCREASE EXTRACELLULAR DOPAMINE IN THE MESOLIMBIC SYSTEM? Terry E. Robinson and Dianne M. Camp*. Dept. of Psychology and Neuroscience Program, University of Michigan, Ann Arbor, MI

Intracerebral microdialysis in freely-moving rats was used to test the hypothesis that drugs of abuse have in common an ability to preferentially increase the extracellular fluid (ECF) concentrations of dopamine (DA) in the mesolimbic system (DiChiara & Imperato, *PNAS* 85:1988, 5274). One dialysis probe (250 µm O.D., concentric style) was placed chronically into the nucleus accumbens (ACC) and one into the contralateral dorsolateral caudate nucleus (STR). The next day at least 3 baseline samples were collected (1.5 µl/min; 20 min intervals) and then each animal received either 0.75, 1.5 or 3.0 mg/kg of *d*-amphetamine sulfate (AMPH, wt. of salt). The basal concentration of DA in ECF was significantly higher in the STR than ACC (25.6 vs 17.7 fmol/min-corrected). There were also regional differences in DA metabolism, with HVA (but not DOPAC) concentrations being 2-fold greater in STR than ACC. AMPH produced a dose-dependent increase in the ECF concentrations of DA in both structures, but 1.5 and 3.0 mg/kg produced a significantly greater increase in the STR than the ACC (data expressed as fmol/min). When AMPH-stimulated DA release was expressed as a percent of baseline there was no statistically significant regional difference in the effect of any dose of AMPH. These data do not support the hypothesis that drugs of abuse preferentially increase the synaptic concentration of DA in mesolimbic structures; although they may preferentially influence mesolimbic DA activity in other ways.

227.14

EFFECTS OF DOPAMINE DEPLETIONS ON DAYS 15 AND 20 AFTER BIRTH ON INTRACRANIAL SELF-STIMULATION AND NEUROLEPTIC SENSITIVITY IN ADULT RATS. K.S. Sidhu*[1], J.R. Stellar[1], and J.P. Bruno[2]. 1-Northeastern Univ. Boston, MA 02115; and 2-Ohio State Univ. Columbus, OH 43210.

Stellar et al. (Pharm.Biochem.Beh. 30:365, 1988) showed that rats receiving 6-OHDA lesions on neonatal day 3 and undergoing lateral hypothalamic self-stimulation (LHSS) as adults were 1) normal in LHSS reward and 2) depressed in LHSS operant motor capacity when compared to controls. We now extend these conclusions to rats given 6-OHDA lesions at day 15 or day 20 after birth.

Stellar et al. (1988) also showed from dose-response pimozide studies that LHSS in these day 3 lesioned rats was markedly subsensitive to dopamine receptor blockade. In preliminary form, we now report that same result for the day 15 lesion, but show normal-range sensitivity to pimozide for day 20. All LHSS testing was done with the rate-frequency curve method to measure reward and motor performance capacities independently.

Supported by the Whitehall Foundation.

THE EFFECTS OF UNILATERAL 6-HYDROXYDOPAMINE LESIONS ON INPLACE TURNING IN RATS. K.E. Sabol, J.B. Richards, and C.R. Freed. Univ. Colo. Health Sci. Ctr., Denver,CO 80262.

Rats trained to rotate show a strong contra- and a milder ipsilateral turning deficit after unilateral 6-hydroxydopamine (6-OHDA) lesions. Here, we looked at the effects of unilateral 6-OHDA lesions on an alternate turning paradigm: rats were trained to run inplace for water with an asymmetric body posture, on a circular treadmill. After CRF training (6 days each direction), 7 rats were given unilateral 6-OHDA lesions (8 ug free base in 2 ul ascorbic acid/saline vehicle), and 5 rats received vehicle injections. The coordinates were A: 4.4 mm post. to Bregma; L: 0.9 mm right of midline; and V: 7.5 mm below dura, nosebar -2.3 mm. The lesioned rats had dopamine depletions >95%. Turn rate was reduced in both directions 6-8 wks post-lesion. Two control and 2 lesioned rats were looked at in detail: The lesioned rats, when turning contralateral, ran longer before stopping to drink, and paused longer before starting to run again. This indicates that in the contralateral direction, the lesioned rats had difficulty making the transition between running and drinking, and vice versa. After CRF testing, rats were trained on an FR5 schedule. The lesioned rats had a reduced turn rate only in the contralateral direction. To summarize, rats with unilateral 6-OHDA lesions have bilateral inplace turning deficits with a more severe impairment contralateral to the lesion.

227.16

"MODERATE" NEONATAL DOPAMINE (DA) DEPLETION: SPATIAL MEMORY IMPAIRMENT BUT RESPONSIVENESS TO ENRICHED ENVIRONMENT. S.J.E. Murtha, B.A. Pappas, G.A.S. Park*, R.M. Szirtes*, K. Condon* and J.N. Armstrong. Dept. of Psychol., Carleton University, Ottawa, Canada K1S 5B6.

Within 36 h of birth, rats received bilateral intraventricular 6-hydroxydopamine (15 ug free base total) injections with or without desmethylimipramine pretreatment to protect noradrenergic terminals. This resulted in moderate, persisting loss of frontal cortical (63% loss) and caudate (75%) DA. Half of the rats were raised in enriched environments and the other half as dyads in standard (impoverished) cages. Behavior was assessed at 80 days. Both enriched rearing and neonatal DA depletion caused increased exploration of an elevated plus maze. DA depletion did not alter the effect of enrichment. Enriched rearing enhanced the spatial memory of control and of DA depleted rats as assessed by the Morris water maze procedure. The DA depleted rats rapidly learned the platform location, but showed impaired 48 h retention of the location. This impairment was partly ameliorated by enriched rearing. Thus, moderate neonatal DA depletion does not affect the response to enriched rearing but does cause an enduring hyperactivity and impaired spatial memory. The latter may be analogous to the impaired effortful processing which occurs with DA lesions in humans (i.e., Parkinson's disease). Moderate neonatal DA depletion causes unique, severe and permanent behavioral changes.

DOPAMINE DEPLETIONS IN DEVELOPING RATS: AGE-DEPENDENT EFFECTS OF D1 AND D2 RECEPTORS IN THE CONTROL OF SENSORIMOTOR BEHAVIOR. **B.J. Johnson* and J.P. Bruno. (SPON: G. Berntson). Dept. of Psychology, The Ohio State University, Columbus, Ohio 43210.**

Depletions of brain dopamine (DA) in adult rats produce sensorimotor deficits followed by eventual recovery. This recovery is mediated by residual DA neurons since these animals regress back to their initial deficits when challenged with doses of DA antagonists that have no effect on normal rats. In contrast, rats depleted of DA during the first 3 weeks of development are spared from the initial deficits seen in rats depleted as adults.

To assess whether residual DA neurons mediate this sparing phenomen we measured the effects of the antagonists haloperidol (D1/D2), SCH 2390 (D1), or sulpiride (D2) on the sensorimotor behavior of adult rats given 6-HDA (100-250 µg, ivt) or its vehicle at 3, 15, or 20 days of age. Vehicle-treated animals displayed sensorimotor deficits after receiving (ip) each of the DA antagonists. Rats depleted at 15-20 days also exhibited these deficits but they were less sensitive than controls. Rats depleted at 3 days of age were insensitive to any DA antagonists. These results suggest 2 different mechanisms underlying behavioral sparing, depending upon the age at the time of depletion.

MEDIAL PREFRONTAL CORTICAL LESIONS INCREASE STRESS SENSITIVITY IN THE RAT. G.E. Jaskiw, A. Braun, F. Karoum, N. Breslin and D.R. Weinberger. CBDB, NIMH, Neurosciences Center at St. Elizabeths Hospital.

Destruction of efferents from the medial prefrontal cortex (MPFC) of the rat induces transient disturbances in subcortical catecholaminergic indices and in exploratory behavior which attenuate by the fourth posotperative week. Since the MPFC may play a unique role in the rat's response to stress, we hypothesized that later disturbances in MPFC lesioned animals could be elicited by stress. Cohorts of rats received bilateral sham (S) or ibotenic acid (IA) (5$\mu g/\mu l$ AP $\pm$ 3.5, ML $\pm$ 0.7, VD - 3.5 mm) lesions of the MPFC and were evaluated after a minimum 6 week recovery period. In cohort 1 either a 24 hour or a 48 hour food deprivation stress reduced the exploratory activity of IA lesioned rats in a novel environment. Cohort 2 animals received an injection of the anxiogenic β-carboline FG-7142 (15mg/kg/ip) or vehicle (V) 15 minutes before introduction to photocell monitors. The IA/FG rats show a marked attenuation of locomotion. Moreover, a significant but smaller attenuation was seen in IA/V rats compared to the the S/V group, suggesting that MPFC lesioned rats had an altered response to the stress of a V injection alone. The latter was consistent with results from the third cohort in which each of DA, DOPAC and HVA were elevated by 20% within the nucleus accumbens of MPFC lesioned animals 7d after one week of daily V injections. These and other results suggest that loss of the modulation provided by the MPFC markedly augments sensitivity to a variety of stressful stimuli and in particular alters the effects of stress on limbic dopamine turnover.

6-HYDROXYDOPAMINE INJECTIONS IN POSTERIOR GLOBUS PALLIDUS: DIMINISHED BRAIN STIMULATION REWARD OR MOTOR FUNCTION? **J. C. Hall, C. J. Corral-Yagnam* and D. B. Neill. Dept. of Psychology, Emory University, Atlanta, GA 30322.**

The effect of striatal dopamine depletion on self-stimulation of lateral hypothalamus in rats was assessed using the autotitration method. In our procedure, stimulation intensity decreased 3 uA every 5th bar press; the rat could reset the intensity back to maximum by responding on a second lever. Bilateral injection of 5.6 ug 6-hydroxydopamine (6-OHDA) into posterior globus pallidus produced a decrease in response rate and resetting at higher intensities, i.e., the rats would not perform at the low currents previously accepted. These injections also reduced the reset-lowering (reward-enhancing) effect of intraperitoneally administered amphetamine. Although we conclude that these data indicate posterior pallidal 6-OHDA injections lower the reward of hypothalamic stimulation, we also consider some motoric hypotheses, due to sensorimotor impairments exhibited by these animals.

228.1

COEXISTENCE OF NADPH-DIAPHORASE ACTIVITY WITH CRF ANTI-IDIOTYPE IMMUNOREACTIVITY. G. J. Michael, S. A. Joseph and K. M. Knigge. Neuroendocrine Unit, Univ. Rochester Med. Ctr., Rochester, NY 14642.

A corticotropin-releasing factor anti-idiotypic antibody (CRF-AIA) made in this laboratory is hypothesized to recognize neurons that are postsynaptic to CRF neurotransmission in the central nervous system. Several immunochemical studies were performed to elucidate the relationship between CRF anti-idiotype immunoreactivity and reduced nicotinamide adenine dinucleotide phosphate- (NADPH-) diaphorase in the rat brain.

In order to determine the histologic relationship between these two neuronal markers, dual staining histochemistry was performed. After fixation with 4% paraformaldehyde/ 0.2% picric acid and cutting on a vibratome, serial rat brain sections were processed for CRF-AIA immunocytochemistry using the avidin-biotin complex method (Vector Labs.), NADPH-diaphorase histochemistry (Scherer-Singler, U.,*et al.*J. Neurosci. Meth., 9:229, 1983) or dual staining. All neurons found stained with one of the activities in the dual stained preparations also contained the other activity.

Biochemical analysis was conducted of rat neural membranes solubilized and electrophoresed on nondenaturing polyacrylamide gels as described by Kuonen, *et al.*(J. Neurochem., 50:1017, 1988). Western blot analyses of neural proteins revealed that a high molecular weight complex (> 400 kD) possessed both NADPH-diaphorase activity and CRF-AIA immunoreactivity. The 180 kD band of diaphorase activity did not crossreact with the CRF-AIA.

Dual staining of brain sections with NADPH-diaphorase histochemistry and CRF immunocytochemistry was also conducted. Examination at the light microscopic level revealed that CRF-like immunoreactive processes often could be found associated with NADPH-diaphorase cells and processes.

We hypothesize that NADPH-diaphorase is a marker for central neurons that are postsynaptic to CRF neurotransmission.

228.2

Coexistence of Corticotropin-Releasing Factor (CRF) and Enkephalin (ENK) in the Paraventricular Nucleus (PVN) of the Rat Hypothalamus. S Pretel and D Piekut, Neuroendocrine Unit, University of Rochester, Rochester, N.Y. 14642.

Coexistence of two or more putative neurotransmitters has become a prominent feature in the CNS. It usually is demonstrated using immunocytochemical labeling of antibodies against the neurochemicals of interest. In the present study the coexistence of two peptides, CRF and ENK is demonstrated using a) immunocytochemical labeling of antibodies and b) immunocytochemical labeling of antibodies to one peptide and the mRNA of the other peptide. Double-label immunocytochemistry (ICC) was obtained by the sequential labeling of two antigens in the same tissue section, yielding a brown and a blue reaction product respectively (Piekut, '87). Immunocytochemical labeling of the antibodies and labeling of the mRNA was also performed on the same tissue section; the slide was first processed for ICC and second for in situ hybridization (ISH) of synthetic oligonucleotides, complemenary to the mRNA for either CRF or ENK (generously provided by Drs. Young and Brownstein, NIH). ISH was performed by 3' endlabeling of the oligonucleotides (48 bases) with ^{35}S-deoxy ATP, using terminal deoxynucleotidyl transferase. Prehybridization and hybridization solutions were the same, except the latter did not contain any labeled probe. They consisted of 50% deionized formamide, 20% 20XSSC, 20%$H_2$0, 4% denatured salmon testes DNA, 1% t-RNA (25mg/ml), 2% 50XDEN, 10% dextran sulfate. The ISH solution also contained 2µl of labeled probe. After ICC processing, the slides were prehybridized for 3-4 hrs at 37°C, followed by application of the hybridization solution and incubation overnight at 37°C. They were exposed to NTB2 emulsion for 25 (CRF) or 34 (ENK) days. PVN neurons which contained CRF and ENK are observed throughout the rostro-caudal extent of the parvocellular (pc) component of the PVN. The majority of these double-labeled neurons was found in the medial and posterior lateral pcPVN. Most of the ENK labeled neurons (>75%) contained the genetic appartus to synthesize CRF, whereas a smaller portion of the CRF neurons (<30%) contained the genetic apparatus to synthesize ENK. We conclude that CRF and ENK coexist in subpopulations of PVN neurons. Both peptides are involved in the regulation of stress behavior. They could potentially initiate the involvement of different groups of CNS neurons in different stress responses. Supported by Grant #NS 18626.

228.3

LOCALIZATION OF CORTICOTROPIN-RELEASING FACTOR (CRF)-LIKE IMMUNOREACTIVITY IN MONKEY (Saimiri sciureus) OLFACTORY BULB AND ITS EFFERENTS. J.L. Bassett, S.L. Foote and M.T. Shipley[1]. Dept. Psychiatry, Univ. Calif. San Diego, La Jolla CA 92093; [1]Dept. Anat. & Cell Biol., Univ. Cincinnati 45267.

Several lines of evidence suggest that olfactory bulb projection neurons utilize a glutamate-like moiety as a neurotransmitter. Recently, Imaki et. al. (in press) have shown that many mitral and tufted cells in the rat olfactory bulb are immunoreactive for CRF and contain the mRNA for this peptide, raising the possibility of a cotransmitter within this system. The distribution of CRF has not been examined in the primate olfactory bulb or its efferents.

In the present study, sections through the monkey olfactory bulb and its target areas were processed for immunohistochemistry using a polyclonal antiserum directed against the human form of CRF (donated by J. Rivier & W. Vale). Within the olfactory bulb, nearly all mitral and many tufted cells contained CRF-like immunoreactivity. CRF-positive fibers were seen within the olfactory tract and olfactory stria. Immunoreactivity with a fine, particulate appearance, as well as numerous immunoreactive coarse, varicose fibers and isolated puncta were seen within the anterior olfactory nucleus and layer Ia of the olfactory tubercle and pyriform cortex. CRF-positive cells were seen within layer III of the latter two regions. Immunoreactive fibers and varicosities also were seen within olfactory recipient regions of the amygdala.

228.4

NOVEL BRAINSTEM LOCALIZATIONS OF CORTICOTROPIN-RELEASING FACTOR (CRF) mRNA BY HYBRIDIZATION HISTOCHEMISTRY. J. Imaki*, T. Imaki*, P.E. Sawchenko and W. Vale, Peptide Biology Laboratories, The Salk Institute, La Jolla, CA 92037.

Though best known for its role in the hypothalamo-adenohypophyseal system, CRF is broadly distributed in the CNS. Current knowledge is based largely on immunocytochemical (ICC) findings, but the sensitivity afforded by *in situ* hybridization (ISH) histochemistry has provided new insights. We have used both approaches to compare in the brainstem the distributions of CRF peptide and preproCRF mRNA, the latter achieved using a ^{35}[S]-labeled 1.2 kb antisense cRNA probe. Localizations afforded by ICC and ISH data were congruent in many regions of the brainstem, including the parabrachial, laterodorsal tegmental, lateral reticular and medial vestibular nuclei, the inferior olive and the nucleus of the solitary tract. Other cell groups, including the nucleus prepositus hypoglossi, the nucleus of Roller, the ventral nucleus of the lateral lemniscus, and discrete parts of the medial geniculate complex, contained a substantial number of cells showing a clear mRNA signal but contained few, if any, CRF-immunoreactive cells. None of the localizations suggested by ISH were evident using sense strand cRNA probes. In suggesting that CRF mRNA is prominently expressed in some precerebellar and auditory relay nuclei, the results contribute to recent indications that preproCRF-derived peptide(s) may serve as transmitters or modulators in arenas beyond the neuroendocrine and autonomic systems with which CRF has been most commonly associated.

COMPARISON OF DISTRIBUTION OF PEPTIDERGIC NEURONS BETWEEN THE BED NUCLEUS OF STRIA TERMINALIS AND AMYGDALA. X.Bao, S.Y.Shu. Dept. of Neurobiology, Fourth Military Medical University, Xi'an, People's Republic of China.

To investigate relationships of peptidergic distribution between the bed nucleus of stria terminalis(BST) and amygdala(AMYG), immunohistochemical studies for the CCK,VIP,NT,CRF,GAL,SOM, CGRP,alpha-MSH,ANG II,L-ENK,B-END and SP were performed in the BST and AMYG of the rat.

In the oval nucleus of BST and lateral central nucleus of AMYG, a dense immunoreactivity of VIP, CRF,NT,CGRP,L-ENK,SP and SOM was observed in both parties. In the anterodorsal nucleus of BST and medial central nucleus of AMYG, all the immunoreactive positive fibers and CRF,NT,SOM and SP positive perikarya were found. VIP,CCK,CRF,NT, GAL,SOM,L-ENK and SP positive cell bodies were observed in the principal nucleus of posterior BST and in the lateral or basal nucleus of AMYG as well. In addition, all the immunoreactive positive fibers and VIP,CRF,SOM,NT,GAL,CGRP,L-ENK and SP positive cell bodies were demonstrated in the ventral part of BST and medial AMYG.

The results indicate that there are some mediolateral and anteroposterior correlations between the BST and AMYG.

MORPHOLOGICAL EVIDENCE FOR A SUBSTANCE P PROJECTION FROM MEDIAL SEPTUM TO HIPPOCAMPUS. C.L. Shurlow* and G.M. Peterson, Department of Anatomy and Cell Biology, East Carolina University School of Medicine, Greenville, N.C. 27858-4354.

Substance P-immunoreactive (SP-ir) perikarya are present at the lateral border of medial septum (MS) and SP-ir fibers are present in the hippocampal formation. SP levels within the hippocampus decrease following ablation of the MS. Together these data suggest that SP-ir neurons in the MS project to the hippocampus. However, the reduction of hippocampal SP levels could result from destruction of SP fibers passing through the MS. To determine if the SP-ir perikarya in MS project to the hippocampus we have combined anterograde tracing and immunocytochemistry. Sprague-Dawley rats were iontophoretically injected with *Phaseolus vulgaris* leucoagglutinin (PHA-L) through a glass micropipet (tip 10-15 µm in diameter). Following survival of one week rats were transcardially perfused with paraformaldehyde and five sets of adjacent sections of MS and hippocampus were cut at 40 µm. Sections were incubated in a cocktail of rabbit anti-SP (1:4000) and goat anti-PHA-L (1:1000), followed by fluorescein isothiocyanate (FITC) labeled anti-goat IgG (1:50) to label the PHA-L and by biotinylated anti-rabbit IgG (1:200) and avidin-conjugated Texas Red (1:50) to label the SP-ir fibers. Adjacent sections were processed for either SP or PHA-L alone or by omitting primary antibodies. Sections were observed under a fluorescent microscope using band pass filters designed specifically to discriminate the emission spectra of FITC from Texas Red. In the double-labeled sections, numerous fibers were observed to contain both SP-ir and PHA-L-ir in the MS and in the CA-2 region of the hippocampus. This co-localization of SP in PHA-L labeled fibers in the MS and hippocampus indicate that one source of SP in the hippocampus is from the MS.

IDENTIFICATION OF SUBSTANCE P-CONTAINING PROJECTIONS TO THE VENTRAL RESPIRATORY GROUP IN THE RAT. J.R. Holtman, Jr., D. F. Speck and L. J. Marion. Departments of Pharmacol. and Physiol., Coll. of Med., Univ. of Kentucky, Lexington, KY 40536.

The procedure of retrograde tracing with rhodamine-labelled microspheres combined with immunohistochemistry was used to identify substance P afferents to the VRG in the rat. Four rats were anesthetized with pentobarbital (50mg/kg, i.p.). A micropipette containing rhodamine bead solution in normal saline was positioned at the site of maximal inspiratory activity in the VRG. A pressure injection of 50-100nl was made at this site. Rats were allowed to recover for 3-5 days. The rats were reanesthetized and colchicine (150ug) was administered into the lateral ventricle. Twenty-four hours later the animals were perfused and the brain was removed and processed using the indirect immunohistochemical procedure. Double-labelled neurons (rhodamine beads plus substance P) were found in the caudal raphe nuclei (obscurus, pallidus and magnus). In addition, neurons were found more laterally near the ventral surface of the medulla in the paraolivary/parapyramidal nuclei. Neurons containing only rhodamine beads were found in classical respiratory nuclei with known projections to VRG. Results of this study suggest that substance P afferents may influence the activity of inspiratory neurons in the VRG. (Support by HL-36050 to JRH).

228.8

LOCALIZATION OF SUBSTANCE P mRNA IN CHOLINERGIC CELLS OF THE RAT LATERODORSAL TEGMENTAL NUCLEUS: IN SITU HYBRIDIZATION HISTOCHEMISTRY AND IMMUNOCYTOCHEMISTRY. E.L. Sutin and D.M. Jacobowitz. Lab. of Clin. Sci., NIMH, Bethesda, MD 20892 and University of California San Diego, La Jolla CA 92093.

Immunocytochemical studies have shown that the neuropeptide, substance P (SP) is colocalized within cholinergic neurons of the laterodorsal tegmental nucleus (LDT) of the rat brain. In this study, in situ hybridization histochemical techniques in combination with immunocytochemistry and acetylcholinesterase (AChE) histochemistry were used to study the colocalization of messenger RNA (mRNA) encoding for SP in LDT cells. To demonstrate that SP is synthesized within cholinergic cells, alternate serial sections were hybridized with a ^{35}S-labeled 33-mer synthetic oligonucleotide probe encoding for SP using in situ hybridization histochemistry and processed either histochemically for AChE, or immunocytochemically for choline acetyltransferase (ChAT). Serial section analysis was also used to demonstrate the correlation between SP neuropeptide and SP mRNA in the same cells of the LDT. The methodology of in situ hybridization histochemistry complements the ability of standard immunocytochemical procedures to detect cellular peptides and protein because the combined use of these techniques provides a cross check of their specificity. This study definitively reveal that the cholinergic neurons of the LDT contain the genetic message to synthesize SP.

228.9

CO-LOCALIZATION OF SUBSTANCE K AND SUBSTANCE P IN THE MATING PATHWAY OF THE MALE GOLDEN HAMSTER M. Damlama and J.M. Swann. Institute of Animal Behavior, and Department of Biological Sciences, Rutgers University, Newark, NJ 07102.

In the male Golden hamster the medial nucleus of the amygdala (M), the bed nucleus of the stria terminalis (BNST), and the medial preoptic area (MPOA) have been shown to be critically involved in normal mating behavior. These areas contain steroid concentrating neurons, and in many species, all three areas contain numerous neuropeptides. In the Golden hamster, these areas contain substance P (SP) immunoreactivity which is steroid hormone dependent such that, castration decreases the number of immunoreactive neurons, and testosterone treatment restores it to normal levels. In these areas the neuronal distribution of substance K (SK), a related neuropeptide, seems to be similar to that of SP. We now report preliminary data suggesting that these two peptides co-exist within single neurons in M, BNST, and MPOA.

Adult male Golden hamsters were injected with colchicine into the lateral ventricle and perfused with 2% paraformaldehyde 48 hours later. SP and SK immunoreactivity was visualized simultaneously with immunofluorescence techniques, or individually in DAB reacted material.

Extensive cell body and fiber immunoreactivity for both neuropeptides was observed in M, BNST, and MPOA. In all immunoreactive neurons and their processes, SP and SK immunoreactivity appeared to be co-localized. In the BNST, the strongest immunofluorescent labeling was found in the medial division throughout its caudal extent. Maximal labeling in the MPOA was seen in the lateral and dorsal parts of post commissural median preoptic nucleus (MPN). Here it appeared on a continuum with caudal medial BNST as the latter extends ventrally. Labeled neurons in MPN and BNST were of small size (9-16 μm) emitting two to three primary dendrites. Immunoreactivity in M was confined to its caudal extent. However, due to intense fiber labeling in M, individual cell morphology could not be precisely characterized at this time.

The physiological and behavioral significance of the co-occurrence of these tachykinins in the mating pathway of the male hamster remain to be elucidated.

SUBSTANCE P IMMUNOREACTIVITY IN FROG MOTOR NERVE TERMINALS. M. Matteoli*, P. De Camilli§ and C. Haimann*#. CNR Ist.Fis.Centri Nervosi, #CNR Center of Cytopharmacol. Dept. of Pharmacol. and Center for the Study of Periph. Neuropathies, Milano, Italy and §Dept. of Cell Biol., Yale Univ. School of Medicine, New Haven, USA (Spon. M. Vitadello)

Substance P (SP) is an undecapeptide widely distributed in the central and peripheral nervous system, where it functions as a peptide neurotransmitter. It has been reported that SP may exert a modulatory role on the function of neuronal and muscle nicotinic Acetylcholine receptors. In addition, SP has been found to induce an increase in quantal release of ACh at the frog neuromuscular junction. However, whereas SP-like immunoreactivity has been shown to be present in a variety of different cholinergic synapses, no evidence has been so far reported for the presence of SP in motor nerve terminals. We have now shown by immunohistochemical methods the presence of SP in frog motor neurons and neuromuscular junctions. The pattern of immunoreactivity is similar to that observed for calcitonin-gene related peptide-immunoreactivity and suggests a localization of SP in large dense core vesicles. These results, together with previous findings, suggest a physiological role for SP at the frog neuromuscular junction.

228.11

CHOLECYSTOKININ AND SOMATOSTATIN GENES ARE EXPRESSED IN THE HUMAN THALAMUS. J.-M. Burgunder* and W.S. Young III, Neurologic Clinic, University of Berne, CH-3010 Berne, Switzerland and Laboratory of Cell Biology, NIMH, Bethesda MD 20892.

Cholecystokinin (CCK) gene is expressed in thalamocortical and thalamostriatal neurons of the rat (Mol Brain Res 4:179,1988). In the cat, this peptide is found in some intralaminar and midline nuclei whereas somatostatin (SS) is expressed in the reticular nucleus of the same species but not in the rat. Since the putative neurotransmitters used by thalamic neurons are still incompletely known, especially in humans, we investigated the expression of the CCK and SS genes in the human thalamus using hybridization histochemistry. Serial, 12μm cryostat sections from two thalami from humans without known neurological disease were probed with synthetic, 48-base oligonucleotides against human CCK or human SS mRNAs. They were labeled using [^{35}S]dATP and terminal transferase. A vasopressin sense probe served as control and did not show any specific hybridization pattern.

CCK mRNA was expressed by many neurons located in several nuclei of the dorsal thalamus. They were especially numerous and widespread in the intralaminar nuclei (e.g., centrolateral) but smaller numbers were found in other nuclei as well (e.g., in the ventral group). SS mRNA was found in many neurons of the reticular nucleus and in a few of the zona incerta, but not in the dorsal thalamus. Neurochemical features of the human thalamus, for the genes studied here, resemble features found in the cat. SS may play a role in modulating dorsal thalamic impulses which may be conveyed to the striatum and, partly, to the cortex through CCK innervation.

228.12

TRH AND SOMATOSTATIN RECEPTORS MAPPING IN ADULT HUMAN HYPOTHALAMUS. D. Jordan*, M. Najimi*, J. Champier*, F. Chigr*, N. Kopp*, A. Slama* J. Bertherat* and J. Epelbaum. Lab. Pathol. Anatomy. A. Carrel Univ., Lyon, France and INSERM U 159, Paul Broca Center., Paris, France.

Eight adult human hypothalami (from 22 to 82 year old subjects, postmortem delay : 12 to 48 hours) were processed for both ^{3}H-Me TRH and ^{125}I Tyr0-Dtrp 8 Somatostatin 14 quantitative in vitro autoradiography. Each peptide displayed a specific mapping within the hypothalamus as revealed by a rostro-caudal analysis of 20 μm frozen serial sections.

A high density (> 600 fmol/mg protein) of Somatostatin binding sites is present in the anterior preoptic region and the posterior infundibular nucleus, while a moderate density (300 to 500) occurs in the anterior area, dorsomedial, ventromedial, and lateral mammillary nuclei and a low one (< 200) in the paraventricular and periventricular nuclei.

The highest density of TRH binding sites is observed in the diagonal band of Broca, the lateral preoptic area, and the infundibular nucleus (> 120 fmol/mg protein), while a moderate binding is quantified in the ventromedial nucleus (< 100) and a low one in the paraventricular nucleus (< 70).

In conclusion, one might point out the low density of TRH and Somatostatin binding sites in the paraventricular and periventricular nuclei in which both peptides are synthetized. In contrast, the high density of TRH and Somatostatin binding sites in the infundibular nucleus indicate that most interactions between both peptides occur at the terminal level.

228.13

IMMUNOREACTIVE ANP (IR-ANP) IN RAT AND RABBIT RETINAS.
D.E. Palm*, L.C. Keil*, J.W. Sassani* and W.B. Severs.
Depts. Pharmacol. & Ophthalmol., Col. Med., Penn State Univ. Hershey, PA 17033

IR-ANP was found in rat retina by RIA, but "receptors" have not been detected. Here, we report results of retinas from 6 S.D. rats and 6 albino rabbits. Tissue was obtained after pentobarbital anesthesia, and cardiac perfusion with neutral buffered formalin, then fixative. Sections (8 µ) were incubated with anti-rat (1-28)1°Ab 1:500 (with or without pre-absorbtion with 30 µg/ml synthetic rat (1-28)-ANP at 4°C overnight. After applying goat anti-rabbit 2° Ab, slides were processed with the Vectostain ABC kit, using diaminobenzidine as the chromogen. The anti-rat ANP had less than 0.01% cross-reactivity with oxytocin, arg-8-vasopressin, angiotensins I, II and NPY did not cross-react. Human ANP showed 7% cross-reactivity; atriopeptins I, II, III - 45-55%, and auriculin B, 100%. Only the outer and inner plexiform (OPL, IPL) layers of the rat and rabbit retinas showed IR-ANP, which was abolished by pre-absorbed 1° Ab. OPL staining was more intense, and appeared to be localized in photoreceptor terminals, although horizontal and/or bipolar cell processes could not be excluded. The border between the IPL and ganglion cell layer was demarcated by IR-ANP. Although the role of ANP in the retina is unknown, intraocular pressure control emerges as a possibility.

ATRIAL NATRIURETIC PEPTIDE-LIKE IMMUNOREACTIVITY (ANP-LIR) IN GLIAL CELLS OF THE PARENCHYMA AND GLIA LIMITANS OF THE CANINE BRAIN.
J.C. McKenzie* and R.J. Cowie. SPON: (B.H. Turner). Dept of Anatomy, Coll. of Medicine, Howard University, Washington, DC, 20059.

Atrial natriuretic peptide has been localized in areas of the rodent brain which regulate cardiovascular function and fluid/electrolyte balance. We are currently investigating the distribution of ANP-LIR in the more cytoarchitecturally complex canine brain. Dogs (4) were deeply anesthetized with sodium pentobarbital and perfused with saline followed by 4% formaldehyde. Brains were removed, blocked, immersed in sucrose and sectioned at 50 um on a freezing microtome. Sections were incubated 72 h at 4 deg C in primary antiserum (anti-rat ANF IV; 1:10,000) and processed by the ABC technique. Small numbers of astroglia-like cells were intensely stained in many regions of the brain including neocortex and brain stem. In gray matter, positive glial cells presented as dense ovoid masses of processes from which longer processes often emerged to contact local vessels. In white matter, positive cells more closely resembled fibrous astrocytes with long filamentous processes. Isolated astrocytes of the glia limitans also displayed intense ANP-LIR, often sending long processes into the parenchyma to contact microvessels. The localization of ANP in astroglia represents the 2nd putative peptide neurotransmitter/neuromodulator to be identified in glial cells. Interestingly, the first was angiotensin II, an endogenous antagonist of ANP. We suggest that these two systems may interact in the control of local blood flow.

ATRIAL NATRIURETIC PEPTIDE-LIKE IMMUNOREACTIVITY (ANP-LIR) IN BASAL FOREBRAIN-RELATED NEURONS AND PATHWAYS OF DOG AND CAT.
R.J. Cowie and J.C. McKenzie*. Dept. of Anatomy, Col. of Medicine, Howard University, Washington, DC, 20059.

Atrial natriuretic peptide has been localized in areas of the rat brain, some of which regulate cardiovascular function and fluid-electrolyte balance. We are currently investigating ANP-LIR in the more cytoarchitecturally complex carnivore brain. Three dogs and a cat were anesthetized with pentobarbital and perfused with saline, followed by 4% formaline. Brains were removed, blocked, immersed in sucrose and frozen sectioned at 50 um, incubated 72 h in primary antiserum (anti-rat ANF IV; 1:10,000), and processed by the ABC technique. Substitution of normal rabbit serum for primary antibody provided controls. Preliminary results indicated that both species possessed medium-to-large sized cells extending dorsolaterally in bridges from each of the highly vascularized core/caps of the Islands of Calleja (ICC) into the entopeduncular n., and from the bed n. of the stria terminalis to the amygdala. Additional cells of various sizes were labeled in the septal-accumbens region, lateral hypothalamus (LH), Forel's field H (FfH), lat. habenular n., substantia nigra/ventral tegmental area, and the PAG/dorsal raphe. Many ANP-LIR fibers coursed within the LH, FfH, and parts of the PAG. Minor differences were noted in labeling patterns between species. Findings of an ANP-LIR system extend the known peptidergic neuromodulators of the striatopallidal complex and support suggestions of a neuroendocrine function for the ICC.

CHARACTERIZATION OF NEUROKININ-1 AND -3 BINDING SITES IN RAT BRAIN USING SELECTIVE RADIOLIGANDS
T.V. Dam, B. Martinelli*, E. Escher* and R. Quirion. Douglas Hosp. Res. Ctr. McGill Univ. Montréal, Québec, Canada; Dépt. de pharmacol., Fac. de Méd. Univ. de Sherbrooke, Sherbrooke, Québec, Canada and F. Angelini Res. Inst., Rome, Italy.

The existence of three brain neurokinin (NK) receptors namely the NK-1, NK-2 and NK-3 subtypes has been proposed with substance P (SP), neurokinin A (NKA) and neurokinin B (NKB) acting as their preferred endogenous ligands, respectively. However, the selectivity of these NKs is limited since each one shows appreciable affinity for the other receptor classes. Therefore, the development of better radioligands is crucial in order to selectively label a given receptor subtype. In this study, we use two selective tritiated radioligands, [^{3}H]-Sar^9 Met(O$_2$)-SP ([^{3}H]-SM-SP) and [^{3}H]-Suc-(Asp^6, MePhe^0)-SP (6-11) ([^{3}H]-senktide) to characterize brain NK-1 and NK-3 binding sites respectively. Rat brain sections and membrane binding assays were prepared and performed as described before (Quirion, R. and Dam, T.V. J. Neurosci., 6: 2187-2199, 1986). The results show that [^{3}H]-senktide binds to a single class of high affinity (Kd=4.1nM), low capacity (54.56 fmol/mg protein) sites which are mostly concentrated in layers IV and V of the cortex and in the hippocampus, this distribution being reminiscent to that reported for the NK-3 receptor. On the other hand, [^{3}H]-SM-SP appears to label NK-1 sites since high densities of binding is seen in the striatum. Thus, these two new ligands should be most useful to selectively characterize NK-1 and NK-3 receptors. (Supported by Medical Research Council of Canada).

INHIBITION OF NEUROKININ-INDUCED PLASMA EXTRAVASATION AND BRONCHOCONSTRICTION BY THE NK-1 ANTAGONIST, GR71251.
C.C. Jordan*, I.J.M. Beresford*, G.B. Ewan*, R.M. Hagan*, S.J. Ireland*, M.L. Stephens-Smith* & P.Ward* (SPON: Brain Research Assn). Glaxo Group Research Ltd, Ware, Herts, SG12 0DP, U.K.

Tachykinins may mediate neurogenic inflammation and bronchoconstriction in respiratory disease. It is thus of interest to characterize the neurokinin receptors involved. Plasma extravasation (PEV), measured as accumulation of Evans blue-tagged plasma proteins, was induced by intradermal injection of tachykinins in the skin of the anaesthetized rat. This effect was mimicked by the NK-1 selective agonists substance P methylester (SPOMe) and δ-aminovaleryl[Pro^9,MeLeu^{10}]-SP(7-11) (GR73632). In animals pretreated with mepyramine (10mg/kg, i.v.), the novel NK-1 selective antagonist, GR71251, (0.1-0.5µmol/kg, i.v.), attenuated PEV induced by GR73632 (1-1000 pmol, i.d.).

In the anaesthetized guinea-pig, insufflation pressure was markedly increased by SPOMe (1-10nmol/kg, i.v.) and GR73632 (0.1-1.0nmol/kg, i.v.). The response to SPOMe was unaffected by mepyramine (5mg/kg i.v.) but was inhibited by GR71251 (3µmol/kg, i.v.).

HAMSTER URINARY BLADDER (HUB) AND GUINEA-PIG TRACHEA (GPT) MAY EACH CONTAIN A DIFFERENT SUBTYPE OF THE TACHYKININ PEPTIDE NK-2 RECEPTOR. H.C. Cheng; S.L. Harbeson; S.A. Shatzer* and S.H. Buck (SPON: W.E. Heydorn). Merrell Dow Research Institute, Cincinnati, OH 45215.

Neurokinin A (NKA) is the most potent mammalian tachykinin peptide in producing contraction of the HUB and the GPT (pD_2 approximately 8.0 in both tissues). NKA is at least 10X more potent than substance P or neurokinin B in both tissues (Dion et al., Life Sci. 41:2269, 1987). Based on the high potency of septide (slightly NK-1 selective) and DiMeC7 (NK-2 inactive) in GPT, McKnight et al. (Reg. Peptides 22:126, 1988) have suggested that GPT contains a unique tachykinin receptor rather than NK-2 or NK-1. We have investigated the tachykinin receptors in HUB and GPT using the new peptide Leu^9-CH_2NH-Leu^{10}-NKA(4-10) (MDL 28,564). MDL 28,564 inhibited iodinated NKA binding in HUB membranes with a K_I of 200 nM (NKA K_I = 1 nM). NKA stimulated phosphatidylinositol (PI) turnover with EC_{50} of 3 nM in chopped HUB and in chopped GPT muscle. In HUB, MDL 28,564 stimulated PI turnover with EC_{50} of 100 nM and maximum efficacy only 10% of that of NKA. In GPT, however, MDL 28,564 stimulated PI turnover with EC_{50} of 1 uM and maximum efficacy 100% of that of NKA. In contraction assays (in the presence of enkephalinase inhibition), MDL 28,564 up to 10 uM did not produce any contraction in HUB whereas it produced a full contraction at 10 uM in GPT. These results indicate that HUB and GPT contain NK-2 receptors that can be distinguished by C-terminal modifications in NKA. These receptors are most likely NK-2 subtypes.

229.4

CROSS-LINKING OF ^{125}I-IODOHISTIDYL^1-NEUROKININ A (INKA) TO TACHYKININ PEPTIDE NK-2 RECEPTORS IN HAMSTER URINARY BLADDER. S.H. Buck, B.O. Fanger; A.C. Wade* and S.A. Shatzer; Merrell Dow Research Institute, Cincinnati, OH 45215.

The tachykinin peptide NK-2 receptor from bovine stomach has been cloned and functionally expressed in Xenopus oocytes. It is a G-protein linked receptor with molecular weight of 43,000 (Masu et al., Nature 329:836, 1987). The hamster urinary bladder contains a high number of INKA binding sites that appear to be NK-2 receptors linked to phosphatidylinositol turnover. We have used BIS(sulfosuccinimidyl) suberate (BS^3) to investigate the INKA binding protein in this tissue. 1 nM INKA and 25 mg bladder membranes were incubated in PBS buffer at 25°C for 2 hr. The membranes were pelleted by centrifugation and resuspended in buffer containing 5 mM BS? The pellets (+ dithiothreitol) from this step were separated by SDS-PAGE with 10-20% gels which were then exposed to film. A single major band of 43,000 was observed. Unlabeled NKA blocked labeling of this band with an IC_{50} of 6 nM. 1 uM NKA blocked at least 95% of labeling of the band. Substance P, senktide, bombesin, bradykinin, α-MSH, somatostatin, or VIP did not compete for labeling. Neurokinin B competed with less potency than NKA. Under nonreducing conditions (- DTT), a second labeled band (86,000) was seen that contained most of the specific binding (blocked by 1 uM NKA). These results indicate that hamster urinary bladder contains an NK-2 receptor protein that is similar to the reported cloned receptor. This protein may be associated with another similarly sized molecule.

CENTRAL BINDING SITES FOR MELANOTROPIC PEPTIDES W. Lichtensteiger, M. Schlumpf and *A. Eberle, Inst. of Pharmacology, Univ. of Zürich, Zürich, and *Zentrum für Lehre u. Forschung, Basel, Switzerland

Melanotropic peptides affect brain function, but the site of action is uncertain. We studied binding of 3H(Nva 13)-alpha-MSH to membranes of Long Evans rat hippocampus and by in vitro autoradiography. Scatchard and competition data indicate the existence of high (Kd 4-8 nM) and low affinity sites (Kd 5 uM) for alpha-MSH. Slightly lower affinities are found with desacetyl-alpha-MSH which also occurs in brain, and gamma-1-MSH which displays only week activity on melanocytes. The fragment Lys-Pro-Val NH2 containing the C-terminal message sequence had a comparatively high affinity. ACTH 4-10 with the central message sequence was virtually inactive at the high affinity site but bound to the low affinity site. A particular activity of the C-terminal sequence has been reported for certain central actions. Quantitative autoradiography revealed high densities of the high affinity site in hippocampus, dentate gyrus, cortical areas, cerebellum and several brainstem areas. Our data provide a basis for central actions of MSH peptides and support the idea of a possible central role.

MOUSE VAS DEFERENS (MVD) AND RAT BRAIN BINDING STUDIES SUGGEST TWO DELTA OPIOID RECEPTORS. L.K.Vaughn, W.S.Wire, Y.Shimohigashi, G.Toth, V.J.Hruby, T.F.Burks, H.I. Yamamura. U. of Arizona, Tucson, AZ 85724, Kyushu U. Fukuoka, Japan.

Certain enkephalin analogs which contain the conformationally restricted amino acid E-(2R,3S)-cyclopropylphenylalanine ((2R,3S)-V^EPhe) have been shown to be active at brain but not MVD δ-opioid receptors (Shimohigashi et al., FEBS Lett. 222:71,1987). We compared the ability of a selective δ-opioid compound, [D-Pen^2,pCl-Phe^4,D-Pen^5]-enkephalin (pCl-DPDPE), and [D-Ala^2,(2R,3S)-V^EPhe^4,Leu^5]-enkephalin methyl ester (CP-OMe), to inhibit [^{3}H]pCl-DPDPE binding in both rat brain and MVD. 500 μg protein from rat brain homogenate or 1000 μg protein from MVD homogenate were incubated with 800 pM [^{3}H]pCl-DPDPE and with varying concentrations of unlabelled pCl-DPDPE or CP-OMe in 50 mM Tris buffer with 5 mM $MgCl_2$, 100 μM PMSF, 1 mg/ml BSA, pH 7.4 for 4 h at 25°C. Specific binding was defined with addition of 10 μM naltrexone. pCl-DPDPE recognized brain and MVD binding sites with equal affinity, however, CP-OMe showed 33 fold lower affinity in MVD compared to brain.

	BRAIN		MVD	
	IC_{50} (nM)	(Hill slope)	IC_{50} (nM)	(Hill slope)
pCl-DPDPE	1.24	0.99	1.30	1.06
CP-OMe	2.18	0.86	73.84	1.04

This suggests that MVD δ-opioid receptors may be distinct from brain δ-opioid receptors. Supported by USPHS grants.

EVIDENCE FOR TWO SUBTYPES OF U50,488-SENSITIVE KAPPA$_1$ RECEPTORS. L. Liu*, J.A. Clark, M. Edelson* and G.W. Pasternak. (SPON: J. Posner). The Cotzias Laboratory of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center, New York, NY 10021.

In the presence of high concentrations of mu and delta ligands, ^{3}H-ethylketocyclazocine selectively labels kappa receptors in the guinea pig cerebellum. Opiates with kappa actions, including U50,488, tifluadom, Mr2034, Mr2266, and Win44,441, all compete binding with K_i values under 10 nM and Hill coefficients of approximately one. Dynorphin A also potently lowers binding with a K_i of 0.27 nM and a Hill coefficient of 0.83 ± 0.20 (n=4). However, competition studies with dynorphin B yield a Hill coefficient of 0.46 ± 0.03 (n=5) and nonlinear regression analysis gives a best fit for two sites (K_i 0.13 nM and 40 nM). Similarly, α-neoendorphin also produced a biphasic competition curve best fit with two components (K_i 0.12 nM and 33 nM). Competition studies with α-neoendorphin in the presence of a fixed concentration of dynorphin B suggest that both compounds label the same site (kappa$_{1b}$) with high affinity. These data suggest that ^{3}H-ethylketocyclazocine labels two U50,488-sensitive subtypes of kappa receptors in the guinea pig cerebellum, which we have termed kappa$_{1a}$ and kappa$_{1b}$. Classical kappa opiates have high affinity for both kappa receptor subtypes, as does dynorphin A. In contrast, both dynorphin B and α-neoendorphin selectively label kappa$_{1b}$ receptors. We find similar results with ^{3}H-U69,593.

229.8

KAPPA$_3$ BINDING: DEVELOPMENT OF A SELECTIVE BINDING ASSAY. E. Huang,* B. Hersh,* L. Liu,* and G.W Pasternak (SPON: K. Foley). The Cotzias Laboratory of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center, New York, NY 10021

We have characterized the binding of ^{3}H-NalBzoH to κ_3 receptors in calf striatal membranes and compared it to the U50,488-sensitive κ_1 receptors in the guinea pig cerebellum. ^{3}H-NalBzoH labeled κ_3 sites with high affinity (K_D 0.74 ± 0.04 nM) and high density (Bmax 14.6 ± 0.69 fmoles/mg wet weight tissue), approximately twice levels of μ receptors and far greater than κ_1 receptors. This site correlates with neither μ nor δ receptors. Although a large number of κ ligands examined competed binding quite potently with K_i values under 10 nM, U50,488 (1 μM) did not significantly inhibit ^{3}H-NalBzoH binding in calf striatal membranes despite its potent inhibition of ^{3}H-NalBzoH binding to κ_1 receptors in the guinea pig cerebellum (K_i 6.1 nM). ^{3}H-NalBzoH binding in calf striatal membranes was highly stereospecific and selective for opioids. Thus, in calf striatal membranes ^{3}H-NalBzoH labels a novel subtype of κ receptor, termed κ_3. Differences in sensitivity to U50,488 clearly differentiate κ_3 from κ_1 sites present in the guinea pig cerebellum. The high affinity of ethylketocyclazocine, tifluadom and cyclazocine for κ_3 sites distinguish them from κ_2 sites reported in rat brain homogenates. We have also identified κ_3 receptors with similar characteristics in rat and mouse brain.

DIFFERENTIAL EFFECT OF DIVALENT CATIONS ON MU_1, MU_2 AND DELTA OPIATE RECEPTOR BINDING. K. Kinouchi,* K.M. Standifer and G.W. Pasternak. (SPON: W. Shapiro). Memorial Sloan-Kettering Cancer Center, New York, NY 10021 USA.

Recent work has suggested the existence of a variety of opiate receptor types and subtypes. Mu receptors, with their high affinity for morphine, were easily distinguished from delta receptors which bound the enkephalins selectively. Evidence now indicates the presence of two subtypes of mu receptors, termed mu_1 and mu_2, which can be differentiated on the basis of their binding selectivity and pharmacological actions. In the present study we have examined the actions of three divalent cations on the binding of mu_1, mu_2 and delta receptors. Magnesium, manganese and calcium all increased mu_1 binding. Of the three, magnesium was the most effective, elevating binding 3-fold. Manganese increased binding 2-fold and calcium increased binding only 70%. The divalent cations also increased mu_2 binding, but far less than mu_1: 50% for magnesium, 35% for manganese and 15% for calcium. Against delta binding magnesium increased binding 70%, manganese by 60%, and calcium produced no effect. Saturation studies revealed a mixed effect on K_D and Bmax for the mu receptors. The increased mu_1 and mu_2 binding resulted from an increase in both affinity and Bmax. The modest effects on delta binding appeared to be predominently a change in Bmax. The differential sensitivity of mu_1 and mu_2 binding towards divalent cations supports the concept of multiple mu receptors.

229.10

EVIDENCE AGAINST A SIMPLE BIMOLECULAR MODEL FOR MU_1 BINDING. K.M. Standifer, J.A. Clark, and G.W. Pasternak. The Cotzias Laboratory of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center, NY, NY 10021.

In thalamic membranes ^{3}H-DADL in the presence of DPDPE labels mu_1 sites almost exclusively. Our data suggest a complex binding model consisting of at least two steps and three receptor states:

The first step consists of the rapid binding of the ligand to the receptor to form a high affinity complex ($L{\cdot}R_{ha}$; $\tau_{1/2}$ ~10 min) followed by a slower conversion of this bound receptor in the presence of Mg^{++} to yield a very high affinity state ($L{\cdot}R_{vha}$; $\tau_{1/2}$ ~75 min). EDTA prevents the conversion of $L{\cdot}R_{ha}$ to $L{\cdot}R_{vha}$. Gpp(NH)p rapidly dissociates the $L{\cdot}R_{vha}$ complex ($\tau_{1/2}$ ~2 min), suggesting the possibility that the $L{\cdot}R_{vha}$ complex includes a G-protein, but has little effect on the dissociation of the $L{\cdot}R_{ha}$ state. In contrast, the $L{\cdot}R_{ha}$ state is more sensitive to Na^+ than the $L{\cdot}R_{vha}$ state. These results illustrate the complexity of opiate binding mechanisms and raise serious questions regarding the use of computer models based upon simple bimolecular interactions between a ligand and its receptor.

229.11

PHOTOAFFINITY LABELING MULTIPLE MU AND KAPPA RECEPTORS. G.W. Pasternak, K.M. Standifer,* L.L. Steele* The Cotzias Laboratory of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center and Departments of Neurology and Pharmacology, Cornell U. Medical College, New York, NY 10021

The benzoylhydrazone derivative of naloxone (NalBzoH) labels both mu and kappa receptors in standard homogenate binding assays. We now report that ^{3}H-NalBzoH is an effective photoaffinity label for multiple classes of mu and kappa receptors. Using differing binding conditions, we can selectively label mu_1, mu_2, $kappa_1$ or $kappa_3$ receptors. In homogenates from the guinea pig cerebellum, ^{3}H-NalBzoH labels U50,488-sensitive $kappa_1$ receptors. In homogenates from calf striatum, ^{3}H-NalBzoH selectively labels a U50,488-insensitive kappa receptor ($kappa_3$). Membranes can be labeled with ^{3}H-NalBzoH using selective binding conditions, washed to remove unbound radioligand and the ^{3}H-NalBzoH covalently linked to proteins with exposure to UV light. ^{3}H-NalBzoH dissociates from mu receptors quite slowly ($\tau_{1/2}$ 24 hr at 25°C and 96 hr at 0°C), but Gpp(NH)p (100 μM) or lowering the pH to 5 dissociates ^{3}H-NalBzoH quite rapidly, with a $\tau_{1/2}$ under 15 min. Following exposure to UV ^{3}H-NalBzoH is stable to both Gpp(NH)p and low pH, suggesting the formation of covalent bonding. Binding in all assays is stable to solubilization of membranes with SDS. This approach may be a useful method to affinity label, characterize and purify opiate receptor subtypes.

229.12

CROSS-LINKING OF 125I-BETA-ENDORPHIN TO A MU-DELTA OPIOID RECEPTOR COMPLEX IN RAT NEOSTRIATUM. A.N.M. Schoffelmeer*, Y-H. Yao* and E.J. Simon. Dept. of Psychiatry, NYU Medical Center, New York, NY 10016 and Dept. of Pharmacol., Free Univ., Med. Faculty, Amsterdam, 1081 BT, The Netherlands (A.N.M.S.).

In a modified Krebs-HEPES buffer at 37°C ^{3}H-DAGO and human ^{125}I-beta-endorphin bound to rat striatal homogenates with Kd values of 7.5 and 4.6 nM, respectively. The Bmax values were 97 and 261 fmole/mg protein in agreement with a selective labelling of mu receptors by ^{3}H-DAGO and that of both mu and delta receptors by ^{125}I-beta-endorphin. Displacement curves of DAGO and the delta agonist DSTBULET against 2 nM ^{125}I-beta-endorphin were monophasic with half maximal inhibition at 30 and 500 nM, respectively. Saturation curves of ^{3}H-DAGO showed that 500 nM DSTBULET caused a non-competitive inhibition of mu receptor binding. ^{125}I-beta-endorphin (2 nM) was cross-linked to mu and delta receptors with 1 mM BSCOES. SDS-PAGE followed by autoradiography of the gels revealed a major band of about 80 kDa that was diminished by 10/uM naloxone and strongly reduced not only by 30 nM DAGO but also by 500 nM DSTBULET. These data provide strong evidence for the existence in rat striatum of a mu-delta opioid receptor complex with non-competitively interacting mu and delta binding sites and indicate that under physiological conditions striatal mu- and delta-opioid receptors represent physically associated glycoproteins.

229.13

TYR-MIF-1 BINDING SITES ARE PRESENT IN SH-SY5Y HUMAN NEUROBLASTOMA CELLS: THEIR REGULATION MAY DIFFER FROM THAT OF MU OPIATE RECEPTORS. J.E. Zadina, S.L. Chang, L-J. Ge*, A.J. Kastin and R.E. Harlan. VA Medical Center and Tulane Univ. Sch. of Med. New Orleans, LA 70146

Human neuroblastoma SH-SY5Y cells express mu and delta opiate receptors and develop tolerance to the effects of opiates (Yu and Sadee, JPET, 240:350-355, 1988). We tested these cells for the presence of binding sites for Tyr-MIF-1 (Tyr-Pro-Leu-Gly-NH_2), a recently isolated brain peptide with antiopiate activity. In rat brain, Tyr-MIF-1 binding sites decrease after chronic morphine, while opiate receptors increase (Zadina et al., Life Sci. 44: 555, 1989). SH-SY5Y cells were grown and synaptic plasma membranes (SPM) prepared from them according to the methods of Yu and Sadee, 1988 and Zadina et al., 1989. Specific binding (per mg protein) of Tyr-MIF-1 to SPM from SH-SY5Y cells was comparable to that of SPM from both Charles River and Zivic-Miller rat whole brain. Treatment of SH-SY5Y cells with retinoic acid significantly ($p < 0.05$) increased the binding of both ^{3}H-DAGO, in good agreement with Yu and Sadee (1988), and ^{125}I-DAGO. In contrast, Tyr-MIF-1 binding was significantly ($p < 0.05$) decreased in one experiment and did not change in another. SH-SY5Y cells thus provide a second model in which opiate receptors and Tyr-MIF-1 binding sites may be differentially regulated.

229.14

NON-MATURE OPIOID RECEPTORS IN DEVELOPING STRIATUM AND HIPPOCAMPUS J.Barg*, V.Hatini* and R.Simantov (SPON:M.Devor) Dep. of Genetics, Weizmann Ins. of Sci., Rehovot, Israel

The developmental pattern of the three opioid receptor subtypes μ, δ and k was determined in the rat and guinea pig hippocampus and striatum. In the guinea pig the total receptor density in the two brain regions reached a peak value at the embryonic days 45 and 55, respectively, and then decreased one day after birth. A similar decrease in total receptor density before birth was evident also in the rat, indicating therefore that during the embryonic period the receptors undergo, at least in these two brain structures, an apparent regressive developmental pattern. Various opioids were used to characterize the receptors that participate in this process, but the results were surprising; DAGO, DPDPE and U-50,488 that are widely used to characterize the three receptor subtypes in adult tissues were non-selective during the early developmental period. These and additional experiments indicate that opioid receptors in embryonic hippocampus and striatum cannot be classified to μ, δ and k receptors, possibly because the protein is yet 'non-mature'. This finding supports therefore the notion that a common gene may code for more than one opioid receptor subtype, and the final opioid selectivity of the receptor depends on post-translational modifications. Alternatively, the receptors in embryonic tissues may not possess the mature interaction with other membrane-bound components like the GTP-binding proteins.

229.15

PRESENCE OF ZETA AND OTHER OPIOID BINDING SITES IN CEREBELLUM OF ADULT AND DEVELOPING HUMANS. D.M. Gibo*, P.J. McLaughlin and I.S. Zagon (SPON: R. Hamilton). Dept. Anatomy, Penn. State Univ. Coll. Med., Hershey, PA 17033.

The presence of at least 3 types of opioid binding sites have been documented in adult and developing mammalian CNS. Recently, a new opioid receptor, zeta (ζ), related to cell replication, has been identified in abnormal neural tissue. [Met^5]-enkephalin, which exhibits high affinity for the zeta receptor has been immunocytochemically localized in germinative cells of the developing rat cerebellum; neurons derived from these germinative cells are not immunoreactive. In this study, zeta and other opioid binding sites, and the developmental patterns of their expression, were determined in human cerebellum. Binding assays to [Met^5]-enkephalin, DAGO, DADLE, and EKC were used to probe for ζ, μ, δ, and κ sites, respectively, in developing (embryonic to 90 days) and adult human cerebellum. Specific and saturable binding to radiolabeled [Met^5]-enkephalin, DADLE, and EKC, but not DAGO, were recorded for both developing and adult cerebellum. Bmax values were significantly greater (3-6 fold increase) in developing tissue than adult cerebellum; Kd values did not differ with age. These results indicate that opioid binding sites, including those related to growth, are present in the human cerebellum, and in greatest number during ontogeny.

Supported by NIH Grant NS-20500.

AUTORADIOGRAPHIC CHARACTERIZATION OF BINDING SITES FOR THE ANTIPSYCHOTIC PEPTIDE DES-ENKEPHALIN-γ-ENDORPHIN (ORG-5878) IN THE RAT BRAIN.
E. Ronken[1*], J.A.D.M. Tonnaer[2], Th. de Boer[2*], V.M. Wiegant[1*]. (SPON: European Neuroscience Association). 1) Rudolf Magnus Institute for Pharmacology, University of Utrecht, The Netherlands; 2) Dept. CNS Pharmacology, Organon Int. B.V., Oss, The Netherlands.

The non-opioid effects of the endogenous neuropeptide γ-endorphin resemble those of classical neuroleptic drugs in rat behavioural models. These properties are shared by the non-opioid congeners of γ-endorphin, of which des-enkephalin-γ-endorphin (β-endorphin(6-17); DEγE; Org 5878) is the shortest and most potent peptide. In addition, DEγE has antipsychotic properties in certain schizophrenic patients. We studied the binding of [^{35}S]Methionine-DEγE ([^{35}S]β-endorphin(5-17); 1400 Ci/mmol) to coronal rat brain cryosections using in vitro autoradiography. Incubations were done with 500 pM [^{35}S]Met-DEγE and specificity was assessed by coincubation of adjacent sections with 1 μM DEγE. Displaceable binding was found in a number of anatomically defined brain areas which constitute a major part of the mesolimbic feedback circuitry. This specific topography of DEγE binding may be relevant with respect to the antipsychotic properties of the peptide. Structure-activity relationship studies suggest that the binding is selective for DEγE-related peptides and does not involve dopamine D_2 receptors.

229.17

CHARACTERIZATION AND ANALYSIS OF SUBTYPES OF RECEPTORS FOR SUBSTANCE P. E. Burcher*, D.P. Geraghty*, D. Regoli*[1], G. Drapeau*[1] and B.G. Livett[2]. Dept. of Biological Sciences, Deakin Univ., Vic 3217, Australia, [1]Dept. of Pharmacology, Sherbrooke Univ., Canada JIH 5N4 and [2] Dept. of Biochemistry, Melbourne Univ., Vic. 3052, Australia.

We have investigated the binding characteristics of the radioligands [^{125}I]-Bolton-Hunter SP (BHSP), BH-[Sar^9 Met-$(O_2)^{11}$]-SP (BH-SarSP, Lew, R. et al., Regul. Pept. 22:113, 1988) and [^{3}H]-SP in tissue homogenates. Membranes were prepared as described previously (Burcher, E. et al., JPET, 236:819, 1986) and incubated with 0.01-1 nM BH-SarSP (rat brain, rat submandibular gland, SG) and 0.01-3 nM BHSP and 0.5-20 nM [^{3}H-SP] (bovine adrenal medulla, BAM). In brain and SG, BH-SarSP binding was of high affinity (K_D's 0.26, 0.10 nM respectively). Rank potency orders for inhibition of BH-SarSP binding were similar in both tissues, suggesting binding to an NK1 receptor, but most competitors were 4-60 times less potent as inhibitors in brain compared with SG. In BAM, no specific binding of BHSP occurred but binding of [^{3}H]-SP was saturable and reversible with K_D 1.46 ± 0.73 nM. Specific binding of [^{3}H]-SP was inhibited by SP > neurokinin A ≈ SP(3-11) > SP(1-9) > SP(1-6) > neurokinin B, with Lys^3 apparently essential for effective competition. These data suggest (1) that SP receptors in rat brain and SG have different characteristics indicating possible subtypes of the NK1 receptor, and (2) that SP receptors in BAM are not of the NK1 type but represent a novel SP receptor subtype.

229.18

SUBSTANCE P-INDUCED REDUCTION IN CYTOSOLIC ^{3}H-*myo*-INOSITOL IN RAT PAROTID ACINAR CELLS. M.M. Dietl*, Y. Torrens*, J.-C. Beaujouan* and J. Glowinski*. (SPON: L. Di Giamberardino) Collège de France, INSERM U.114, Chaire de Neuropharmacologie, 75005 Paris, France.

Coincubation of rat parotid acinar cells with substance P (SP) and ^{3}H-*myo*-inositol resulted in a significant reduction of labeled cytosolic inositol. This effect was rapid (30sec), the maximal reduction (about 45%) being observed at 15min. The response to SP was temperature-dependent since at 4°C no reduction was observed. The SP-induced reduction of cytosolic ^{3}H-*myo*-inositol was dose-dependent (EC_{50}=5.7±2.4 nM). Spantide, a SP antagonist, at 10^{-5}M, competitively shifted the effect of SP (EC_{50}=30.0±5.1 nM). [L-Pro^9]SP and SP methyl ester, two selective agonists of NK1 receptors, reduced the accumulation of ^{3}H-*myo*-inositol. Long SP C-terminal fragments were more potent than shorter ones. SP N-terminal fragments and SP free acid were without effect. [Pro^7]NKB, a selective neurokinin (NK)B analog, had no effect. The rank order potency of tachykinins was SP>NKA>NKB. These findings and the close correlation between EC_{50} values and IC_{50} values obtained in binding studies implicate the NK1 receptor. Activation of muscarinic receptors by carbachol also resulted in a reduction of cytosolic ^{3}H-*myo*-inositol in rat parotid acinar cells, an effect reversed by atropine. Atropine alone had no effect. Moreover, atropine was unable to alter SP-induced reduction of cytosolic ^{3}H-*myo*-inositol. Other neurotransmitters (5HT, glutamate, CCK, NT, BK) were without effect on cytosolic ^{3}H-*myo*-inositol accumulation. In conclusion, NK1 and muscarinic receptors seem to be implicated in the regulation of membrane transport of inositol in rat parotid gland. The measurement of cytosolic ^{3}H-*myo*-inositol in rat parotid glands could be adopted as a simple, sensitive, and specific method for screening the biological activity of potential agonists and antagonists at NK1 receptors.

PHOTOAFFINITY LABELLING THE SUBSTANCE P RECEPTOR USING A p-BENZOYLPHENYLALANINE-CONTAINING SUBSTANCE P ANALOG. N.D.Boyd*, C.F. White*, S.E. Leeman, R. Cerpa*+, E.T. Kaiser*+ Dept. of Physiol., Univ. Mass. Med. Sch., Worcester, MA 01655 and +Lab. of Biorg. Chem/ Biochem.,Rockefeller Univ., New York, NY 10021

A photoactive analog of substance P (SP), containing L-p-benzoylphenylalanine in place of Phe^8, was prepared as a probe for the SP receptor by solid-phase peptide synthesis methodology. The ^{125}I-Bolton-Hunter conjugate of Phe^8(pBz)-SP bound, in the absence of light, in a saturable and reversible manner to an apparently homogeneous population of binding sites on rat submaxillary gland membranes (B_{max}=0.5 pmoles/mg, K_d=1.2 nM; parameters similar to those characterizing the binding of SP to the same membrane preparation.) ^{125}I-Phe^8(pBz)-SP binding was competitively inhibited by SP and other tachykinin peptides with a specificity appropriate for SP/NK-1 receptors. Upon irradiation at 350nm, about 70% of the ^{125}I-Phe^8(pBz)-SP bound to the SP receptor became covalenty attached yielding radiolabelled bands of Mr=53000 and Mr=46000. Labelling of both bands occurs with characteristic SP receptor specificity and both bands are equally sensitive to the inhibitory effects of GppNHp. The 46kDa receptor peptide is most likely derived from the higher molecular weight species by proteolytic nicking. The high affinity of ^{125}I-Phe^8(pBz)-SP for SP receptors and remarkable photoincorporation efficiency suggest that this photoaffinity ligand will be of considerable value in the molecular characterization of SP receptors.

IMMUNOHISTOCHEMISTRY OF SUBSTANCE P BINDING SITES IN THE GUINEA PIG TRACHEA. W.Kummer*, A. Fischer*, U.Preissler*, J.Y.Couraud*[2] and Ch. Heym*. (SPON: J.Y. Jew) Inst. f. Anatomie und Zellbiologie, Univ., D-6900 Heidelberg, FRG; [2] Dept. de Biologie, CEN/SACLAY, France.

Recently, anti-substance P (SP) anti-idiotypic antibodies (anti-Id ab) have been demonstrated as a tool for cytochemical identification of SP receptors in the central nervous system (Couraud et al., J. Histochem. Cytochem., 36:1397-1401, 1988). We used this approach for studying the localization of SP binding sites in the guinea pig trachea. Immunoreaction was considered to be specific when it could be abolished by preabsorption of the anti-Id ab with a C-terminal specific monoclonal SP-antibody.

Specific labelling was seen at the lateral membranes of the epithelial cells, over the trachealis muscle and on singly lying cells in the lamina propria mucosae. The results are in general agreement with previous autoradiographic studies (Hoover and Hancock, J.Auton.Nerv.System, 19:171-174, 1987), but provide information on cellular localization of SP binding sites due to the higher resolution of immunohistochemistry.

230.1

GANGLIOSIDE EXPRESSION DURING SYNAPTOGENESIS *IN VITRO*.

J. Witt*[1], S. Fitzgerald*[2], P. Nelson[2] and J. Moskal[1] (SPON: P. Kornblith). [1]Dept. Neurosurgery and Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10467 and [2]LDN, NICHD, NIH, Bethesda, MD 20814.

Two model systems that undergo synapse formation, *in vitro*, were used in these studies; NG108-15 cells in coculture with fetal rat myotubes and murine dorsal root ganglia cocultured with spinal cord. Thin layer chromatograms of glycolipid extracts from various tissues were incubated with A2B5, a monoclonal antibody that recognizes a family of gangliosides. A2B5-positive bands, identified by autoradiography, were scraped from the TLC plates and quantitated by liquid scintillation spectrometry. In NG108-15 x muscle cocultures compared to N18TG2 x muscle cocultures (which do not make synapses) there was a marked decrease (approx. 50%) in a ganglioside that comigrated with GM2. Both NG108-15 x muscle and N18TG2 x muscle cocultures showed a 1.5 to 2-fold increase in two gangliosides-one comigrating with GD1a and the other with GT1b-compared to muscle, NG108-15 or N18TG2 cells cultured alone. In murine spinal cord (SC) cultures a ganglioside was identified that migrated between GD1a and GT1b. This ganglioside was not found in dorsal root ganglia (DRG) cultured alone or in SC x DRG cocultures. Further, a ganglioside that comigrated with GT1b was found to be reduced in SC x DRG cocultures by 70% compared to SC or DRG cells cultured alone. These results demonstrate that ganglioside expression undergoes significant modulation in cocultures capable of making synapses and that it may be possible to identify specific gangliosides that play a key role in synaptogenesis.

230.2

COLD ACCLIMATION INCREASES POLARITY OF GANGLIOSIDES IN SALAMANDERS. L.Irwin, K.Talentino*, J.Cohen*, C.Nelson*. Dept. Biology, Simmons Col., Boston, MA 02115

While the biological importance of ganglioside heterogeneity remains unexplained, growing evidence suggests that ganglioside patterns may be subject to ecophysiological adaptation within phylogenetically prescribed genetic limits. To test the influence of chronic temperature shifts on ganglioside patterns axolotls (Ambystoma mexicanum) were randomly assigned to groups acclimated for 3 weeks at either 15 C or 23 C. Metabolic rates were determined using closed-system dissolved oxygen analysis. Brain gangliosides were extracted with chloroform: methanol (2:1), isolated on a bed of silicic acid, purified by ion exchange and reverse-phase chromatography, and chromatographed on thin-layer plates of silica gel in chloroform:methanol: 0.2% aqueous calcium chloride. Individual gangliosides were visualized with resorcinol reagent and quantified by scanning laser densitometry. Gangliosides from the cold acclimated animals showed a consistent shift toward a higher concentration of more polar (tri- and tetrasialo-) molecules. Metabolic rates were significantly depressed in the cold acclimated salamanders as well. Studies are continuing to determine if ganglioside composition and metabolic rate are causally or coincidentally related. (We thank Biomed Instruments, Inc., for the loan of densitometry equipment and software.)

230.3

EXPRESSION AND SYNTHESIS OF GANGLIOSIDE 9-O-ACETYL-GD3 IN MOUSE GLIOMA C26 AND SUBCLONES. D.M. Bonafede, A.C. Missias* and M. Constantine-Paton. Dept. of Biology, Yale University, New Haven, CT 06511.

We are using the mouse glioma line C26 as a model for the synthesis and expression of ganglioside 9-O-acetyl-GD3, which has been implicated in migratory events in neural development (Mendez-Otero et al.,1988, J.Neurosci. 6: 564; Schlosshauer et al.,1988, J.Neurosci. 6: 580), as well as in malignancy (Cheresh et al.,1984, JBC 259: 7453). The JONES mAb (Constantine-Paton et al.,1986, Nature 324: 459) is used for detection of 9-O-acetyl-GD3 and mAb R24 (Pukel et al.,1982, J.Exp. Med. 155: 1133) for detection of GD3.

Approximately 30% of C26 glioma cells carry the JONES epitope on their surface. By limiting dilution subcloning we generated four lines, with expression ranging from 0 to 85%. Ganglioside extraction and HPTLC analysis showed the ganglioside profile of this tumor to be restricted to the GM3 synthetic pathway. C26 and the 3 positive subclones have abundant GM3, and varying levels of GD3 and 9-O-acetyl-GD3; the negative line has a synthetic block in the conversion of GM3 to GD3, which leaves GM3 as its only ganglioside.

Preliminary results from experiments in which negative cells, supplied with exogenous pure GD3 in their tissue culture medium (20 μM), incorporated GD3 in their plasma membranes (a 12 hour incubation was sufficient) and started expressing 9-O-acetyl GD3 (after 3 days), suggest that 9-O-acetyl-GD3 is synthesized from GD3 by acetylation of the terminal sialic acid, rather than by direct addition of an acetylated sialic acid to GM3. GD3 incorporation and conversion to 9-O-acetyl-GD3 were monitored by immunostaining with mAbs R24 and JONES, respectively.

We characterized the cell morphologies of the 4 subclones, and, because the different subclones seem to have different proliferation rates, we are using BrdU/FdU to detect any correlations between 9-O-acetyl-GD3/GD3 expression and cell division times.

CHRONIC OPIATE ADMINISTRATION INCREASES POLYSIALYLGANGLIOSIDES IN RAT BRAIN. J. Fishman*, M. Cahill*, and K. Carlson. Dept. of Pharmacology, U. Mass. Med. Sch., Worcester, MA 01655

Gangliosides and other sphingolipids have been shown to modulate a variety of cellular functions (Hannun and Bell [1989] Science 243, 500-507). Utilizing high performance thin-layer chromatography (HPTLC), we have observed that animals which have become physically dependent to the opiate agonist etonitazene (ET) by oral self-adminstration have significantly elevated polysialylgangliosides in synaptic vesicles from striatum, with no change in the monosialylgangliosides GM_1 or GM_3. In hippocampus, we observed decreases in GM_1, GD_{1a}, and GD_{1b}, but increased GT_{1b}. Small but variable changes in gangliosides were observed in cerebellum but no changes were observed in lower brainstem or cortex. Further observations with animals allowed to withdraw from opiate dependency for 2 days showed a potentiation of the ganglioside changes in striatum. Since chronic opiate administration alters monoamine metabolism and receptor binding kinetics in rat brain, the above changes in gangliosides may be responsible, at least in part, for the manifestation of physical dependency. ISOLATION AND PARTIAL CHARACTERIZATION OF A LAMININ/COLLAGEN RECEPTOR ON ASTROCYTES.

N.J.Tawil*,M.Houde* and S.Carbonetto. The Centre for Neurosciences, McGill University, Montreal General Hospital Research Institute, Montreal,Canada H3G 1A4.

We have reported (Turner et al., 1989, J.Neurosci. in press) the isolation of a monoclonal antibody (Mab 3A3) that inhibits neurite outgrowth by PC-12 cells on laminin (LN) and collagen (CN) as well as nerve regeneration in vivo (Toyota et al.,1988, Soc. Neurosci. Abstr.,14:498). Mab 3A3 detaches rat astrocytes in culture from LN and CN, but not from fibronectin or polylysine-coated substrata. Mab 3A3 does not bind to its electroblotted antigen but it does immunoprecipitate proteins of 180 and 125 kDa from detergent extracts of astrocytes. Antisera that recognize the β_1 subunit of the integrin family of heterodimeric, adhesive receptors crossreact in immunoblots with the 125 kDa protein immunoprecipitated by Mab 3A3. These and other data suggest strongly that Mab 3A3 recognizes a dual LN/CN receptor ($\alpha \approx 180$ kDa;$\beta_1 \approx 125$ kDa) of the integrin family. Immunocytochemical studies indicate that Mab 3A3 binds to some regions of the astrocyte surface in a pattern distinct from other β_1 integrins. We have immunoaffinity purified the LN/CN integrin from neonatal rats and have generated α and β_1 specific antisera. These reagents together with microsequencing of the protein will be valuable in molecular cloning of this integrin alpha subunit.

AVIAN NEURAL CREST CELL ADHESION TO LAMININ: CHARACTERIZATION OF A NOVEL INTEGRIN HETERODIMER.

T.E. Lallier and M. Bronner-Fraser. Developmental and Cell Biology, University of California, Irvine 92717

Neural crest cells adhere to and migrate avidly on laminin. *In vivo*, antibodies to a laminin-heparan sulfate proteoglycan complex, to the HNK-1 epitope, or to the β_1 subunit of integrin (CSAT) perturb cranial neural crest cell migration. *In vitro*, CSAT and HNK-1 antibodies block attachment of neural crest cells to laminin, suggesting that their proper migration requires interactions with a laminin-rich matrix.

Here, we describe two distinct mechanisms of neural crest cell adhesion to laminin using the quantitative cell adhesion assay of McClay. At low laminin coating concentrations (1 ug/ml), neural crest cell adhesion is inhibited by the HNK-1 and CSAT antibodies. This adhesion is unaltered over a range of divalent cation concentrations from 1 uM to 1 mM for Ca^{++}, Mg^{++} or Mn^{++}. At high laminin coating concentrations (10 ug/ml), neural crest cell adhesion is inhibited by the CSAT antibody, but not by the HNK-1 antibody. Adhesion at this coating concentration of laminin requires 1 mM Ca^{++} or Mn^{++} for binding, and these cations cannot be substituted by Mg^{++}. Neural crest cell adhesion to laminin at all coating concentrations is unaffected by heparin and sensitive to trypsin proteolysis. The E8 fragment of laminin acts similarly to intact laminin at high and low coating concentrations. In immunoprecipitates using the CSAT antibody, the HNK-1 antibody immunoblots a 105 kD glycoprotein under non-reducing conditions, possibly representing a new integrin subunit on the surface of neural crest cells. We conclude that neural crest cells possess multiple receptors for laminin which may function independently. (Supported by USPHS HD15527).

CHARACTERISTICS OF THE BINDING OF CRANIN TO LAMININ.
N. R. Smalheiser. Univ. of Chicago, Chicago, IL 60637.

Cranin is a 120 kDa laminin-binding membrane glycoprotein, found on the cell surfaces of neural and certain non-neural cells (N.S. and N. Schwartz, PNAS 84, 6457, '87). Binding of cranin to laminin is of very high apparent affinity; requires divalent cations; is destroyed by gentle proteolysis of laminin or cranin; and is blocked by polyclonal anti-laminin antiserum, but not by an antiserum against the cross-arm (E1 fragment) of laminin.

More recently, thermolability studies were performed. When laminin was heated for 20 min to 57-62°, laminin remained soluble, and structurally and antigenically intact, but binding was sharply lost. Heating to ~60° is known to denature the coiled-coil alpha helices in the long arm. Moreover, an antiserum to the end of the long arm of laminin (E3 fragment; gift of D. Hall, UCSF) blocked binding to cranin in 14 day embryonic chick brain, although an antiserum to the denatured, reduced distal portion (domain G) of the laminin A chain had no effect. Protease-, heat-, and antiserum-sensitivity all suggest that cranin binds within the long arm, though these treatments might exert effects on some other site within laminin. The role of N-linked carbohydrates was then investigated by treating cranin with N-glycanase or endo F. This did not affect its ability to bind laminin; its apparent MW shifted by ~10 kDa, but still appeared as a broad, fuzzy band. Cranin may play a role in mediating neurite growth, since conditions which abolish the ability of laminin to bind cranin also destroy the major neurite-promoting activity of intact laminin. ASSAY OF CELL ADHESION RECEPTOR INVOLVMENT IN NEURON-GLIA INTERACTION.
T. N. Stitt and M. E. Hatten, Dept. Pathology, Columbia University, College Of Physicians and Surgeons, New York, N.Y. 10032

Neuron-glia interactions are important to glial-guided neuronal migration, to the neuronal regulation of astroglial differentiation and to glial support of axon extension. To provide a rapid, specific assay for receptor systems involved in cell-cell contacts between granule neurons and astroglial cells, cerebellar granule cells, purified from early postnatal mice, were metabolically labelled with 35S-methionine, plasma membranes were prepared and the kinetics of binding of radiolabelled material to either primary glial cells or to the mouse G26-24 astrocytoma cell line (Stitt and Hatten, 1987) was measured in the presence or absence of antibodies against astrotactin, N-CAM, NILE, integrin, N-cadherin and the peptides RGD and YIGSR. Addition of astrotactin antiserum reduced granule cell membrane binding by 60% below control levels. N-CAM , NILE and N-cadherin, and integrin antisera had no effect. Inclusion of the fibronectin cell attachment peptide RGD (1 mg/ml) in the assay also did not reduce membrane binding, suggesting that integrin alone does mediate initial neuron-glial binding. Similarly addition of the laminin cell attachment peptide YIGSR (1 mg/ml) failed to block membrane binding. These results are consistent with results from *in vitro* blocking assays with a microculture system (Edmondson *et al*, J. Cell Biol. 106:505, 1988). Experiments are in progress to analyze the effects of combinations of anti- N-CAM, NILE and integrin antibodies with RGD and YIGSR peptides.

230.9

BIOSYNTHESIS OF NEURAL CELL ADHESION MOLECULE IN CHICK MYOTUBES.
J.M.LYLES and C.L.WEILL. Dept. of Neurology, Louisiana State Univ. Med. Center, New Orleans, LA 70112.

The neural cell adhesion molecule (NCAM) is expressed in skeletal muscle as several Mr forms: 120K and 150K which are attached to the external cell surface via phosphoinisitol tails and 140K which is membrane inserted. We have examined NCAM biosynthesis by S-35 methionine labelling in cultured chick myotubes. The main polypeptide initially synthesized has an Mr of 172K; lesser amounts of 146K and 134K forms are also synthesized. Their size range broadens during chase periods, indicating glycosylation, including polysialation, and processing, to yield forms of: 165-172K, 144-150K and 125-138K, which correspond to the desialated 150K, 140K and 120K forms. Secreted NCAM was detected with an Mr of 200K and is not appearently highly glycosylated. Degradation studies indicate two populations of NCAM: one with a short half life of circa 4 hours and a longer lived species. Hence, the production of different forms with different cellular localizations and half-lifes may modulate the role of NCAM in cell adhesion in vivo.

230.10

STRUCTURE AND CHARACTERIZATION OF NG-CAM AND A CLOSELY-RELATED MOLECULE.
M. Grumet, M.P. Burgoon*, V. Mauro*, G.M. Edelman, & B.A. Cunningham*. Rockefeller Univ. NY NY 10021.

The neuron-glia cell adhesion molecule, Ng-CAM, is a glycoprotein found only on neurons and Schwann cells which binds specifically to the surfaces of neurons and astroglial cells. The molecule is comprised of components of Mr 200,000 and 135,000 which have identical amino acid sequences for at least the first 20 residues and an Mr 80,000 which is immunologically related to the Mr 200,000 but not to the Mr 135,000. To study the structure of Ng-CAM in detail, we searched for cDNA clones in libraries prepared from chick embryo brain mRNA. A 105 bp cDNA probe for Ng-CAM was synthesized in a polymerase chain reaction using as primers oligonucleotides based on amino acid sequences within the Mr 135,000 polypeptide. This probe recognized a cDNA clone with a 1.2 kb insert which in Northern blots of embryonic chick brain hybridized to at least one mRNA species $\geq$6 kb which is long enough to code for the Mr 200,000 polypeptide. Sequence analysis of this and related clones confirmed that they correspond to Ng-CAM by extensive matches to amino acid sequences of fragments within the Mr 135,000 polypeptide. Moreover, several repeated domains were identified which are homologous to C2 domains of immunoglobulins indicating that, like N-CAM and other CAMs, Ng-CAM is a member of the immunoglobulin superfamily. We have also identified cDNA clones which are homologous to but distinct from Ng-CAM and other CAMs suggesting that they may represent a new molecule, possibly a CAM. Supported by NS21629 & NS22789.

230.11

ADHESION MOLECULE AMOG IS HOMOLOGOUS TO A Na,K-ATPase BETA SUBUNIT.
K.J. Sweadner, H. Antonicek*, and M. Schachner. Mass. General Hospital, Boston, MA 02114, and U. Heidelberg, Heidelberg, FRG.

AMOG (adhesion molecule on glia) was implicated in neuron-astrocyte adhesion by the blocking effects of a specific monoclonal antibody (Antonicek et al., 1987. J. Cell Biol. 104, 1587-1595); purified AMOG in liposomes binds to subclasses of neurons (Antonicek & Schachner, 1988. J. Neurosci. 8, 2961-2966). Immunoaffinity-purified AMOG antigen has subunits resembling the α (catalytic) and β (glycoprotein) subunits of the Na,K-ATPase, but the smaller subunit alone is sufficient for adhesion. A cDNA coding for AMOG was cloned (Pagliusi et al., 1988. J. Neurosci. Res. 22, 113-120), and subsequently sequenced (Gloor et al., submitted). It is the same as an independently-cloned protein (tentatively named β2) that is 35% identical to the β subunit of the Na,K-ATPase (Martin-Vasallo et al. 1989. J. Biol. Chem. 264, 4613-4618). Here we show that AMOG/β2 specifically associates with certain Na,K-ATPase α subunit isoforms.

Purified Na,K-ATPase from brain and immunoaffinity-purified AMOG have subunits with indistinguishable electrophoretic mobilities in SDS. Polyclonal antisera raised against AMOG reacted with both subunits of Na,K-ATPases purified from brain and kidney, and antisera raised against purified Na,K-ATPase reacted with immunoaffinity-purified AMOG subunits. Epitope differences were revealed, however, by the relative intensity of the cross-reactivity. Monoclonal antibodies raised against the α subunit of AMOG reacted preferentially with the α2 and α3 isoforms of Na,K-ATPase, while isoform-specific Na,K-ATPase monoclonal antibodies detected α2 and a small amount of α3 in purified AMOG. AMOG/β2 distribution in the brain, like that of the α isoforms, is widespread but heterogeneous at the cellular level. Adhesion is a new role postulated for the β subunit of the Na,K-ATPase, which is well-known to face the cell exterior.

230.12

HIGH AND LOW AFFINITY OUABAIN-BINDING SITES OF NA,K-ATPASE IN RAT BRAIN DEMONSTRATED BY QUANTITATIVE AUTORADIOGRAPHY.
A.A. Maki*, P.E. Filuk*, D.G. Baskin and W.L. Stahl (Spon: D. Farrell). V.A. Medical Center and Univ. Washington Sch. Med., Seattle, WA 98108.

Quantitation of the number of ouabain binding sites in identified regions of brain at high anatomical resolution is desirable in order to understand long-term regulation of the Na,K-pump and its modification in disease states. The cellular distribution of high and low affinity ouabain-binding sites in brain is largely unknown. Sites with high affinity for ouabain can be demonstrated in tissue sections by quantitative autoradiography (QAR)(Antonelli et al., J. Neurochem. 52:193-200, 1989). However, it was unclear if low affinity sites could be identified. In order to answer this question equilibrium binding studies were carried out with 1-5000 nM [^{3}H]ouabain. Binding kinetics were studied at 50 nM and 1500 nM. Specific low affinity sites were found in rat somatosensory cortex(SSC) and both kinetic and equilibrium studies yielded similar K_d values (589-728 nM). Binding at these sites was blocked by K^+ (IC_{50}=4 mM). Specific high affinity sites in lamina 3-4 of SSC also had similar K_d values (8-17 nM). These high affinity binding sites were blocked by erythrosine B (IC_{50}=10 μM) and K^+(IC_{50}=1.4 mM). Therefore, the QAR method permits discrimination and quantitation of both high and low affinity [^{3}H]ouabain-binding sites in nervous tissue.

230.13

PRODUCTION AND CHARACTERIZATION OF POLYCLONAL ANTIBODIES TO NA,K-ATPASE. J.H. Peng and J.C. Parker, Jr.* Dept. of Pathology, Univ. of Missouri-Kansas City Sch. of Med., Truman Med. Ctr., Kansas City, MO 64108.

We have recently reported the purification of Na,K-ATPases from human and rat brainstem tissues. In order to characterize Na,K-ATPase immunochemically, we have further prepared polyclonal antisera to these antigens. Each rabbit was immunized bi-weekly with 100 ug of the highly purified preparations initially emulsified with an equal volume of Freund's complete adjuvant, and subsequently boosted with antigen emulsified with incomplete adjuvant by subcutaneous injection at many sites of the neck and scapular regions. Ten days after the last immunization, antisera were obtained through cutting of the marginal ear vein. Antisera were checked for their immunoreactivities by Western blotting using peroxidase-anti-peroxidase method and chloronaphthol as a chromogen. All sera showed strong immunoreactivity with titers of 8,000 for anti-rat, and 4,000 for anti-human Na,K-ATPase sera. All sera cross-reacted well with alpha 2 bands, but less with alpha 1 bands. Anti-human sera cross-reacted strongly with human enzyme, but weakly with rat enzyme, and vice versa. The patterns of immunoreactive fragments were found to be different, when blots of the protease-digested peptide fragments of the alpha 1 and alpha subunits were stained with these specific antisera. These antisera will be a valuable reagents for immunocytochemical localization.

230.14

CHARACTERIZATION OF A Na, K - DEPENDENT ADENOSINE TRIPHOSPHATASE FROM A PLANARIAN. L. G. Hammerland* and J. F. Ash*. (SPON: V. Yip). Dept of Anatomy, Univ. of Utah Sch. of Med., Salt Lake City, UT 84132.

Although the Na,K-ATPase is assumed to be a ubiquitous and vital component of animal cell membranes, biochemical and molecular analyses have been focused on a few examples among vertebrates and crustacea. A wider evolutionary study of this enzyme might help elucidate important features, such as structure/activity relationships, the role of the inhibitory ouabain binding site and the significance of different isoforms seen, for instance, in neurons versus glia. We have surveyed a number of primitive invertebrates for ouabain toxicity and found that ouabain killed freshwater planaria, but not hydra.

In this study we have obtained a subcellular membrane fraction from the brown planaria, *Dugesia dorotocephala*, and initiated a characterization of associated ATPase(s). A Na^+ and K^+ stimulated, ouabain inhibited activity is the major ATPase in this fraction. The apparent K_ms for Na^+ (7.7 mM) and K^+ (1.2 mM) are similar to those vertebrate enzymes. The apparent K_i for ouabain is <10 μm. As seen with purified vertebrate Na,K-ATPase, the planaria enzyme appears to have a high affinity FITC binding site which has allowed us to estimate the MW of the catalytic α subunit (110-115 kD) by electrophoretic mobility. This is significantly larger than the value obtained for a vertebrate α subunit. (Supported by NSF Grant DCB 8517961)

230.15

FOLATE TRANSPORT BY BRAIN SLICES AND CNS CELL LINES. S.R. Snodgrass, Z.H. Zhang and M.H. Morita* (SPON:M.C. Citron). Neurology Research Lab., Childrens Hospital Los Angeles and Dept. Neurol., Univ. So. Calif. Schl. of Med., Los Angeles, CA 90027.

Distribution and uptake of folates within the CNS may explain their selective neurotoxicity. The only published study of brain folate transport reported that uptake of 5-methytetrahydrofolate (MTHF) was not found (J. Neurochem. 29:121,1977). We studied the uptake of 3H folic acid (FA) and 3H MTHF by rat brain slices, cultured mouse astrocyte PC12 cells, and C6 rat glioma cells. All showed saturable uptake of both FA and MTHF. Transport of each is inhibited by the other and by methotrexate. Transport of each was inhibited by pterin, reported to have no effect on peripheral folate uptake. Differences between preparations included absence of high affinity MTHF uptake in C6 cells, stimulation of MTHF uptake in NGF treated PC12 cells, and stimulation of FA but not MTHF uptake in PC12 cells by growth in folate-depleted media. Our data suggest but do not prove that at least two different folate uptake systems exist in the CNS. Autoradiographic studies of uptake in brain slices are an important part of this analysis and will be shown. CNS and peripheral folate transport differs.

PROCESS OUTGROWTH, GROWTH CONES AND GUIDANCE MECHANISMS II

231.1

DYNAMICS OF SENSORY NEURON DEVELOPMENT IN *DROSOPHILA MELANOGASTER*. K.E. Whitlock* and J. Palka. Dept. of Zoology, University of Washington, Seattle, WA 98105.

The arrival time of sensory axons in the central nervous system and their behavior prior to the establishment of the definitive adult projection pattern has not previously been described in *D. melanogaster*. We have studied sensory neurons arising in the wing by staining them in fixed tissue with the fluorescent dye 1,1'-dioctadecyl-3,3,3',3 -tetramethylindo-carbocyanine perchlorate (di I), (Godement, P., et al., Development 101, 1987). We find sensory axons in the CNS as early as 9-12 hours after pupariation (25°C), and all components of the adult pattern are present by 36 hours. The sequence of axon arrival in the CNS parallels the development of their corresponding sensory populations in the periphery. Growth cones, numerous in the entering nerve bundle, become concentrated at the leading edge of growing axon projections. Solitary, apparently exploratory fibers with prominent growth cones are often seen but are usually confined to the area that will contain the final adult wing sensory projections. The developing sensory tracts have a fuzzy appearance due to the presence of abundant short branches, possibly reflecting growth cone exploration. With the passage of time these are lost and the mature tracts look smooth except in areas of terminal axon arborization, suggesting the opperation of a selective pruning process during the early development of the sensory projections.

231.2

PUTATIVE MUSCLE PIONEERS IN THE DEVELOPMENT OF THE *DROSOPHILA* EMBRYONIC MUSCULATURE. M.E. Halpern, J. Johansen and H. Keshishian. Biology Dept., Yale Univ., New Haven, CT.

In *Drosophila* embryos the bodywall muscle fibers are arranged in the final segmental pattern by 13 hours post-fertilization (stage 16), and are contractile by 16 hours. Previously we discovered that precise features of motoneuronal outgrowth and growth cone exploration lead to highly stereotypic muscle fiber-specific axonal projections. We now describe the development of the target muscle fibers in relation to the timing of neurite outgrowth and neuromuscular innervation, from studies at the light microscope level and from Lucifer yellow dye-filling of presumptive precursor cells in staged embryonic filets. At 9-10 hours (stage 13), when the first axons exit the CNS, the mesodermal somatopleura consists of segmented clusters of unfused spheroidal cells. However, intracellular dye-fills reveal larger, segmentally repeated cells that share several properties with grasshopper muscle pioneers, including a bipolar shape, extended growth cone-like processes at each end, and an early appearance among the developing myoblasts. Within an hour (stage 14), mesodermal cells aggregate and fuse to form muscle fibers. Lucifer yellow fills at this stage indicate transient dye-coupling between developing longitudinal muscle fibers. By stage 15, coupling is lost and each muscle fiber is an independent syncytial cell. The onset of phalloidin staining at late stage 15 indicates the presence of filamentous actin in the muscle sarcomeres. Shortly afterwards (stage 16), as a result of the coordinated program of axonal outgrowth, the first neuromuscular contacts are made synchronously throughout the bodywall, and the neurotransmitter glutamate is detectable in motoneuronal endings. Time lapse video microscopy and the use of muscle-specific markers will enable us to examine further the role of the *Drosophila* putative muscle pioneers in the development of the musculature. These observations indicate that the mechanisms underlying the organization of embryonic muscle patterns are broadly conserved among insects.

231.3

GROWTH CONES OF MONOPOLAR AND MULTIPOLAR NEURONS IN *DROSOPHILA* LARVAL CNS CULTURE DIFFER IN MORPHOLOGY AND MOTILITY Yun-Taik Kim* & Chun-Fang Wu (Spon: M. Burg). Dept. of Biology, University of Iowa, Iowa City, IA 52242.

Growth cones play a central role in axonal guidance and branching and establishing synaptic connections. Thus, morphological differences between neuronal types might in part result from intrinsic differences among their growth cones. We examined the growth cones of monopolar and multipolar neurons in dissociated larval *Drosophila* CNS cultures (Wu *et al.*, *J. Neurosci.* 3:1888, 1983) with phase-contrast optics. Analysis of contrast-enhanced video images indicated that growth cone morphology can be well characterized by several morphometric parameters including the number and length of filopodia, and area, roundness, convexity and concavity of lamellipodium boundary. In addition, the growth cone dynamics is best described by the motility index and boundary flow plots.

We found that the overall composition of nerve cell types was strikingly different among cultures prepared from different CNS regions. Monopolar neurons were the major cell type in brain cultures while multipolar neurons were predominant in ventral ganglion cultures. Moreover, the growth cones of monopolar and multipolar neurons show intrinsic differences in their morphology and motility. Compared to multipolar neurons, growth cones in monopolar neurons have larger lamellipodia of less erratic shape accompanied with fewer and shorter filopodia, which are correlated with higher motility and less directionality in motion. These morphological and behavioral distinctions may result from differences in adhesion and transport properties that may reflect intrinsic differences in axonal and dendritic growth cones.

Supported by NIH grants NS 26528 and HD 18577.

231.4

PROJECTION OF MOTOR AXONS IN HYPEREXCITABLE *DROSOPHILA* MUTANTS. V. Budnik, Y. Zhong*, and C.-F. Wu. Dept. of Biology, University of Iowa, Iowa City, IA 52242.

There is considerable evidence in vertebrates that nerve connectivity can be influenced by electrical activity. The body wall muscles of *Drosophila* larvae provide a promising invertebrate preparation in which to study the role of excitability in the development and maintenance of muscle innervation. The ventral longitudinal muscles have been the focus of extensive electrophysiological investigation. In addition, mutations are available which either eliminate nerve activity, or increase excitability and enhance neuromuscular transmission in these muscles.

We have initiated an anatomical study of neuromuscular junctions in mutants which affect electrical activity by analyzing mutants which induce hyperexcitability. To visualize nerve terminals we have used anti-HRP immunocytochemistry.

Wild-type ventral longitudinal muscles are innervated in a relatively stereotypic fashion. In muscles 12 and 13, for example, a projection from the segmental nerve branches off over the muscles giving rise to sparsely branched neurites which run approximately parallel to the muscle fiber. We found that in *ether a go-go* (*eag*) mutants, and more dramatically in *eag Shaker* double mutants, this basic pattern of innervation is altered. The alterations can be described as substantial ramification of neurites throughout the muscle fiber, an increase in the density of varicosities, and, as a result, an increase in the total number of varicosities. Preliminary results indicate that these alterations can be reversed by introducing a mutation which reduces nerve excitability in the double mutant background. Supported by NIH grant NS 26528.

231.5

NAVIGATION DECISIONS BY PIONEER NEURON GROWTH CONES *IN VIVO*. **J.S.Duerr, T.P.O'Connor, and D. Bentley, Department of Molecular and Cell Biology, University of California, Berkeley, CA 94720.**

In grasshopper limb buds, the Til pioneer neurons establish a stereotyped pathway from the periphery to the central nervous system. DiI was used to label living Til neurons in a semi-intact preparation. The behavior and morphology of extending growth cones and filopodia were observed for several hours with computer-enhanced fluorescent video microscopy. Growth cone morphologies and filopodial arrays differed in different regions of the limb, correlating well with morphologies observed in fixed tissue. Growth cone behavior during two steering events was observed. The normal pathway contains turns at two presumptive navigation cues, the trochanter/coxa segment border and the Cx1 guidepost neurons. Growth cone behavior differs at these two decision points. At the segment border, the growth cones usually send branches in opposite directions along the presumptive border; the 'incorrect' branch is eventually withdrawn. At the decision point for the turn to the Cx1 neurons, the first major branch to leave the trochanter/coxa border usually forms in the correct direction. Examination of living pioneer neurons reveals different behaviors by growth cones and filopodia in regions hypothesized to differ in the type of guidance cues which they provide.

231.6

DEVELOPMENTAL EXPRESSION AND PURIFICATION OF A NERVOUS SYSTEM SPECIFIC ANTIGEN FROM GRASSHOPPER. Rolf O. Karlstrom* and Michael J. Bastiani (Spon: J. Pollock), Dept. of Biology, Univ. of Utah, Salt Lake City, UT 84112.

Surface molecules specific to the nervous system during embryogenesis may play a role in the cellular interactions necessary for nervous system development. The 1C10 MAb recognizes an antigen specific to the nervous system in grasshopper embryos. The antigen was determined to be on cell surfaces by labelling live embryos.

The 1C10 antigen is first expressed on presumptive ectodermal cells and at the gastrulating midline early in development (10-20%). Later, neural ectoderm cells, some neuroblasts, and developing sensory structures in the legs and body wall express the 1C10 antigen. During the period of rapid neuron generation from 35-50% of development, neuroblasts and their families of ganglion mother cells and neurons express high levels of the antigen. Axons express the antigen from the time of early axon formation (30-33% of development) to approximately 60% of development, when axonal expression is no longer seen. This window of axonal expression coincides with the developmental period when complex axonal pathfinding establishes the embryonic nervous system. Antigen expression is seen on nerve cell bodies and a subset of glial cells into the adult.

The 1C10 MAb immunoprecipitates a 38 kD doublet from embryonic membranes. Using a MAb affinity column microgram quantities of the antigen have been purified. Sequencing attempts show the amino terminal is blocked. We are continuing to purify the 1C10 antigen in order to generate polyclonal serum and for the generation of peptide fragments for sequencing.

(Supported by NIH grant NS25387, McKnight Scholars Award, and NSF Graduate Fellowship to R.O.K.)

231.7

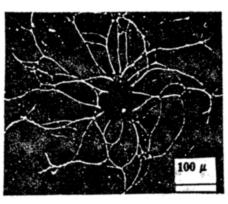
RESTRICTED SPATIAL AND TEMPORAL EXPRESSION OF A NERVOUS SYSTEM SPECIFIC ANTIEN DURING DEVELOPMENT OF THE GRASSHOPPER. E.C.Seaver*, R.O.Karlstrom*,andM.J.Bastiani(SPON: D. Yoshikami). Dept. of Biology, Univ. of Utah, SLC, UT 84112.

In an attempt to identify molecules important for pathfinding of growing axons, monoclonal antibodies(MAb) have been generated against embryonic grasshopper tissue. One MAb, 2B2, specifically recognizes developing neurons in the grasshopper. The expression pattern of the antigen(s) recognized by the 2B2 MAb was examined over the entire course of embryonic development. Initial labeling occurs at 30% of embryonic development when the first growth cones are extended. During early neurogenesis the MAb appears to recognize all axons in the CNS. In contrast to fasciclin I, II, and III, the antigen(s) recognized by the Mab is not seen outside the nervous system. As embryonic development proceeds (70%) the labeling pattern becomes restricted to a subset of axons within each ganglion in a segmentally repeated pattern. This pattern continues throughout the remaining period of embryonic development. Preliminary evidence suggests that the 2B2 MAb does not label adult grasshopper ganglia.

Immunoprecipitation of the antigen(s) recognized by the 2B2 MAb from grasshopper embryonic tissue yields a band of 160kD and possibly of 38kD when analyzed by SDS PAGE. Labeling of live embryos and electron microscopic studies indicate that the antigen recognized by the 2B2 MAb is a cell surface molecule.

The restricted spatial and temporal pattern of expression of the antigen(s) recognized by this MAb during embryogenesis suggests a specific role in the development of the nervous system.(Supported by the McKnight Foundation and NIH grant #NS25387.)

231.8



A SIMPLE METHOD FOR GROWING AND MAINTAINING DISSOCIATED *HERMISSENDA* CNS NEURONS IN CULTURE. S. Sombati, R. Forman, R. Lee* and R. DeLorenzo, Dept. Neurology, Medical College of Virginia - VCU, Richmond, Va. 23298.

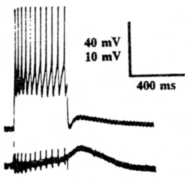
The mollusc *Hermissenda* is a popular experimental preparation for the study of cellular physiology and neuronal plasticity. Analysis of some biophysical, pharmacological and biochemical properties of CNS neurons, including synaptogenesis, have until now been limited by the unavailability of neurons in culture. We report here a simple method for culturing *Hermissenda* neurons.

The brain of *Hermissenda* was treated with protease (Sigma type XXIV, 2mg/ml) for 40 min at 22°C. After wash, neurons of interest, including the identified neuron LP1, were dissociated in a 35 mm culture dish containing 8-10 drops of the culture medium (isotonic L-15 solution plus 10% FCS) on a poly-lysine coated glass cover slip (PCGS). The cultures were maintained at 15-18°C and fed twice weekly.

Three factors seemed to be critical to obtaining successful cultures: 1) the degree of enzymatic treatment; 2) the temperature at which the cells are maintained during culture; and 3) use of PCGS as the substrate for cell attachment.

Most large cells (soma >50μ) were multipolar. These neurons had numerous, long (1 mm at day 3) and highly branched processes emerging from the soma (see figure). Some smaller neurons exhibited either monopolar or bipolar morphology. Often, many neurons appeared to have their processes intermingled.

Cultured neurons could be maintained up to 3 weeks and are suitable for physiological, pharmacological, biophysical and biochemical investigations, some of which are currently being undertaken in our laboratory.



231.9

MEMBRANE PROPERTIES AND CONNECTIVITY OF *HERMISSENDA* NEURONS IN CULTURE. R. Forman, S. Sombati, R. Lee*, and R. DeLorenzo, Dept. Neurology, Medical College of Virginia - VCU, Richmond, VA. 23298.

Individual neurons were isolated from the CNS of the nudibranch mollusc *Hermissenda* and maintained in culture for periods of up to 21 days. Within 24h following dissociation, these cells initiated neurite outgrowth, typically from multiple sites on the soma. Cells with no closely neighboring cells often showed symmetrical patterns of neurite outgrowth, while cells plated at higher density showed selective orientation of their processes with respect to one another.

Conventional electrophysiological recording techniques applied to 30 neurons ranging in age from 1 to 7 days revealed resting potentials between -40 and -70 mV, overshooting action potentials in response to depolarizing current stimuli, varying degrees of spike frequency adaptation during long depolarizations and prolonged afterhyperpolarizations following spike trains. All these observations were within the range of similar phenomena recorded from *Hermissenda* neurons *in situ*.

Pairwise recording from cells with intermingled processes showed evidence for both rectifying and non-rectifying electrical coupling and for chemically mediated transmission (see figure). A cultured identified neuron (LP1) formed rectifying electrical junctions with neighboring cells. Evidence for chemical transmission included synaptic delay and changes in the amplitude of post-synaptic potentials as a function of external [Ca^{2+}] and of postsynaptic membrane potential.

GROWTH CONES OF APLYSIA NEURON L10 EXHIBIT TARGET-SPECIFIC BEHAVIORS. D. Hawver and S. Schacher, Dept. Pharmacology & Ctr. Neurobiol. & Behav., Columbia CPS & NYS Psych. inst., New York, NY 10032.

We have previously shown that selective synapse formation in vitro by neuron L10 of Aplysia is associated with specific patterns of neurite outgrowth (Hawver and Schacher, Soc. Neorosci. Abstr. 14:749, 1988). L10 neurites adhere to and extend along appropriate targets (RB neurons), while crossing over or turning away from inappropriate targets (RUQ neurons). To explore the mechanisms responsible for the generation of these patterns, we have used phase and fluorescence microscopy to examine the early interactions of L10 growth cones with both RB and RUQ growth cones and neurites. While the majority of L10 interactions with either RB or RUQ resulted in L10 crossing over the target (RB:58% n=19, RUQ:45% n=22), a large fraction of L10-RB contacts resulted in adhesion and overlapping of L10 along the target neurite (37%), compared to only 9% of L10-RUQ contacts. In contrast, L10-RUQ interactions were often characterized by either retraction of contacts (23%) or by edge-skirting behavior(23%) -- turning to follow along the edge of the target by repeatedly establishing and retracting contacts without overlapping. Only 5% of L10-RB interactions resulted in retraction of contacts, and none exhibited edge-skirting behavior. When a single L10 cell was cultured with both RB and RUQ cells, multiple types of interactions were observed. This suggests that the growth cone behaviors which lead to the formation of target-specific patterns are mediated by signals acting locally, at the level of individual growth cones, rather than cell-wide.

231.11

REQUIREMENT OF CALMODULIN FOR CALCIUM MEDIATED CHANGES IN GROWTH CONE MOTILITY. K.A. Polak*, A.M. Edelman*, M.H. Xia* and C.S. Cohan (SPON: D.M. Higgins). Dept. of Pharm. & Ther., Dept. of Anat. Sci., SUNY Buffalo, Buffalo NY 14214.

In neuron B19, isolated from the buccal ganglion of *Helisoma trivolvis*, it has been demonstrated that changes of intracellular calcium levels influence growth cone motility and neurite elongation. Neurotransmitters such as serotonin (5-HT), which increase intracellular calcium levels presumably through receptor mediated activation of membrane calcium channels, suppress neurite elongation. The mechanism(s) by which changes in intracellular calcium regulate neurite elongation have not yet been characterized. As some of the effects of calcium in a variety of systems are mediated by calmodulin, we tested the possibility of such an interaction in the regulation of neurite outgrowth. In these experiments a new calmodulin antagonist with increased selectivity, CGS9343B (CGS), was used to inhibit calmodulin activity during the application of serotonin to B19. Subsequent effects on growth cone movements and neurite elongation were then analyzed.

Identified neurons B19 were isolated and cultured in conditioned medium. Rates of growth cone advance were measured over a 120 minute period of which the first 45 minutes served as a control period. In addition, total cell outgrowth was determined after approximately 48 hours in culture.

The addition of 100μM 5-HT to the culture medium resulted in a significant decrease in rate of growth cone advance ($p<.001$), as reported previously. However, administration of 1.8μM CGS to the culture medium prior to 5-HT blocked inhibitory effects of 100μM 5-HT, both on rate of growth cone advance and total outgrowth. CGS alone had no significant effect on either parameter. Preliminary experiments indicate that CGS is not acting at membrane calcium channels as a competetive antagonist. These observations suggest that calmodulin may play a regulatory role in mediating the effects of calcium on growth cone movements.

231.12

ELECTRICAL STIMULATION DIFFERENTIALLY EFFECTS GROWTH CONES OF DIFFERENT IDENTIFIED NEURONS. C.S. Cohan and M.H. Xia*. Dept. of Anatomical Sciences, SUNY Buffalo, Buffalo, New York 14214.

A variety of signals have recently been shown to alter neurite outgrowth by influencing growth cone movements. One signal, action potentials, when generated in the cell bodies of *Helisoma* neurons, reversibly inhibits growth cone motility. The quantitative features of electrical activity may play an important role in determining neuronal growth responses. In the present experiments, changes in stimulation frequency were used to assess 1) how the parameters of electrical activity influence growth cone movements and 2) whether different identified neurons respond differently to the effects of electrical activity.

Identified *Helisoma* neurons B4 and B19 were isolated from buccal ganglia and cultured in conditioned medium. Twelve hr after plating, neurons were stimulated by an intracellular microelectrode within the cell body while growth cone movements were measured. During experiments neurons were observed for a 45 min control period, followed by a 45 min stimulation period, followed by a 45 min recovery period.

Growth cones of neurons B4 and B19 exhibited a decrease in growth rate at a threshold frequency of 2/sec. Higher stimulation frequencies caused greater inhibition of growth rates indicating that stimulus frequency had a graded effect on growth cone movements. However, B4 was significantly more sensitive to stimulation than B19. For example, at 2/sec B4 growth rates were inhibited by 58% whereas B19 growth rates were inhibited only by 29%. Moreover, B4 displayed a unique effect; growth rates *increased* during the recovery period for stimulation frequencies of 1 and 2 per sec. These data indicate that growth cones of different *Helisoma* neurons respond differentially to electrical activity.

231.13

CADMIUM MIMICS THE EFFECTS OF AXOTOMY ON THE ACTION POTENTIAL IN AN IDENTIFIED NEURON OF HELISOMA. P.J. Kruk and A.G.M. Bulloch. Department of Medical Physiology, University of Calgary, Calgary, Alberta, Canada, T2N 4N1.

After axotomy, the action potential (AP) of buccal neuron 4 (B4) of the freshwater snail Helisoma shows a loss of pseudoplateau on the declining phase. In principle, this could be due to the axotomy-induced elevation of intracellular calcium, which can block calcium inward current and/or activate calcium dependent potassium outward current. This study was designed to determine which of these two currents, if either, is actually affected by axotomy.

The AP of B4 was recorded in an acute preparation that did not alter morphology of the neuron. The AP waveform recorded both from (1) B4 in normal saline two days after in situ axotomy, and (2) from intact B4 in saline containing 0.1 mM cadmium sulfate, exhibited identical changes (loss of pseudoplateau) when compared to the normal waveform. Neither resting potential nor input resistance of B4 were significantly affected by axotomy or cadmium.

These results suggest that the axotomy-induced changes in the AP waveform result from a modulation of calcium conductance rather than from a modulation of calcium-dependent potassium conductance.

231.14

LAMININ IMMUNOREACTIVITY IN THE CNS OF THE SNAIL, *HELISOMA TRIVOLVIS*. J. D. Miller* and R. D. Hadley. Dept. Anat. & Cell Biol., Med. Univ. S. C., Charleston, S.C. 29425.

The extracellular matrix (ECM) is involved in many morphogenetic processes including neuroblast migration and synaptogenesis. In this study, evidence is presented supporting the hypothesis that a **laminin-like** molecule is present in the ECM of *Helisoma* brain tissue. We suggest that this molecule may function as a neurite outgrowth promoting factor (NOPF) in *Helisoma* conditioned media (CM).

Immunofluorescence of snail brain utilizing an antibody directed against mouse EHS tumor laminin (EHS-LAM) revealed a basement membrane and intensely labeled cells within the ganglionic sheath. Identical (though less intense) fluorescence was obtained with an antibody directed against the B chains of EHS-LAM, whereas an antibody directed against the A chain showed no specific reactivity.

On Western blots of Triton-extracted brain tissue, antibodies directed against whole EHS-LAM recognized multiple proteins of ~400kD under reducing conditions and one protein of ~120kD under both reducing and non-reducing conditions. The same antibody showed no reactivity on blots of CM. On blots of both reduced brain tissue and reduced CM, antibodies directed against EHS-LAM B chains showed specific recognition of a protein between ~500-700kD and multiple proteins between ~200-450kD. This antibody showed no specific reactivity on blots of gels run under non-reducing conditions.

Triton-extracted brain tissue (but not EHS-LAM) supported the outgrowth of *Helisoma* neuron B5 in culture. We are presently investigating the possibility that the laminin-immunoreactive proteins described above are related to and/or function as the NOPF in *Helisoma* CM.

This work was supported by a Fellowship from the Klingenstein Foundation to RDH. We thank Dr. Roy Ogle for his generous gift of antibodies.

ACTIVITY DEPENDENT LOCALIZED CALCIUM ENTRY IN ISOLATED LEECH NEURONS IN CULTURE. N. Lasser-Ross*, S.R. Young and W.N. Ross. (SPON: F. Horvath) Dept. of Physiology, N.Y. Medical College, Valhalla, NY 10595.

Individual leech neurons, including their axon stumps, can be removed from segmental ganglia and will sprout new processes in culture (Dietzel et al. (1986), J. Physiol. 372, 191-205). Selected cells were grown on Con A and injected with fura-2 free acid. A sequence of high spatial resolution fluorescence images (excitation at 380 nm) was acquired with a CCD camera while the cell was intrasomatically stimulated to fire single action potentials. The location and magnitude of calcium entry were determined from the normalized change in fluorescence intensity following the action potential. In Retzius cells low level changes were detected in most of the soma. A larger signal was detected in the axon stump with the highest levels found where the processes sprouted from the tip. Calcium entry into new processes was detectable but at a much lower level than into the rest of the cell. In cells without an obvious stump the highest level of calcium entry was found where the new processes sprouted from the soma. Since these cells have been shown to be isopotential (Ross et al. (1987) J. Neurosci. 7, 3877-3887) the location of calcium entry also indicates the location of voltage dependent calcium channels.

Supported by the NIH and the Whitaker Foundation.

GROWTH-INHIBITING INTERACTIONS BETWEEN GROWTH CONES OF SEGMENTAL HOMOLOGUES IN THE LEECH CNS. W.-Q. Gao and E.R. Macagno. Dept. of Biological Sciences, Columbia University, New York, NY 10027.

In vitro studies have documented inhibitory interactions that result in growth cones stopping or slowing their growth. We have been examining this phenomenon *in vivo* in the leech CNS, where we have found that several neurons extend transient longitudinal projections (*J. Neurobiol.*, 18:295, 1987). Neighboring AP neurons, for example, extend oppositely-directed projections along the same paths in the interganglionic connectives. Their growth cones meet one other at about halfway between the segmental ganglia and grow past each other only a short distance before they stop. They remain near each other for a few days before the projections disappear altogether. Ablation of one of the homologues before the projections begin to atrophy, however, induces the remaining stopped growth cone to extend again (see above reference). When we examined the growing tips of these projections in their initial stages in the light microscope at high magnification, we observed typical growth cone features, including enlarged flattened regions as well as numerous filopodia, suggesting that they were growing vigorously. Soon after meeting each other, however, these growth cones became smaller and increasingly simpler, with fewer filopodia. Examination of restarted growth cones following ablation of the homologue shows that they do not reestablish their initial morphologies (i.e., large size and many filopodia), though they grow rapidly towards the adjacent ganglia and on to the periphery. Detailed study of the stopped axons filled with different dyes suggests, within the limit of resolution of the light microscope, that they are in direct contact at several locations, although no indication of dye-coupling was found. We are currently examining these putative contacts at the ultrastructural level.

IN THE LEECH NERVOUS SYSTEM, 130 AND 260 KD GLYCOPROTEINS UNIQUE TO SENSORY, GLIAL, MUSCLE AND CONNECTIVE TISSUE CELLS ARE DISTINGUISHED BY THEIR CARBOHYDRATE MOIETIES. R.N. Cole, I.S. Thorey, M.L. Bajt, and B. Zipser. Neuroscience Program, Dept. of Physiology, Michigan State Univ., East Lansing, MI 48824.

Four different 130 kD surface glycoproteins are found on the full set and nested subsets of sensory afferents (Peinado et al., Brain Res., 410:335, 1987). A fifth 130 kD surface glycoprotein is expressed on both peripheral and central glial cells. In addition, connective tissue and muscle cells in the nervous system are identified by still other 130 and 260 kD surface proteins. We are obtaining evidence that the cell-type specificity of these glycoproteins is due to their different carbohydrate domains. The carbohydrate domains may be recognition sites during the formation of the nervous system as suggested by antibody perturbation data (Zipser et al., Neurosci. Abst. 1989).

The neuronal and glial cell surface glycoproteins are of the high mannose/hybrid type with a fucosylated invariant core since they bind to Con A and to lentil lectin. The full set sensory protein is recognized by mab Lan3-2 binding to a specific mannose epitope, that can be cleaved by N-glycanase. Coprecipitation of the full set and the 3 subset sensory proteins with mab Lan3-2 suggests that the sensory proteins possess closely related carbohydrate epitopes. Sensory and glial proteins are not coprecipitated by glial or sensory mabs, demonstrating that the sensory glycans are not shared by glia.

On immunoblots, the 130 kD connective and 260 kD muscle surface proteins run as broad bands suggestive of glycosylated proteins. These connective tissue and muscle proteins do not bind to Con A or lentil lectin, and therefore, are not of the high mannose/hybrid type.

231.18

ROLE OF 130 KD SENSORY PROTEINS IN AXONAL PATHFINDING BY FUNCTION IN THE LEECH GERMINAL PLATE. B. Zipser, R. J. Morell, and M. L. Bajt. Dept. of Physiology, Neuroscience, Program. Michigan State University, East Lansing, MI 48824.

Sensory afferents are "color-coded" through unique 130 kD surface glycoproteins of the high mannose type. A given sensory afferent is labeled with the main sensory protein (Lan3-2) and at least one of the subsensory proteins (Laz2-369, Laz6-212 and Laz7-79). The peripheral cell bodies of sensory afferents project their axons as common tightly fasciculated tracts through the body wall into the central ganglia. The entry of the central neuropile is the decision point where afferents separate from their joint tract and choose either dorsal or ventral tracts. The majority of afferents with subsensory proteins Laz6-212/Laz7-79 prefer the dorsal tracts (Peinado et al., Brain Res., 410: 335, 1987).

We tested the role of the main sensory protein on sensory afferent growth by organ-culturing the germinal plate in Fab fragments of mab Lan3-2. The 9-10 day (20C) germinal plate is fully antibody permeable. Control embryos, grown in Fab fragments of a mab directed against an internal sensory protein (Lan3-6), exhibited the normal pattern of sensory afferent tracking in the central ganglion. In experimental embryos, the central tracking of sensory afferents was dramatically modified.

Thus, sensory afferent growth is under the control of the main sensory protein. The main sensory protein appears to function in axonal self-self recognition and in axon-matrix interactions while the subsensory proteins may function in modality-specific recognition.

231.19

ROLE OF EMBRYONIC GLIA IN DEVELOPMENT OF THE LEECH NERVOUS SYSTEM. R.J. Morell, R.N. Cole, and B. Zipser. Dept. of Zoology, Neuroscience Program, MSU, E. Lansing, MI 48824.

We are studying the role of embryonic glial processes in the development of the leech nervous system. Using monoclonal antibodies (Mabs Laz6-297 and Laz6-56) specific to a 130 kD surface glycoprotein that is expressed on macroglia in the adult, we have documented the embryonic expression of this glial antigen at the sites of neurogenesis, migration, and neurite extension.

In order to determine whether the glial processes prefigure axon tract formation, we double labelled embryos with the glial Mabs and neuron-specific Mabs. In the CNS we stained the first detected axonal processes, which belong to the Bipolar cells, with Mab Laz1-1; and in the PNS we stained the pioneering afferents with Mab Lan3-2. In both cases, the earliest neuronal processes were seen to extend along established glial tracts.

To investigate whether developing axons utilize the 130 kD surface glycoproteins expressed along glial processes, we performed antibody pertubation experiments. When germinal plates are organ-cultured in the presence of Laz6-297, we detect aberrant projections by the Bipolar cells, suggesting that they pioneer CNS tracts using glial surface antigens as their guide. In these same experiments we also observed a greater degree of neuronal differentiation in experimental groups over controls, as measured by the segmental level at which peripheral and central neurons are seen to differentiate. It appears that the glial Mab stimulates a trophic response.

231.20

SEGMENTATION OF THE LEECH GERMINAL PLATE PROCEEDS IN REGISTER WITH A CHAIN OF MYOGENIC MIDLINE CELLS. I.S. Thorey and B. Zipser. Dept. of Physiology, Neuroscience Program, Michigan State University, East Lansing, MI 48824.

The leech germinal plate is derived from 5 pairs of teloblasts producing bilateral bandlets of blast cells. Primary blasts cells divide and then aggregate into segmentally reiterated somites and central ganglia. The progress of segmentation in the leech germinal plate can be visualized by staining myogenic cells with monoclonal antibody Laz10-1 which recognizes a unique mesoderm/muscle surface protein.

The future segmentation of the leech germinal plate is prefigured by a chain of myogenic cells expressing the Laz10-1 protein at the primary axis of embryonic symmetry. These cells and their interconnecting processes form a myogenic fascicle which is already present on the midline during the production of primary mesoblast cells. The 32 somites and central ganglia aggregate in register with the myogenic cell bodies. The somites form laterally halfway between 2 consecutive myogenic cell bodies. The ganglionic primordia aggregate at the midline just posterior of the myogenic cell bodies. The myogenic cell bodies differentiate into the CNS muscles.

In the mesoderm, the expression of Laz10-1 protein fluctuates during the development of the germinal plate. Laz10-1 protein expression is elevated when mesodermal cells aggregate into cohesive tissues, e.g. in the nascent mesoderm and in the forming somites.

PALMITOYLATION OF GAP-43 IN INTACT GROWTH CONES AND ISOLATED GROWTH CONE MEMBRANES IN VITRO. Sean I.Patterson* and J.H.Pate Skene, Dept. Neurobiology, Stanford University, CA 94305.

Covalent binding of palmitic acid to proteins has been shown to confer subcellular localization by membane attachment, and may regulate the function of some proteins. In intact growth cones incubated with 3H-palmitate in vitro, the major acylated protein has previously been identified as the neuronal growth-associated protein, GAP-43 (J.Cell Biol. 108, 613-624). In order to study the regulation of palmitoylation we have developed an in vitro acylating system using membranes from lysed growth cones. Lysed growth cones incorporated 3H-palmitoyl coenzyme A into GAP-43 more rapidly than 3H-palmitate, and this process was more efficiently competed by excess unlabelled palmitoyl-CoA than unlabelled palmitate, suggesting that the slower labelling observed with the free fatty acid may be partially due to its conversion to the precursor for acylation. Preliminary results indicate that the incorporation of 3H-palmitate into lysed growth cone membranes may be blocked by homologs of tunicamycin, an antibiotic that contains a fatty acyl chain. Separation of non-acylated GAP-43 from GAP-43 attached to membranes could be achieved by pelleting growth cone membranes (100,000x*g*, 60min). Washed growth cone membranes rapidly incorporated 3H-palmitate into GAP-43, implicating an endogenous membrane associated deacylating activity that may play a role in the regulation of proteins attached to membranes through acylation. Growth cone membranes therefore provide a simple and experimentally amenable model for the characterization of protein acylation and deacylation, and for exploring acylation as a potential regulatory system.

Phosphorylation Sites on the Growth-Associated Protein GAP-43. S.M. Schuh, S.A. Spencer, and M. Willard. Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

GAP-43, a neuronal phosphoprotein, is a major protein of growth cones; in addition, it is a component of presynaptic terminals, where its phosphorylation has been reported to be associated with changes in synaptic efficacy. To identify the phosphorylation sites on GAP-43, we phosphorylated purified GAP-43 with purified protein kinase C and ^{32}P-ATP, and analyzed radioactive tryptic peptides by reverse phase HPLC chromatography followed by amino acid sequencing. A single site, serine 41, that is adjacent to a region reported to bind to calmodulin, was phosphorylated. To investigate whether this site is also phosphorylated in living cells, we labeled primary cultures of rat superior cervical ganglia and several established cell lines with ^{32}P-orthophosphate. Reverse phase chromatography of tryptic fragments of GAP-43 from these cultures yielded 6 peaks of radioactivity. One of these coeluted with a hexapeptide containing phosphorylated serine 41. When the superior cervical ganglia cultures were treated with phorbol ester to stimulate protein kinase C, the radioactivity in this peak was increased 100%, whereas no change was detected in the other five peaks. These results demonstrate that serine 41 is the major phosphorylation site of protein kinase C in vitro. They suggest that, in living cells, GAP-43 is phosphorylated at multiple sites, of which only serine 41 is a substrate for protein kinase C. Supported by NIH grant EYO 2682.

232.3

NGF-STIMULATED IN SITU PHOSPHORYLATION OF GAP-43 IN ISOLATED GROWTH CONES. K.F. Meiri and D.A. Burdick*, Dept. Pharmacology, SUNY Health Science Center Syracuse N.Y. 13210.

Little is known about the intracellular signal transduction processes that regulate growth cone motility and pathfinding functions. In PC12 cells the action of NGF involves stimulation of the A & C kinases, but the consequences of the subsequent protein phosphorylations are not clear. In certain non-neuronal cells, activation of signal transduction mechanisms **has** been definitively linked to both shape changes and motility: In platelets, activation of the α2 receptor and then kinase C alters the association of actin with membranes; migration of leucocytes towards NGF involves kinase C. Investigations in growth cones have been hampered by the difficulties of isolating events in the growth cone from those occurring elsewhere. Subcellular fractions of isolated growth cones (IGCs) facilitate such studies, and we report here that intact IGCs can synthesize radiolabelled ATP from ^{32}P orthophosphate, and utilize it to phosphorylate proteins in situ. We have used this preparation to demonstrate the phosphorylation of specific IGC proteins by both direct stimulation of kinase C and by exposing IGCs to extracellular ligands. We have shown stimulation of GAP-43 phosphorylation when IGCs are incubated with NGF, both in vitro and in situ using this intact IGC model. GAP-43 phosphorylation is also stimulated when IGC membranes of were depolarized with potassium. In both cases rapid dephosphorylation of GAP-43 occurs, demonstrating that GAP-43 phosphorylation in response to extracellular stimuli is dynamically regulated. Supported by NS26091 and March of Dimes.

232.4

SPECIFIC PROTEOLYSIS OF B-50 (GAP-43) IS INHIBITED BY ACTH. P.J. Coggins* and H. Zwiers* (SPON: M.A. Bisby). Depts. of Medical Physiology and Medical Biochemistry, University of Calgary, Calgary, Alberta T2N 4N1 Canada

The neuronal protein B-50 (GAP-43) was originally identified as a rat synaptosomal plasma membrane protein whose PKC mediated phosphorylation was specifically inhibited in the presence of ACTH. Extraction of the membrane fraction under mild, non-denaturing conditions yielded a protein complex highly enriched in B-50, B-50 kinase (i.e. PKC) and a protease that specifically cleaved B-50 at Ser41, the single site of PKC mediated phosphorylation. The short sequence adjacent to Ser41 (i.e. B-50 35-51) contains the calmodulin binding domain of B-50 and phosphorylation prevents association of the two proteins. In the present study we have used the same protein complex to investigate the proteolysis of B-50 to B-60 (B-50 41-226) in the presence and absence of ACTH 1-24 and fragments derived from it. In common with its action on kinase activity the results demonstrated a time, dose and structurally dependent inhibition of B-50 proteolysis by ACTH (IC50 of approx. 2 μM). ACTH 1-10, ACTH 11-24 and a combination of both fragments were ineffective. In addition, calmodulin (0.2 and 20 μM) also reduced the amount of B-60 detected. Therefore, B-50 and ACTH both of which have been implicated in diverse aspects of neuronal plasticity interact on two biochemical levels, phosphorylation and now, proteolysis.

232.5

CHICKEN GAP-43 AND PROTEIN KINASE C ARE CLOSELY ASSOCIATED WITH THE NEURONAL MEMBRANE SKELETON. P.Fernyhough and D.J. Moss, MRC Cell Biophysics Unit, Kings College, London.

The membrane associated cytoskeleton, termed membrane skeleton, has been isolated from chick brain and cultured sympathetic neurons (Moss, D. J., Eur. J. Biochem. 135:291, 1983). This complex contains an approximately equal amount of actin and a similar complement of actin filaments when compared with the erythrocyte membrane skeleton. In addition, we have shown that the chick brain membrane skeleton is a major location of GAP-43, protein kinase C (PKC), and the neuron-specific glycoprotein contactin (Ranscht, B., J. Cell Biol. 107:1561, 1988). Chick GAP-43 and rat GAP-43 are biochemically similar, and endogenous phosphorylation of chick GAP-43 within the membrane skeleton is enhanced upon treatment with phorbol esters. PKC is highly enriched in the membrane skeleton relative to detergent-soluble fractions as shown by immune blot using antibodies specific for PKC types II and III. Membrane skeleton prepared from a human neuroblastoma cell line is also a source of PKC and its abundance may be regulated by growth factors, such as NGF and insulin.

232.6

CARBACHOL-INDUCED CHANGES IN THE PHOSPHORYLATION OF GROWTH-ASSOCIATED PROTEIN KINASE C SUBSTRATE B-50 (GAP-43) IN NEURONAL GROWTH CONES. C.O.M. VanHooff, P.N.E. DeGraan, L.H. Schrama, M. DeWit, A.B. Oestreicher and W.H. Gispen (SPON: E.E. Codd). Div. Mol. Neurobiol., Rudolf Magnus Inst., Inst. Mol. Biol. & Med. Biotechnol., and Lab. Physiol. Chem., Univ. of Utrecht, Padualaan 8, 3584 CH Utrecht, NL.

Neuronal growth cones, the highly motile tips of neurites, contain high levels of the growth-associated protein B-50 (GAP-43). Using growth cone membranes we recently provided evidence for a role of this neuron-specific protein kinase C (PKC) substrate in signal transduction (VanHooff et al., *J. Neurosci.* 8:1789, 1988). In the present study we investigated whether external stimuli, such as K^+ depolarization and muscarinic receptor activation, could modulate B-50 phosphorylation in the intact growth cone. B-50 phosphorylation was monitored by quantitative immunoprecipitation of B-50 from $^{32}P_i$ prelabeled intact growth cones, isolated from 5 day old rat forebrain. Depolarization with 30 mM K^+ induced a transient Ca^{2+}-dependent increase in B-50 phosphorylation, which is maximal after 15 sec and declines to basal level within 5 min. This increase, as well as that induced by 100 nM 4β-phorbol 12,13-dibutyrate (PDB), can be inhibited by the PKC inhibitor staurosporin. Carbachol enhanced B-50 phosphorylation in a concentration-dependent manner (50% at 10^{-3} M). Since the effect of carbachol could be inhibited by atropine (10^{-7} M) and staurosporin, we conclude that activation of muscarinic receptors on the growth cones stimulated PKC-mediated B-50 phosphorylation. The carbachol-induced increase in B-50 phosphorylation was parallelled by an increase in [^{3}H]-inositol phosphate accumulation, which could be attenuated by PDB. Our data support the hypothesis that PKC-mediated B-50 phosphorylation exerts a negative feedback on receptor-mediated (poly)-phosphoinositide hydrolysis.

232.7

DISTRIBUTION OF GAP-43 IN RELATION TO DEVELOPMENT OF THE RAT MESENCEPHALIC DOPAMINERGIC SYSTEM. C.W. Shults,†* D.M. Armstrong,* L.I. Benowitz,§ †Neurology Service, VA Med. Ctr., San Diego, *Dept. Neuroci., UCSD, La Jolla, CA, §Dept. Psychiatry, Harvard Med. Sch., McLean Hosp., Belmont, MA

Adjacent sagittal sections of embryonic rat brain were immunolabelled for growth-associated protein-43 (GAP-43) and for tyrosine hydroxylase (TH). At E14 thick GAP-43 immunoreactive (GAP-43-IR) fibers ran from the ventricular zone toward, but did not reach, the ventral pial surface in certain regions of the mesencephalon. Previous studies of the developing mesencephalon demonstrated that radial glia follow a similar pattern and TH-IR cells align along radial glia. GAP-43-IR fibers ran to the developing striatum and along the course of the fasciculus retroflexus. TH immunoreactive (TH-IR) cells were noted at the mesencephalic flexure with some TH-IR fibers running rostrally toward, but not yet reaching, the developing striatum. At E15 and E16, GAP-43-IR fibers continued to course from the ventricular zone toward the ventral pial surface in certain regions of the mesencephalon. At E15, 16, and 18, GAP-43-IR fibers appeared to precede and be more widely distributed than TH-IR fibers in the developing dopaminergic nigrostriatal tract and fasciculus retroflexus. Our observations suggest that GAP-43 may play a role in developmental organization of the substantia nigra and the ventral tegmental area and their respective projections to the striatum and habenula.

GAP-43 EXPRESSION WITHOUT NEURITE EXTENSION
J. Thomas Megerian, James P. Sullivan* and William L. Klein Department of Neurobiology & Physiology, Northwestern University, Evanston Il. 60208

Previous studies from other laboratories have shown that introducing the gene for neuronal Growth Associated Protein-43 (GAP-43) into non-neuronal cells results in the formation of neurite-like processes. Here, in order to determine whether its expression is sufficient for neurite outgrowth, GAP-43 was visualized by immunoflourescence in both primary and cloned cell cultures. In N1E-115 mouse neuroblastoma and SH-SY5Y human neuroblastoma, we detected strong labeling in cells induced to undergo neuritogenesis. However, in non-induced cultures GAP-43 was expressed as robustly. Thus in both lines, dividing cells that lacked neurites continuously expressed GAP-43. Primary cultures of embryonic rat basal forebrain also expressed GAP-43 but in a much more selective fashion. In both primary cells and differentiated cell lines, labeling was present in cell bodies, neurites and growth cones. For cells containing several processes, labeling was not restricted to one neurite. Our results, showing GAP-43 expression without neurite extension, demonstrate that GAP-43 function in neuritogenesis depends on the induction of other critical components. Supported in part by NIH grants NS 21088, 23348, & 21234 to WLK.

GAP-43 IMMUNOCYTOCHEMICAL DISTRIBUTION IN DEVELOPING CULTURED NEURITES AND GROWTH CONES
R.W. Burry[1], D. Hayes[1,*], N. Perrone-Bizzozero[2], L. Benowitz[2] and J.J. Lah[1]. [1]Dept. Anat., & Neurosci. Prog, Ohio State Univ, Columbus, OH, [2]McLean Hosp., Harvard Med. Sch., Belmont, MA

The developmentally regulated protein GAP-43 is present at high levels in the cerebellum during neuritic outgrowth and synapse formation. To determine the cellular distribution of GAP-43, cell cultures of granule neurons were studied with light microscopic immunocytochemistry. Anti-GAP-43 labeled the neuritic outgrowth at 1 day after plating. By 10 days in culture most neurites labeled heavily, and some isolated neurites have lost labeling for GAP-43. By 14 days, the majority of neurites labeled lightly, while many isolated neurites had no GAP-43 labeling. In cultures at 45 days, the majority of neurites had lost GAP-43 label, with only a few still intensely labeled. We conclude that the pattern of GAP-43 distribution in cultured granule neurons parallels developmental changes in vivo, and these cultures can be used to effectively study subcellular distribution of GAP-43.

DOES NCAM DISTRIBUTION DEPEND ON UNDERLYING CYTOSKELETAL COMPONENTS? H. Safferstein* and F.J. Roisen (Spon: R. Dagirmanjian). Dept. of Anatomical Sciences & Neurobiology, University of Louisville, School of Medicine, Louisville, KY 40292.

The distribution of NCAM during differentiation of the Neuro-2a cell line is dependent on the underlying cytoskeleton. Our previous studies demonstrated that the level of differentiation can be regulated by exposure to unique neuritogenic signals. Neuro-2a cells grown in media with limited serum, dibutyryl cyclic AMP, or ganglioside GM1 exhibit increased levels of neuritogenesis, respectively. TEM of neurites formed in response to these stimuli revealed a correlation between the level of differentiation and the cytoskeletal organization. We have shown, previously, that each of these signals produces a characteristic NCAM pattern. In this study, we utilized cytoskeletal disruptive agents to probe the role of structural organelles in NCAM distribution. Exposure of Neuro-2a to cytochalasin D (microfilaments), colcemid (microtubules), or taxol (microtubule stabilization and promotion) disrupted the NCAM pattern produced by GM1. However, the simultaneous addition of cytochalasin D and taxol augmented the linear distribution of NCAM-positive material seen in cultures grown in GM1. Immunoelectron localization studies are in progress to visualize NCAM's relationship to cytoskeletal organelles. Supported by NIH grant NS24524 to FJR.

232.11

EXPRESSION OF NCAM ANTIGEN IN THE NORMAL AND REGENERATING GOLDFISH RETINOTECTAL SYSTEM
M.Bastmeyer,B.Schlosshauer* and C.A.O.Stuermer, Friedrich-Miescher-Lab. der Max-Planck-Ges. und Max-Planck-Inst. für Entwicklungsbiol.,Tübingen, FRG.

The goldfish visual system is unique in that it grows throughout life. The retina adds neurons circumferentially at its peripheral margin, the tectum in a crescent shaped zone around its caudal pole. The axons from the newborn ganglion cells travel as a bundle through distinct aspects of the nerve and tract and along the dorsal and ventral periphery of the tectum. The neural cell adhesion molecule (NCAM) is well known to mediate adhesion between neurons and neurites in the developing nervous system. Using the monoclonal antibody D3, which recognizes the intracellular domain of the 180 kD form of NCAM in the chick (Schloßhauer, J.Neurochem.52: 82-92, 1989) we analyzed the distribution of this antigen in the retinotectal system of adult goldfish.

On cryostat sections of normal fish, Mab D3 labels cells exclusively in the marginal growth zones of the eyes and the tecta. In the eyes, nerves and tecta it stains the paths of the youngest, still growing axons. Following optic nerve section (ONS) retinal axons in fish regenerate and reinnervate the tecta from rostral to caudal. Correspondingly, in tecta at 2 weeks after ONS the retinorecipient layers exibit staining only rostrally but throughout the rostrocaudal extent by 5 weeks. Regenerating optic nerves are also intensively stained. After eye enucleation the optic nerves and the retinorecipient layers of the tecta are unlabeled, suggesting that regenerating axons express the antigen whereas nerve glia and tectal cells do not, except those in the caudal growth zone. Accordingly, retinal axons and their growth cones growing *in vitro* are Mab D3 positive.

Thus, NCAM antigen is expressed by newly proliferated cells in the eyes and tecta and by growing retinal axons in normal adult goldfish. The antigen reappears on regenerating retinal axons after ONS.

232.12

A UNIQUE NCAM GLYCOFORM PRESENT ON A SUBSET OF AXONS IN FROG BRAIN. B. Key* and R.A. Akeson. Basic Research, Children's Hospital Medical Center, Cincinnati, Ohio, 45229.

We have previously described the expression of a unique glycosylated form of NCAM in the olfactory bulb of frogs (Neurosci. Abstr., 14:919, 1988). This NCAM glycoform was detected with a monoclonal antibody (Mab) called 9OE. In the present study we have analysed in detail the distribution of this unique NCAM in the brain of the adult bullfrog. Serial transverse sections of frog brain were reacted with Mab 9OE and visualized by the ABC immunochemical technique. Mab 9OE labelled a discrete ventrolateral quadrant of the telencephalon. In addition subsets of axons in several nerve fiber tracts were also labelled. These pathways included the ventrolateral olfactory tract (VLOT), the medial olfactory tract (MOT) and the accessory olfactory habenular tract (AOHT). The VLOT projects from the accessory olfactory bulb to the amygdala. Both of these regions were labelled by Mab 9OE and have previously been implicated in the control of reproductive behaviour. Both the MOT and AOHT have also been shown previously to contain a subset of LHRH immunoreactive axons that are believed to have a similar function. Interestingly, the distribution of these fibers resembles that of Mab 9OE labelled axons. No labelling was observed on any structures in the spinal cord, brain stem, cerebellum, tectum and pallium. The presence of a unique NCAM glycoform on a subset of axons may represent a novel mechanism for the development of specific functionally related axon pathways in the vertebrate central nervous system. (Supported by NIH grants NS23348 and HD21065).

NEURITE OUTGROWTH OVER MONOLAYERS OF CELLS THAT EXPRESS TRANSFECTED HUMAN N-CAM.

P. Doherty, C.H. Barton*, G. Dickson*, and F.S. Walsh. Department of Neurochemistry, Institute of Neurology, London WC1N 3BG.

We have cultured both human and rat sensory neurons on monolayers of 3T3 and/or L-cells that have been stably transfected with full length cDNAs for a variety of human N-CAM isoforms. Neurons grown on monolayers expressing transmembrane or GPI-linked N-CAM isoforms exhibited a greater degree of morphological differentiation than neurons grown on monolayers of control cells or cells transfected with a cDNA encoding a secreted N-CAM isoform. The increased morphological differentiation was associated with significant increases in immunoreactive neurofilament protein. Modification of the extracellular structure of N-CAM, consequent to the expression of a glycosylated 37 amino acid sequence normally found expressed exclusively in muscle N-CAM isoforms, did not obviously affect the ability of transfected cells to support increased neuronal differentiation. These data provide direct evidence for both transmembrane and lipid-linked N-CAM isoforms being components of the regulatory machinery that determine process outgrowth.

232.14

IMMUNO-ELECTRONMICROSCOPIC LOCALIZATION OF CELL ADHESION MOLECULE L1 IN DEVELOPING RAT PYRAMIDAL TRACT. E.Joosten, A.Gribnau and T.Gorgels (SPON:P.Apkarian). Dept.Anat.and Embryol.,Univ.of Nijmegen,6500HB Nijmegen,The Netherlands.

The glycoprotein L1 has been proposed to function in the PNS as an adhesion molecule involved in fasciculation and onset of myelination. In this study the localization of L1 was studied during the development of a major central path way: the pyramidal tract (PT).The (sub)-cellular localization of L1 was determined both by pre-embedding staining on vibratome-sections and by immunogoldlabelling on ultracryosections in developing rat PT at C5. Polyclonal antibodies to mouse L1 were a generous gift of Dr.F.Rathjen (Dept.Mol. Neurobiol.,Hamburg,FRG). On arrival at C5,i.e. between P1 and P4, PT growth cones of pioneer fibres did not exhibit L1-ir, but L1-ir was noted when situated adjacent to other small unmyelinated axons. L1-ir was observed on later arriving,i.e. between P4 and P10, small unmyelinated fasciculating PT axons. During PT myelination,i.e. between P10 and P21,a slight L1-ir was noted in between unmyelinated PT-axons but L1-ir was also observed within the axoplasma of (un)-myelinated axons. Axons ensheated by oligodendrocytic processes did not express the L1 antigen. Furthermore,both compact myelin as well as glial processes were L1-neg. From these results it may be deduced that:1. L1 is only involved in guidance of outgrowing PT fibres by means of axon-fasciculation, 2. In contrast to developing PNS L1 is not involved in the onset of myelination in this central tract.

EVIDENCE FOR THE INVOLVEMENT OF C KINASE IN LAMININ INDUCTION OF NEURITE OUTGROWTH. John L. Bixby and Perseus Jhabvala*, Dept. of Pharmacol., Univ. of Miami Sch. of Med., Miami, FL 33136.

We are interested in the intracellular events underlying the induction of neurite outgrowth by ECM/integrin interactions, and particularly the involvement of specific protein kinases. We have begun to study these events by culturing chick ciliary ganglion (CG) neurons on various ECM and non-ECM substrates, in the presence and absence of drugs that affect C kinase activity. The tumor promoter TPA, an activator of C kinase, potentiates process outgrowth from CG neurons cultured on suboptimal laminin (LN) concentrations, but not on optimal LN concentrations. TPA also strongly potentiates growth on fibronectin and collagens that is similar in extent to that observed on LN in control conditions. TPA does not, however, induce CG neuron process outgrowth on non-permissive substrates (poly-D-lysine or tissue culture plastic). Manipulations that elevate intracellular cAMP levels (expected to activate A kinase) reduce process extension on LN. The C kinase inhibitors H7 and sphingosine reversibly block LN-induced neurite outgrowth in a dose-dependent fashion. H7 does not inhibit the neurite outgrowth induced by concanavalin A in the same neurons. Our results suggest that 1) activation of C kinase is an important step in the neurite outgrowth induced by LN binding to its integrin receptor(s), 2) there are other important functions of these receptors involved in neurite outgrowth, and 3) the "neurite" growth induced by concanavalin A in CG neurons occurs through a distinct mechanism from that induced by LN. Supported by the MDA, the PMAF, and a BRSG from the NIH.

232.16

A NEURONAL CELL LINE (PC12) EXPRESSES TWO β_1-CLASS INTEGRINS THAT RECOGNIZE DIFFERENT CELL ATTACHMENT SITES IN LAMININ. K.J.Tomaselli*, D.E.Hall, L.F.Reichardt, L.A.Flier*, D.C.Turner*, and S.Carbonetto. HHMI/UCSF, SF CA 94143; Biochem.& Mol.Biol.,SUNY, Syracuse NY; Montreal Gen.Hosp.Res.Inst.,Montreal, Quebec.

The role of β_1-class integrins in attachment of PC12 cells has been studied with specific antibodies. PC12 cells express two α/β_1 heterodimers: α_1/β_1 and α_3/β_1. A monoclonal antibody (3A3) recognizes the α_1/β_1 heterodimer and precipitates two PC12 cell surface proteins of M_r 180,000 (α_1) and 120,000 (β_1). An antiserum to the cytoplasmic domain of the chicken integrin α_3 subunit (gift of Dr. R.O. Hynes) recognizes the α_3/β_1 dimer and precipitates two proteins of M_r 140,000 (α_3) and 120,000 (β_1). The α_1/β_1 dimer functions as a receptor for laminin and collagens I and IV. Function-blocking studies with antibody 3A3 indicate that α_1/β_1 is the major receptor for collagen on PC12 cells, but is not the only β_1 integrin receptor for laminin. Attachment of PC12 cells to proteolytic fragments of laminin confirms this hypothesis. PC12 cells attach to two different laminin elastase fragments: fragment E1-4, derived from the intersection of the long and short arms of laminin, and fragment E8, which consists of the long arm and the terminal heparin-binding globular domain E3. Attachment to either fragment is blocked by β_1 integrin antibodies. Antibody 3A3 inhibits attachment to fragment E1-4 but has no effect on attachment to fragment E8. These results indicate that PC12 cells express two β_1-class integrins that bind to separate sites on laminin: α_1/β_1, binds to a site at the top of the laminin cross, and α_3/β_1 recognizes a site in E8, most likely near the end of the long arm.

232.17

EVIDENCE FOR INVOLVEMENT OF THE INTEGRIN ALPHA 3 SUBUNIT IN PROCESS OUTGROWTH ON LAMININ. D.O. Clegg, E.A. Wayner*, J. Snyder*, D.B. Gervin*, A. Bradshaw*, G. Cann*, E.S. Choi*, P.D. Sullivan*, D.M. Eckley*. Neuroscience Research Institute, University of California, Santa Barbara, California 93106; and Department of Biochemical Oncology, fred Hutchinson Cancer Research Center and Pacific Northwest Research Foundation, Seattle, Washington 98104.

The beta$_1$ subunit of the integrin family of cell surface receptors has been implicated in mediating neurite extension on laminin, but the identity of the alpha subunit(s) that combine with beta$_1$ to mediate outgrowth on laminin have not been identified. At least three different alpha subunits can combine with beta$_1$ to form heterodimers that interact with laminin: alpha$_1$, alpha$_3$, and alpha$_6$. The alpha$_3$-beta$_1$ heterodimer appears to be a promiscuous matrix receptor that can mediate cell attachment to laminin, collagen, and fibronectin.

We have analyzed the effects of function blocking anti-alpha$_3$ monoclonal antibodies on neurite extension by the human neuroblastoma cell line SY-5Y. We have found that these antibodies will bring about rapid retraction of neurites on laminin substrates. Control anti-alpha$_2$ antibodies had no effect. These results suggest that the alpha$_3$-beta$_1$ heterodimer can mediate neurite outgrowth on laminin and may be present on neurons *in vivo*. Experiments are in progress to determine the effects of other function blocking monoclonal antibodies on neurite outgrowth properties of this cell line. Our goal is to determine the roles of different integrin alpha subunits in the development of the nervous system.

232.18

NEURITE OUTGROWTH OF RAT FETAL SEPTAL CELLS IN CULTURE IS STIMULATED BY MATRIGEL, LAMININ, AND LAMININ-DERIVED SYNTHETIC PEPTIDES. *M. Jucker[1]*, H.K. Kleinman[2]*, H. Kametani[1]*, E.L. Bresnahan[1], G.R. Martin[1]*, and D.K. Ingram[1]* (SPON: M. Talan). [1]Gerontol. Res. Ctr., Natl. Instit. on Aging, NIH, Baltimore, MD 21224; [2]Lab. Dev. Biol. Anom., Natl. Instit. of Dental Res., NIH, Bethesda, MD 20892

Laminin, a major glycoprotein of basement membrane, is a potent stimulator of neurite outgrowth *in vitro* for a variety of cells. Using fetal septal cell cultures, we examined cell development as affected by laminin, Matrigel (a mixture of basement membrane proteins), or synthetic peptides corresponding to sequences in laminin chains. Cell suspensions were made from septal tissue dissected from fetal rat brains (E16-17). Aliquots of 0.3-0.6 x 10^5 viable cells were grown in 12 mm wells containing 0.5 ml DMEM and either laminin (0-50 μg), Matrigel (0-50 μl), or laminin derived synthetic peptides (0-100 μg) as coated onto plastic or added to medium. Cell attachment and process formation were quantified by automated image analysis at 3, 7, 10 days. Uncoated and untreated dishes showed no significant adhesion or outgrowth. Compared to controls, cultures with laminin or Matrigel showed greatly enhanced survival, and neurite outgrowth was also stimulated in a dose-dependent manner by these materials. A synthetic peptide derived from the laminin A-chain sequence also promoted survival and neurite outgrowth although processes were shorter than using the native protein. A laminin B1-chain peptide (YIGSR: Graf J. *et al., Cell* 48:989, 1987) did not promote survival or process formation. Preliminary *in vivo* results also showed that fetal septal cells suspended in Matrigel exhibited viability and neurite outgrowth when transplanted to hippocampus and lateral ventricle of rats. These studies indicate that fetal septal cell development is stimulated by laminin and that a synthetic peptide can partially duplicate this activity to suggest *in vivo* applications.

232.19

LAMININ: IS IT THE YELLOW BRICK ROAD OF THE DEVELOPING AUDITORY RECEPTOR? T. R. Van De Water[1], V. Galinovic-Schwartz*[1] and G.S. Swanson[1,2], [1]Laboratory of Developmental Otobiology, Depts. of Otolaryngology and Neuroscience, [2]Developmental Biology Unit, Imperial Cancer Research Fund, Oxford University, Oxford, England.

Laminin is an extracellular matrix glycoprotein that has been implicated as a possible hapten for the guidance of neurites both in vitro (Hammerback, etal., Dev. Biol. 126:29-39, 1988) and in the developing optic tract (Cohen, etal., Dev. Biol. 122:407-18, 1987). The pattern of laminin distribution in embryonic mouse and chick auditory receptors was examined by immunohistochemical localization using species specific polyclonal antibodies. Mouse embryos from 13 to 18 gestation days and chick embryos from Hamilton & Hamburger Stages 18 to 40 were used in this study. The relationship between neuritic ingrowth and the basement membranes of the sensory portions of the cochlear duct was examined. Where nerve fibers are first seen in close association with the basement membrane of the presumptive sensory areas (but not yet penetrated into these areas) we failed to detect any tracts of laminin staining that might act to guide these dendrites. Laminin staining of basement membranes underlying auditory sensory areas becomes intermittent at the sites of nerve fiber penetrations. Other regions of the basement membrane underlying sensory areas not penetrated by neurites remain intact and show continuous staining for the presence of laminin. No inter-epithelial staining for laminin was found within the epithelium in the regions of ingrowing auditory nerve fibers. This observation is in contrast to that found by Cohen, etal. 1987 in the developing optic tract where the pattern of laminin distribution correlates with inter-epithelial spaces along which the axons of the retinal ganglion cells grow. In the nerve bundles themselves, laminin staining was predominantly associated with the perineural sheath and often contiguous with that of the epithelial basement membrane. In the non-sensory areas of epithelium staining was detected, in heaviest concentration, in the apical portions of the prospective stria vascularis epithelium. Our observations are incompatible with the hypothesis that laminin plays an active role in directed neurite ingrowth to the sensory areas of the auditory receptor in chick and mouse embryos. Rather, in the developing murine cochlear duct, the presence of an intact basement membrane, as shown by laminin staining, appears to correlate with the absence of neurite ingrowth.

CREMASTER NUCLEUS SUBSTANCE P PATHWAY CONTAINS A SEXUALLY DIMORPHIC POPULATION OF INTRASPINAL NEURONS. B.W. Newton. Dept. of Anatomy, U. of Arkansas for Med. Sci., Little Rock, AR 72205

The cremaster nucleus (CN) is sexually dimorphic, with males containing a greater number of motoneurons than females. The substance P (SP) innervation of the CN is also sexually dimorphic: males have a massive SP pathway which females lack. Previous studies (Brain Res. 301:243; Neurosci. Lett. 57:185) suggest the SP pathway to the male CN is of intraspinal origin. Adult rats were given subarachnoid colchicine and 36 hrs later SP-immunoreactivity (IR) was visualized using the PAP technique. The male lumbar spinal cord (laminae V, VII) contains a large number of SP-IR neurons immediately dorsal to and within the SP pathway to CN. This population of SP-IR neurons is sparse in females. Previous studies (Soc. Neurosci. 14:285) show that exogeneous neonatal androgens induce the formation of a male-like SP pathway to the female CN. Investigations are underway to determine if this androgen-induced SP pathway in females also contains SP-IR intraspinal neurons. Supported by BRSG RR05350 and the Arkansas Caduceus Club.

ANDROGEN-REGULATED PROTEIN EXPRESSION DURING DEVELOPMENT OF A SEXUALLY DIMORPHIC NEUROMUSCULAR SYSTEM. Nancy G. Forger, G.L. Firestone* & S.M. Breedlove, Depts. Psychology & Physiology-Anatomy, University of California, Berkeley, CA 94720.

Survival of the bulbocavernosus/levator ani (BC/LA) muscles of rats beyond the neonatal period is dependent on androgen and, as a consequence, the BC/LA normally degenerates in females. Treatment of perinatal females with androgen permanently rescues the BC/LA muscles and their innervating motoneurons in the spinal nucleus of the bulbocavernosus (SNB; Breedlove & Arnold '83). To identify the molecular events mediating androgenic rescue of this neuromuscular system, we examined androgen-regulated protein expression in the BC/LA using 2-dimensional gel electrophoresis. BC/LA muscle tissues were removed from perinatal Sprague-Dawley rats and incubated at 37 °C for 4 h in serum-free media supplemented with [^{35}S]methionine. Labeled proteins were separated by isoelectric focusing in the first dimension, SDS-PAGE in the second, and visualized by autoradiography.

BC/LA tissue of untreated females lacked an acidic ~26 kDa protein doublet which was abundantly expressed in the BC/LA of males and in other striated muscles from both sexes. Perinatal androgen treatment for 96 h induced expression of the 26 kDa doublet in the BC/LA of females. Based on position in 2-D gels, we tentatively identified the doublet proteins as isoforms of fast muscle myosin light chain 1 ($LC1_f$); immunoprecipitation of the doublet proteins with polyclonal antibody to $LC1_f$ confirmed this identification. Expression of other identified muscle-specific proteins (e.g. myosin LC3) was not sexually dimorphic in the BC/LA. Therefore, $LC1_f$ expression may play a role in the androgenic sparing of the BC/LA-SNB neuromuscular system.

233.3

CHANGES IN MOTONEURON SIZE INDEPENDENT OF CHANGES IN TARGET MUSCLE SIZE WITH ANDROGEN EXPOSURE IN ADULTHOOD. Marianne Leslie, N.G.Forger, S.M.Breedlove, Department of Psychology, University of California, Berkeley, CA 94720

Last year we reported significant sex differences in size of motoneurons of the retrodorsolateral nucleus (RDLN) and one of the muscles it innervates, the flexor digitorum brevis (FDB); motoneuron size was larger in males than in females. In the present study, we examined the influence of adult exposure to testosterone (T) on this neuromuscular system.

At 60 days of age, male Sprague-Dawley rats were castrated (GdX, N=21) or sham-castrated (Sham, N=17); females were ovariectomized and implanted with blank (OVX, N=14) or T-filled silastic capsules (OVX+T, N=17). All animals were sacrificed 45-47 days later; spinal cords were frozen sectioned at 50μ and thionin stained. Mean soma and nuclear areas were determined from camera lucida drawings of 20 RDLN cells from each animal. FDB muscles were removed and weighed.

RDLN	SHAM	GDX	OVX+T	OVX
-Soma(μ^2)	1013 ± 24*	979 ± 23	1038 ± 28*	937 ± 20
-Nucleus(μ^2)	244 ± 10	240 ± 6	259 ± 10	240 ± 13
FDB mass(mg)	48 ± 1.3*	48 ± 0.8*	39 ± 1.0	39 ± 1.3

*Significantly different from untreated OVX females $p<.025$.

We again found a significant sex difference in RDLN motoneuron size. Androgen treatment of adult OVX females significantly increased soma area over that in control females, thus eliminating the sex difference. Castration did not significantly reduce motoneuron size compared to that of control males. We found no significant differences in nuclear area. FDB mass was found to be strikingly sexually dimorphic, but no change in FDB mass was observed following T manipulation in either males or females. This neuromuscular system may provide a useful model of general sex differences in motoneurons and body size.

DIMINISHED IMMUNOREACTIVITY IN A SEXUALLY DIMORPHIC ENKEPHALINERGIC FIBER SYSTEM IN THE PREOPTIC AREA OF THE AGED FEMALE RAT. R. E. Watson, Jr., M.C. Langub, Jr.*, and J. W. Landis*. Dept. Anatomy and Neurobiology, Univ. of Kentucky, Lexington, KY 40536

A sexually dimorphic enkephalin (ENK) fiber system, in which expression is governed by the gonadal steroids in both an organizational and activational manner, is present in the periventricular preoptic nucleus (pePOA) of the rat in only the female. This system is not expressed until puberty (Devl. Br. Res. 44: 49-58). In this study, the effects of aging and associated reproductive senescence upon expression of this dimorphic system were investigated. Estrous cycles of young adult (12 week) and aged (19 month) female F344 rats were followed for 3-8 weeks. Young adult rats had normal 4-5 day estrous cycles. Aged females had repeated pseudopregnancy-like cycles typified by 10-12 day periods of leucocytic smears interrupted by 1-2 days of smears with nucleated and cornified cells. Animals were perfused and the brains prepared for immunocytochemistry (ICC) using either a polyclonal antiserum to met-ENK or a monoclonal antiserum to leu-ENK. The female-typical dense ENK-immunoreactive (ir) fiber plexus in the pePOA was present in all female young adult rats. In contrast, in 5 of 7 aged females analyzed to date, the female-typical dense ENK-ir band was absent (3) or greatly attenuated (2). In an effort to determine whether normal estrogen responsivity of this system is retained in the aged female, young and old rats were ovariectomized. Two weeks later, empty or 17ß-estradiol (E2) containing silastic capsules were implanted subcutaneously, and 4 or 14 days later the brains were prepared for ENK ICC. In young rats the female-typical ENK-ir plexus was re-expressed following E2 exposure. However, in the aged females E2 did not result in enhanced ENK-ir in the pePOA. These data indicate that the aging process is associated with diminished expression of the female-typical ENK-ir fiber plexus in the pePOA, and that with age this system may become increasingly refractory to the activational actions of E2. These observations may aid in identifying the physiological significance of this sexually dimorphic system. {Supported by the University of Kentucky Medical Center Research Fund}.

INTERACTIONS OF A SEXUALLY DIMORPHIC ENKEPHALIN FIBER SYSTEM WITH TARGET TYROSINE HYDROXYLASE NEURONS IN THE PERIVENTRICULAR PREOPTIC AREA: ELECTRON MICROSCOPY.

M. C. Langub, Jr.*, B. E. Maley, and R. E. Watson, Jr. Department of Anatomy and Neurobiology, Univ. of Kentucky Medical Center, Lexington, KY 40536.

A dense plexus of enkephalin (ENK) immunoreactive (ir) fibers that responds powerfully to the steroid environment during development and adulthood is present in the periventricular preoptic area (pePOA) of the female rat. To elucidate the functional significance of this sexually dimorphic system, it is important that the neurochemical identity of target neurons in the pePOA that receive afferent input be identified. Using light-level double labelling techniques (Soc. Neurosci. Abstr. 14: 1181) a close relationship has been observed between tyrosine hydroxylase (TH) -ir cells and ENK-ir fibers in the pePOA. In the present study, female Sprague-Dawley rats were perfused with buffered 4% paraformaldehyde and 0.3% glutaraldehyde. ENK-ir was localized using a rat monoclonal antiserum to leu-ENK (Sera-Lab) with diaminobenzidine (DAB) as a substrate. Sections were then re-incubated in rabbit polyclonal antiserum to TH (Pel-Freeze) and reacted using tetramethylbenzidine (TMB) as a substrate and stabilized using the technique of Horn and Hoffman (Br. Res. 409: 133-138). Ultrastructurally, TH-ir neurons in the pePOA were identified by the presence of the distinct spicule-like TMB reaction product. In contrast, ENK-ir elements were identified by the more dispersed DAB reaction product. Abundant DAB-containing ENK-ir terminals in the pePOA were observed in apposition to single TH-ir neurons. Many of the ENK-ir terminals contained a mixture of small, clear vesicles and large granular vesicles. In addition, many ENK-ir terminals were in apposition to unlabelled perikarya and dendrites. These data provide morphological evidence for synaptic interactions between enkephalinergic and catecholaminergic systems in the pePOA. This circuitry may be important to the control of sexually differentiated function. (Supported by the University of Kentucky Medical Center Research Fund)

233.6

SEXUAL DIFFERENTIATION OF ADULT LORDOTIC RESPONSE TO CHOLECYSTOKININ IN RATS.

P.E Micevych, C.Ulibarri, & P.Popper. Department of Anatomy & Cell Biology, Laboratory of Neuroendocrinology, Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

The neuropeptide cholecystokinin (CCK) has a sexually dimorphic distribution in the limbic-hypothalamic system of the rat. The number of cell bodies and the levels of CCK are much higher in males than in females. CCK also has a sexually dimorphic effect on lordotic behavior. Infusions of the biologically active form of CCK, sCCK-8, into the ventromedial nucleus of the hypothalamus (VMH) of estradiol-treated female rats inhibit lordosis. Similar infusions in males have no effect.

On the day of birth (postnatal day 1 = PND 1), males were either castrated or received sham surgeries under cold anesthesia. On PND 2, females received either 0 or 100 ug testosterone propionate (TP). Treatments were counterbalanced across litters. On PND 90 all animals were implanted with unilateral cannulae directed at the VMH. After one week the rats were tested for female sexual behavior following estradiol benzoate (EB) injections. The animals were tested either after progesterone (P) injection or sCCK-8 infusion. P injections were 4 h before tests; sCCK-8 infusions were 10 min before tests. Rats were placed with vigorous males and their response to 10 mounts assessed. The experimental animals received either 0, 5, 50, or 100 ug CCK/0.3 ul artificial CSF in a Latin Square design. After the last test, the rats were injected with 5 ug EB/0.1 ml safflower oil, and decapitated 48 h later. The brains were removed, frozen, sectioned, and processed for ^{125}I-sCCK-8 binding.

As expected, control males did not respond to sCCK-8 infusions, however control females, TP-treated females, and neonatal castrates showed clear inhibition of lordosis behavior after infusions of sCCK-8. The degree of inhibition increased with increased dose of sCCK-8. Control females showed the highest levels of sCCK-8 binding in the VMH. Control males, TP-treated females and neonatal castrates had similar levels of binding. Supported by NS 21220.

233.7

DISTRIBUTION OF PROGESTERONE RECEPTOR-LIKE IMMUNOREACTIVITY IN THE BRAIN OF THE RAT.

C. Ulibarri & P.E Micevych. Dept Anatomy & Cell Biology, Laboratory of Neuroendocrinology, Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

Several laboratories have published characterizations of antibodies directed against progesterone receptors (PR). Although these antibodies crossreact with PR in fowl, guinea pigs, and humans, as yet there are no reports of immunohistochemical visualization of PR in rats. We were interested in determining if an antibody (PR6; gift from David Toft, MAYO, MN) that recognizes PR in other species could also be used to visualize PR in rat brain. PR-6 was generated against chick oviduct. The rat uterus was used as a positive control tissue since the PR concentration in the rat uterus is similar to that in the chick oviduct.

Female Long Evans rats were ovariectomized and allowed to recover for one week. Forty-eight and twenty-four hours before perfusion, the females received either 25ug estradiol benzoate (EB)/0.1ml safflower oil, or vehicle. One to four hours before perfusion, the females received 0, 500, 1000, or 1500 ug progesterone (P)/0.1ml safflower oil. Under deep anesthesia, the females and intact males were perfused transcardially with either paraformaldehyde, acrolein, picric acid, Bouin's fixative, mercuric formaldehyde, buffered acetone, parabenzoquinone, or paraformaldehyde and glutaraldehyde. The brains and uteri were removed and postfixed with paraformaldehyde for 2-4 hours. They were then cryoprotected in 25% sucrose in paraformaldehyde for 24 hours. Serial sections were cut on a sliding microtome and processed for localization of PR6-immunoreactivity.

Intense PR6-immunoreactivity was observed in uteri from EB and EB + P-treated females. In both male and female brains, we observed PR6-immunoreactivity in the medial preoptic area, arcuate nucleus, ventromedial nucleus, paraventricular nucleus, and midbrain central gray. Cells in the hippocampus, subfornical organ, septohypothalamic nucleus, median preoptic area, and bed nucleus of the stria terminalis were intensely immunoreactive. The most intense staining was seen in rats treated with both EB + P. Supported by NS 21220.

233.8

ONTOGENY OF CHOLECYSTOKININ mRNA AND RECEPTORS IN MALE AND FEMALE RATS.

L.A. Abelson*, P.Popper, C. Ulibarri, & P.E Micevych. (SPON: C.H. Sawyer). Dept Anatomy & Cell Biology, Lab. of Neuroendocrinology, Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

The sexually dimorphic distribution of the neuropeptide cholecystokinin (CCK) in adults rats may reflect a sexually dimorphic distribution of both message and receptors. The purpose of this research was to delineate the pattern of CCK mRNA and receptors in developing animals and to determine if CCK mRNA and receptors for CCK are distributed dimorphically in developing pups. On postnatal day 1 (day of birth = PND 1), 5, 10, 15, and 30, male and female pups were killed and processed for either [^{125}I]-sCCK$_{26-33}$ receptor autoradiography or in situ hybridization.

The CCK riboprobe was a ^{35}S-labelled single-stranded cRNA transcribed from a genomic probe for the entire coding sequence for the CCK gene (gift from Dr. J. Dixon, Purdue University, IN). The CCK oligoprobe (Operon Tech., Inc., CA) was directed against the RNA that codes for CCK$_{26-33}$. For in situ hybridization pups were perfused with 4% paraformaldehyde/0.2% glutaraldehyde in 0.1M Sorensen's phosphate buffer. The riboprobe was hybridized according to Angerer et al in In Situ Hybridization; oligoprobe hybridization was according to the protocol supplied by Genofit (Geneva, Switzerland). Autoradiograms were prepared by dipping slides in emulsion. The distribution of prepro-CCK mRNA was mapped.

For receptor autoradiography, the pups were decapitated, the brains removed, frozen at -70°C, and cut at 10um on a cryostat. Sections were processed for ^{125}I-sCCK$_{26-33}$ binding as described previously (Akesson, et al, Neuroendo. 45:257,'87). The sections were opposed to Hyperfilm (Amersham) and analyzed for specific binding using a PDP-11 Spatial Data Analysis system. On PND 1 and 5, there were very low levels of CCK binding. On PND 10 binding was apparent in the claustrum and cingulate cortex. By PND 15, CCK receptors were apparent in the ventromedial nucleus (VMH). On PND 30, the pattern of CCK binding in the VMH was similar to that seen in the adult; highest binding was seen in VMHvl and VMHdm with the relatively low levels in the VMHc. Supported by NS 21220.

233.9

ENKEPHALIN-IMMUNOREACTIVE NEURONS OF THE HYPOTHALAMIC VENTROMEDIAL NUCLEUS CONCENTRATE ESTROGEN IN MALE AND FEMALE RATS.

T.R. Akesson and P. E Micevych. Department of Anatomy and Cell Biology, Laboratory of Neuroendocrinology, and Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

The ventromedial nucleus (VMH) and its projections to the preoptic area and midbrain represent essential components of a circuity that regulates estrogen-dependent reproductive behavior. A role for endogenous opiates in this circuitry is indicated by the findings that; 1) the distribution of met-enkephalin immunoreactive (mENKir) cells precisely overlaps the distribution of estrogen-concentrating (E-conc.) cells in the ventrolateral subdivision of the VMH (VMHvl), 2) mENKir fiber density is steroid sensitive in preoptic regions (Watson, et al., Dev. Brain Res., 44:49, '88), 3) mENK injections in the periaqueductal central grey inhibit lordosis (Bednar, et al., Neurosci. Lett., 79:341, '87), and 4)messenger RNA coding for preproenkephalin in the VMHvl is stimulated by estrogen (Romano, et al., Neurosci. Abstr., 12:692, '86). Whether estrogen activates expression of mRNA's coding for preproenkephalin by a direct genomic effect or via a second population of neurons has yet to be determined. Since the morphological signature of an estrogen receptive cell is concentration of labeled estrogen in its nucleus, we combined steroid autoradiography with immunohistochemistry for mENK.

Males were found to have a population of 5114 ± 577 mENKir cells, 3098 ± 303 E-conc. cells and 1481 ± 228 cases of coexistence in the VMHvl whereas in females, there were 4432 ± 211 mENKir cells, 4754 ± 696 E-conc. cells, and 1251 ± 25 cases of coexistence. Thus, there was no apparent sex difference in the numbers of mENKir cells, however differences in the size of the E-conc. population resulted in differential proportions of doubly labeled cells. In males, 48% of the E-conc. cells contained mENK and only 26% of the E-conc. cells were mENKir in females. These findings identify a subset of mENKir neurons that are directly activated by estrogen and a sex difference which may be importantly involved in the regulation of reproductive behavior. (Supported by HD 22869 to TRA and NS 21220 to PEM).

233.10

ESTROGEN-CONCENTRATING CELLS WITHIN THE MEDIAL PREOPTIC AREA: SEX DIFFERENCES AND COLOCALIZATION WITH GALANIN-IMMUNOREACTIVE (GAL-I) CELLS.

GJ BLoch*, RA Gorski, PE Micevych and TR Akesson, Dept. of Anatomy and Cell Biology, Lab. of Neuroendocrinology, UCLA School of Medicine, Los Angeles, CA 90024.

The distribution of GAL-I cells in the medial preoptic area (MPOA) overlaps with the distribution of estrogen-concentrating cells, and because estrogen (E) is also known to increase anterior pituitary GAL mRNA and plasma GAL levels [Kaplan et al., Proc. Nat. Acad. Sci., 85:7408, '88], we looked for evidence of E-concentration by GAL-I cells within the rat MPOA. In addition, because of the larger size of the anteroventral periventricular nucleus (AVPv) in females [Bloch and Gorski, J. Comp. Neurol., 275:613, '88], we compared the number of E-concentrating, GAL-containing cells within the AVPv of the female with that in the male. Approximately 33% of the E-concentrating cells within the central portion of the medial preoptic nucleus (MPNc), its medial portion (MPNm), lateral portion (MPNl), and the AVPv were GAL-I in males and females, which represented 47% of the GAL-I cells. The number of estrogen-concentrating and doubly labeled cells was greater within the AVPv of females than males. Within the MPN of each sex, the density of doubly labeled cells was highest in the MPNc and decreased progressively in the MPNm and MPNl. The high percentage of doubly labeled cells suggests that GAL within the MPOA may participate in the regulation of gonadal steroid-sensitive reproductive function. (Supported by HD 01182 to RAG, NS 21220 to PEM and HD 22869 to TRA).

233.11

POSSIBLE AFFERENT PROJECTIONS TO THE SPINAL NUCLEUS OF THE BULBOCAVERNOSUS IN ADULT MALE RATS.
P. Shen*, A.P. Arnold, and P.E. Micevych. (SPON: D.B. Lindsley). Department of Anatomy and Cell Biology and Department of Psychology, Laboratory of Neuroendocrinology, Brain Research Institute, UCLA, Los Angeles, CA 90024.

The spinal nucleus of the bulbocavernosus (SNB) consists of androgen-sensitive motoneurons in the rat spinal cord. The SNB motoneurons and their target muscles are present in adult male rats but reduced or absent in adult females. To begin to define an androgen-sensitive neural pathway from the brain to the periphery, we attempted to identify supraspinal afferents to the SNB. Fluorogold (5% in distilled water) was iontophoresed (5uA, 20min, 30um electrode tip) into the SNB region of adult male rats. After approximately a four-week survival time, the rats were sacrificed, perfused, and their brains and spinal cords isolated. The spinal cords were cut into 50um sections and viewed under a fluorescence microscope. Brains from animals with good injection sites in the spinal cords were cut at 80um and viewed under fluorescence. The brain sites which contained a significant number of fluorescently labeled cells were the gigantocellular reticular nucleus (including the ventral and alpha nuclei) and the lateral vestibular nucleus. Many labeled cells were found in the ventral medullary reticular nucleus, raphe obscurus nucleus, raphe magnus nucleus, and the caudal pontine reticular nucleus. Labeled cells were also observed in the paramedian reticular nucleus, the spinal vestibular nucleus and the paraventricular nucleus of the hypothalamus. Supported by NIH grants NS23468, GM07185 and HD15021.

233.12

CALCITONIN GENE-RELATED PEPTIDE mRNA IN MOTONEURONS: EFFECT OF CASTRATION. P. Popper and P.E Micevych. Dept Anatomy & Cell Biology, Laboratory of Neuroendocrinology, Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

Calcitonin gene-related peptide (CGRP)-like immunoreactivity is widely distributed in motoneurons of the spinal cord and brainstem. Within the spinal nucleus of the bulbocavernosus (SNB) the number of CGRP-positive motoneurons increases following castration, and testosterone reduces the number to intact levels. In the present study we used in situ hybridization to investigate the effect of testosterone on steady state levels of CGRP mRNA in adult male rat SNB. Eighteen adult male Long Evans rats were used. Six were intact, six were castrated for four weeks, and six were castrated and implanted with testosterone-containing Silastic tubing. Rats were killed by intracardiac perfusion of 4% paraformaldehyde in 0.1M phosphate buffer and the spinal cords removed. The spinal cord were postfixed for 2 hours and then cryoprotected with 10% sucrose in phosphate-buffered saline. Serial sections (20 um) were cut at -15 °C on a cryostat. The sections were stored at -70°C until hybridization. Tissue sections were processed for in situ hybridization using a ^{35}S-labelled single-stranded cRNA transcribed from a genomic probe from the 3' end of the calcitonin gene (gift from Dr. Rosenfeld, UCSD, La Jolla) and a ^{35}S-oligonucleotide probe complementary to the mRNA segment coding for residues 7-21 of CGRP. Motoneurons containing message for CGRP were identified by overlying silver grains. At the level of L5 and L6, motoneurons in the retrodorsolateral nucleus, dorsolateral nucleus, ventral motor pool, and SNB were observed to contain CGRP mRNA. Comparisons across treatment groups were analyzed using ANOVA. Supported by NS23468 to PEM.

233.13

CALCITONIN GENE-RELATED PEPTIDE LIKE-IMMUNOREACTIVITY IN MOUSE SPINAL NUCLEUS OF THE BULBOCAVERNOSUS IS AFFECTED BY CASTRATION. L.Clemens, C.Wagner, P.Popper, C.Ulibarri, & P.E Micevych. Dept Zoology & Neuroscience Program, Michigan State University, East Lansing, MI 48824, Dept Anatomy & Cell Biology, Laboratory of Neuroendocrinology, Brain Research Institute, UCLA School of Medicine, Los Angeles, CA 90024.

The mouse spinal nucleus of the bulbocavernosus (SNB) is located at levels L5-L6. It contains approximately 100 motoneurons that innervate primarily the bulbocavernosus muscle. In rats calcitonin gene-related peptide like-immunoreactivity (CGRP-LI) in SNB motoneurons is dependent on circulating testosterone levels. In this study immunohistochemistry was used to investigate the changes in CGRP-LI in SNB motoneurons in male B6D2F1 mice that were tested for male sex behavior. Comparisons were made between sham castrated males, castrated males that continued to exhibit male sex behavior eleven weeks after castration (continuers), castrated males that did not (non-continuers), and males that were castrated for four weeks and not tested for male sexual behavior. Mice were tested for male sexual behavior and then either castrated or sham-castrated (N = 10). Five weeks later, they were retested for six weeks. Castrated males were divided into continuers (N = 10) and non-continuers (N = 7). Mice were perfused with 4% paraformaldehyde in 0.1M Sorenson's buffer. The spinal cords were removed, postfixed for 2-3 hours and cryoprotected. Serial sections (30 um) were taken through the SNB. Alternate sections were processed for CGRP-LI according to avidin-biotin peroxidase-antiperoxidase method using polyclonal anitbodies raised in rabbits (gift from Dr. Sternini, CURE, UCLA). The nuclei of CGRP-LI containing neurons and unstained were counted. In sham-castrated males 45.3$\pm$2.8% of the SNB neurons had CGRP-LI. There was a significant decrease in CGRP-LI neurons after castration [ANOVA $F(2,24) = 7.10$, $p < 0.01$)]. In continuers, 25.3$\pm$4.3% and in non-continuers, 20.2$\pm$3.2% of the SNB neurons had CGRP-LI. There were no differences between continuers and non-continuers, [Orthogonal comparison $F(1,24) = 0.73$, ns]. Supported by NS 23468 and HD 06760.

ENDOCRINE CONTROL AND DEVELOPMENT IV

234.1

MATCHING OF PRE- AND POSTSYNAPTIC SIZE IN NEUROMUSCULAR JUNCTIONS OF ANDROGEN-SENSITIVE MUSCLES. N. Nagaya and A.A. Herrera, Dept. of Biological Sciences, University of Southern California, Los Angeles, CA 90089.

The development and maintenance of synapses involves mechanisms which match pre- and postsynaptic structure and function. In vertebrate skeletal muscles, such mechanisms may account for the well-documented correlation between neuromuscular junction (NMJ) and muscle fiber size. We are using histology to examine this relationship in the forearm flexors of male Xenopus laevis. These muscles are sexually dimorphic, mixed in fiber type, and undergo seasonal hypertrophy or atrophy as plasma androgen levels increase or decrease, respectively. Experimental manipulation of androgen levels mimics these seasonal changes. In non-sexually dimorphic muscles, we found that the correlation between NMJ and fiber size is maintained throughout life and tends to maintain synaptic efficacy during growth. In androgen-sensitive muscles, however, there is no overall correlation between NMJ and fiber size. Histology also reveals more abandoned synaptic sites than in non-sexually dimorphic muscles, suggesting extensive remodelling. Our inability to detect a correlation may be due to androgen-induced synaptic remodelling. In addition, the relation between NMJ and fiber size may vary between fiber types. Observations to test these possibilities are in progress.

234.2

HORMONE MANIPULATION AND THE DEVELOPMENT OF LARYNGEAL MUSCLE FIBER NUMBER IN *XENOPUS LAEVIS*. Melanie Marin*, Martha Tobias, and Darcy Kelley, Dept. of Biol. Sci., Columbia Univ., N.Y., N.Y. 10027.

Sex differences in the larynx of *Xenopus laevis* contribute substantially to sex specific vocal behavior. Adult male larynges have more muscle fibers than females. Antiandrogen treatment prevents fiber addition in juvenile males (Sassoon and Kelley, Am. J. Anat., 1986). When during development does this sexual difference first appear? Does androgen secretion affect muscle fiber addition, and if so, when?

At metamorphosis, both males and females average 7,000 laryngeal muscle fibers. Throughout the first year of post-metamorphic (PM) development males add fibers at a much faster rate than females. At 3 mos (PM), fiber numbers are 20,000 for males and 12,000 for females; by 6 mos PM, males average 31,000 and females 11,000 fibers. Adult males have 35,000 and females 20,000 fibers. Testosterone (T) treatment for 5 wks at metamorphosis does not increase fiber number in intact males or females. At 6 mos PM, T treatment significantly decreases fiber number in males (to 24,000) but does not affect females. Castration at metamorphosis retards muscle fiber addition, resulting in only 12,500 (38% of expected) at 9 mos PM. Castration at 6 mos PM, however, does not block further fiber addition. Subsequent T treatment does not affect fiber number. Females ovariectomized and given testes at metamorphosis have significantly increased fiber numbers (26,000) at 9 mos PM.

These results suggest that gonadal hormones play a significant role in the development of laryngeal muscle fiber number. The castration experiments place this period of hormonal control between metamorphosis and nine months PM. That any muscle fibers at all are added after castration raises the possibility that events before metamorphosis set the stage for later myogenesis. Supported by NS 19949.

SLOW MUSCLE FIBERS WITH MULTIPLE TERMINALS IN THE SONGBIRD SYRINX W. Bleisch, C. Scharff* and F. Nottebohm Laboratory of Animal Behavior, Rockefeller University, NY, NY 10021

The muscles of the syrinx, the vocal organ of birds, contain several types of fibers. The female syrinx has a higher proportion of slow fibers than the male syrinx and testosterone treatment causes females to exhibit a male-like pattern. Most syringeal fibers are innervated at single focal terminals, but some slow fibers receive multiple terminals. To study this heterogeneity of fiber type and innervation, we combined immunocytochemistry to classify zebra finch muscle fibers with techniques to visualize neuromuscular junctions. One monoclonal antibody, mAb S58, directed against a slow class of myosin, labels only fibers which have multiple terminals. We also examined the distribution of immunoreactivity for neural cell adhesion molecule (NCAM). S58 positive fibers have elevated NCAM immunoreactivity, indicating that most, and perhaps all, fibers which have multiple terminals express high levels of NCAM. This suggests that NCAM may play a role in the maintenance of multi-terminal innervation in adult muscle.

ANDROGENIC REGULATION OF MOTOR UNITS IN SEXUALLY DIMORPHIC MUSCLES OF FROGS. M. Regnier and A.A. Herrera, Dept. Biol. Sci., Univ. of Southern Calif., Los Angeles, CA 90089.

Male frogs use their forearm flexors to clasp females during mating. Muscle size and contractility have been shown to vary in response to seasonal fluctuations in circulating androgens, with muscles being larger and more slowly contracting during the breeding season. Castration and androgen treatment cause changes that mimic these seasonal differences. In confirmation of previous work we found that castration reduces fiber size by 20-40% in two androgen sensitive forearm flexors (sternoradialis & flexor carpi radialis of Xenopus & Rana). The non sexually dimorphic sartorius muscle was not affected significantly by castration. To determine the cellular basis of these androgen effects we are correlating changes in muscle size and contractility with the histochemical properties of fibers. Preliminary evidence suggests that the capacity for oxidative metabolism is reduced by castration. Work is in progress to confirm this finding and measure the fatigue resistance and contraction kinetics of these muscles. We are also examining the possible roles of myogenesis, fiber death, and fiber type conversion in these changes, as well as testing whether motor units are equally or differentially sensitive to androgens.

234.5

ANDROGENIC REGULATION OF MOTONEURONAL DENRITIC MORPHOLOGY IN THE ADULT RAT. M. Sasaki* and A.P. Arnold, Dept. Psychology, UCLA, Los Angeles CA 90024-1563.

Previous reports indicated that androgens regulate the soma size and dendritic length of motoneurons in the spinal nucleus of the bulbocavernosus (SNB) of the adult rat. To replicate and extend these findings, we made quantitative measurements of the morphology of SNB dendrites after intracellular iontophoresis of HRP. Adult male rats were castrated and implanted with Silastic tubes containing testosterone (T) or nothing. One month later, bulbocavernosus motoneurons were identified by antidromic activation, and then stained by intracellular iontophoresis of HRP for reconstruction and measurement of individual dendritic trees.

As previously reported, soma size was significantly larger in T-treated castrates (1173 ± 43 um^2, n=31) than in blank-treated castrates (894 ± 53 um^2, n=28). However, there was no significant difference in overall dendritic length per neuron between groups (T-treated castrates: 22,170 $\pm$1048 um, n=10; blank-treated castrates: 21,676 $\pm$ 988 um, n=11). However, there were significant positive correlations between the cross-sectional area of the soma and the following parameters: total dendritic length, dendritic membrane surface area, and dendritic volume. Because soma size differs between groups, a modest effect of androgen on dendritic length would be expected in a larger sample of dendrites. Nevertheless, these results suggest that the effect of androgen on dendritic length is less than previously reported. Interestingly, dendritic growth cones were found at the distal ends of dendrites, most prominently in T-treated castrates and in the larger motoneurons of castrates, suggesting that these dendrites grow during adulthood. Supported by NIH grant HD15021.

EFFECT OF SEX AND ANDROGEN TREATMENT ON DENDRITIC DIMENSIONS IN THE FERRET PREOPTIC AREA. J.A. Cherry, M.J. Baum and T.J. DeVoogd, Dept. Biology, Boston Univ., Boston MA 02215 and Dept. Psychology, Cornell Univ., Ithaca, NY 14853.

In male ferrets a nucleus exists dorsally at the border of the preoptic area (POA) and anterior hypothalamus (AH) which is not present in females. Dendritic characteristics of neurons in the dorsal POA/AH were studied using Golgi-Cox stained brains from adult male and female (n=4/group) ferrets which had been gonadectomized and treated daily for 5 weeks with either testosterone propionate (TP, 5 mg/kg) or oil vehicle. Dendrites from multipolar neurons (n$\geq$15 neurons/group) were traced 3-dimensionally from 120 um sections with the aid of a semi-automated computer and microscope system; adjacent sections were used when necessary to follow cut-off dendrites. Somal areas were measured on a digitizing tablet.

Overall effects of Sex (2-way ANOVA, $p<0.05$) were found in measures of total dendritic length, dendritic density (the number of intersections of dendrites with concentric spheres of increasing radii from the cell body), and median radial distance (the distance at which there are an equal number of intersections proximal and distal to the cell body). There were no overall effects of Hormone on any measure, but significant Sex X Hormone interactions were observed for all three variables. These interactions were due to an apparently inhibitory effect of TP on dendritic dimensions in females together with a smaller trophic effect of TP in male dendrites. In contrast, dendritic measures were similar for oil-treated males and females. Mean somal area of male cells was significantly greater than females, irrespective of adult treatment. These results suggest that in the dorsal POA/AH of ferrets, dendrites of male and female multipolar neurons respond differently to androgen exposure in adulthood.

DEVELOPMENT OF SEX DIFFERENCES IN DENDRITIC LENGTH IN *XENOPUS LAEVIS* LARYNGEAL MOTOR NEURONS . James Watson and Darcy Kelley. Dept. Biol. Sci., Columbia Univ., N.Y., N.Y. 10027

In adult *X. laevis*, laryngeal motor neurons are more numerous and have longer dendrites in males than in females. The number of axons innervating the larynx becomes dimorphic before metamorphosis (Dennison and Kelley, Abstr. Soc. Neurosci., 1989), and laryngeal muscle dimorphism is established by postmetamorphic fiber addition (Sassoon and Kelley, Am. J. Anat., 1986). To determine how and when CNS sex differences are established, laryngeal motor neuron morphology was examined using the fluorescent dye, DiI. Metamorphic male (n=2) and female (n=3) froglets were fixed, their brains were embedded in 15% gelatin, and the 4th root of the IX-X cranial nerve complex was injected with DiI in ethanol. After 4-5 days at 37°C, 50 µm sections were prepared with a vibratome and micrographed. Primary apical dendrites were measured on type I and II laryngeal motor neurons (males, n=15; females, n=29; terminology of Kelley et al., J. Neurobiol., 1988). Males were found to have longer dendrites than females (Mean $\pm$ SD: 28.6 ± 5.2 µm vs. 23.7 ± 8 µm; $p<0.05$). This sex difference was due to a greater percentage of female neurons having short dendrites, male dendrites were uniformly long. Previous Golgi impregnations of n. IX-X neurons in adults revealed that dendrites were longer in both sexes (30-60µm), the variability in female dendritic length was small, and the sex difference in primary dendritic length was greater than was found here (meta: 1.2:1; adult: 2:1). Thus, while a sex difference in dendritic length is apparent by metamorphosis, a different adult pattern may be established by post-metamorphic dendritic remodeling in either sex or cell loss in females. Supported by NS23684 and NS08403.

DELAYED EXPOSURE TO GONADAL STEROIDS ENABLES VOCAL LEARNING IN ADULT ZEBRA FINCHES. S.W. Bottjer & S.J. Hewer. Department of Biology, USC, Los Angeles, CA 90089-0371.

Male zebra finches normally learn a specific song pattern during development. By the time they reach adulthood (>90 days), the song pattern has "crystallized"; this stereotyped song pattern is maintained without change throughout adulthood, and zebra finches are normally incapable of learning new song patterns as adults. We have previously reported that the development of learned vocal behavior in juvenile birds is dependent on circulating gonadal steroids: castration of juvenile male zebra finches combined with systemic exposure to anti-steroid drugs disrupts normal development of song production (Bottjer & Hewer, 1988). We wondered if delayed exposure to steroid hormones would result in any improvement in vocal behavior of such birds as adults; such an outcome might indicate that lack of exposure to steroids during development could prolong the so-called critical period for vocal learning.

We addressed this question as follows: males were anesthetized and castrated at 20 days of age. They received Silastic implants of an anti-androgen (flutamide) and/or an anti-estrogen (tamoxifen) from 20 to 95 days, during which time their vocal behavior was recorded periodically. At 95 days the anti-steroid implants were replaced with one containing testosterone, and song behavior was recorded for an additional 6 weeks. The vocal behavior of adult birds improved substantially in response to steroid exposure. This result suggests that normal exposure to steroids contributes to the curtailment of the capacity for song learning, and that the critical period for vocal learning can be extended by preventing such exposure.

234.9

CHRONIC TESTOSTERONE TREATMENT IMPAIRS VOCAL LEARNING IN MALE ZEBRA FINCHES DURING A RESTRICTED PERIOD OF DEVELOPMENT. S. Korsia & S.W. Bottjer. Dept. of Biology, USC, Los Angeles, CA 90089-0371.

Juvenile male zebra finches learn their song during a specific period of development. We have previously reported that development of learned vocal behavior in juvenile males is impaired by chronic administration of testosterone (T) from the day of birth until adulthood. T-treated males produce a very limited number of syllables and tend to repeat a single syllable in a pattern lacking the phrasing characteristic of normal song (Korsia & Bottjer, 1988). We investigated whether chronic testosterone administration later in development has a similar disruptive effect on the process of song learning. Normal development of song behavior in the case of delayed treatment might indicate the existence of a restricted sensitive period for susceptibility to chronic testosterone exposure.

Male birds were divided into three groups: one group received subcutaneous implants of T from the day of birth until day 20, at which age they received 1 or 2 Silastic implants packed with 10 mm of crystalline T; the second group received 1 or 2 Silastic T implants at day 20; the third group received 1 or 2 Silastic T implants at day 25. Song behavior was recorded until day 90, when stereotyped song has crystallized. Chronic T administration at day 25 failed to disrupt vocal learning in about 50% of the birds, whereas earlier treatment always impaired song development. This result suggests that chronic T treatment disrupts song acquisition only when administered during early life.

THE DEVELOPMENT OF AFFERENT PROJECTIONS TO RA IN MALE ZEBRA FINCHES: AN EM STUDY. K. Herrmann and A.P. Arnold. Dept. of Psychology, UCLA, Los Angeles, CA 90024-1563.

We used quantitative electron microscopic techniques to measure the development of synaptic input to the neuropil of nucleus RA in young zebra finches, since the ontogeny of these projections figures prominently in current theories of song learning and sexual differentiation of the brain. We lesioned HVc or MAN in male zebra finches of different ages: 25 days (d), 53d, and adulthood. After a survival time of 60-80 hours (HVc-lesion) or 80-120 hours (MAN-lesion), the animals were perfused, and tissue blocks including RA were dissected out and processed according to conventional electron microscopic techniques. Lesion-induced electron-dense degeneration was used to identify synapses from either HVc or MAN occurring in the neuropil of RA. Untreated control animals of the same age were also analyzed.

In control animals the density of synapses/100 um^2 increased slightly between day 25 and 53 and remained constant thereafter (25d:12.69; 53d: 15.42; adult:14.85). The occurrence of naturally degenerating synapses was fairly low in controls (25d:1%; 53d:0.8%; adult:0.6%). The incidence of terminals of HVc origin declined slightly with age (25d:10.53%; 53d:6.01%; adult:8.32%), whereas the terminals from MAN axons decreased more drastically (25d: 22.32%; 53d:4.55%; adult:1.41%). The ratio of axospinous to axodendritic terminals was 3:2 for HVc-originating terminals and 1:1 for those from MAN, irrespective of age. These values can be used to calculate the total number of synapses of each type in RA during development. These results imply that song learning is correlated with a reorganization of HVc and MAN synapses in RA. Supported by DFG grant He1539/1-1 and NIH grant NS19645.

234.11

TAMOXIFEN FAILS TO BLOCK ESTRADIOL-INDUCED MASCULINIZATION OF THE ZEBRA FINCH SONG SYSTEM. G.A.Mathews* & A.P.Arnold. (SPON:H.-J.Bischof). Department of Psychology, UCLA, Los Angeles, CA 90024-1563.

Estradiol masculinizes the female zebra finch song system while antiestrogens masculinize the female and hypermasculinize the male song systems. Although antiestrogens can be estrogenic when administered alone, they are typically antiestrogenic when administered with estradiol. We asked whether tamoxifen was capable of being an antiestrogen in the song system by antagonizing the effects of exogenous estrogen.

Zebra finch chicks received daily subcutaneous injections of 100ug tamoxifen (TAM), 20ug estradiol benzoate (EB), 100ug TAM combined with 20ug EB (TAM+EB), or vehicle, for the first 20 days after hatching. At 60 days the animals were killed and their brains were sectioned at 50um and stained with thionin for light microscopic analysis.

In females neuronal soma area (n.s.a.) in HVc and HVc volume were increased by EB alone (by 100% & 54% respectively, over control) and TAM alone (68% & 71%). Both compounds induced Area Xs in females. In addition, TAM increased n.s.a. in female RA (51%). In males n.s.a. in MAN and HVc were increased by EB alone (15% & 81%) and TAM alone (22% & 40%). TAM alone in males also increased n.s.a. in RA and Area X volume. TAM potentiated the EB effects: In females, TAM+EB increased volumes of Area X (92%), HVc (43%), and RA (64%), over EB alone. In males, n.s.a. in MAN was increased by TAM+EB (18%) over EB alone. These results show that simultaneous treatment with tamoxifen and estradiol does not prevent the masculinization caused by estradiol alone, suggesting an estrogenic role for tamoxifen in its effects on the song system. Supported by NIH grant NS19645.

NEURAL PLASTICITY IN HVC RELATED TO SONG ACQUISITION IN THE DEVELOPING ZEBRA FINCH. R.P. Clower and T.J. DeVoogd. Dept. of Psychology, Cornell University, Ithaca, NY 14853.

The principal song control nuclei of adult male zebra finches are much larger than those of adult females. These differences arise during development, when males are acquiring their permanent repetoires. Since females normally never sing, there may be specific anatomical requirements for learning to sing which are only met in young males. It is during the second month after hatching that males learn most of their adult repetoires, but closure of the sensitive period for acquisition of specific syllables appears to be delayed when young males are deprived of an appropriate song model. The present research studies the structural plasticity necessary for song learning by using multi-level analyses of male and female song control areas in young and adult normal animals and in animals deprived of exposure to song.

RA and HVc in normal male and female zebra finches at 10, 20, 30, 55 and 100+ days of age, as well as in males raised to 30 and 55 days by females only, were evaluated using an array of light and electron microscopic measures. In HVc of normally raised males, there is a peak at day 55 in total neuron number; the nucleus contains 33% more neurons at this age than at 100+ days (adulthood) ($p<.02$). Together with trends toward a 55 day peak in HVc volume and total synapses, this peak may represent an overproliferated state that disappears as song patterns stabilize. In HVc, there appear to be more synapses/neuron in females than in males across development ($p<.02$), possibly due to the presence in male HVc of many small, newly generated neurons that support relatively few contacts. At day 30, PST's in HVc of males raised by females only are 14% shorter than in HVc of normally raised males ($p<.02$), and neuronal density tends to be lower in HVc of song deprived males. Since these differences do not exist at day 55, it appears that some aspects of song system development are delayed when an appropriate song model is unavailable.

Overall, these results suggest that multi-level plasticity in HVc is important for early song acquisition in male zebra finches, and in particular that the continuation of neurogenesis in male HVc through the second month of development may play a critical role in permitting the actual production of song in males.

234.13

HORMONAL CONTROL OF TESTOSTERONE-METABOLIZING ENZYMES IN THE BRAIN OF THE ZEBRA FINCH.

A. Vockel* and J. Balthazart, Lab. General. and Comparative Biochemistry, University of Liège, Belgium. (SPON: ENA)

We recently described the distribution of testosterone-metabolizing enzymes (aromatase, 5α- and 5β-reductases) in the zebra finch (*Taeniopygia guttata*) brain using radioenzyme assays combined to the Palkovits punch method. A number of sex-differences in the activity of these enzymes were observed especially in nuclei of the song-control system. The hormonal controls of these differences have now been analyzed by gonadectomizing birds of both sexes and giving them a replacement therapy with silastic implants of testosterone (T). Five nuclei of the song system (*X, MAN, RA, ICo, HVc,*) and 3 preoptic-hypothalamic areas (preoptic anterior [POA], periventricular magnocellular nucleus [PVM] and posterior medial hypothalamic nucleus [PMH]) were studied. Data were analyzed by two-way ANOVAS with sex (male/ female) and treatments (intact/ gonadectomized/ gonadectomized+T) as factors. The activity of the 5α-reductase was higher in males than females for the 5 song control nuclei and was not affected by the treatments. On the contrary, the activity of this enzyme was not sexually dimorphic but was enhanced by T in POA, PVM and PMH. The activity of the 5β-reductase was higher in females than in males in all nuclei of the song system and in POA but was not influenced by the changes in T level in any of these nuclei. Both sex and treatment effects were observed in the control of the aromatase. The production of estrogens was dimorphic (females>males) in RA and PMH (and also in HVc of intact birds). It was increased by T in POA, PVM and PMH and also in RA but not in HVc. These data show that some of the sex differences in T-metabolizing enzymes result from the exposure to different levels of T while others persist even if birds are exposed to the same hormonal conditions. These are presumably the result of organizational effects of steroids.

234.14

ENDOCRINE AND NEUROENDOCRINE SYSTEMS DURING SEXUAL DIFFERENTIATION IN JAPANESE QUAIL. M.A. Ottinger, M.A. Abdelnabi*, Quichang Li* and B. Alston-Mills*. Depts. of Poultry Science and Animal Sciences, Univ. of Maryland, College Park, MD 20742.

Gonadal steroids stimulate permanent effects on central neuroendocrine systems during sexual differentiation. Experiments were conducted to monitor changes in gonadal steroids in blood, gonads and adrenal glands and hypothalamic levels of monoamines and luteinizing hormone releasing hormone (LHRH) in male and female quail between day 10, posthatch through day 7, posthatch. In males, levels of testosterone (T) peaked late in embryonic development; estradiol (E) levels remained relatively lower. In females, E was elevated relative to T in all samples, increased throughout development and declined posthatch. Hypothalamic LHRH concentrations also increased late in the embryonic development. Similarly, hypothalamic monoamines (norepinephrine, dopamine, epinephrine and serotonin) peaked late in embryonic development with a minor peak at day 1, posthatch. These data give support for early function of the endocrine system with involvement of the monoaminergic systems, particularly during the time of sexual differentiation.

235.1

DORSAL RAPHE STIMULATION MODIFIES DENDRITIC SPIKING OF NIGRAL DOPAMINERGIC NEURONS *IN VIVO* F. Trent*, and J.M. Tepper (SPON: I. Creese)
Center for Molecular and Behavioral Neuroscience, Rutgers University, Newark, NJ 07102

A serotonergic projection from the dorsal raphé nucleus (DR) to dopaminergic (DA) neurons of the substantia nigra, pars compacta has been identified at both the light and electron microscopic levels. *In vitro* intracellular recordings from nigral DA neurons have shown that application of serotonergic agonists results in an increase in the amplitude of dendritic calcium spikes evoked by direct intracellular depolarization, suggesting a possible role for serotonergic afferents in the modulation of dendritic dopamine release in substantia nigra. The present study was designed to examine the effects of DR stimulation on the excitability of the somadendritic region of nigral DA neurons *in vivo*, in order to test the physiological significance of the *in vitro* studies.

Adult male Sprague-Dawley rats were anesthetized with urethane, and bipolar stimulating electrodes were implanted in the anterior-lateral neostriatum and DR. Extracellular single unit activity of nigral dopaminergic neurons was recorded by conventional means, and antidromic responses were elicited from the neostriatal stimulating site. Antidromic responses of nigral DA neurons consist of either an initial segment (IS) spike only, or a full IS-somadendritic (SD) spike, with IS-only responses predominating. The proportion of full IS-SD antidromic responses to total antidromic responses was used as an index of somadendritic excitability. Only neurons exhibiting at least 15% IS-SD antidromic responses were studied.

In the control condition, antidromic responses to neostriatal stimuli at the antidromic threshold consisted of 33.1±2.7% IS-SD spikes. Electrical stimulation of the DR with a train of 1-5 pulses (250 μA, 250 μs) delivered 2-7 ms prior to the antidromic response significantly and reversibly reduced this proportion to 24.4±3.0% (t=5.7, df=22, p<.0001), without significantly altering the neostriatal-evoked post-stimulus inhibitory period. Admininstration of the serotonergic receptor antagonist, metergoline (0.5 - 1.0 mg/kg, i.v., n=4), eliminated the DR-induced reduction in IS-SD spikes, suggesting that DA dendrites are subject to modulation by serotonergic afferents *in vivo*. Further studies are needed to determine whether this effect is mediated by direct DR-nigral afferents or indirectly, through DR-striatal projections.

Supported by MH45286 and the Rutgers University Research Council.

235.2

SEROTONERGIC INVOLVEMENT IN THE CLASSICAL DOPAMINE MEDIATED STEREOTYPY AND CATALEPSY. E.S. Onaivi*,B. Costall* and R. J. Naylor*, (SPON: D.A. Brase) Dept. Pharmacology and Toxicology, MCV/VCU, Richmond, VA 23298, and Postgraduate School of Studies in Pharmacology, University of Bradford, Bradford, BD7 1DP, England.

Dopamine (DA) agonists induce stereotypy while the classical antagonists produce catalepsy in laboratory animals. In this study we assessed the nature of serotonergic (5-HT) influence on dopamine mediated behaviors and the neurochemical correlates using HPLC with electrochemical detection. The stereotype behavior of BKW mice in the following groups: (a) Vehicle, (b) apomorpine (0.25-5 mg/kg), (c) 5-hydroxytrptophan (5-HTP; 200-400 mg/kg) and (d) 5-HTP plus apomorphine were assessed in individual perspex observation cages using a modification of the rating system of Naylor and Olley. Haloperidol-induced catalepsy in naive and following dorsal or medial raphe nucleus (DRN or MRN) lesions were evaluated. 5-HTP maximally potentiated the apomorphine stereotypic response at doses which caused significant changes in striatal and limbic brain neurochemistry implicating raised levels of DA, and 5-HT in animals treated with 5-HTP plus apomorphine when compared to mice treated with vehicle, apomorphine or 5-HTP alone. The electrolesion of DRN but not the MRN reduced the intensity of haloperidol-induced catalepsy whereas the MRN lesions actually potentiated this response. The results suggests an interaction of serotonergic mechanisms on these classical DA dependent behaviors. Although, the neuronal and molecular events leading to serotonergic and dopaminergic interactions are not fully understood, the control of dopamine neurotransmission by serotonergic mechanisms are being exploited.

235.3

SEROTONIN (5-HT) REGULATES CHOLINE ACETYLTRANSFERASE (ChAT) ACTIVITY AND SUBSTANCE P IN THE DEVELOPING STRIATUM. L. Ni*, S. Schotland*, and G.M. Jonakait (SPON: R.P. Hart), Dept. of Biological Sciences, Rutgers University, Newark, N.J. 07102

To assess the effects of serotonergic innervation on cholinergic and substance P (SP)-containing neurons of the developing striatum, 3-day-old rat pups received 5,7-dihydroxytryptamine intracisternally to destroy serotonergic neurons. Tryptophan hydroxylase activity in the cortex fell 76-82%, confirming a successful lesion. Four days after the lesion, ChAT activity in the striatum fell 34±4.0% ($p<.01$), but recovered after 4 weeks to control levels. By contrast, SP levels remained normal during the first week after surgery, but fell to 56±3.1% ($p<.02$) of control thereafter. SP levels had not recovered 4 weeks after surgery.

To determine whether the direct action of 5-HT on striatal cells might account for maintenance of ChAT activity, organotypic tissue cultures of E16 rat striata were grown for 10 days. Cultured striata lack all afferent input. In the presence of 5-HT agonists 8-OH-DPAT (10uM) and alpha-methyl-5-HT (2uM), ChAT activity increased 150-166%. Agonist-induced increases in ChAT were blocked by mianserin (1 or 10 uM) and ketanserin (2 uM) respectively. These data suggest that the direct activation of 5-HT receptors within the developing striatum can facilitate the restoration of ChAT activity in denervated striata.

235.4

NEOSTRIATAL PREPROTACHYKININ (PPT) mRNA FALLS FOLLOWING INHIBITION OF SEROTONIN (5-HT) SYNTHESIS. P. D. Walker, L. Ni*,S. Schotland*, R.P. Hart and G. M. Jonakait. Dept. of Biological Sciences, Rutgers University, Newark, NJ 07102.

Substance P is a neurotransmitter in projection neurons of the neostriatum (NS). Following blockade of afferent dopamine neurotransmission, striatal SP peptide and PPT (the peptide precursor of SP) mRNA levels are decreased (Bannon et al., Brain Res. 3:31, 1987). Since the NS also receives a substantial serotonergic projection from the midbrain raphe, we sought to determine whether 5-HT inhibition alters NS PPT mRNA levels.

Adult female rats received Alzet minipumps (Model 2ML2) containing *p*-chlorophenylalanine (*p*CPA). *p*CPA suppresses 5-HT formation by inhibiting tryptophan hydroxylase (TPH). Each pump delivered 100 mg/kg/day of *p*CPA for 14 days. Control animals received sham surgery but no pump. TPH activity in dorsal raphe nuclei from *p*CPA-treated animals was inhibited by 70-80% after 1, 2, and 3 weeks. At these times total NS RNA was subjected to Northern blot analysis using a radioactive RNA probe for rat PPT. PPT mRNA levels were normalized to levels of 28S ribosomal RNA. One week after pump installation, striatal PPT mRNA had fallen to 18%, but recovered gradually over the next two weeks to 65% of control.

These results suggest that serotonin plays a role in the regulation of SP biosynthesis in the NS. Because the midbrain raphe projects to substantia nigra as well as NS, further studies are required to determine whether the effects of 5-HT inhibition on SP biosynthesis in the NS are mediated by the nigrostriatal pathway. Funded by MH43365, and AHA-NJ. GMJ and RPH are Johnson & Johnson Discovery Research Fellows.

DOPAMINERGIC REGULATION OF STRIATAL NEUROPEPTIDE Y SYSTEMS. L. Midgley*, K.Merchant*, L. Bush*, J.W. Gibb, G.R. Hanson. (SPON:F.Matsuo). Univ. of Utah, Salt Lake City, UT 84112.

Recent reports have shown that the number of striatal neuropeptide Y (NPY) neurons, as well as their labeling intensity, are decreased by treatment with multiple daily doses of the dopamine (DA) antagonist, haloperidol (Neurosci. 26 [1988] 819). This finding suggests that the striatal NPY system is regulated by dopaminergic mechanisms. To study this possibility further, we administered the potent indirect DA agonist, methamphetamine (METH), and assessed the response of the striatal NPY system by measuring striatal content of NPY-like immunoreactivity. Eighteen hours after METH treatment (5 doses, 10 mg/kg/dose given every 6 hr), NPY levels were significantly decreased to 73% of control. In order to characterize the nature of this response, selective D-1 (SCH 23390) and D-2 (sulpiride) antagonists were given alone and coadministered with METH. Treatment with sulpiride alone decreased striatal NPY levels to 52% of control and when combined with METH, NPY content decreased further to 42% of control. In contrast, SCH 23390 administered alone had no effect on striatal NPY content, but may have attenuated the METH effect as NPY levels decreased to only 85% in animals which received both drugs. These findings suggest that D-2, and possibly D-1, receptors have a role in the regulation of striatal NPY projections. (Supported by USPHS grants DA 00869 and DA 04222).

NEUROTENSIN REGULATES ENDOGENOUS ACETYLCHOLINE RELEASE FROM RAT BRAIN SLICES: REGIONAL SPECIFICITY. A. Beaudet, D.M. Araujo, R. Quirion and P.A. Lapchak. Neuroanat. Lab, Mtl. Neurol. Inst. and McGill Univ., Dept. of Psychiatry, Montreal, Quebec, Canada.

Neurotensin (NT) receptors were recently shown to be selectively associated with the perikarya and dendrites of basal forebrain cholinergic (ACh) neurons (Neurosci. Lett. 83, 47-52, 1987). Several lines of evidence suggest that NT receptors might also be associated with ACh axons in several brain areas, thus providing a basis for NT-ACh interactions in the brain. In the present study we tested whether NT is involved in the regulation of ACh release from areas enriched in cholinergic markers and NT receptors. NT (10 μM) increased evoked (25 mM K^+) ACh release from slices of parietal cortex (36.2 ± 8.8%) and striatum (50.1 ± 10.5%) and decreased evoked ACh release from slices of frontal cortex (28.7 ± 5.3%): these effects were concentration-dependent. Spontaneous ACh release was not altered by NT in these three brain areas. In contrast, in slices of the basal forebrain, diagonal band and hippocampus, NT (10 μm) did not significantly alter either spontaneous or potassium-evoked ACh release. These results indicate that NT modulates ACh release from both corticopetal and intrinsic neostriatal neurons and may therefore exert a widespread influence on the regulation of cholinergic neuronal activity in the brain. (Supported by MRC, Canada and FRSQ, Quebec).

TONIC REGULATION OF THE NEUROTENSIN SYSTEMS BY BASALLY RELEASED DOPAMINE IN THE BASAL GANGLIA OF THE RAT. K.M. Merchant*, J.W. Gibb and G.R. Hanson, Department of Pharmacology and Toxicology, University of Utah, Salt Lake City, UT 84112.

Elimination of central dopaminergic activity by treatments with reserpine causes a substantial increase in the content of neurotensin (NT)-like immunoreactivity (NTLI) in the striatum but decreases the nigral concentration of this peptide by about 30% of control. These data suggest that basal dopaminergic activity tonically but differentially regulates the NT systems in these basal ganglia structures. The present study characterizes the roles of dopamine D-1 and D-2 receptors in mediating this tonic regulation. Administration of 4 doses (every 3h) of the D-2 selective agonist, LY 171555 (5 mg/kg), completely blocked the reserpine mediated increase in striatal NTLI level but did not affect the nigral response. On the other hand, an identical treatment with the D-1 selective agonist, SKF 38393 (18 mg/kg), prevented the decrease in nigral NTLI content induced by reserpine but only slightly attenuated the striatal response. These data indicate that tonic dopaminergic regulation of striatal NT systems is mediated chiefly by the D-2 receptors whereas that in the substantia nigra is mediated by the D-1 receptors. This hypothesis was confirmed when treatments with the D-2 selective antagonist, sulpiride, increased only the striatal NTLI content whereas treatment with the D-1 antagonist, SCH 23390, decreased the NTLI content only in the substantia nigra. (Supported by USPHS Grants DA 00869 and DA 04222)

ROLE OF GLUTAMATE IN DOPAMINE-MEDIATED NEUROTENSIN CHANGES. N.A.Singh*, K.M.Merchant*, J.W. Gibb and G.R.Hanson. Dept. Pharmacol. and Toxicol., Univ of Utah, Salt Lake City, UT 84112.

Previous studies have demonstrated that methamphetamine (METH) induced neurotensin (NT) increases in the striatum, nucleus accumbens and substantia nigra are primarily mediated by dopamine D1 receptors. To determine if other neurotransmitter systems play a role in DA-mediated peptide responses, we coadministered selective glutamatergic and cholinergic antagonists with METH. Firstly, animals were given a combination of MK-801 (2.5mg/kg, a selective noncompetitive NMDA antagonist) fifteen minutes prior to METH (10mg/kg) for five doses at 6-hr intervals and sacrificed 18hr after the last dose. MK-801 alone did not alter NT levels in the striatum, n. accumbens or s. nigra; however MK-801 completely blocked METH-induced increases in NT in all structures examined. MK-801 was found to be a very potent blocker of these METH effects since doses of this NMDA antagonist as low as 0.1mg/kg completely prevented the METH-induced NT changes. Secondly, the muscarinic antagonist, atropine, was coadministered with multiple doses of METH. Unlike MK-801, atropine had no significant impact on METH-induced changes in NT levels. These findings suggest that glutamate projections (related to NMDA systems), but not cholinergic neurons, are involved in the D1 regulation of extrapyramidal and limbic NT systems.(Supported by grants DA 00869 and DA 04222).

NEUROTENSIN-EVOKED OVERFLOW OF ENDOGENOUS DIHYDROXY-PHENYLACETIC ACID FROM SUPERFUSED RAT STRIATAL SLICES IS GREATLY DIMINISHED BY STRESS. L.P. Dwoskin and S.T. Buxton*. Univ. KY Col. Pharmacy, Lexington, KY 40536.

Neurotensin (NT) has been suggested to be an endogenous neuroleptic (Nemeroff, Biol. Psych. 15:283, 1980) and is predicted to influence the release of DA. Single striatal slices (6 mg) were superfused (1 ml/min) with Kreb's buffer. After 1 hr, NT (0.3-30 uM) was added to the buffer and 15 one-ml samples collected. Samples were assayed by HPLC-EC (Gerhardt et. al., J. Neurosci. Meth. 26:217, 1989). NT in a dose-related manner increased the amount of DOPAC collected in superfusate from slices from Sprague-Dawley rats from both Sasco and Harlan suppliers. Although the maximal amount of NT-evoked overflow of DOPAC was not different (1660 ±490 and 1930 ±320 pg/ml/mg tissue, Sasco and Harlan, respectively), the shapes of the dose-response curves were very different. The results from the Sasco rats revealed an S-shaped curve (EC50 3 uM), and that from the Harlan rats an inverted-U (apex at 1 uM). Stress was induced by subjecting the rat (and the experimenter) to loud, irritating, vacuum pump noise for a 5 min period prior to sacrifice. This unquantitated stressful event greatly diminished the amount of DOPAC collected in experiments using rats from both suppliers. This serendipitious finding will be followed-up in future experiments. Supported by NIMH Grant MH42934.

NEUROTENSIN REVERSES THE EFFECTS OF AMPHETAMINE ON IN VIVO DOPAMINE METABOLISM IN THE ACCUMBENS BUT NOT THE STRIATUM. R. Rivest[1], F.B. Jolicoeur[1], F. Crespi*[2] and C.A. Marsden*[2]. [1]Dept. psychiatry, Fac. of Med., Univ. of Sherbrooke, PQ, Canada J1H 5N4 and [2]Dept. of Physiol. and Pharmacol., Queen's Med. Centre, Nottingham, UK, NG7 2UH.

The antagonistic properties of neurotensin (NT) on the behavioural hyperactivity induced by dopaminergic agonists are thought to be mediated via the mesolimbic system rather than the nigrostriatal pathway (Ervin et *al.* Nature. 291, 73-76, 1981; Jolicoeur et *al.* Neurosc. Biobehav. Rev. 7, 385-390, 1983). In the present study, we examine the effect of intracerebroventricular (ICV) administration of NT in combination with amphetamine, on the extracellular level of DOPAC measured by *in vivo* differential pulse voltammetry in both the nucleus accumbens and the striatum. Male Wistar rats (250-280 g) were anaesthetised using chloral hydrate (400 mg/kg i.p.) and stereotaxically implanted with a guide cannula in the left lateral ventricle and with an electrically-pretreated 12 µm carbon fiber electrodes in the nucleus accumbens and the striatum. Saline 1 ml/kg or amphetamine 2mg/kg/ml s.c. were administered, followed five minutes later with an ICV injection with saline 10 µl or NT 10 µg/10µl and the extracellular DOPAC was recorded every five minutes for two hours. Compared with baseline value, amphetamine produced similar decrease in extracellular DOPAC in the nucleus accumbens (52%) and the striatum (47%). NT produced a significant increase in the DOPAC peak in the accumbens (30%) and the striatum (25%). However, when administered with amphetamine, NT partly reversed the decrease induced by the drug in the accumbens but not in the striatum. Together, these results support previous neurobehavioural data indicating that NT reduce the hyperactivity induced by amphetamine by a specific action on the mesolimbic dopaminergic system.

REGULATION OF MESOLIMBIC DOPAMINE/CHOLECYSTOKININ NEURONS AND THEIR POST-SYNAPTIC CELLS; EFFECTS OF AMPHETAMINE. Y.L. Hurd, N. Lindefors*, S. Brené*, E. Brodin*, W. O'Connor*, T. Hökfelt, U. Ungerstedt* and H. Persson*. Depts. of Pharmacology, Histology and Medicinal Chemistry, Karolinska Institute, Box 60400, S-10401 Stockholm, Sweden.

Activation of dopamine (DA) neurotransmission in the nucleus accumbens has been frequently theorized to mediate the reinforcing effects of psychomotor stimulants, e.g. amphetamine (AMP) and cocaine. However,it has been observed that repeated self-administration of cocaine attenuates the enhanced overflow of DA previously evident during first-time exposure to the drug. In the present study the effect of acute and repeated (1.5mg/kg; twice daily for 7 days) AMP administration on extracellular levels of DA, cholecyctokinin (CCK),GABA and acetylcholine in the nucleus accumbens of halothane-anesthetized rats was assessed by in vivo microdialysis. Acute AMP increased DA overflow in saline pretreated rats, concomitant with a reduction of DOPAC and HVA levels. However, following repeated AMP administration, DA overflow was attenuated although the reduction of the DA metabolites was maintained. Extracellular basal and K^+ stimulated CCK levels were slightly elevated following repeated treatment of AMP. Regulation of DA/CCK release and characterization of the cells types were assessed by in situ hybridization and immunocytochemistry. Presynaptic modulation of mesolimbic DA/CCK neurons comcomitant with supersensitive post-synaptic receptors are proposed.

DIRECT GABAERGIC-DOPAMINERGIC SYNAPTIC INTERACTIONS IN THE RAT SUBSTANTIA NIGRA: AN ULTRASTRUCTURAL DOUBLE LABELLING IMMUNOCYTOCHEMICAL STUDY. B.A. Flumerfelt, I. Mendez* and K. Elisevich. Depts. of Anatomy and Clinical Neurological Sciences, University of Western Ontario, London, Canada, N6A 5C1.

The substantia nigra contains a prominent intrinsic GABAergic system, and a striato-nigral GABAergic projection, and there is evidence of physiological and pharmacological effects of GABA on dopaminergic neurons in the substantia nigra. However, the structural nature of the GABAergic-dopaminergic interactions in the substantia nigra is not clear. Simultaneous localization of GABA immunoreactive terminals and tyrosine hydroxylase (TH) immunoreactive neurons was achieved with the PAP method, using two different chromogens with distinct reaction products that are easily differentiated at the light and electron microscope levels. GABA-positive neurons and terminals were first localized with 3,3'- diaminobenzidine, then TH-positive neurons were localized using benzidine dihydrochloride. GABA immunoreactive terminals made symmetrical synaptic contacts with TH-positive dendrites in the substantia nigra pars compacta and pars reticulata. The present results demonstrate a direct GABAergic input to dopaminergic neurons in the substantia nigra, supporting the view that GABA modulates dopaminergic neurons within the substantia nigra and likely originates within the striato-nigral system.

GABA RELEASE IN SUBSTANTIA NIGRA MEASURED BY MICRODIALYSIS: MODULATION BY DOPAMINE. B. K. Yamamoto. Dept. of Pharmacology, Northeastern Ohio Univs. College of Med., Rootstown, OH 44272

Previous findings indicate that the effects of locally applied GABA on substantia nigra-reticulata (SN-R) neuronal activity is inhibited by dopamine (DA). To test the hypothesis that DA modulates GABA neurotransmission, the present study used microdialysis to examine the effect of the locally applied D1 antagonist, SCH 23390, on in vivo GABA release in the SN-R of awake-behaving rats. Male Sprague-Dawley rats (n=6) were chronically implanted with guide cannulae. The tip of the cannula was positioned dorsal to the SN-R. Three days after surgery, a microdialysis probe (210 µm O.D., 1.0 mm length) was inserted through the guide cannula to extend into the SN-R. The probes were perfused with artificial CSF (pH 6.5) at a flow rate of 2.0 µl/min. The amino acid content of each 25 µl dialysate sample was assayed by pre-column derivatization and HPLC/EC. Basal levels were allowed to stabilize for at least 3 hrs. Following this baseline stabilization period, SCH 23390 (500 µM) was infused directly into the SN-R via the probe for 40 min while simultaneously measuring GABA release. SCH 23390 increased basal GABA release in SN-R by 54%. These increases returned to baseline within 1 hr after the end of the drug infusion. The effects of a D-2 antagonist on GABA release will also be presented. These data may indicate that dendritic DA release in SN-R inhibits striatonigral GABA transmission via the D-1 receptor and thus may regulate motor output commands from the striatum.

MODULATION OF GABA RELEASE IN VIVO BY GABA-B RECEPTORS IN THE RAT STRIATUM. R.Singh* and R.G.Fariello (SPON: F.A.Davis), Dept.of Neuro. Sci. Rush Med. Ctr., Chicago, IL 60612.

GABA containing neurons and terminals in the rat striatum(ST) are targets of local GABAergic interneurons. In this study, we have examined if GABA release in ST is under feedback control by GABA autoreceptors, specifically GABA-B. Male rats (250-300 g) were anaesthetized with halothane/O_2 and dialysis probes were implanted into the anterior caudate. Lactate-Ringer buffer (pH-7.4) was perfused through the probes at 1 ul/min. Dialysates were collected at 20 min intervals and analyzed by OPA derivatization and HPLC with fluorescence detection. After 3 baseline samples, a specific GABA-B agonist, baclofen (100uM) was added to the perfusate for 40 min and sampling continued for 2 h. Baclofen decreased GABA release by 22±6 % from the basal levels. This decrease was maximal within 20 min and returned to base line by 40 min. Glutamate release was also decreased by 30±12 % from the basal levels and this effect was present up till 40 min after which the levels returned to baseline. These results indicate that GABA-B receptors inhibit GABA release in ST and may also affect glutamatergic cortical input.

235.15

DOPAMINE MODULATION OF THE GABA PATHWAY PROJECTING FROM THE NUCLEUS ACCUMBENS TO THE VENTRAL PALLIDUM IN CONCIOUS RATS. A. Bourdelais* and P.W. Kalivas (SPON: R. Kuczenski). Dept. of VCAPP, Washington State University, Pullman, WA 99164-6520.

Locomotor activity induced by amphetamine (AMP) and cocaine has been shown to be associated with a rise in extracellular dopamine (DA) levels in the nucleus accumbens (NA). An increase in spontaneous locomotion produced by DA agonists in the NA is prevented by pretreatment with an injection of a GABA agonist in the ventral pallidum (VP). This has led to the postulate that DA may be acting in the NA to inhibit GABA release in the VP. In the present experiments, intracranial dialysis was used to directly compare the effect of cocaine and AMP on extracellular GABA concentration in the VP with changes in locomotor behavior in concious rats. Rats were chronically implanted with a guide cannula 3mm above the VP. At 6-8 days postsurgery the rat was placed in a photocell apparatus and a dialysis probe was inserted into the VP via the guide cannula. After a 2 hr equilibration period, 4 x 20 min baseline samples were collected and the rat was then injected with one of the following: saline, 15.0 mg/kg cocaine (i.p.), or 2.0 mg/kg AMP (s.c.). 20 min samples were collected for another 180 min. Artificial CSF, at a flow rate of 2.31 ul/min was used for dialysis. HPLC-EC was used to measure GABA levels, with OPA/t-butylthiol precolumn derivatization. Baseline concentration for GABA was 0.15 pM/ul. After cocaine administration a maximal GABA decrease of (30%) was seen by 80 min. After AMP administration a significant decrease in GABA concentration (36%) was seen by 40 min.

235.16

DOPAMINE-GABA INTERACTIONS IN THE LIMBIC FOREBRAIN FOLLOWING LOCAL APPLICATION OF K+, AMPHETAMINE AND FLUPENTHIXOL. J. Kehr*, F. Weiss, A. Carlsson*, G.F. Koob, and U. Ungerstedt*. (SPON: S. Foote) Dept. of Pharmacology, Karolinska Institute, Stockholm, Sweden; Research Institute of Scripps Clinic, La Jolla, CA.

Recent evidence suggests a significant role for GABA in the mediation of dopamine (DA) related functions within the basal forebrain. We have further investigated DA-GABA interactions in this brain region by measuring the effects of DA stimulation or blockade on extracellular GABA concentrations in the nucleus accumbens (NAS) and ventral pallidum (VP) using in vivo microdialysis. Perfusate was collected simultaneously from two microdialysis probes implanted into the NAS and VP of halothane anesthetized rats and assayed for both DA and GABA (NAS) or GABA only (VP). Drugs, including K+, d-amphetamine [AMP] and flupenthixol [FLU] were administered directly into the NAS via the perfusion medium at 30 min pulses. K+ (30mM) stimulated both GABA and DA release (450-800% of basal) in the NAS, followed by a late, gradual rise in VP GABA concentrations (>200%) of basal). In contrast, while AMP (100uM) produced substantial increases in DA overflow (>5000% basal), this enhancement of DA activity was not associated with changes in extracellular GABA levels in the NAS. AMP, however, elevated GABA levels in the VP and produced a sharp "spike" (300% of basal) in GABA release which occurred with a delay of approximately 20-30 min after termination of AMP administration. This effect was antagonized by concurrent administration of FLU (100uM). The same treatment (AMP+FLU) strongly enhanced GABA release in the NAS (>250% basal). The results suggest a differential regulation of GABA activity within the NAS and the GABAergic efferents by DA, and confirm an important role for the NAS-VP pathway in the effects of mesolimbic DA stimulation.

L-GLUTAMIC ACID EVOKES Ca^{2+}-INDEPENDENT RELEASE OF DOPAMINE FROM RAT STRIATUM VIA DOPAMINE UPTAKE SYSTEM. G. Lonart and M.J. Zigmond. *Department of Behavioral Neuroscience and Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260*

We have examined the effects of exogenous L-glutamate (10 mM) on the in vitro release of dopamine from rat striatum. Slices (350 um) were superfused (100 ul/min) with a Krebs-bicarbonate buffer containing a physiological concentration of Mg^{2+} (1.2 mM). L-Glutamate produced a 7.5-fold increase in endogenous dopamine efflux. The NMDA receptor antagonists, 2-amino-5-phosphonovaleric acid (0.1 mM) and MK 801 (0.01 mM), reduced this effect by 70%. The glutamate-induced release of dopamine was insensitive to the removal of Ca^{2+}, addition of tetrodotoxin (0.5 uM), or pretreatment with reserpine (5 mg/kg, s.c.). However, the inhibitor of high affinity dopamine, nomifensine (0.01 mM), completely abolished the effect. These data suggest that L-glutamate might evoke a Ca^{2+}-independent release via the high affinity dopamine uptake system in the rat striatum. (Supported in part by USPHS grants NS-19608, MH-43947, and MH-00058.)

235.18

EFFECT OF RITANSERIN ON THE INTERACTION OF AMFONELIC ACID AND NEUROLEPTIC-INDUCED STRIATAL DOPAMINE METABOLISM. P.G.Conway, L.Brougham* and D.B.Ellis* Dept. of Biological Research Hoechst-Roussel Pharmaceuticals Inc. Somerville, NJ 08876.

In the present study we evaluated the interaction of amfonelic acid (AFA) with the typical neuroleptic haloperidol (H) or the atypical antipsychotic clozapine (C) on rat striatal dopamine metabolism in the absence or presence of the 5HT2 receptor antagonist ritanserin. In the absence of ritanserin, AFA significantly enhanced H stimulated DOPAC accumulation by 36% above that produced by H alone. This effect is believed to be due to AFA's ability to facilitate dopamine release produced by the potent H-induced increase in nigralstriatal impulse flow. In contrast, AFA did not potentiate the ability of C to stimulate DOPAC. This lack of potentiation could be explained by C's known potent 5HT2 receptor blocking activity attenuating its stimulatory effects on impulse flow. To test this we introduced 5HT2 receptor blocking activity to H by combining this drug with ritanserin and again studied the interaction with AFA on dopamine metabolism. In the presence of ritanserin AFA failed to potentiate the effects of H on DOPAC accumulation; an effect similar to that seen with C. These results extend the idea that 5HT2 receptor blockade modulates nigralstriatal dopaminergic neurotransmission. Additionally, when 5HT2 receptor blockade is added to the profile of H this drug functions similarly to C in the AFA interaction test.

235.19

THE EFFECTS OF EXCITATORY AMINO ACIDS ON DOPAMINE NERVE TERMINALS IN THE NEOSTRIATUM OF THE ANESTHETIZED RAT: AN IN VIVO ELECTROCHEMICAL STUDY. *M.N. Friedemann[1] and G.A. Gerhardt[1,2] (SPON: L. Adler). Depts. of Pharmacology[1] and Psychiatry[2], Univ. of Colorado Health Sciences Center, Denver, CO 80262.

The striatum receives a substantial cortical input containing the excitatory neurotransmitter, glutamate. In order to investigate the effects of selective glutamate agonists on dopamine (DA) -containing nerve terminals, high-speed electrochemical measurements were used to study the effects of locally applied N-methyl-D-aspartate (NMDA) and kainate (KA) in the neostriatum of the anesthetized Sprague-Dawley rat. Local application of KA via pressure ejection (1-10 mM barrel concentration) resulted in long-lasting and non-recoverable DA overflow. NMDA also evoked DA overflow at barrel concentrations of 0.1-10 mM in a somewhat dose-dependent fashion. Lower concentrations of NMDA (10 μM), which did not elicit DA release alone, potentiated potassium-evoked DA overflow. This potentiation was inhibited by the non-selective antagonist, kynurenate (20 μM). Studies with more selective NMDA antagonists are underway to elucidate the receptor specificity of the NMDA effects. The effects of glycine, a potential NMDA receptor modulator, are also under investigation. Supported by USPHS AG06434 AND AG00441.

EFFECTS OF EXCITATORY AMINO ACIDS ON *IN VIVO* DOPAMINE RELEASE AND METABOLISM IN THE NUCLEUS ACCUMBENS. M. M. Payson* and B. A. Donzanti. Northeastern Ohio Univ. Col. of Med., Dept. of Pharmacology, Rootstown, OH 44272.

Excitatory amino acids (EAA) induce a marked increase in spontaneous locomotor activity when injected into the nucleus accumbens (NA). Although pharmacological studies suggest that this hyperactivity is the result of EAA-induced dopamine (DA) release, *in vitro* experiments have failed to show any effect of these neuroexcitants on endogenous DA release. The present study assessed the effects of EAA on endogenous DA release from the NA of the awake rat using intracranial microdialysis. Rats were implanted with guide tubes and allowed 2 days to recovery from surgery prior to insertion of a microdialysis probe into the NA. Dialysate samples were collected for 20 minutes at a flow rate of 1.5 μl/min and subsequently analyzed for DA, DOPAC, and HVA content using HPLC-ECD. Following baseline stabilization, either N-methyl-D-aspartate (NMDA), kainate (KA), MK-801, or high K^+ was infused through the probe for 20 minutes. The infusion of NMDA (2 mM) and KA (2 mM) produced a marked increase in extracellular DA, a marked decrease in DOPAC and HVA, and a noticable increase in locomotion. High K^+ (80 mM) produced the same neurochemical profile but did not increase spontaneous movement. A lower concentration of KA (0.2 mM) did not alter locomotion or DA release. MK-801 (0.1 mM) did not alter spontaneous DA efflux. Thus, EAA apparently release newly synthesized DA from the NA and the glutamate input to the NA appears to be non-tonic.

235.21

DOPAMINE RECEPTORS MODULATE NORADRENALINE RELEASE FROM RAT FRONTAL CORTEX. Z.L. Rossetti*, L. Pani, C. Portas* and G.L. Gessa (SPON: S.A. Tjioe) Department of Neuroscience, University of Cagliari, 09124 Cagliari, Italy.

Dopamine (DA) neurons with cell bodies located in the ventral tegmental area provide a diffuse innervation to the frontal cortex. Brain microdialysis in conscious animals was used to investigate whether DA receptors, other than α_2-adrenoceptors, might control the release of noradrenaline (NA) from nerve terminals in the rat frontal cortex. NA in perfusates (50 μL/30 min) was quantitated by HPLC-EC. The selective α_2-adrenoceptor agonist clonidine (0.3 mg/kg, ip) reduced NA release (-50%), whereas yohimbine (5 mg/kg, ip), a selective α_2-adrenoceptor antagonist, increased cortical NA release (about 250% of baseline). Quinpirole, a selective DA D_2 receptor agonist, caused a dose-dependent decrease in NA release. A maximal inhibition of about 50% of baseline was observed at the dose of 150 μg/kg, sc. (-)Sulpiride, a selective DA D_2 receptor antagonist, at the dose of 100 mg/kg, ip, produced a 180% increase in NA release, the output remaining elevated for over 2 hr. Yohimbine (5 mg/kg ip), which prevented the inhibitory effect of clonidine, failed to prevent the response to quinpirole (50 μg/kg sc). Vice versa, the response to quinpirole (50 μg/kg sc) was prevented by (-)sulpiride (150 mg/kg ip). These results indicate the existence of DA D_2 receptors modulating the release of NA in the frontal cortex.

235.22

MODIFICATION OF EXCITABILITY OF CORTICOSTRIATAL AFFERENTS: EVIDENCE FOR AUTO AND HETERORECEPTOR REGULATION. M. Garcia-Munoz, S.J. Young* and P.M. Groves. University of California, San Diego. La Jolla, CA 92093

Considerable evidence suggests that synaptic release of transmitters may be regulated by neuroactive substances via non-synaptic interactions. Thus, interactions involving nigral dopamine(DA) and cortical glutamate-containing terminals in the striatum have been suggested using several different methods. For instance, decreased electrical excitability of the nigrostriatal terminal fields has been observed after frontal cortex stimulation. The experiments reported here were designed to address the following questions: Does the release of DA alter the excitability of corticostriatal terminals? Is the excitability of cortical terminals affected by glutamate release? Male Sprague-Dawley rats were anesthetized with urethane. Bipolar stimulating electrodes and cannulae for local drug infusion were placed in the striatum. Single unit extracellular recordings were obtained from the contralateral medial prefrontal cortex. Terminal excitability was measured by determining the threshold for antidromic activation of a contralateral cortical cell on 100% of non-collision trials. The mean threshold was 1.8 ±0.1 mA and the antidromic latency 15.4 ±0.6 ms. Excitabilty of the cortical terminal field decreased following striatal administration of amphetamine (1 μM/ 300nl/ 5min) or electrical stimulation of mesencephalic DA cells (1.5mA/ 1Hz/ 2min) The decrease in excitability could be blocked or reversed by local application of sulpiride (10nM) or haloperidol (1μM, 300nl/ 5min) . In a subset of cortical neurons, increases in firing rate were associated with increased excitability and vice-versa. This relation was abolished by local administration of NMDA-receptor antagonists. Experiments examing these excitabilty effects following striatal kainic acid lesions will also be reported. These results suggest that glutamate and dopamine exert opposing influences on the excitability of the corticostriatal terminal field.

The work was partially supported by a grant from the National Institute on Drug Abuse .

REGIONAL LOCALIZATION OF RECEPTORS AND NEUROTRANSMITTERS II

236.1

ENDOGENOUS HOMOVANILLIC ACID LEVELS DIFFER BETWEEN RAT AND RABBIT CAUDATE, HIPPOCAMPUS AND CORTICAL REGIONS. L. Grondin*, T.A. Reader, and K.M. Dewar (SPON: H.H. Jasper). CRSN, Département de physiologie, Université de Montréal, Montréal (Qué.) Canada.

Endogenous dopamine (DA) and its metabolites 3,4-dihydroxyphenylacetic acid (DOPAC), 3-methoxy-tyramine (3MT) and homovanillic acid (HVA) were measured by HPLC-ED in the entorhinal-piriform (EnPi), cingulate (CIN), sensorimotor (SSM) and visual (VIS) cortices as well as in the caudate (CAU) and hippocampus (HIP) of Sprague-Dawley (SD) rats and New-Zealand rabbits. The DA, DOPAC and 3MT contents were similar in both species. The HVA levels however, although they followed the DA distribution, were several-fold higher in rabbits than in SD-rats for all cortices, HIP and CAU. In addition, total metabolite contents and DA turnover (DA metabolites/DA ratios) were significantly higher in the rabbit than in the rat, suggesting an increased release and/or metabolism in the former species. The HVA/DA ratios were much greater for rabbit regions than for SD-rats, indicating an increased DA release in the former species since the DOPAC/DA ratios (index of intraneuronal degradation) were similar. It can be proposed that the elevated DA turnover documented for the rabbit is a consequence of an increased release of DA as reflected by the larger HVA/DA indexes.

236.2

AUTORADIOGRAPHIC LOCALIZATION OF TWO SUBTYPES OF THE CANINE ALPHA-1 ADRENERGIC RECEPTOR R.R. Dean*, E. Mignot* and W.C. Dement Stanford Sleep Disorders Center, Stanford Univ. Sch. of Med, Palo Alto, CA 94304

The two subtypes of the alpha-1 adrenoceptor (α-1a, high-affinity and α-1b , low-affinity), previously demonstrated in the rat on the basis of different pharmacological properties, were shown to be present in the canine CNS using Scatchard analysis and drug competition studies (Mignot et al. Brain Res.in press). In the present study, the α-1a and α-1b receptor subtypes were localized autoradiographically in the canine CNS (n=6). 15 μ thick frozen sections were thaw-mounted onto gelatin coated slides. Slides were incubated for 40 min. at 30° C in 1nM [^{3}H]-Prazosin; 80 nM WB 4101 was used to mask the a-1a sites (50 mM Tris, pH. 7.4, 1.25×10^{-4}M ascorbate). Incubation was followed by a 30 min rinse, then a 15 min rinse in ice-cold buffer and then dipped in dH_2O to remove residual buffer salts. Anatomically adjacent tissue sections were incubated under the same conditions but with BE 2245 (100 μM), which has a binding profile similar to prazosin, to determine the nonspecific binding. After thorough drying, slides were apposed to tritium-sensitive film. Following an appropriate exposure period the resulting autoradiograms were developed using standard photographic techniques and analyzed using an Imaging Research Inc. computerized microdensitometric image-analysis system. α-1b receptors were localized directly in the presence of WB 4101, a compound with much higher affinity for the α-1a receptors. The relative distribution of α-1a was obtained by subtraction of the α-1b from the total α-1 (prazosin) binding.The relative distribution of the two receptor subtypes in a number of brain structures was studied. Structures exhibiting a higher density of the α-1a subtype included nuc. lemnisci lateralis, nuc. pontis oralis, nuc. tr. mesenceph. n. trigemini,nuclei pontis, substantia nigra, central grey, putamen, nuc. parataenealis, and nuc. ruber. Structures possessing a larger percentage of the α-1b subtype included the caudate, lateral and medial geniculate, several amygdala nuclei, nuc. medialis dorsalis, stria medullaris thalami, and centromedial nuc. of the thalamus.

COMPARATIVE DISTRIBUTION OF ALPHA-1 AND ALPHA-2 ADRENERGIC BINDING SITES IN THE LOCUS COERULEUS AND THE NUCLEUS TRACTUS SOLITARII OF THE RAT BRAIN BY QUANTITATIVE AUTORADIOGRAPHY

G. Chamba*, D. Weissmann*, C. Rousset*, B. Renaud and J. F. Pujol*. Laboratoire de Neuropharmacologie, CNRS UMR 12, Université C Bernard, 8 Av. Rockefeller, 69373 LYON and CERMEP, 59 Bvd Pinel, 69003 LYON, FRANCE.

Many studies have shown that noradrenergic neurons of the locus coeruleus (LC) and of the nucleus tractus solitarii (NTS) play a major role in various physiological processes including control of blood pressure, neuroendocrine regulation and behavioral mechanisms.

The present study was performed to compare the precise rostro-caudal distribution of alpha-1 and alpha-2 adrenergic binding sites within the LC and the NTS. Distribution of the density of [3H] prazosin and [3H] idazoxan binding sites were analyzed by quantitative autoradiography on 20 µm frontal sections, every 200 µm throughout these two regions. Binding of each ligand to their respective adrenoceptors was specific and saturable. The results obtained show: i) that the density of alpha-1 binding sites was 3 to 4 times higher than the density of alpha-2 binding sites in the two regions analyzed, ii) that the rostro-caudal distribution of the two types of adrenergic binding sites was differential and heterogenous in the LC and in the NTS.

These results will be analyzed in relation with the cellular localization of alpha-1 and alpha-2 binding sites on noradrenaline-containing elements.

QUANTITATIVE AUTORADIOGRAPHY OF CORTICAL α_1-ADRENERGIC RECEPTORS IN SUICIDE VICTIMS. *V. Arango, L. Hoffman, P. Ernsberger, D.J. Reis and J.J. Mann.* Div of Neurobiology and Lab of Psychopharmacol, Cornell Univ. Med. Coll., New York, NY 10021.

We previously reported increased β-adrenergic receptors in the prefrontal cortex (PFC) of suicide victims by both membrane binding (Mann et al. *Arch Gen Psych 43:954, '86)* and autoradiography (Arango et al. *Soc Neurosci Abstr 14:171, '88).* Other adrenergic receptor subtypes have not been examined in suicide. Using quantitative autoradiography, we sought to determine the normal distribution of α_1-adrenergic receptors in PFC (area 9) and temporal cortex (TC, area 38) and whether α_1 receptors are altered in suicide. Suicide victims and controls were paired for assay by matching for postmortem delay, age and gender (PFC: 10 pairs, TC: 8 pairs). Toxicology was negative for centrally active drugs. Slide-mounted sections were preincubated in Kreb's buffer then incubated with 2 nM ^{3}H-prazosin to label α_1-adrenergic receptors. Non-specific binding was defined by 10 µM phentolamine. Sections and ^{3}H-standards were exposed to Ultrofilm for 7 weeks and developed in GBX. The resulting autoradiograms were quantified using a PC-based image analysis system. In both cortical areas α_1 receptors formed a distinct laminar pattern, with 4 clear bands for which receptor density was: layers I-II > VI = III > IV-V (identified by overlapping with adjacent Nissl-stained section; ANOVA, $p < .01$). TC had more binding in all layers than PFC (ANOVA, $p < .001$). In layers IV-V of PFC, suicide victims had more α_1 sites than controls (ANOVA, $p < .03$). In summary: a) α_1 receptors in both PFC and TC are distributed in a distinct laminar pattern; b) α_1 receptors are selectively increased in layer IV-V of PFC in suicide victims; c) α_1 receptor density is higher in TC than in PFC; d) there are no differences in α_1 receptor binding in TC of suicide victims compared to controls. We conclude that in contrast to β-receptors, the alteration in α_1-receptors in suicide selectively involves some cortical layers.

236.5

SELECTIVE LOCALIZATION OF D1 RECEPTORS TO STRIATONIGRAL NEURONS IN THE RAT. M.B. Harrison, R.G. Wiley* and G.F. Wooten. Dept. of Neurology, UVA School of Medicine, Charlottesville, VA 22908 and *Depts. of Neurology and Pharmacology, Vanderbilt Univ., Nashville, TN 37212.

To investigate the cellular localization of dopaminergic receptor subtypes in the striatum, we have studied the autoradiographic distribution of D1 and D2 receptors after a lesion of striatonigral neurons produced by micro-injection of volkensin into the substantia nigra. Volkensin is taken up by terminals and retrogradely transported to the soma where it is cytotoxic (Wiley and Stirpe, Brain Res., 438(1988)145-154). Six rats received injections of volkensin (1.3-10.8 ng); after 17-21 day survival, the brains were processed for autoradiography, with adjacent sections examined for binding of ^{3}H-SCH23390 (D1 antagonist), ^{3}H-spiperone (D2 antagonist), and in 2 animals, ^{3}H-hemicholinium (^{3}H-Hch) (a presynaptic cholinergic marker). The resultant lesion localized to the dorsomedial quadrant of the rostral striatum. Specific binding in the striatum, both contralateral and ipsilateral to the injection site was compared, with the following results: D1 decreased from 171 fmol/mg± 15 (mean ± S.E.) to 24± 6 (mean decrease 86%**); D2, from 127± 8 to 77± 4 (mean decrease 39%**); ^{3}H-Hch, from 117± 20 to 52± 18 (mean decrease 56%*). When the percent change was compared among the three groups, a significant difference was found between the decreases in D1 and D2 binding** and D1 and ^{3}H-Hch binding*, but not between D2 and ^{3}H-Hch. These data suggest that striatonigral neurons express D1 receptors selectively. The reduction in D2 binding may reflect the presence of a population of D2 receptors on striatonigral neurons or alternatively may reflect transsynaptic effects of the toxin or secondary changes on cholinergic interneurons following the loss of striatonigral neurons ($^{**}p<.01$; $^{*}p<.05$).

236.6

PRE AND POST SYNAPTIC DOPAMINE D2 RECEPTORS OF THE NIGROSTRIATAL, MESOLIMBIC, AND MESOCORTICAL PATHWAYS ARE ENCODED BY THE SAME mRNA. D.M. Weiner and M.R.Brann (SPON: P. Gardner), Research Scholars Program, HHMI,and Laboratory of Molecular Biology, NINDS, Bethesda MD 20892.

Based on the recently reported sequence of a D2 receptor cloned from rat brain (Bunzow, et al., Nature. 336, 783), we prepared a series of cDNA probes to determine the distribution of mRNA encoding this receptor. Three probes were generated corresponding to regions encoding the n-terminal, c-terminal, and large third cytoplasmic loop of the receptor. The specificity of the probes was verified by two criteriae. First when *in situ* hybridizations of rat brain were performed each probe used individually showed an identical pattern of labeling as did a mixture of the three probes. Secondly, the mixture of probes hybridized to a single mRNA of 2.9 kb on northern blots of total RNA from rat brain. Within the forebrain, D2 receptor mRNA was abundant throughout the caudate-putamen, nucleus accumbens and olfactory tubercle. Moderate to low levels of mRNA were observed in the diagonal band, various septal nuclei, medial habenular nucleus, claustrum, dorsal endopiriform nucleus, and entorhinal cortex. Within the mesencephalon, D2 receptor mRNA was abundant within the substantia nigra pars compacta and ventral tegmental area. Comparison of the distribution of the mRNA and ligand binding indicates that both the pre- and post-synaptic D2 receptors of the nigrostriatal, mesolimbic and mesocortical pathways are derived from the same mRNA.

236.7

AUTORADIOGRAPHIC EVALUATION OF D_1 AND D_2 DOPAMINE RECEPTORS FOLLOWING CENTRAL DOPAMINERGIC DENERVATION B. E. Mileson and R. B. Mailman University of North Carolina Curriculum in Toxicology and Biological Research Center, Chapel Hill, NC 27599

Chemical denervation of greater than 90 % of central dopamine neurons by intracisternal (IC) injection of 6–hydroxydopamine results in a behavioral supersensitivity to agonist challenge. The mechanism responsible for mediating this locomotor supersensitivity remains unknown. Compensatory changes in striatal dopamine receptor density or ligand affinity have not been found using homogenate binding techniques. In the present study, film autoradiographic techniques were used to examine D_1 and D_2 dopamine receptor density in local striatal regions and in the terminal areas of the mesolimbic dopaminergic tracts, the nucleus accumbens and the olfactory tubercles. Single concentrations of the [^{125}I] iodinated ligands, SCH23982 (D_1) and iodosulpride (D_2) were used to compare slide–mounted lesioned and control brain sections. No differences in D_1 receptor binding was seen in the rostral, central or caudal regions of the striata. In addition, no localized changes in D_1 receptors were seen in either the nucleus accumbens or olfactory tubercles. No significant increase in D_2 receptor binding was seen in the striata, nucleus accumbens or olfactory tubercles of lesioned rats compared to controls. This information indicates the behavioral supersensitivity exhibited by IC–lesioned rats is not due to increases in dopamine receptor number or ligand affinity in any brain region. Supported by ES01104, MH40537, and Training or Center Grants ES07126, HD03110 and MH33127.

236.8

GENETIC SELECTION FOR AGGRESSION IN MICE: AUTORADIOGRAPHIC ANALYSIS OF ALTERATIONS IN DOPAMINE RECEPTOR DENSITIES. L.L. Devaud, R.B. Cairns*, J.L. Gariepy*, R.B. Mailman, and M.H. Lewis. Biological Sciences Research Center and Departments of Pharmacology, Psychiatry and Psychology, University of North Carolina, Chapel Hill, NC 27599.

ICR mice have been selectively bred over 19 generations for high or low levels of isolation–induced aggression. The low aggressive (NC100) line has decreased concentrations of dopamine, DOPAC, and HVA in the nucleus accumbens and, to a lesser extent, in the caudate nucleus. Quantitative receptor autoradiography was employed to determine if these neurochemical changes were associated with compensatory changes in dopamine receptor density. D_1 and D_2 dopamine receptor densities were estimated by quantifying ^{125}I–SCH23982 and ^{125}I–iodosulpride binding sites, respectively, in brains of high (NC900) and low (NC100) aggressive mice. Slight (5–10%), but consistent, increases in the density of D_1 sites were observed in the rostral caudate of NC100 mice; larger increases (ca. 20%) in D_1 sites were observed in the nucleus accumbens. NC100 mice also exhibited an increased density of D_2 sites in the same regions. However, the line difference was more pronounced in the caudate nucleus (ca. 20%) than in the nucleus accumbuns (10%). Both the line differences and regional differences are consistent with the neurochemical data. The apparent increase in dopamine receptor density in a mouse line displaying low levels of aggression provides additional support for the hypothesis that dopamine systems play an important role in mediating genetic selection effects on behavior. (Supported by PHS Grants HD07201 and HD03110)

236.9

SIMULTANEOUS LOCALIZATION OF DOPAMINERGIC RECEPTOR BINDING SITES IN RAT NEURAL TISSUES. M.A. Ariano, F.J. Monsma, Jr.[1], A.C. Barton[1], H.C. Kang,[2*] R.P. Haugland,[2*] & D.R. Sibley.[1] Anatomy & Neurobiology, UVM College of Medicine, Burlington, VT 05405; [1]ETB, NINDS-NIH, Bethesda, MD 20892, & [2]Molecular Probes, Eugene, OR 97402.

Specific antagonist ligands for the D_1 and D_2 dopamine receptors have been chemically derivatized to the fluorescent compounds, fluorescein, rhodamine, Texas Red®, and Bodipy®. This has allowed the simultaneous ***regional*** and ***cellular*** visualization of these dopamine receptor populations in slices of rat forebrain, pituitary, retina, and superior cervical ganglion (SCG). The regional localizations of the two dopamine receptors reflect previous work ascertained using *in vitro* receptor autoradiographic methods. The most robust regional localization of the D_1 receptor type was found in the striatum and nucleus accumbens, displaying a membranous neuropil distribution. Medium sized neurons were the most prominent cell type that exhibited D_1 binding sites. Also, large cortical pyramidal neurons displayed this type of dopamine receptor population. The pituitary gland and the SCG did not show D_1 binding sites, however the outer nuclear layer of the retina exhibited some fluorescence for this receptor subtype. The D_2 receptor was also prevalent within the striatum and nucleus accumbens, but did not show as much staining intensity as the D_1 receptor subtype. Medium sized and an occasional large neuron demonstrated fluorescent binding sites for D_2 receptors in these forebrain regions. The anterior pituitary showed that about 30% of the cells were reactive for the D_2 subtype, with little fluorescence present in the posterior lobe. The retinal photoreceptor outer segments were highly fluorescent for the D_2 antagonist probe, as was the outer nuclear layer. The postganglionic neurons of the SCG and a fine rete within the parenchyma showed D_2 receptor binding. The fluorescent probes enable concurrent detection of the two subtypes of dopaminergic receptors in various rat neural tissues.

236.10

Corticothalamic neurons in rat cingulate cortex contain DARPP-32. C.C. Ouimet. Psychology Dept., Florida State Univ., Tallahassee, FL 32306.

DARPP-32 is a protein whose phosphorylation is regulated by dopamine and by cyclic AMP (Walaas et al., Nature 301: 69,1983). DARPP-32 is enriched in neurons that receive a dopamine input and contain the D_1 dopamine receptor, and is most highly concentrated in dopaminoceptive regions of the basal ganglia (Ouimet et al., J. Neurosci., 4: 111, 1984; Walaas and Greengard, J. Neurosci., 4: 84, 1984). In addition, DARPP-32 is enriched in a subset of layer VI neurons in cerebral cortex. In the present study, retrograde tracers were used to determine if the DARPP-32- immunoreactive neurons in layer VI of cingulate cortex project to the thalamus. Small injections of fluorgold or fluorescent latex microspheres were placed in the mediodorsal and anterior nuclei. After post-injection survival times of 2-10 days, animals were sacrificed and processed for immunocytochemistry. Layer VI neurons containing DARPP-32 immunoreactivity were consistently labeled with tracer. Additional tracer injections into thalamic relay nuclei such as the lateral geniculate and ventral posterior nuclei also retrogradely labeled DARPP-32-containing cells in layer VI in appropriate neocortical regions. These data suggest that cyclic AMP and possibly dopamine regulate DARPP-32 in some corticothalamic neurons, and raise the possibility that the DARPP-32-containing layer VI cells are targets for cortical dopamine fibers.

236.11

LOCALIZATION OF SEROTONIN$_{1B}$ AND SUBSTANCE P BINDING SITES IN THE FACIAL NUCLEUS FOLLOWING MOTONEURON DEGENERATION. S.J. Tallaksen-Greene, R.P. Elde and V.S. Scybold Dept. of Cell Biology and Neuroanatomy, University of Minnesota, Minneapolis, MN 55455.

Serotonin (5-HT) and substance P (SP) have been shown to coexist within nerve fibers in the facial nucleus of the rat. Iontophoretically applied 5-HT and SP have both been reported to have an excitatory effect on somatic motoneurons. To examine the question of whether facial motoneurons have receptors for 5-HT and/or SP we used *in vitro* autoradiography combined with chemical ablation of facial motoneurons. Animals received unilateral injections of the suicidal transport agent, ricin (0.5µg in 0.5µl phosphate-buffered saline, with 0.01% Fast Green dye), into the facial nerve, just distal to the exit of the nerve from the skull. The extent of facial motoneuron loss was assessed using a Thionin stain and cholinesterase histochemistry. [^{125}I]-iodocyanopindolol (^{125}I-ICYP) was used to label 5-HT$_{1B}$ binding sites, and [^{125}I]-labeled Bolton-Hunter substance P (^{125}I-SP) was used to label SP binding sites. A computerized densitometry system was used to quantify the density of autoradiographic grains representing radiolabeled ligand binding sites.

A nearly complete ipsilateral loss of facial motoneurons was observed 7-10 days following unilateral ricin injection into the facial nerve. In all cases, the medial subnucleus was spared because injections were made distal to the point where the posterior auricular nerve leaves the facial nerve. The number of facial neurons was reduced by 80-100% in the ipsilateral subnuclei of the intermediate and lateral divisions of the nucleus. Associated with the loss of motoneurons was an ipsilateral reduction in the density of both 5-HT$_{1B}$ and SP binding sites compared to values obtained from either the contralateral facial nucleus or control animals. These data suggest that there may be 5-HT$_{1B}$ and SP binding sites on the dendrites and perikarya facial motoneurons.

236.12

AUTORADIOGRAPHIC LOCALIZATION OF THE 5HT$_3$ ANTAGONIST ^{3}H-BRL43694 IN THE DORSAL VAGAL COMPLEX OF THE FERRET. R.A. LESLIE, D.J.M. REYNOLDS*, P.M. GRASBY* and D.G. GRAHAME-SMITH*. M.R.C. Unit and University Department of Clinical Pharmacology, Radcliffe Infirmary, Oxford, U.K. OX2 6HE.

5HT$_3$ antagonists are effective anti-emetics in cytotoxic- and radiation-induced emesis. Radioligand binding studies in brain membrane homogenates have identified binding sites for these compounds (eg., Kilpatrick, G.J. et al. Eur. J. Pharmocol. 159:157, 1989). We used autoradiography to localize binding sites for ^{3}H-BRL43694 (granisetron) in ferret brain. In addition, we removed one nodose ganglion in some animals to see the effect of vagal lesion on binding. Anesthetized ferrets were perfused with saline and their brains removed. Cryostat sections were incubated in 10nM ligand in HEPES buffer with or without the addition of 100 µM unlabelled GR38032F. Sections were washed, dried and exposed to Amersham Hyperfilm for six weeks. Tritium standards were exposed along with sections for quantitative analysis. Specific binding (128±4.2 fmol/mg wet wt.; ±SEM) was seen in the solitary nucleus (NTS) and area postrema (AP; 71±4.0 fmol/mg). Nodosectomy reduced binding in the NTS by 65%. Our results suggest that 5HT$_3$ binding sites are concentrated in a medullary nucleus involved in mediating vomiting and that some of the binding sites in the NTS may occur on vagal afferents.

We thank Beechams Pharmaceuticals for ^{3}H-BRL43694 and Glaxo Group Research for GR38032F.

236.13

CELLULAR ORIGIN OF THE DEPOLARIZATION-INDUCED RELEASE OF TAURINE FROM CEREBRAL CORTEX SLICES FROM DEVELOPING MICE. S.S. Oja, M. Pelto-Huikko* and Pirjo Kontro. Tampere Brain Research Center, Department of Biomedical Sciences, University of Tampere, Box 607, SF-33101 Tampere, Finland.

Potassium stimulation evokes a massive release of pre-loaded taurine, an inhibitory neuromodulator, from cerebral cortex slices from developing mice. It is not known which tissue pools accumulate the label and which cellular structures this release originates from. We have assessed the release of endogenous taurine from cerebral cortex slices from adult and developing mice by high-performance liquid chromatography and studied changes in taurine-like immunoreactivity by peroxidase-antiperoxidase reaction using rabbit taurine antiserum. The potassium-stimulated release was more than six times greater and considerably more prolonged in 3-day-old than in adult mice. In the adults taurine-like immunoreactivity was localized in astrocytes and oligodendroglia. Neurons were generally not stained. Potassium stimulation did not change this pattern. In 7-day-old mice immunoreactivity was most intense in neurons and nerve endings in the outermost cortical layers. Immunoreactivity clearly decreased in neurons and nerve endings after potassium stimulation. The results show differences in the cellular origin of the stimulated release of taurine in the developing and adult cerebral cortex and focus attention to the role of taurine in the regulation of neuronal activity in the immature brain.

236.14

MOLECULAR WEIGHT OF THE MELATONIN RECEPTOR. D.S. Pickering and L.P. Niles. Dept. of Biomedical Sciences, Division of Neuroscience, McMaster University, Hamilton, Ontario, CANADA L8N 3Z5.

It is only within the past three years that the pharmacological characterisation of melatonin receptors has been achieved by use of the radioligand 2-[^{125}I]iodo-melatonin. Differences in the pharmacological profile of the receptor are apparent between hamster brain and chick retina. It was the goal of this study to further characterise the melatonin receptor at the molecular level by using the technique of target-size analysis.

Radiation inactivation is a method whereby the in situ functional molecular mass of a receptor can be determined. We exposed frozen (-45°C) whole tissue homogenates to high doses of ionising radiation (0-30 Mrad, using 1.5 Mev electrons). Simultaneous irradiation of a series of enzyme standards of known molecular mass permitted creation of a calibration curve (mass vs. dose) from which the size of the melatonin receptor was determined: hamster hypothalamus, 43.7 ± 1.2 kDa (n=4); chick retina, 53.3 ± 3.4 kDa (n=3). As an internal control, the size of the β-adrenergic receptor was calculated to be 55.9 ± 2.4 kDa (n=4).

In summary, the melatonin receptor from chick retina was found to be considerably larger (22%) than that from hamster hypothalamus. This is consistent with an interspecies difference in the receptor.

This work was supported by the OMHF and MRC of Canada.

MELATONIN RECEPTOR SITES IN THE CHICKEN BRAIN: LOCALIZATION BY QUANTITATIVE RECEPTOR AUTORADIOGRAPHY. J. A. Siuciak and M. L. Dubocovich. Dept. of Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL. 60611.

The avian pineal gland, through the secretion of its primary neurohormone melatonin, regulates circadian rhythms of activity, sleep like behavior and serotonin levels in different brain regions. The aim of this study was to localize melatonin receptor sites in chicken brain using in vitro autoradiography. Coronal brain sections were thaw-mounted on slides, incubated with 2-[^{125}I]-iodomelatonin in 170 mM Tris-HCl buffer (pH 7.4, 25 °C), rinsed in Tris-HCl buffer (0 °C), and allowed to air dry. Slides were apposed to X-ray film for one week. Specific binding, defined with 3uM melatonin, was unevenly distributed through the chicken brain. Autoradiographs were analyzed with an image analysis system. The highest density of binding sites was found in areas of the midbrain (optic lobe tectum, Edinger-Westphal nuclei, dorsal and dorsolateral oculomotor nuclei) and in the diencephalon (nucleus rotundus, tectothalamic tract, and the ventrolateral geniculate and dorsolateral and lateral thalamic nuclei). Lower density of binding sites was observed in the optic chiasm, hypothalamus, cerebellum and striatum. This regional distribution of 2-[^{125}I]-iodo-melatonin binding corresponds closely to that found in chicken brain homogenates (Dubocovich et al., 1989). Supported by grants MH42922 and DK38607 to MLD and NS07140-06 to JAS.

236.16

TYROSINE HYDROXYLASE (TH) IMMUNOREACTIVE NEURONS IN THE HYPOTHALAMUS OF CATTLE AND PIGS. L. S. Leshin, R. D. Kineman*, C. R. Barb*, T. E. Kiser*, G. B. Rampacek* and R. R. Kraeling*. USDA-ARS, Athens, GA 30613 and Animal and Dairy Sci. Dept., Univ. of Georgia, Athens, GA 30602.

Hypothalamic catecholaminergic neurons were examined in cattle (n=3) and pig (n=4) brains to identify anatomical sites possibly involved in the regulation of gonadotropin and prolactin secretion. Coronal and sagittal frozen sections (60 μm) of Zamboni's fixed hypothalamic-preoptic area tissue were incubated with TH primary antisera (Eugene Tech) for 24 hr, then visualized by biotin-avidin D-peroxidase immunocytochemistry. In both species, TH immunoreactive perikarya were observed in the lateral and caudal aspects of the arcuate nucleus (ncl), in the periventricular ncl, anteriorly within ncl periventricularis preoptica, in the dorsal-lateral region of the paraventricular ncl, suprachiasmatic ncl and supramammillary ncl. Some scattered cells were observed surrounding the ventromedial ncl and along the ventral hypothalamic surface between the supraoptic ncl and median eminence. Perikarya tended to be either bipolar, fusiform or multipolar, 3-5 processes, with numerous branched arborizations. Immunoreactive fibers were observed throughout these areas and within the median eminence. The location of TH immunoreactivity coincides with some areas previously reported to contain ß-endorphin and luteinizing hormone releasing hormone.

236.17

LOCALIZATION OF HISTAMINERGIC NEURONS IN THE FROG BRAIN. W. Briner, P. Guth, & C. Norris. Tulane University Medical Center, Depts. of Pharmacology and Otolaryngology, New Orleans, LA 70112.

Histamine (HA) is a suspected neuromodulator and has been found in the brains of several species (Panula, 1986). We examined the CNS of the frog using a well characterized antibody to HA with immunocytochemistry (ICC).

Rana pipiens were pretreated with colchicine, histidine which is the precursor of HA, and quinacrine which blocks histamine-methyl transferase, and perfused with a 3% 1-ethyl-3-(3-dimethylamino-propyl)carbodiimide and then by 3% paraformaldehyde in buffer (Panula et al., 1988). Frozen sections were taken and ICC performed using the ABC method.

Histaminergic neurons were found in many of the same areas as other species including; hypothalamus, periventricular area, optic tectum, thalamic regions, and cortex.

We report preliminary findings of light labelling in the cerebellum and its nuclei as well as in the vestibular nuclei. These regions are of special interest because of the effects of antihistamines on vestibular function.

236.18

BRAIN NEUROTRANSMITTER DISTRIBUTION IN THE WINTER FLOUNDER. L.W. Crim* and D.M. Evans* (SPON: N.M. Sherwood). Marine Sciences Research Laboratory/Ocean Sciences Centre, Memorial University of Nfld., St. John's, Nfld., A1C 5S7,

Biogenic amine neurotransmitters were determined in winter flounder brains collected from fish in prespawning or postspawned condition. Whole brains were dissected under ice-cold conditions into 7 regions including 1) olfactory lobes, 2) telencephalon, 3) optic tectum, 4) cerebellum, 5) mid-brain, 6) rhombencephalon and 7) the hypothalamus. After sonication of brain pieces in 0.2M perchloric acid, the supernatant was directly submitted to HPLC/EC analysis of norepinephrine (NE), dopamine (DA) and serotonin (5-HT). The greatest NE concentrations were found in the flounder telencephalon, mid-brain and hypothalamus while the rhombencephalon, olfactory lobe and optic tectum contained relatively lower NE levels. The olfactory bulbs were the richest source of DA in the flounder brain; smaller, yet detectable amounts of DA were localized in the mid-brain, telencephalon, rhombencephalon and the flounder hypothalamus. Detectable amounts of 5-HT were obtained in the mid-brain, hypothalamus, telencephalon and flounder rhombencephalon.

Although flounder brain neurotransmitter levels were generally similar irrespective of fish reproductive condition, significantly greater levels of NE ($P<0.05$) were found in the optic tectum of postspawned flounder compared with fish in prespawning condition.

DIFFERENTIATION, MORPHOGENESIS AND DEVELOPMENT: NEUROGENESIS AND CONTROL OF NEURON NUMBER

237.1

NEUROGENESIS AND HODOGENESIS IN THE OLFACTORY SYSTEM OF RAT EMBRYOS. M.-C. Bélanger*, S. Miloševič*, L. Bertrand* and R. Marchand, Lab. Neurobiol., Hôp. Enfant-Jésus, 1401, 18e Rue, Québec, (QC) G1J 1Z4.

Recent studies show that the olfactory system is functional early during foetal life. We wanted to verify the anatomical bases of this phenomenon by searching a correlation with the neurogenesis and the hodogenesis of the cell groups of this system. Neurogenesis was studied by injecting ^{3}H-thymidine to precisely-timed (E10, E11 and E12) gestating rats and, to trace early tracts, crystal of DiI (D282, 1,1'-dioctadecyl-3,3,3'3'-tetramethylindocarbocyanine perchlorate) were implanted into the olfactory epithelium, the vomeronasal organ and the olfactory bulb of precisely-timed fixed embryos.

The autoradiographic data show that olfactory neurons are among the first to be generated in the rostral telencephalon. In the adult, they are found among the mitral cells of the accessory olfactory bulb, the periglomerular cells of the special glomerular complex, the primary olfactory cortex, the bed nucleus of the accessory olfactory tract, the medial amygdaloid nucleus and the bed nucleus of the stria terminalis. In very young embryos (E13, E14), all these neurons constitute a longitudinal column (the rostral portion of the basal forebrain cell column) that extends along the ventrolateral edge of the telencephalic vesicles. At these early stages, a well-differentiated marginal zone is associated to the cell column. Under epifluorescence, we could trace orthogonally, the lateral olfactory tract from the olfactory bulb to the region of the bed nucleus of the accessory olfactory tract and retrogradely, the olfactory nerve to the cell bodies of the olfactory epithelium that showed a bright fluorescence. Therefore, we suggest that the rostral portion of the basal forebrain cell column serves as a template for guiding the first axons that emerge from the primordial mitral neurons en route to their target structures. The coupling of these two techniques opens a wide field for the study of the strategies involved in the morphogenesis of the nervous system. (Supported by MRC, FRSQ and FCAR).

QUANTITATIVE RELATIONSHIPS BETWEEN THE NOSE AND THE FOREBRAIN IN XENOPUS LAEVIS TADPOLES. G. A. Monti Graziadei and P. P. C. Graziadei. Dept. of Biological Science, Florida State University, Tallahassee, FL 32306.

Previous experiments in Xenopus laevis have shown that removal of the olfactory anlagen impairs the development of the telencephalon. Here we report the results obtained from those cases in which asymmetrical regeneration of the olfactory organs occurs. The olfactory anlagen were removed from 22-24 stage Xenopus embryos. The animals, sacrificed at stage 50, were embedded in paraffin, serially sectioned, and stained with hematoxylin. The nasal organs and brains were reconstructed with an IBM PC-based 3-D reconstruction program, and the respective volumes calculated. Our results indicate that the asymmetric development of the nasal organs is always accompanied by asymmetric development of the two hemispheres, and this relationship is linear. Although the forebrain in amphibians receives inputs from other sensory modalities, the olfactory input seems to be a major influence in determining its full development. (NSF Grant BNS 86 17022.)

237.3

DIFFERENTIAL DISTRIBUTION OF DIVIDING CELLS IN THE DEVELOPING CNS OF THE LEECH *HIRUDO MEDICINALIS* REVEALED BY BRDU INCORPORATION. C.A. Baptista*, T. Gershon* and E.R. Macagno. (SPON: M.-M. Poo). Dept. of Biological Sciences, Columbia University, New York, NY 10027.

The sex ganglia of *Hirudo* contain several hundred PE neurons which are not found in other segmental ganglia (SG). These cells can first be identified by the end of embryogenesis (30 days after egg-laying), with the majority appearing postembryonically. Early ablation of the male genitalia results in the complete absence of these cells (Baptista and Macagno, *J. Neurobiol.* 19:707, 1988). To shed some light on the nature of this interaction, we have begun to examine the frequency and spatial distribution of terminal cell division by exposing animals to pulses of bromodeoxyuridine (BrdU) and visualizing the incorporated nucleotide with anti-BrdU. We have detected a large population of labeled cells in the CNS of 20-30 day embryos. In contrast with younger animals, animals exposed to BrdU at these stages and examined within a few days show a dramatic difference between the sex and neighboring SG, with many more labeled cells in the former. When these animals are examined postembryonically, they still exhibit a large number of labeled cells, with more in the sex SG. However, if postembryonic animals are exposed to a pulse of BrdU between 30 and 65 days of development, when the number of PE neurons is rising sharply, the frequency of cell division appears to be very low in all SG. Ablation of the male organs in 10-day-old animals caused a reduction in the number of new cells seen in the sex SG, eliminating in most cases the differential distribution of cell division. We are currently using morphological criteria and immunochemical properties to test whether any of the cells labeled with BrdU correspond to the PE neurons.

CORRELATIONS BETWEEN TARGET-ORGAN GROWTH AND ADDITION OF CELLS IN THE PeIb CLUSTER OF LYMNAEA STAGNALIS. K.G. Bina* and R.P. Croll. Dept. of Psychol. and Dept. of Physiol. Biophys., Dalhousie University, Halifax, NS Canada B3H 4J1.

Recent studies demonstrate that most serotonergic cell clusters add to their cell numbers at different rates post-embryonically in Lymnaea stagnalis. For e.g. cells in the PeIb cluster show a sudden increase in number and size at about the time of sexual maturity (Croll & Chiasson, J. Comp. Neurol., 280:122-142, 1989). This study focuses on the relationship between the growth of the penis (the target organ of the neurons in the PeIb cluster) and the addition and/or differentiation of the cells in the PeIb cluster. Correlations drawn between penis size and shell length suggest that at about the time of sexual maturity the penis length also shows a dramatic increase. Nickel-lysine back fills performed on the penis nerve to determine the addition of cells innervating the penis in the PeIb cluster with age, suggests that cells are added at the time of sexual maturity. This was supported by the lack of serotonin-like immunoreactivity in sexually immature penis and the appearance of serotonergic projections in the sexually mature penis. Baptista and Macagno (J. Neurobiol.,19:707-726,1988)suggest that in leech the penis may have a trophic influence resulting in postembryonic addition of cells in the CNS. Our studies on the effect of penile ablation on addition of cells in the PeIb cluster, the effect of serotonin depletion in the CNS on the growth of penis and penis transplantation will be discussed.

PERSISTING HIPPOCAMPAL PRIMORDIUM FOLLOWING PRENATAL ADMINISTRATION OF METHYLAZOXYMETHANOL. S. Chen and D. Hillman. Dept. Physiol. & Biophys. NYU Med. Ctr. NY 10016.

In Nissl stained coronal sections of adult rats injected with methylazoxymethanol (MAM) at gestational day 15 (G15), an abnormal cellular nodule was found located on the ventricular wall between the caudate and corpus callosum. This aberrant nodule was negative for acetylcholinesterase as compared to the intense staining in the adjacent striatum. Serial reconstruction through the region revealed that the nodule continued along the ventricle extending caudally onto the hippocampal region adjacent to the fornix. The hippocampal formation was markedly reduced in size and ectopic cells extended from the nodule and appeared to be streaming into the dispersed CA2 layer near the junction of CA1 and CA2. These cells were clustered in columns that dispersed through the external plexiform layer. Following G16, or G17 days injections, the cellular nodule was much smaller in size while the hippocampus was larger. Interruptions were also commonly found in the CA1 layer of these animals, but located more medially. This study suggests that the cellular nodule may represent a persisting primordial anlage of the subventricular stem cells which normally would have proliferated and migrated to their final destination. The topographical distribution of interruptions may be either a direct toxic effect of MAM on developing neurons and glia, or a secondary effect due to a deficit of selected afferents projecting into this region. MIGRATION OF NEURONS TO THE TRIGEMINAL PRINCIPAL SENSORY NUCLEUS OF THE RAT. W.M. Al-Ghoul* and M.W. Miller. UMDNJ- Sch. Osteopathic Med., UMDNJ- R.W. Johnson Med. Sch., and Rutgers Univ., Piscataway, NJ 08854.

During their migration, post-mitotic neurons move from their site of generation to their final destination. We examined neuronal migration in the trigeminal principal sensory nucleus (PSN) with autoradiographic and immunohistochemical techniques. The subjects for this study were fetuses and pups from timed pregnancies. Three experiments were performed. **(1)** Neurons generated on gestational day (G) 12 and G14 were identified using [^{3}H]thymidine autoradiography. It took 3-8 days for neurons born on G12 and 4-10 days for neurons born on G14 to complete their migration to the PSN. **(2)** Changes in the positions of these two neuronal subpopulations were determined using a combined autoradiographic-immunohistochemical technique; one subpopulation was labeled with [^{3}H]thymidine and the other with bromodeoxyuridine. Early-generated neurons ended up in the medial PSN, whereas late-generated neurons ended up in the lateral PSN. **(3)** Radial glial fibers were examined using the antibody Rat 401. These fibers that extended from the fourth ventricle through the PSN were identified throughout the third week of gestation; no immunoreactivity was detected by postnatal day 5. Thus, the results show that neurons initially arrive at the PSN in the order of their time of generation but are distributed by an inside-to-outside pattern. This migration is organized by a transient array of radial glial fibers. Funded by DE 07734, AA 06916, AA 07568.

CHRONOLOGY OF NEURON ORIGIN IN FEMALE RAT PARACERVICAL (PG) AND INFERIOR MESENTERIC (IMG) GANGLIA. H.H. Traurig and R.E. Papka. Anatomy & Neurobiology, Univ. of Kentucky, Lexington, KY 40502 & Anatomical Sciences, Univ. of Oklahoma, Oklahoma City, OK 73190.

PG and IMG provide autonomic innervation to the female reproductive tract and other pelvic organs. We have previously observed the development of phenotypic expressions of neurotransmitter markers by PG neurons during fetal and neonatal life. The present study determined the pattern of prenatal neurogenesis of autonomic neurons in the PG and IMG. Timed-pregnant rats were injected with tritiated-thymidine to label fetal PG and IMG neuroblasts proliferating on a particular gestational day beginning on day 14 (E14). PGs and IMGs were subsequently obtained from the adult female offspring (50-60 days) of these injected rats, serially sectioned and processed for autoradiography. The proportions of PG or IMG neurons arising on a particular gestational day were estimated from the daily declines in neurons previously labeled as neuroblasts on each gestational day. Results showed that virtually all neurons were labeled in rats exposed to tritiated-thymidine on E14 or E15 (93%). A few PG and IMG neurons arose on E14 or earlier, most neurons were generated on E15-E16 and 80% originated by E17. A few neurons arose as late as E21 or later. Thus, the majority of autonomic neurons innervating the female reproductive tract are generated on E15 through E17. (Supported by NIH grant NS23354 and UKRF4-31293.)

237.8

GENERATION PATTERNS OF SPINAL SYMPATHETIC AND PARASYMPATHETIC PREGANGLIONIC NEURONS IN THE RAT SPINAL CORD. R.P.Barber,* P.E.Phelps and J.E.Vaughn. Div. of Neurosciences, City of Hope, Duarte, CA 91010.

We have studied the embryonic generation of spinal cholinergic preganglionic autonomic neurons in the rat using a monoclonal antibody against choline acetyltransferase combined with tritiated thymidine autoradiography to label dividing cells. The thoracic and upper lumbar segments contain four subgroups of cholinergic sympathetic neurons that span the intermediate gray from the lateral funiculus to the dorsal gray commissure (Barber et al., 1984). Sympathetic preganglionic neurons in upper thoracic and upper lumbar spinal cord were generated on days E11-12, with peak generation in these two regions being E11 and E12, respectively. The single group of parasympathetic neurons in the first sacral segment was generated between E11-13, with the peak generation on E13. At all spinal levels, the range and peak generation of the autonomic motor neurons coincided with that of somatic motor neurons at the same rostrocaudal spinal level. Findings that these neurons are generated synchronously raise the possibility that visceral and somatic motor neurons may be derived from the same region of the germinal zone. In addition, they indicate that visceral efferent neurons do not obey the general ventrodorsal gradient of spinal neurogenesis since, despite the simultaneous time of origin, such cells are located substantially more dorsally than somatic motor neurons. Supported by NIH grant NS25784.

237.9

DEVELOPMENT OF CHOLINERGIC PREGANGLIONIC NEURONS IN UPPER THORACIC RAT SPINAL CORD. P.E. Phelps, R.P. Barber*, and J.E. Vaughn. Division of Neurosciences, Beckman Res. Inst. of the City of Hope, Duarte, CA 91010.

A monoclonal antibody against choline acetyltransferase (ChAT) was used to study the embryonic development of ChAT expression within sympathetic preganglionic neurons. On E21, all four subgroups of sympathetic neurons were immunoreactive and distributed in their characteristic pattern across the intermediate zone, forming striking arrays of transverse dendritic bundles. In contrast, on E15-16, ChAT+ sympathetic neurons appeared in laterally located, triangular shaped groups, with their processes extending 50-75% of the distance across the intermediate zone. Our findings suggest that the transverse dendritic bundles are formed between E15 & 19. In addition, the ChAT+ sympathetic neurons in both E15 & 16 specimens are found in the ventral spinal cord, whereas at later ages they have achieved their more dorsal location. These observations, combined with our other findings that thoracic somatic and autonomic motor neurons have identical generation times, suggest that both populations may be derived from the same, or adjacent parts of the ventral ventricular zone, despite their different final positions. Younger stages will be studied for differences in migratory pathways of these two types of spinal cholinergic motor neurons.

Supported by NIH grant NS25784.

237.10

CORRELATION OF NEURONAL BIRTHDATE AND TRANSMITTER PHENOTYPE FEMALE RAT PG NEURONS. K.A. Sullivan R.E.Papka and H.H.Traurig Dept. of Anat. and Neurobiol., Univ. of Kentucky,Lexington KY., Dept. of Anatomical Sciences, Univ. of Oklahoma, Oklahoma City, OK.

We have previously reported that approximately 80% of PG neurons are generated by E15 and E16 while a significant proportion arise on E19. In the present study, timed pregnant rats received tritiated thymidine (^{3}HT) to label proliferating fetal neuroblasts. When these offspring reached adulthood, immunohistochemistry or histochemistry for peptide/transmitter localization was combined with autoradiography on sections of the PG to correlate phenotypic expression of transmitter markers with neurogenesis. Preliminary results indicate that NPY containing neurons are generated as early as E15 and as late as E20. TH-containing neurons appear to be generated later in development. Very few neurons generated on E14 and E15 contain both ^{3}HT and TH labels, while double-label is more commonly observed on E18-E20. (Supported by NIH Grant NS-22526).

BRAIN/BODY GROWTH IN ALLIED RATS. M.D. Mann and A.L. Towe, Departments of Physiology and Biophysics, Univ. Neb. Sch. Med., Omaha, NE 68105 and Univ. Wash. Sch. Med., Seattle, WA 98195

Of the specimens used by J.M. Taylor in her study of the reproductive biology of *Rattus assimilis* (*Univ. Calif. Pub. Zool.*, 1961, 60:1-66), the skulls and skins of 89 wild-caught and 82 laboratory-born/reared specimens are available for study in the Museum of Vertebrate Zoology at the University of California, Berkeley. The lab-reared group spans ages at death of 16 days to 3.5 yr pp, and, therefore, is one of the most complete developmental studies available. We measured all cranial volumes (E), and related them to body weight (P), body length (BL) and tail length (TL). In the lab-reared group, we also considered these variables as functions of age (A) at death.

Comparing E with P in the wild-caught group, we obtained a reduced major axis with slope, b = 0.247, comparable with those for other rats, $\bar{b} = 0.280$ (± 0.054) for 10 species (Mann *et al.*, *Brain Behav. Evol.*, 1988, 31:111-124). In this sense *R. assimilis* is not an unusual rat. Comparing E with BL, b = 0.748, and comparing BL with P, b = 0.332. Thus, the three slopes calculated for E:P, E:BL and BL:P bear the appropriate relations $0.247 = (0.748)(0.332)$ [$b_{E:P} = b_{E:BL} \times b_{BL:P}$]. Comparing BL with TL, b = 0.715.

For lab-reared animals, all variables were fitted by two linear regressions on age, one in the rapid growth of youth and one in the slow growth of adulthood. The slope ratios showed that $E \propto BL$ and $E \propto P^{1/3}$ throughout life, but TL stabilized at the end of rapid growth. Therefore, $E(A) = kBL(A)$. The simplest explanation is that for every fiber that is added to the spinal cord from brain, the brain itself increases by the volume of one cell body. Whatever the reason, brain and body growth in rodents differ sharply from those in primates and carnivores. The mean E:P slope of 1/3 for different species of rodents (Mann *et al.*) may simply reflect a normal growth pattern of rodents, rather than some more obscure constraint on brain/body relations.

237.12

PATTERNS OF GROWTH IN GOLDFISH OLFACTORY BULB AND SENSORY EPITHELIUM. J. Silveira and P.C. Brunjes. Dept. of Psychology, Univ. of Virginia, Charlottesville, VA 22903.

Goldfish exhibit slow growth throughout much of their life, making them a useful model for developmental processes. We have demonstrated that goldfish olfactory receptor sheets (rosettes) and olfactory bulbs grow in proportion to the rest of the fish. Rosettes expand by 1) adding lamellae (fleshy radiations containing sensory epithelium) medially and 2) elongating existing lamellae. Laminar volume analysis of olfactory bulbs showed that proportionately less volume is represented by the granule cell layer in large versus small fish, suggesting addition of neuropil instead of cells during growth. The present study investigated patterns of mitotic activity in growing rosettes and bulbs using ^{3}H-thymidine autoradiography. Olfactory bulbs of fish exposed to ^{3}H-thymidine in aquarium water (100μCi/l) had only a few labeled cells at the granule cell layer periphery ($< 1/100\mu m^2$), suggesting that the increase in bulb size seen with fish growth is due to the addition of neuropil, rather than the addition of new cells. Rosettes exhibited substantial cellular proliferation, but labeled cells were distributed evenly throughout the structure suggesting no foci of cellular production.

ANGIOGENESIS IN NORMAL AND DEPRIVED OLFACTORY BULBS. D.L. Korol and P.C. Brunjes. University of Virginia, Charlottesville, VA 22903.

Permanently blocking stimulus access to olfactory receptors on the day after birth (P1) results in a series of changes within the olfactory bulb, including rapid decreases in metabolism and protein synthesis and later reductions in bulb cell number and laminar volume. Perhaps decreased cellular activity resulting from deprivation reduces regional blood flow, subsequently altering vascular development. Altered angiogenesis might in turn impair bulb growth. To address this hypothesis we examined the development of vasculature in olfactory bulbs of rats that underwent unilateral naris closure or sham surgery on P1. At several postnatal ages pups were perfused with either a WGA-HRP or an india ink/gelatin solution. Computerized imaging was used to determine area fractions of blood vessels across the extent of the bulb. In normal bulbs considerable increases in vascular area and complexity were observed in nearly all laminae between P10 and P20. After 30 days of deprivation 10-20% reductions in vessel area in the glomerular and external plexiform layers were observed. Deprived bulbs, therefore, are not merely miniaturized versions of normal bulbs: they contain less vasculature per unit area. The possibility that deprivation-induced changes in the vasculature arise prior to reductions in bulb size is presently being evaluated. Supported by NS23154 and HD07323

PRENATAL CELLULAR PROLIFERATION IN THE FOREBRAIN OF THE PRECOCIAL MOUSE *Acomys cahirinus* P. C. Brunjes, D. L. Korol and K. G. Stern*. Univ. of Virginia, Charlottesville, VA 22903.

Acomys, like the laboratory rat and mouse, is a member of the rodent subfamily muridae. However, unlike its altricial cousins, *Acomys* is born after a long (39 day) gestation period with functional ears and eyes and quite sophisticated locomotor capabilities. Widespread differences in the development of the olfactory bulb, hippocampal formation and visual cortex have been reported between the species in both prenatal and postnatal life. We have examined the time of cell production in *Acomys* with ^{3}H-thymdine techniques to specify patterns of early growth. Substantial differences were observed between *Acomys* and the rat, with *Acomys* exhibiting much later and more protracted periods of proliferation. For example, mitral cell production was observed to occur near day E17 in *Acomys*, while most proliferation is completed in the rat 2-3 days earlier. Hippocampal pyramidal cells were generated in *Acomys* between E19-21, and dentate granule cells between E21 and birth. Labelled cells were first observed in the visual cortex on E17, with production ending by E35. The protracted development in *Acomys* suggests it is quite suitable for detailed examinations of early growth, while the differences between the species suggest they are ideal for examining phylogenetic differences in brain development. Supported by NS23154 and HD07323

EXPRESSION OF JONES GANGLIOSIDES IN EXPLANTS OF RAT CEREBELLUM. R. Méndez-Otero and M. Constantine-Paton. Instituto de Biofísica Carlos Chagas Filho, UFRJ, Rio de Janeiro, RJ, 21944 and Dept. of Biology, Yale University, New Haven, CT. 06511.

In dissociated cell cultures of postnatal rat cerebellum, JONES gangliosides are expressed by neuronal and glial sub-populations (Méndez-Otero et al., Soc. Neurosci. Abstr., 13: 1636, 1987). To test the hypothesis that JONES expression is associated with migrating granule cells, we have used cerebellar explant cultures where the temporal relationship between granule cell migration and differentiation has recently been described (Hockberger et al., J. Neurosci. 7: 1370, 1987). Explants were prepared from P2-P6 postnatal rats, fixed after different intervals in culture and immunostained. After 1 to 3 days in vitro (young cultures), JONES gangliosides are expressed by the vast majority of granule cells and by the radiating glial processes. JONES immunoreactivity decreased progressively with distance from the explant thus paralleling the maturation of granule cells. The results confirm our hypothesis that expression of JONES gangliosides is correlated with migrating behavior in vitro.

MONOCLONAL ANTIBODIES TO CARBOHYDRATE ANTIGENS IDENTIFY SUBSETS OF OLFACTORY AND VOMERONASAL AXONS IN THE RAT. G.A. Schwarting and J.E. Crandall. Depts. of Biochemistry and Developmental Neurobiology, E.K. Shriver Center, Waltham, MA 02254.

Cell surface glycoconjugates are thought to play an important role in cell-cell interactions during development of CNS pathways. Monoclonal antibodies were raised against PC12 cells in order to obtain stage and region specific carbohydrate antigens in the nervous system. Two of these monoclonal antibodies, CC1 and CC2, were used to examine the expression of glycoconjugates in the forebrain of postnatal rats. CC2 reacts with complex glycolipids which contain terminal α-fucose residues. In the forebrain of 15 day old rats, CC2 reacts with surfaces of axons in both the olfactory nerve and vomeronasal nerve. No immunoreactivity is seen in the glomeruli of the main olfactory bulb. In contrast, CC2 immunoreactivity is seen throughout the accessory olfactory bulb. CC1 monoclonal antibody reacts specifically with the glycolipid globoside, which contains a terminal N-acetylgalactosamine residue. In the forebrain, CC1 reacts with the axons of the vomeronasal nerve. CC1 immunoreactivity is also distributed in the glomeruli and external plexiform layer of a restricted portion of the accessory olfactory bulb. Thus CC1 reacts with a subset of the neuropil that is stained with CC2. (Supported by NIH grants NS25580 and NS24386).

238.3

COMPOSITION OF THE EXTRACELLULAR MATRIX AT THE GLIAL SEPTUM LEVEL IN THE EMBRYONIC RAT BRAIN. A. Nadeau, S. Woerly and R. Marchand. Lab. Neurobiol., Hôp. Enfant-Jésus, 1401, 18e Rue, Québec, (QC) Canada, G1J 1Z4.

Van Hartesveldt et al. (1986) described, within the midline raphe, a transitory glial structure that appears to extend within the midbrain, hindbrain and cervical spinal cord. This structure would be present from at least embryonic day 15 to postnatal day 7 or 8. More recently, the same structure which is closely associated to the floor plate has been shown to promote and orient commissural axonal growth through the secretion of a diffusible factor (Tessier-Lavigne et al., 1988). To better circumscribe the biochemical nature, the origin and extent of the glial septum in the developing brain, we have aimed our study at two main aspects of the development of this structure. First and based upon the important implication of various extracellular matrix (ECM) components in the growth and orientation of axons towards their target structures, we have focused our attention upon the identification of different molecular elements of the glial septum ECM. The second aspect of the study was oriented towards the morphological development and organization of the glial septum. Precisely timed embryos of various ages were fixed in 10% formalin, embedded in paraffin and cut at 10µm. Specific histochemical techniques known to reveal different ECM elements were applied to these sections. Other embryos were also injected with ^{3}H-thymidine to determine the time of origin of the floor plate cells. The results show the presence of collagen, possibly of types I, III and IV, carboxylated and sulfated glycosaminoglycans and reticulin fibers that are associated to basement membranes. The glial septum is rich in several ECM molecules that are known to provide a favorable environment for axonal migration. Our data also indicate that the cells of the floor plate are generated as precociously as day 11 of gestation, that the glial septum is formed rapidly thereafter, and that it does not extend rostrally farther than the fovea isthmi. (Supported by MRC, FRSQ and FCAR).

238.4

TRANSIENT EXPRESSION OF CYTOTACTIN AND ITS PROTEOGLYCAN LIGAND IN THE BARREL FIELD OF DEVELOPING MOUSE SOMATOSENSORY CORTEX. K.L. Crossin*, S. Hoffman, and G.M. Edelman. Laboratory of Developmental and Molecular Biology. The Rockefeller University. New York, New York 10021

The expression of cytotactin, a high molecular weight glycoprotein, and cytotactin-binding (CTB) proteoglycan, a chondroitin sulfate proteoglycan with which cytotactin interacts, was examined in the developing barrel cortex of postnatal mice. At PN6-7, both molecules and their common HNK-1 antigenic determinant were expressed in the barrel walls and were excluded from the hollows. This molecular exclusion began at about PN2.5-3 concurrent with the entry of thalamocortical axons. This pattern was maintained until PN12, but by PN13 the expression of both molecules was low and uniform throughout the barrel field. The expression of both molecules was perturbed after removal of a row of whiskers and electrocauterization of the whisker follicle, consistent with previous studies showing altered morphology after such treatment. In cellular studies, glia synthesized cytotactin but not CTB proteoglycan, whereas mixed cultures of neurons and glia synthesized both molecules, suggesting that CTB proteoglycan was synthesized by neurons in these cultures. The results are consistent with the idea that there exist molecular correlates of CNS pattern formation and that both glia and neurons contribute to the molecular pattern.

238.5

GLIAL DISTRIBUTION IN THE RODENT BARREL FIELD FOLLOWING MECHANICAL LESIONS OF THE SOMATOSENSORY CORTEX. Eric D. Laywell* and Dennis A. Steindler. Department of Anatomy and Neurobiology, College of Medicine, The University of Tennessee, Memphis.

The unique geometry of the mouse somatosensory cortical barrel field, and its transient cordoning off during development by certain glia and glycoconjugates including the J1/tenascin adhesion molecule (Steindler et al., Dev. Biol., 131:243, 1989), provide an opportunity to study neuron-glia interactions in the developing normal and lesioned cortex. During normal development, by postnatal day 11 there is a transition from predominantly boundary glia (i.e. in the future interbarrel septae) to non-boundary glia (i.e. in barrel hollows). To see if there is a subpopulation of glia that maintains a boundary distribution in adult barrels, but evaded detection in our previous immunocytochemical (ICC) studies due to the reduced expression of the glial fibrillary acidic protein marker (GFAP) during later stages of normal cortical maturation, the following lesion study was performed in adult mice using a similar labeling approach. Stab wounds were made in the somatosensory cortices of adult ICR mice, and following different survival times of up to 14 days, the brains were processed for GFAP-ICC. It appears that there is not a subpopulation of reactive glia that demarcates barrels in the adult, and the pattern of GFAP labeling is similar to that seen in the second postnatal week in normal animals. In the lesioned adult barrel cortex, GFAP-positive astrocytes reside in both boundary and non-boundary positions. Lesion studies are currently underway during and just after the critical period in barrel development, but it is tempting to speculate now that the disintegration of glial boundaries following the stabilization of cortical patterns may be one reason why there is a failure to achieve complete functional reorganization following damage in the adult. Supported by NIH/NINCDS grant NS 20856.

238.6

PLASTICITY OF ADHESION MOLELCULE BOUNDARIES IN THE CORTICAL BARREL FIELD OF NORMAL AND REELER MUTANT MICE. T.F. O'Brien*, K. Harrington*, A. Faissner*, M. Schachner, and D.A. Steindler. (SPON: J. Schweitzer). Dept. of Anat. & Neurobiol., Univ. of Tenn., Memphis, and Dept. of Neurobiol., Univ. of Heidelberg.

We have previously shown glial and glycoconjugate boundaries that delineate developing normal and aberrant vibrissae barrels in normal and reeler mutant mice. The aim of the present study was to define changes in the reeler and normal barrel field boundaries following vibrissae lesions in the first postnatal week. Monoclonal antibodies to the J1/tenascin adhesion molecule, and the 473 proteoglycan expressed by glia (Faissner, Neurosci. Abs. 14:920, 1988), were used in immunocytochemistry studies following lesions of the C row of whiskers on P2-4. In normal (+/+,+/rl) animals, both antibodies revealed altered C row boundaries. This consisted of an attenuated C row with a corresponding increase in size of the adjacent D row of barrels, and a loss of interbarrel boundaries within row C that was not always accompanied by a detectable loss of barrel area. Both antibodies revealed the reeler barrel field in the control hemisphere similar to that previously reported using lectin binding. In the lesioned hemisphere in reeler, the presence of an attenuated band with altered staining adjacent to a row of enlarged barrels suggests that barrel boundaries in reeler are malleable in a way that is comparable to that seen in normal animals. Furthermore, this lesion/boundary study in reeler affords a barrel row assignment that is not so easily accomplished using other approaches. The findings suggest that the reeler defect, although resulting in altered morphogenesis, may not affect neocortical plasticity during development as witnessed by the reorganization of transient adhesion molecule boundaries. Supported by USPHS grant NS 20856, and the Deutsche Forshungsgemeinschaft.

238.7

TENASCIN IN SECONDARY NEURULATION. L-H.J. Liu*, K.S. O'Shea, and R. Chiquet-Ehrismann*(SPON: C.J. D'Amato). Dept. Anatomy & Cell Biol., Univ. of Mich., Ann Arbor, MI.

The distribution of tenascin, an extracellular matrix glycoprotein associated both with mesenchymal-epithelial interactions during morphogenesis as well as with oncogenesis, was examined in secondary neurulation in the mouse embryo. In this process, mesenchyme derived from the primitive streak aggregates, "epithelializes", forms a lumen and merges with the more anterior neuroepithelium, extending the length of the neural tube. In the current investigation, sections through the forming secondary neural tube from day 11 mouse embryos were processed for immunocytochemical localization of tenascin. Briefly, tenascin was initially found throughout the mesenchyme, particularly in the lateral mesenchyme bordering the surface ectoderm. With initial aggregation of mesenchymal cells near the dorsal surface of the embryo, anti-tenascin staining was lost from between forming epithelial cells and was displaced into the region of developing basement membrane. With consolidation of the aggregate, tenascin was densely deposited in the lateral region of the neuroepithelial basement membrane and in basement membranes of notochord and gut. Mesenchymal staining, except at the dorsolateral aspect of the neuroepithelium, was considerably reduced. As in the morphogenesis of other organs, tenascin may play a role in the mesenchymal-epithelial conversion involved in secondary neurulation.

238.8

TOPOGRAPHY OF N-CADHERIN EXPRESSION DURING CNS DEVELOPMENT SUGGESTS BOTH STRUCTURAL AND INFORMATIONAL ROLES. Laura A. Lagunowich* and Gerald B. Grunwald, Department of Anatomy and Training Program in Developmental Biology/Teratology, Thomas Jefferson University, Philadelphia, PA 19107.

N-cadherin is the major calcium-dependent cell adhesion protein expressed in the developing nervous system. Our previous studies have indicated that N-cadherin is expressed throughout the developing chick retina but becomes highly localized in the mature tissue. We now report similar biochemical and immunohistochemical studies of N-cadherin in the developing chick brain and spinal cord. Rostrally, localization of N-cadherin was seen in the ependymal lining of all ventricles and in the choroid plexus. Staining was also seen in the external granule cells of the cerebellum of the hatched chick while staining of other cellular layers of the brain was much reduced by this time. Caudally, specific staining was seen in the raphe of the midbrain and the floorplate of the spinal cord. Parallel biochemical experiments indicate that changes in the topographic expression of N-cadherin are accompanied by molecular modifications as well. 2-D gel autoradiograms of labelled neural retina indicate that N-cadherin is both a phosphoprotein and a sulfoprotein and that these post-translational modifications are developmentally regulated. Thus N-cadherin appears to be generally expressed at high levels throughout the CNS during early developmental stages but becomes restricted in mature tissues. The topographic distribution of N-cadherin in the hatched chick indicates that it has a continuous structural role in the maintenance of supportive components such as the ependyma, choroid plexus and retinal outer limiting membrane and also may have an informational role in specific regions such as the raphe and floor plate where N-cadherin may provide cues for directed axonal growth. Supported by NIH grants NRSA-EY-06067 to LAL and EY-06658 to GBG and March of Dimes grant 5-569 to GBG.

TEMPORAL AND SPATIAL DISTRIBUTION OF NEURAL CELL ADHESION MOLECULE (NCAM) IN THE EMBRYONIC RAT TRIGEMINAL SYSTEM. I.A. Scarisbrick* and E.G. Jones (Spon: Y. Torigoe) Dept. of Anatomy and Neurobiology, Univ. of California, Irvine, CA 92717.

Differential expression of cell adhesion molecules plays an important role in morphogenesis. To investigate the expression of NCAM during the development of the rat Trigeminal (V) system, paraffin embedded Wistar rat embryos of known gestational ages were sectioned and processed for NCAM immunoreactivity (I) using a rabbit antiserum to NCAM and the avidin-biotin technique.

Trigeminal ganglion cells were NCAM-I at their first appearance on embryonic day 10 (E10). Ganglion cells of placodal origin formed small clusters and strands of NCAM-I cell bodies extending medially from the level of the epithelium of the maxillo-mandibular arch, which was itself NCAM-I. The most intense immunoreactivity was seen at the cell surface. Centrally projecting fibers approaching the neural tube and peripherally projecting fibers beginning to sprout at the lateral aspect of the primordial ganglion were intensely NCAM-I. By E12, the neural crest derived basal cap cells, at the base of the first rhombomere, were also NCAM-I. The developing infraorbital nerve was not readily distinguished on E12, but the motor root was evident within the mandibular arch and tufts of centrally projecting fibers extended into the first rhombomere. The infraorbital nerve became intensely NCAM-I on E13 and approached the skin epithelium which was intensely NCAM-I basally. Developing vibrissae follicles became apparent on E14 but were only lightly NCAM-I. Both centrally and peripherally projecting fibers remained intensely NCAM-I, but immunoreactivity at the surface of V ganglion cells was greatly reduced. By E15 the infraorbital nerve reached the developing vibrissae follicles which showed increased levels of NCAM-I.

These results suggest that the differentiating whisker pads may express NCAM as they are contacted by the infraorbital nerve. The further development of this system will be described.

THE PRODUCT OF THE NEUROGENIC NOTCH GENE IS A CELL SURFACE GLYCOPROTEIN. K.M. Johansen*, R.F. Fehon*, J.Johansen[1], & S. Artavanis-Tsakonas. (SPON: K. Frederiksen) Dept. of Biology, Yale Univ., New Haven, CT 06510 and [1]Dept. of Zoology, Iowa State Univ. Ames, IA 50011.

The *Notch* locus of *Drosophila melanogaster* is one of a small number of zygotically acting "neurogenic" genes involved in the correct segregation of neural from epidermal lineages during embryogenesis as well as in other postembryonic developmental events. The *Notch* gene product is predicted by DNA sequence analysis to be a large transmembrane protein with several striking features, most notably an array of 36 EGF-like repeats in the extracellular domain. We show that *Notch* encodes a large, glycosylated surface protein with an apparent molecular weight of 300 kD: 1) antibodies raised against three regions of the putative protein detect *Notch* on Western blots as a high molecular weight, primarily full-length product; 2) immunoelectron microscopy localizes the *Notch* protein to the cell membrane; and 3) lentil lectin column binding demonstrates that the protein is glycosylated, indicative of its surface protein nature. Early labelling in the blastoderm appears ubiquitous except for the pole cells, but as development proceeds some distinctive features emerge: stronger staining is seen within the germ band layer where neuroblast delamination occurs, and the developing embryonic nervous system shows pronounced axonal staining. The eye and wing discs are two other tissues showing a defined localization of *Notch* product: a set of cells within each ommatidial cluster in the eye disc and the presumptive wing veins are selectively labelled.

EFFECT OF PURIFIED EXTRACELLULAR MATRIX COMPONENTS ON THE BEHAVIOR OF NEUROEPITHELIAL CELLS IN VITRO. V. Nurcombe*, J. Drago* and P.F. Bartlett* (SPON: L. Hemmendinger). Walter and Eliza Hall Institute of Medical Research, Royal Melbourne Hospital, Australia 3050.

We have investigated in vitro the role of laminin, fibronectin and type IV collagen in influencing the growth and differentiation of neuroepithelial cells obtained from the telencephalon of embryonic day 10 mice. It was found using thymidine assay that both laminin and type IV collagen were mitogenic. Laminin also promoted neural differentiation, when applied to the culture substrate at concentrations greater than 50 µg/ml, as evidenced by cell flattening and profuse neurite outgrowth. Fibronectin was not mitogenic and its only observable effect was a transient increase in cell attachment and spreading. Both the phenotypic and mitogenic response of neuroepithelium to laminin could be reproduced by the laminin E8 fragment, whereas the E1-4 crossarm had no effect. Evidence will be presented that laminin can markedly potentiate the response of neuroepithelial cells to the soluble family of fibroblast growth factors, and that a particular precursor subpopulation can be stimulated to upregulate its own synthesis of extracellular matrix components.

EVIDENCE FOR THE IN VIVO POLYMERIZATION OF EPENDYMIN: A PROCESS IMPLICATED IN LONG-TERM MEMORY FORMATION. V.E. Shashoua G.W. Hesse* and B. Milinazzo* (SPON: T.O. Fox) McLean Hospital, Harvard Medical School, Belmont, MA 02178

Ependymin, a glycoprotein of the brain extracellular fluid, has been implicated in synaptic changes associated with the consolidation process of long-term memory formation and the activity-dependent sharpening of connections of regenerating optic nerve. In vitro experiments have demonstrated that ependymin has the capacity to polymerize into fibrous insoluble proteins (FIP) when the Ca^{2+} concentration is reduced by the addition of EGTA. Such products, once formed, do not dissolve in 2% SDS in 5 M urea. This property was used to develop an assay for detecting the presence of FIP in Brain. The results show that a reproducible quantity of FIP aggregates is present in goldfish and mouse brain. This was highly concentrated in the synaptosomal fraction and had identical immunoreactivity properties to FIP aggregates obtained by the polymerization of pure ependymin in vitro as well as a cross-reactivity to other protein components of the extracellular matrix such as fibronectin and laminin. Labeling studies with ^{35}S-methionine showed that labeled FIP aggregates associated with the synaptosomal fraction can be obtained in vivo. Comparisons of the amino acid sequence of ependymin with proteins of the extracellular matrix showed that domains with epitopes recognizable by antibodies to fibronectin, laminin and tubulin exist in the ependymin molecule. These results suggest that ependymin can polymerize to form FIP aggregates in vivo, and that they have immunoreactivity properties to major components of the brain extracellular matrix. Supported by NIH Grant No. NS25748.

VAGAL AND ACCESSORY NERVE PROJECTIONS OF A SENSORY GANGLION LOCATED IN THE ACCESSORY NERVE. J.P.O'Reilly* and L.P.Schramm (SPON: J.W. Osborn). THE JOHNS HOPKINS SCHOOL OF MEDICINE. BALTIMORE,MD. 21205.

The accessory (XI) cranial nerve is generally considered a purely motor nerve. However, small ganglia have been described in it. In the present study, retrograde tracing techniques were used to determine the peripheral projections of a ganglion found consistently in XI of the rat. Male Sprague-Dawley rats weighing 250-300 grams were anesthetized, and a ventral incision was made to allow access to the glossopharyngeal (IX), vagus (X), hypoglossal (XII) and XIth nerves. In initial experiments we labeled (fluoro-gold, true blue, or diamidino yellow) individual nerves. In subsequent experiments we labeled (true blue, diamidino yellow) both X and XI. After appropriate survival times, the animals were perfused, and the brainstem and upper cervical spinal cord were prepared for fluorescence microscopy. The presence of labeled soma in XI was recorded. As a precaution against potential peripheral mixing of pairs of dyes, we required that there be no double labeling of neurons in the dorsal motor nucleus of the vagus or the accessory nucleus. Both the Xth and the XIth nerves were found to contain peripheral projections from the accessory ganglion. However, the IXth and XIIth nerves did not show projections from this ganglion. In addition to single-labeled neurons (from both X and XI) in each ganglion, double-labeled neurons were also evident. We conclude that the sensory neurons in the accessory nerve subserve both accessory and vagal functions. Further, a restricted population of these neurons, those with peripheral branches in both the vagus and the accessory nerves, may represent a site of peripheral somato-visceral integration. Supported by NIH Grant HL161315.

BILATERAL INJECTION OF MUSCIMOL INTO THE RAT ROSTRAL VENTROLATERAL MEDULLA FAILS TO DECREASE MEAN RENAL NERVE ACTIVITY. L.R. Poree* and L.P. Schramm, Department of Biomedical Engineering, Johns Hopkins University School of Medicine, Baltimore, MD 21205

Muscimol, a GABA agonist, has previously been shown to decrease mean arterial pressure (MAP) when injected into the rostral ventrolateral medulla (RVLM). In the present study, MAP and renal nerve activity (RNA) were recorded before and after injections of muscimol (125 ng) into the RVLM of anesthetized, paralyzed, and artificially respirated rats. Microinjection (100 nl) of muscimol into the RVLM caused MAP to fall 55 ± 5 mmHg, but it failed to decrease mean RNA. Although mean RNA was unaffected by muscimol treatment, the frequency and amplitude of the discharges were significantly altered. Prior to muscimol treatment, low frequency (0.5-1.5 Hz), high-amplitude bursting activity was superimposed over the higher 6 Hz cardiac-linked activity. Following a train of these low frequency bursts, an extended silent period (1-2 sec) was often observed. After muscimol treatment the activity became non-bursting with only small changes in amplitude. Baroreceptor modulation of RNA was also abolished. These changes in RNA were similar to those observed after transection of the rat spinal cord. Further, after injection of muscimol, electrical stimulation of the superficial, dorsolateral cervical spinal cord elicited substantial inhibitions of RNA. Similar inhibitions had previously been elicited only after full, C1, spinal transection. Supported by NIH Grant HL 16315.

TONIC BRAINSTEM INFLUENCES ON SYMPATHETIC PATHWAYS TO THE KIDNEY AND SPLEEN IN RATS. K. Hayes*, C.P. Yardley* and L.C. Weaver. The John.P. Robarts Research Institute and Dept. of Physiol., Univ. of Western Ontario, London, Ontario, Canada.

Selective brainstem influences on pre- and postganglionic nerves controlling the kidney and spleen were investigated in fifty-two urethane-anaesthetized rats. Changes in renal (RNA), splenic (SNA) and preganglionic greater splanchnic (GSPNA) or white ramus (T13WR) nerve activity were compared after cervical spinal cord transection or blockade of the rostral ventrolateral medulla (RVLM) by unilateral microinjection of glycine. Although cord transection reduced RNA by 27±2%, RVLM blockade decreased RNA by a greater extent (-45±4%). In contrast, cord transection caused a greater decrease in SNA (-48±8%) than did RVLM blockade (-30±2%). This indicates that the decreased RNA after RVLM blockade was caused, in part, by sympathoinhibition. selective for renal nerves, that was unmasked by blockade of excitatory inputs. Similar to splenic nerve responses, cord transection decreased GSPNA by 32±6% while RVLM blockade decreased it by only 16±4%. Activity of T13WR increased by 12±36% after cord transection and decreased by 34±6% following RVLM blockade, responses comparable to those of renal nerves. These results suggest that the different balance of tonic supraspinal excitatory and inhibitory influences on two populations of lower thoracic preganglionic neurons leads to selective control of renal and splenic sympathetic nerves.(Support: Rick Hansen Legacy Fund and Canadian Heart Foundation)

239.4

COMPARISON OF THE DISTRIBUTIONS OF RENAL AND SPLENIC NEURONS IN SYMPATHETIC GANGLIA IN RATS. V. Chevendra* and L. C. Weaver (SPON: S. Sims). The John P. Robarts Research Institute and Dept. of Physiology, University of Western Ontario, London, Ontario, Canada.

Selective connections between pre- and postganglionic sympathetic neurons may depend upon the distribution of postganglionic neurons in different sympathetic ganglia. The distributions of postganglionic neurons innervating the spleen and kidney were compared in rats using retrograde transport of fluorescent dyes True Blue and Fluoro Gold. Crushed splenic and left renal nerves were simultaneously exposed to 1 μl of the dyes (4%) for 45 min. Four days after surgery, sympathetic prevertebral (greater splanchnic and solar plexus) and left paravertebral ganglia (T6 - L4) were removed, cut at 15 μM and labelled neurons were counted (n = 4). The following table illustrates the distributions of 7078 splenic and 6768 renal neurons.

	T6-T9	T10-T13	L1-L4	Splanchnic	Sol plex
Splenic	< 1%	13%	< 1%	64%	22%
Renal	< 1%	66%	14%	14%	5%

Within the sympathetic chain, splenic neurons were located mostly in T11 and renal neurons mostly in T13. In the prevertebral ganglia, renal and splenic neurons were found in different locations. The preferential distribution of renal neurons in the paravertebral ganglia and splenic neurons in the prevertebral ganglia provides an anatomical basis for selective preganglionic innervation. PARASYMPATHETIC AND SYMPATHETIC INNERVATION OF THE HEART IN THE DEVELOPING PIGLET. D.A. Hopkins, J.A. Armour, N. Gootman* and P.M. Gootman. Depts. of Anatomy and Physiology and Biophysics, Dalhousie University, Halifax, NS B3H 4H7, Dept. of Physiology, SUNY-Hlth Sci Ctr, Brooklyn, NY 11203 and Schneider Child. Hosp.-LIJMC, New Hyde Park, NY 11042.

The neonatal piglet is an important animal model of cardiovascular function but relatively little is known about the organization and development of nerves and ganglia innervating the piglet heart. In the present study seven piglets ranging in age from 4-46 days received injections of retrogradely transported fluorescent tracers (True Blue, Diamidino Yellow) into the heart. After 3-7 days, the thoracic ganglia and nerves were identified by microdissection. The brain stem and ganglia were processed for fluorescence microscopy. The results show that the gross anatomy of the thoracic ganglia and cardiac nerves of the piglet are more similar to those in the primate than those in cat and dog. Retrogradely labeled perikarya were observed in the major sympathetic and sensory ganglia, bilaterally. Extremely few double labeled cells were observed. The stellate ganglia were most consistently labeled but when middle cervical ganglia could be identified they also contained labeled perikarya. The brain stem contained labeled perikarya bilaterally in the ventrolateral nucleus ambiguus. Supported by MRC, N.S. Heart Foundation, NIH (HL20864) and LIJMC.

CONNECTIONIST ANALYSIS OF THE NEURAL PATHWAYS INVOLVED IN THE CONTROL OF THE CARDIOVASCULAR FUNCTION IN CATS AND RATS. M.A.L.Nicolelis*, C.H.Yu*, L.A.Baccala* (SPON:I.M.Patel). Dept. Physiol. Biophys., Hahnemann Univ., Philadelphia, PA 19102

A microcomputer-based program was created for storage and modelling of neuroanatomical circuits. As its first application the system was filled with information collected from the literature on the neural control of the cardiovascular system function in cats and rats. A matrix representation of these data was built by defining 39 structures involved in this control process and 123 direct connections between them. These neural structures and their connections were interpreted as a network and its topological properties were analyzed through the employment of graph theory. First, each nucleus of this network was individually classified according to its number of afferents and efferents. Afterwards the network was analyzed as a whole with procedures derived from graph theory. These emphasized distributed features of the network by transforming the original complex system of separated nuclei into a condensed representation formed by clusters of nuclei. This condensed representation and the interactions between the clusters it contains are in accordance with the physiological processes that the cardiovascular control network is known to carry out. The results derived from this biological based network were compared with 20 randomly built matrices containing the same number of nodes and connections. None of the structural properties found in the biological matrix could be reproduced with these latter networks. These results reflect the possibility that structural analysis of neural systems can be used to identify functionally important clusters. Also, these data suggest that different categories of physiological functions may be directly related to the patterns of connectivity of the networks which support them.

PROJECTIONS FROM THE LATERAL PARABRACHIAL NUCLEUS OF RAT. D. ZENG* AND S.L. STUESSE. NEUROBIOLOGY DEPT., N.E. OHIO COLLEGE OF MED., ROOTSTOWN, OH 44272

The parabrachial complex (PBC) is a visceral integrative area involved in taste, pulmonary, and cardiovascular function. The lateral parabrachial nucleus, especially, has been implicated in cardiac control. We injected a sensitive anterograde tracer, Phaseolus vulgaris leucoagglutinin, in the lateral portion of the PBC to see if it projected primarily to "cardiac autonomic" regions of the brain. Rats were anesthetized with Nembutal and PHA-L was iontophoresed into the PBC. The rats survived a minimum of 5 days. Immunohistochemistry was used to detect the presence of PHA-L. The major projection from the lateral PBC was, as expected, the central nucleus of the amygdala. Other rostral areas receiving projections included the hypothalamus (paraventricular, median preoptic, and dorsal nuclei) and the bed nuclei of the stria terminalis. Few thalamic projections were seen. Some fibers projected to the central gray, dorsal raphe, and pedunculopontine tegmental nucleus. Caudal projections were much sparser than rostral but targeted the presumptive A1/C1 area and nucleus ambiguus. Although these areas may be involved cardiac control, some of the projections probably subserve other functions as well.

A 3-DIMENSIONAL DIGITAL BRAIN ATLAS FOR ANATOMICAL DATA COMPARISON AND INTEGRATION. W.T. Rogers, A. R. Moser, and J.S.Schwaber. E.I. duPont Co., Wilmington, DE 19898

A 3-dimensional digital brain atlas has been developed which allows the comparison, integration, and manipulation of neuroanatomical information. This implementation overcomes some of the limitations of standard paper atlases by providing the means for high-resolution matching of experimental data into the 3-dimensional atlas reference frame. In addition to providing the ability to correct for plane of section, atlas software allows limited correction for the inevitable distortion of tissue due to sectioning, mounting, and histological manipulation. The primary advantage of the 3-dimensional digital atlas is that arbitrary planes of sections can be displayed. This, combined with the ability to warp data into the reference frame defined by the atlas, allows accurate comparison of data from different experiments.

The atlas is constructed from gray level electronic images of tissue sections. These images are brought into registration and stacked in a voxel format so that the complete set of images forms a 3-dimensional, electronically-stored representation of the brain. A special purpose image computer combined with a Unix workstation is used to manipulate the atlas data, display experimental mapped tissue sections, and project mapped anatomical data into the coordinate system defined by the atlas. Computer graphics and statistical techniques are used to analyse the composite data stored in the atlas.

While the atlas technology could be used for any species, we have used it for the rat brain. Specifically, it has been used by us to quantitatively compare the vagal motor neuronal populations in two individuals. We have found that the nuclei are highly homologous in both number and distribution of cells.

239.9

MAPPING OF CAROTID SINUS INPUTS AND VAGAL CARDIAC OUTPUTS IN THE RAT. J. Bradd*, J. Dubin*, B. Due*, R.R.Miselis, S. Montor*, W.T.Rogers*, K.M. Spyer and J.S. Schwaber [SPON: R.O. Davies]. E.I. duPont Co., Wilmington, DE 19898

Towards the goal of establishing the brainstem architecture mediating cardiovascular control and specifically the baroreceptor vagal reflex, carotid sinus afferents (CS) were examined using transganglionic transport of cholera toxin-horseradish peroxidase conjugate (CT-HRP). Sections were taken in the transverse and horizontal planes. Cable-like filling of fibers permitted detailed mapping of fibers, branching patterns and terminal fields. Labeled CS fibers ipsilateral to the injected sinus coursed caudally in the tractus solitarius (ts) and terminated in three distinct subnuclei of the nucleus of the tractus solitarius (NTS): dorsal cap of the ts, lateral interstitial and commissural (caudal to the area postrema). Fibers typically leave the ts before branching and then may give rise to multiple branches while traversing a subnucleus of the NTS. Cardiac injections of CT-HRP were made into locations containing vagal postganglionic neurons. Cardiac afferent labeling is prominent in the commissural subnucleus of the NTS, and extends more caudally in the nucleus than does baroreceptor input. Golgi-like labeling was achieved in three populations: two in the nucleus ambiguus (NA) and one in the dorsal vagal nucleus (DVM). A rostral NA population appears to be coextensive with the loose formation of the NA. These are large, multipolar, stellate cells with dendrites oriented in palisades. At the level of the obex, labeled DMV cells are present. These cells are smaller, with less extensive dendrites, typically confined to the DMV. More caudally a scattered population of cardiomotor cells with tortuous dendrites extends from the DMV ventrolaterally through the reticular formation to the NA. All data is integrated into a 3-dimensional digital brain atlas for modeling. Support: E.I. duPont and GM27739

239.10

DIENCEPHALIC PROJECTIONS TO THE NUCLEUS TRACTUS SOLITARIUS; INVOLVEMENT IN CARDIOVASCULAR CONTROL. P.N.Izzo* and K.M. Spyer. Department of Physiology, Royal Free Hospital Sch. Med., Rowland Hill St., London NW3 2PF, England.

Previous electrophysiological studies in the cat have demonstrated that electrical stimulation of the hypothalamus can evoke profound cardiovascular changes. Furthermore, it has been demonstrated that some of these effects are mediated via inhibition of the baroreceptor reflex at the level of the nucleus tractus solitarius (NTS, Mifflin et al., J. Physiol 399: 369,1988). This study seeks to investigate the location of neurones in the hypothalamus that may contribute directly to the integration of cardiovascular control at the level of the NTS.

Injections of horseradish peroxidase (HRP: 10-50nL) were made into the regions of the NTS that receive afferent input from the cardiovascular and respiratory receptors. The majority of neurones retrogradely labelled were found in the hypothalamus and the central nucleus of the amygdala (CNA). In the hypothalamus almost all neurones labelled were found in the paraventricular nucleus (PVN), a small number of neurones were also observed lying ventral to the PVN and close to the third ventrical. This projection to the NTS is bilateral with an ipsilateral predominence. The results obtained in these experiments suggest that inhibition of the baroreceptor reflex by hypothalamic stimulation in the cat occurs either by stimulation of neurones in the paraventricular nuclei and/or by stimulation of fibres of passage originating from the CNA.

239.11

TOPOGRAPHIC PROJECTIONS FROM THE PERIAQUEDUCTAL GRAY (PAG) TO THE VENTROLATERAL MEDULLA (VLM) IN THE RAT. Gary Aston-Jones, E.J. Van Bockstaele, V.A. Pieribone and M.T. Shipley[1] Div Behav Neurobiol, Dept Mental Hlth Sci, Hahnemann Univ, Phila., PA 19102. [1]Dept Cell Bio Anat, U Cincinnati, OH 45267.

Previous studies have demonstrated projections from PAG to VLM in rodent (Beitz, '83). In the present study using WGA-HRP retrograde transport, we find that distinct subregions of PAG project to VLM. At the level of the dorsal raphe, labeled neurons are located ipsilaterally, immediately lateral to the cerebral aqueduct. Further rostrally, a second group of labeled neurons appear dorsally to the cerebral aqueduct. A third group, not reported previously, is found densely labeled just dorsal to the oculomotor nucleus, in the contralateral supraoculomotor nucleus of the central gray (SOM).

Topography of PAG terminations in VLM was examined using discrete injections of Phaseolus vulgaris-leucoagglutinin (PHA-L) into various subregions of PAG. Following injections into lateral PAG, dense anterograde fiber labeling was found above the inferior olive and in the vicinity of B3 serotonin neurons while labeling in VLM proper was less dense. Anterograde labeling from dorsal PAG yielded fibers in caudal VLM. With injections in SOM, a large number of fibers were seen directly beneath the nucleus ambiguus, in nucleus rostral ventrolateral medulla, RVL. These fibers were highly varicose and appeared to be restricted to RVL.

These results also clarified PAG projections to other regions for example, recent studies have found that afferents to locus coeruleus (LC) are surprisingly restricted but were unable to further analyze nearby areas including PAG as possible afferents. We found scattered PHA-L fibers from PAG in LC indicating that this nearby structure may be a minor afferent to the LC nucleus (Ennis et al., this meeting).

Stimulation in PAG has been reported to affect cardiovascular and pain mechanisms, functions also prominently represented in VLM. It is possible that the various subregions in PAG afferent to VLM are functionally distinct in nature, and substantially contribute to the broad integrative properties of the VLM. Supported by PHS grant NS24698 and ONR/AFOSR Contract N00014-86-K-0493.

Axonal projections from caudal ventrolateral medulla to rostral ventrolateral medulla, nucleus tractus solitarius and spinal cord in rabbit. Y.W. Li* and W.W. Blessing. (SPON: C. Straznicky) Centre for Neuroscience, Flinders University of South Australia, Bedford Park, SA 5042.

The caudal ventrolateral medulla (CVLM) contains vasodepressor neurons whose activity inhibits sympathetic vasomotor tone. The present study has investigated the efferent projections of the neurons of the CVLM in rabbit using the Phaseolus Vulgaris Leucoagglutinin (PHA-L) anterograde tracing technique. Twenty N.Z.W. rabbits were anesthetized with Halothane and PHA-L (Vector) was iontophoretically deposited into the CVLM. After 5-14 days of survival rabbits were re-anesthetized and the brains were perfused with aldehyde fixative and sectioned on a Vibratome. PHA-L was localized using anti-PHA-L antibody (diluted 1/5000) combined with the avidin-biotin-peroxidase procedure. Neurons in the CVLM projected in three main directions. 1) Ascending projections coursed rostrally through the ventrolateral reticular formation up to the rostral medulla. Large numbers of PHA-L labeled terminals were seen in a restricted region of the rostral ventrolateral medulla (RVLM) ventromedial to the nucleus ambiguus where sympathetic excitatory neurons are located (Dampney, R.A.L., et al, Brain Res., 249:223, 1982). Some ascending axons continued rostrally through the RVLM, passing ventromedially to the facial nucleus to pontine, midbrain and forebrain regions. 2) PHA-L labeled axons could be followed from the CVLM to the dorsomedial medulla, including the nucleus tractus solitarius. 3) Descending fibres took a straight course through the lateral reticular formation in the medulla. They entered the lateral funiculus of the spinal cord, with the majority terminating in the grey matter at the cervical level. No terminals were observed in the intermediolateral region at the thoracic level. The anatomical finding supports the idea that the vasodepressor neurons affect sympathetic preganglionic neurons by an indirect route, probably by a short inhibitory projection to the RVLM (Blessing, W.W., Am. J. Physiol., 254 : H686, 1988).

239.13

EVIDENCE OF A MONOSYNAPTIC PATHWAY BETWEEN THE CAUDAL RAPHE NUCLEI AND IDENTIFIED SYMPATHETIC PREGANGLIONIC NEURONS IN THE RAT. A. Zagon*, S.J. Bacon* & A.D. Smith Department of Pharmacology, South Parks Road, Oxford, U.K.

Electrophysiological and anatomical studies have suggested the existence of a pathway between the caudal raphe nuclei and the sympathetic preganglionic neurons (SPNs). However monosynaptic connection between them has not yet been shown. We combined anterograde tracing using Phaseolus vulgaris leucoagglutinin (PhAL), retrograde tracing using a conjugate of cholera B chain and HRP (CB-HRP) and electron microscopy to look for such a pathway in rats. Iontophoretic injections of PhAL were made into the region containing the raphe pallidus (RPa), caudal raphe magnus (RMg) and obscurus (ROb) of 5 rats. 12 days later the same rats were given injections of CB-HRP into their left adrenal gland. Fixed tissue from the brainstem and spinal cord (T2-T12) was sectioned and reacted to reveal CB-HRP then incubated with an antibody to PhAL and processed using immunohistochemistry. Serial ultrathin sections from the spinal cord were examined in the electron microscope. When PhAL had been injected into the regions mainly restricted to the RPa and RMg, synaptic contacts were found between PhAL-containing terminals and retrogradely labelled SPNs. Out of the 43 synaptic contacts analysed, 26 were onto somata and 14 onto dendrites. 75% of the total appeared to have symmetric membrane specifications, 20% asymmetric and the remainder could not be classified. Synaptic contacts were not seen when the PhAL injection site involved cells only in the ventral ROb and surrounding gigantocellular reticular formation.

These findings provide evidence of a direct monosynaptic pathway between cells in the RPa and caudal RMg and identified SPNs.

SEGMENTAL ORGANIZATION OF THE C1 PROJECTION TO THE INTERMEDIOLATERAL CELL COLUMN. *I. Jeske and K.E. McKenna.* Dept. of Physiology, Northwestern Univ. Med. Sch. Chicago IL 60611.

An anatomical substrate for selectivity in sympathetic motor outflow was examined by comparing quantitative data from ketamine-xylazine anesthetized male Sprague Dawley rats that were injected with Fluorogold dye (50-80 nl, 4% v/v, FG) into upper (T3-T5) middle (T7-T9) and lower (T11-T13) levels of the intermediolateral cell column (IML). After a survival period of 2 weeks they received colchicine (10μg/10μl) injections into the ipsilateral lateral ventricle to enhance immunofluorescent detection of phenylethanolamine N-methyltransferase containing (PNMT+) neurons in the rostral ventrolateral medulla (RVLM). The number of cells PNMT+; PNMT+ and labeled with FG (FG+); and PNMT- and FG+ were counted under epifluorescent illumination within the C1 area from 1 to 1.7 mm rostral to obex. Bulbospinal neurons projecting to different rostrocaudal extremes of the IML column arose from comparable or intermingled sites in the RVLM, suggesting that the location of a bulbospinal neuron in the RVLM is not anatomically correlated with the spinal segment it innervates. The C1 bulbospinal innervation was segmentally directed to upper thoracic levels of the IML column, since 56±3%, 35±6%, 25±8%, of the PNMT+ population was labeled after upper, middle, and lower level injections, respectively. In comparison, the number of PNMT- bulbospinal neurons, contained in the same area and closely intermingled with the PNMT+ bulbospinal population, remained relatively constant, regardless of which thoracic levels had been injected. These non-catecholaminergic neurons comprised 62±8% of the total bulbospinal population labeled in the C1 area. If selectivity in sympathetic motor outflow at the level of the IML is neurochemically encoded, the finding that the RVLM adrenergic input is directed to upper thoracic segments, which contain functionally identified baroreceptive (Seller H., Pflugers Arch. 343:317-330,1973) and cardioacceleratory (Calaresu et al., Am. J. Physiol. 222(3):700-704, 1972) sympathetic preganglionic neurons, is consistent with a role for C1 neurons in influencing sympathetic outflow preferentially to cardiovascular structures.

CAUDAL VENTROLATERAL MEDULLA (CVL): A SOURCE OF TONIC AND BARORECEPTOR-MEDIATED SYMPATHOINHIBITION. S.L.Cravo*, S.F.Morrison, D.J.Reis. Division of Neurobiology, Cornell Univ.Med.Coll., New York, NY10021.

The caudal ventrolateral medulla (CVL) is a major vasodepressor center. CVL stimulation produces hypotension and bradycardia, while lesion in this area causes hypertension of neurogenic origin. Whether the CVL also mediates the baroreceptor reflex (BR) is not certain since lesions of CVL elevating arterial pressure (AP) do not invariably abolish the reflex. We sought to determine whether the CVL is functionally heterogeneous. Rats were anesthetized with urethane, paralysed and ventilated and AP and splanchnic sympathetic nerve activity (SNA) were recorded. The BR was elicited by electrical stimulation of the aortic depressor nerve (ADN) or infusion of norepinephrine. Local neuronal blockade was produced bilaterally in subareas of CVL by microinjections of kainic acid (KA, 10 mM, 10-20 nl). Injection sites were anatomically reconstructed. KA injected into rostral CVL (CVLr, between 0.8 and 1.8 rostral to the calamus) elicited: a) an increase in MAP (34 ± 6.1 mmHg, n=10), and SNA (to 214% of control), b) abolition of the BR; c) elimination of the cardiac-related rhythm in SNA. KA restricted to caudal CVL (CVLc, between 0.5 rostral and 1 mm caudal to the calamus) also elevated AP (20 ± 4.3 mmHg) and SNA (to 196% of control) but had no effect on the BR or the cardiac rhythm in SNA. We conclude that: (a) the CVL is functionally heterogeneous, (b) neurons in CVLr mediate tonic and baroreceptor-evoked inhibition of SNA, (c) CVLc contains a tonic, baroreceptor-insensitive sympathoinhibitory system, d) dysfunction within the CVL could result in hypertension of neurogenic origin.

DESCENDING PROJECTIONS OF HYPOTHALAMIC (HYP) SYMPATHOEXCITATORY (SE) NEURONS IN THE CAT. Susan M. Barman. Dept. Pharm. & Tox., Mich. State Univ., E. Lansing, MI 48824.

This study was designed to test the hypothesis that the major pathway mediating HYP-induced increases in sympathetic nerve discharge (SND) is a direct projection to the rostral ventrolateral medulla (RVLM). Posterior or lateral HYP stimulation increased inferior cardiac SND (latency, 68-94 ms) and synaptically activated (modal latency, 7-64 ms) 10 RVLM-SE neurons. An SE neuron is one whose activity is correlated to SND and whose firing rate is decreased by baroreceptor reflex activation. HYP-SE neurons (n=14) were antidromically activated by RVLM stimulation. However, antidromic mapping suggested that the axons of 11 of these neurons passed through rather than terminated in the RVLM. These data do not support the hypothesis under consideration. The possibility that HYP-SE neurons project to the periaqueductal gray (PAG) was then tested. HYP-SE (n=15) neurons were antidromically activated by PAG stimulation. Antidromic mapping suggested that these neurons terminated in this region since their longest latency antidromic responses (9-35 ms) were elicited with the least stimulus current when stimulating sites in the PAG (A2.5-3; LO.7-1.3; H-0.6 to +1.5). Antidromic latencies of the same neurons were shortened by 1-18 ms when stimulating other sites at this level or by raising stimulus current at the presumed site of termination. These studies suggest that HYP-induced SE responses are mediated in part via a synapse in the PAG. (Supported by NIH grant HL33266.)

LESIONS OF THE KOLLIKER-FUSE / LATERAL PARABRACHIAL NUCLEI INCREASE ARTERIAL PRESSURE AND WATER INTAKE. D.G. Ward and J.H. Ward*. H.M. Ward Memorial Lab., Valley Home, CA 95384

The role of the parabrachial complex (PBN) in control of basal arterial pressure and water intake was examined in 13 conscious freely-behaving male rats. On Day-0, under ketamine anesthesia (150 mg/kg), a femoral arterial catheter was exteriorized to a spring tether attached between the scapulae, and lesions directed toward the Kolliker-Fuse nucleus were placed bilaterally in one group of animals (lesion) or unilaterally in a second group of animals (control). Mean arterial presure (MAP, mmHg), heart rate (HR, beats/min), basal water intake (H2O, ml) and urine volume (Urn, ml) were measured daily for 8 to 11 days. The average differences in measurements between lesion and control animals (* $p < 0.05$) were as follows:

	Day 1	Day 2	Day 3	Day 4	Day 5	Day 6	Day 7	Day 8
MAP	3.1	19.8*	10.5	12.8	13.3	20.1*	22.3*	27.1*
HR	-21.2	-17.5	-3.4	-9.2	-3.9	-11.9	-81.0*	-14.3
H2O	-3.3	4.4	4.0	15.3*	19.7*	20.8*	8.6	5.2
Urn	-4.9	2.3	3.7	15.1*	20.3*	17.8*	3.6	8.0

Thus, destruction of the Kolliker-Fuse nucleus leads, in the unanesthetized rat, to a slowly developing hypertension, to a transient and parallel hyperdipsia and polyuria preceeding the hypertension, and to a transient bradycardia following the hyperdipsia. These findings suggest the presence of autonomic pathways within the parabrachial complex that are in opposition to known sympatho-excitatory pathways. (supported by USPHS HL36034 and MH43989)

POSTERIOR HYPOTHALAMIC RECEPTORS INVOLVED IN THE PRESSOR RESPONSE PRODUCED BY STIMULATION OF THE C1 REGION. H. Bachelard* and C.A. Marsden* (spon. by Brain Research Association). Dept. Physiology & Pharmacology, Medical School, Queen's Medical Centre, Nottingham, England, NG7 2UH

The increase in the blood pressure (BP) induced by the stimulation of the C1 region is partly mediated via the adrenergic pathway projecting toward the hypothalamus. In this study we have further examined the receptors into the posterior hypothalamus (PH) involved in the pressor response elicited by stimulation of the C1 neurones. Under anaesthesia male Wistar rats were implanted with a guide cannula in the PH. The C1 area was electrically stimulated ipsilateral to the cannula and the BP was continously monitored. Fifteen minutes after the stimulation, saline or drugs were injected i.v. or into the PH followed 15 min later by a second stimulation. The increase in BP produced by C1 stimulation was significantly attenuated by pentolinium (1mg/kg; i.v.), or by the injection into the PH of propranolol (20μg), clonidine (8μg), atropine (8μg) and methysergide (10μg). No significant reduction in the pressor effect have been found after intra-PH administration of d-propranonol (20μg), idazoxan (66μg), chlorphenydramine (12μg), cimetidine (11μg) or naloxone (10μg). Together these results confirm previous observations indicating that C1 stimulation provides excitatory drive to the preganglionic sympathetic neurones of the spinal cord and to the PH that results in increased BP . This response is in part centrally modulated by α2 and ß adrenoceptors but with central cholinergic and serotonergic components involvement.
We thank the FRSQ and the Wellcome Trust for their financial support.

THE VENTRAL LATERAL MEDULLA MEDIATES INSULAR CORTEX SYMPATHETIC RESPONSES. D.F.Cechetto and S.J. Chen*. Robarts Research Inst./Dept. of Physiology, Univ. of Western Ontario, London, Ont. N6A 5K8.

Previously we have demonstrated that the efferent pathway for sympathetic responses originating in the insular cortex (IC) involves a synapse in the lateral hypothalamic area (LHA). This site projects to both the ventral lateral medulla (VLM) and directly to the thoracic spinal cord. To determine the role of the VLM in mediating sympathetic responses from the IC and LHA, in chloralose anesthetized rats, renal nerve responses were recorded, following electrical stimulation of these two forebrain sites before and after bilateral injection (300 nl) of cobalt (a synaptic blocking agent) into the VLM. The results demonstrated that a complete block of the sympathetic nerve response following stimulation of the IC or the LHA could be obtained with cobalt injections into the VLM. The effective injection sites were coincident with the A1 group of neurons. Injections into the rostral VLM in the region of the C1 neurons were much less effective. Chemical stimulation with D,L-homocysteic acid to activate only cell bodies evoked a decrease in arterial blood pressure and sympathetic nerve activity. These responses were also blocked by cobalt injection into the caudal ventral lateral medulla. These results indicate that the efferent pathway for sympathetic responses from the IC through the LHA are mediated by a mandatory synapse in the caudal VLM.

CARDIAC CHRONOTROPIC ORGANIZATION OF THE RAT INSULAR CORTEX. S.M. Oppenheimer*, V.C. Hachinski and D.F. Cechetto. Robarts Research Inst./Dept. of Physiology, Univ. of Western Ontario, London, Ont. N6A 5K8 Canada.

Clinical studies suggest that cortical mechanisms may be involved in arrythmogenesis. Cortical sites mediating only cardiac effects have been scantily identified in the past. The insular cortex has been shown to have extensive autonomic inputs and autonomic effects are elicitable on microstimulation. This area was accordingly chosen as a likely site for cortical representation of heart rate. In 31 rats anesthetized with chloralose the organization of changes in ECG and heart rate were examined in response to cortical microstimulation. In order to evoke only cardiac responses from the rat insula, a new technique was used in which the discriminated R wave of the ECG served as a trigger for the stimulator. Single or paired pulses were delivered to the insula coincident with the P wave every second or fourth PQRT cycle. A map of bradycardia and tachycardia sites was obtained. Increases in heart rate occurred from the rostral part of the posterior insular cortex, while decreases were obtained from the caudal region of the posterior insula. Pharmacological studies suggest these effects are mediated by the sympathetic nervous system. This is the first report of pure chronotropic effects being elicited from a cortical area in a systematic manner, and suggests a possible foundation for the heart rate changes commonly seen during temporal lobe seizures and a cortical site for arrythmogenesis.

L-GLUTAMATE MAPPING OF CARDIOREACTIVE AREAS IN THE POSTERIOR HYPOTHALAMUS. W.B. Sawyer, S.E. Spencer and A.D. Loewy, Departments of Neurology and Anatomy & Neurobiology, Washington University School of Medicine, St. Louis, MO 63110 (Sponsor: S.G. Eliasson)

The posterior hypothalamus has long been regarded as a CNS region that provides a sympatho-excitatory influence on the cardiovascular system and thermoregulation. This idea is largely based on electrical stimulation and lesion experiments. We have used microinjection of the excitatory amino acid L-glutamate to activate cell bodies in the posterior hypothalamus and to test the hypothesis that this is a sympatho-excitatory center.

Fifteen nl microinjections of a 500 mM L-glutamate (7.5 nmole) and ^{3}H-glutamate (1.5 μCi) solution were stereotaxically delivered into the posterior hypothalamic region of pentobarbital anesthetized rats. Animals were ventilated and blood pressure, temperature, and heart rate monitored. The injection sites were subsequently determined by the autoradiographic method. Injections in the posterior hypothalamic nucleus elicited small reductions in blood pressure (-10±1mmHg; mean±SEM) and heart rate (-11±2 bpm). Injections in the dorsal hypothalamic area produced a similar response (BP=-12±3mmHg; HR=-3±4bpm). The most responsive area was in the periventricular zone caudal to the posterior hypothalamic nucleus and centered around the fasciculus retroflexus (ΔBP=-26±4mmHg; ΔHR=-27±8bpm). Injections ventral to this zone involving the supramammillary nuclei were less reactive (ΔBP=-11±1; ΔHR=-6±2), while experiments rostral and involving the periventricular nucleus were similar (ΔBP=-25±3; ΔHR=-10±0).

Minor elevations in rectal temperature were seen after injections in the dorsal hypothalamic area and the supramammillary region.

Chemical stimulation of the posterior hypothalamus elicits hypotension and bradycardia. No pressor responses were seen and the critical area was the periventricular zone, not the posterior hypothalamic nucleus.

INTERACTION BETWEEN PRESSOR AND DEPRESSOR AREAS IN CAT VENTROLATERAL MEDULLA. Philip J. Gatti* and Richard A. Gillis* (SPON: S.N. Pradhan) Depts. Pharm.; Howard Univ. Coll. of Med. & Georgetown Univ. Schl. Med., Washington, D.C. 20059.

Although application of gamma-aminobutyric acid (GABA) to the intermediate area (IA) of the cat ventrolateral medulla produces a profound decrease in arterial blood pressure (BP), application of the GABA antagonist bicuculline (BI) by itself to this area raises BP only when very high doses are used. These data suggest that although there are GABA receptors at the IA which are involved in the control of BP, the GABA tone is very low at this site in the chloralose anesthetized cat. We investigated whether stimulation of the caudal depressor area (CA) in the medulla lowered BP by enhancing this GABA inhibitory tone at the IA. In 4 cats, application of BI (10 ug/5 ul bilaterally) to the IA raised BP by 24 ± 8.2 mmHg. In another group of animals (n=7) the neuroexcitant kainic acid (KA) was first applied to the CA and resulted in a decrease in BP. Thirty minutes later, the same dose of BI was applied to the IA and BP increased by 74 ± 8.7 mmHg. This effect was significantly different from the control BI response ($p < .05$, unpaired Student's t-test). These results suggest either a direct or indirect GABAergic projection from the CA to the IA which when stimulated, will enhance GABA release at the IA to influence cardiovascular function.

CARDIOVASCULAR REGULATION: HYPERTENSION

240.1

MORPHOLOGICAL DIFFERENCES IN STELLATE GANGLION CELLS OF NORMOTENSIVE AND HYPERTENSIVE RATS. D. Peruzzi[1], E.D. Hendley[2], and C.J. Forehand[1] (SPON: E. Ezerman). [1]Dept. of Anatomy and Neurobiology, and [2]Dept. of Physiology and Biophysics, University of Vermont, Burlington, VT 05405.

The size of postganglionic autonomic neurons has been positively correlated with the size of the targets innervated (Voyvodic, J.T., Soc. Neurosci. Abstr., 13:574, 1987). Hypertension is accompanied by cardiac hypertrophy and an increase in the thickness of the smooth muscle wall of resistance vessels (Folkow, B., Clin. Sci. Mol. Med. 55:3, 1987). We have thus asked whether sympathetic ganglion cells in the stellate ganglion of hypertensive rats reflect this change in target size. We compared the cell body size and total dendritic length (TDL) of stellate ganglion cells from spontaneously hypertensive rats (SHR) and the normotensive Wistar-Kyoto rats (WKY) from which they were derived. To do this, we filled individual ganglion cells by intracellular injection with horseradish peroxidase.

The average TDL of SHR stellate neurons (2082 um) was 21% longer than that of WKY neurons (1645 um). Moreover, about half of the SHR neurons had TDL's larger than the largest WKY cells. The range of cell body sizes observed for SHR and WKY overlapped, but the biggest cell bodies were from the SHR and the smallest from the WKY.

We are currently exploring whether the increase in TDL seen in hypertensive rats is specific to the hypertension per se, and/or the associated behavioral hyperactivity. To do this we are using inbred strains derived from the SHR that are hyperactive (HA) but not hypertensive (HT), or vice-versa (Hendley et al., Hypertension, 5:211, 1983). The average TDL of HT stellate neurons is equivalent to that of the SHR and therefore greater than that of the WKY. Studies on the HA cells are now in progress.

240.2

NEURONAL ACTIVITIES OF THE ROSTROVENTROLATERAL MEDULLARY NEURONS IN SPONTANEOUSLY HYPERTENSIVE RATS. T.M. Wong*, R.K.W. Chan* and Y.S. Chan. Dept. of Physiology, University of Hong Kong, Hong Kong.

It is known that the rostroventrolateral medulla (RVL) plays an important role in the control of circulation. It was, therefore, hypothesized that altered neuronal activities of RVL may lead to abnormalities in cardiovascular functions. In support of the hypothesis, we found in a preliminary study that pentobarbitone-anaesthetized spontaneously hypertensive rats (SHR) exhibited exaggerated responses in arterial pressure upon electrical stimulation of RVL neurons compared with the normotensive Wister Kyoto rats (WKY), indicating an enhanced cardiovascular responsiveness in SHR. In this study, we further tested the hypothesis by comparing the extracellular activities of RVL neurons of WKY and SHR. The RVL neurons exhibited single and double spikes and the mean interspike intervals between single spikes or double spikes were similar in the two types of rats. The relative proportion of neurons recorded in WKY exhibiting single and double spikes were 92% and 8%, respectively, whereas the corresponding values in SHR were 45% and 55%, respectively. The differences were statistically significant. In addition, the firing of the RVL neurons was more regular in SHR than in WKY. The results of the present study indicate that the neurons of the RVL in SHR exhibit a higher spontaneous discharge rate than that of normotensive WKY. This together with the enhanced cardiovascular responsiveness upon electrical stimulation of RVL are probably responsible for the development of hypertension in SHR. 240.3

EFFECTS OF DIETARY TRYPTOPHAN ON DAHL SALT INDUCED HYPERTENSION. L. Lark, K. Becker*, R. Park*, and J. A. Weyhenmeyer. Neural and Behavioral Biology Program and College of Medicine, Univ. of Ill., Urbana, IL 61801.

The present study expands on our previous findings that a trp supplemented diet attenuates the development of hypertension in inbred Dahl salt-sensitive (DS/JR) rats (Lark et al., Neurosci. Abstr. 14:974, 1988).

DS/JR and their inbred control Dahl salt-resistant (DR/JR) rats were placed on an 8% salt diet with or without trp supplementation (25 g/kg food) from 4-9 wks of age. Supplemental trp attenuated the development of hypertension in DS/JR, while DS/JR animals on the control diet showed a steady elevation in blood pressure (185 ± 9 vs. 127 ± 5 mm Hg, respectively, $p < .01$). Although the DR/JR rats on the high trp diet had significantly lower blood pressures at the end of the study (127 ± 3 vs. 146 ± 5 mm Hg, respectively, $p < .05$), a consistent developmental trend was not observed. DS/JR rats on control diets drank significantly more water than all other groups, however, no significant differences in urine output were found. Trp supplementation had no effect upon urinary Na^+ output in either strain, but DS/JR rats were found to excrete significantly less Na^+ than DR/JR rats. No significant differences in food consumption were found. High trp diets also had no effect on heart weights, however, DS/JR hearts were significantly larger than DR/JR hearts. We conclude that elevated dietary trp blocks the development of Dahl salt induced hypertension.

Supported by NSF grant BNS 17117.

240.4

MICROINJECTION OF L-GLUTAMATE AND TETRODOTOXIN INTO THE ROSTRAL AND CAUDAL VENTROLATERAL MEDULLA IN ADULT SPONTANEOUSLY HYPERTENSIVE RATS. J.K. Smith* and K.W. Barron. Dept. of Physiology, Univ. of KY, Lexington, KY 40536

The purpose of this study was to compare the responsiveness of the rostral (RVLM) and caudal (CVLM) ventrolateral medulla in 12-15 week old spontaneously hypertensive (SH) and normotensive Wistar-Kyoto (WKY) rats to microinjection of L-glutamate (L-glu), and to estimate tonic output of the CVLM and RVLM by microinjecting the neurotoxin tetrodotoxin. Rats were anesthetized with 1.25 g/kg urethane s.q., implanted with arterial (femoral) and venous (femoral) catheters, artificially ventilated and paralyzed with gallamine triethiodide (10 mg/kg). Using a ventral approach to the brainstem, the mean arterial pressure (MAP) and heart rate (HR) responses to microinjection (30 nl) of L-glu (1, 10 and 100 mM) and tetrodotoxin (10 μM) into the RVLM and CVLM were compared in SH (n=7) and WKY (n=7) groups. Microinjection of L-glu into the RVLM produced equivalent dose-dependent increases in MAP (maximum +33 ± 3 and +36 ± 6 mmHg, SH and WKY groups, respectively) and minimal changes in HR. Similar administration of L-glu into the CVLM caused dose-dependent decreases in MAP and HR; changes in MAP were significantly greater in the SH group than in the WKY group (-52.3 ± 2.9 mmHg for SH, -22.6 ± 2.6 mmHg for WKY). Bilateral microinjection of tetrodotoxin into the CVLM produced significantly larger increases of MAP in WKY rats (+8 ± 4 vs +46 ± 8 mmHg for SH vs WKY). These data indicate that SH rats have a lower tonic activity of neurons in the CVLM, resulting in a lower restraining influence on sympathetic outflow in the SH rat. (Supported by: HL 36552, NIH T32-07632 & KY Heart Assoc).

240.5

INTRACRANIAL PRESSURE MONITORING IN SPONTANEOUSLY HYPERTENSIVE RATS. M.L.LEAVITT*, D.V.LOESCH* and J.C.MAROON*(SPON:N.Mason). Allegheny-Singer Research Inst.,Pittsburgh, PA 15212.

This study monitored cerebrospinal fluid pressure (CSF-p) in conscious adult spontaneously hypertensive rats(S,N=5)and control Wistar rats (W,N=6). Following implantation of a lateral ventricular guide cannula, a push-pull internal cannula was used to infuse art.CSF (2μl/min.) and measure CSF-p once per second over two 5 hr. runs separated by 2 days. During run 2, CSF-p for the two groups was significantly different ($p<.03$) from 270 through 300 min. Starting at 140 min(S) or 190 min(W), CSF-p was consistently and significantly ($p<.04$) increased compared to baseline. Run 1 and 2 measurements were not significantly different from each other for either group. CSF-p in cmH_2O:

	10min	80min	140min	230min	300min
S:	8.2±2.0*	9.3±1.0*	12.8±1.2$^+$	19.8±4.4$^+$	21.8±3.8*$^+$
W:	14.1±0.6	14.2±1.2	17.6±3.0	31.2±5.7$^+$	37.9±4.6$^+$

*$p<.03$,non-paired t,S vs W;$^+p<.03$,paired t,vs 10 min. Thus CSF-p is lower in S compared to W under baseline conditions as well as following ivt art CSF infusion which elevates the pressure of both groups.

240.6

LESIONS OF THE PARAVENTRICULAR NUCLEUS OF THE HYPOTHALAMUS (PVH) ALTER THE DEVELOPMENT OF DOCA-SALT HYPERTENSION IN THE RAT. T. X. Zhang and J. Ciriello. Dept. of Physiology, Univ. of Western Ontario, London, Canada, N6A 5C1.

The PVH has been shown to be involved in the hypertensive process in several different experimental models of hypertension. Recently, we have demonstrated increased metabolic activity in PVH of deoxycorticosterone acetate (DOCA)-salt hypertensive rats. The present study was done to investigate the contribution of PVH to the development of DOCA-salt hypertension in the rat. Arterial pressure (AP) was measured using the indirect tail cuff method. The rats were randomly assigned to 4-groups and the left kidney was removed in all animals. After a 1-wk recovery period the rats were subjected to bilateral PVH lesions or sham PVH lesions followed by the administration of DOCA-salt or sham DOCA-salt. PVH lesions delayed the development and attenuated the level of the hypertension in the DOCA-salt hypertensive rats compared to sham PVH lesioned DOCA-salt hypertensive rats. At the end of the study, the average AP was 178 ± 8, 204 ± 4, 120 ± 5, and 125 ± 6 mmHg in PVH lesioned-DOCA-salt, sham PVH lesioned-DOCA-salt, PVH lesioned-sham DOCA-salt and sham PVH lesioned-sham DOCA-salt animals, respectively. The heart rates among the 4 groups were not significantly different during the period of the experiment. These data suggest that PVH plays an important role in the initial phase of development and in the full expression of DOCA-salt hypertension. (Supported by HSFO).

240.7

DIFFERENCES IN SALT APPETITE IN SALT-SENSITIVE (SHR-S) AND SALT-RESISTANT SHR (SHR-R). M.J. Meldrum, C. Eich*, R. Dawson. Dept. Pharmacodynamics, Coll of Pharmacy, Univ. of Florida, Gainesville, Fl. 32610.

Increased dietary salt exacerbates blood pressure in SHR-S (Taconic Farms) while similar increases in salt intake have no effect in SHR-R (Charles Rivers). We therefore measured salt appetite in SHR-S and SHR-R to determine if it may play a role in the differential response to dietary salt. Animals were placed in metabolism cages and the following 24hr parameters were measured: fluid intake; urine volume; food intake;and urinary Na^+ excretion. Urinary catecholamines (NE,DA) were also assayed by HPLC-EC after alumina extraction. After 2 days of basal measurements (tap water), various concentrations (0.5,1.0,1.5,2.0,2.5,3.0%)of NaCl given randomly were presented as the only drinking fluid, followed by 2 basal days of measurements. SHR-S drank significantly greater quantities of 1.5 and 2.0% NaCl than SHR-R. Urine volume and sodium excretion paralleled differences in fluid intake. Urinary NE excretion was not different between SHR-S and SHR-R however levels were significantly elevated in a concentration dependent manner by NaCl. These differences in salt appetite may reflect differences in sodium chloride regulation between SHR-S and SHR-R which may affect regulation of blood pressure. (Supported by the American Heart Association- Florida Affiliate).

240.8

BAROREFLEX CONTROL IN HYPERTENSION-SENSITIVE (SS/Jr) AND HYPERTENSION-RESISTANT (SR/Jr) RATS. C. A. Murphy* and R. McCarty* (SPON: N. Desmond) Department of Psychology, University of Virginia, Charlottesville, VA 22903.

Baroreflex control of heart rate was examined in adult male inbred SS/Jr and SR/Jr rats. Animals were surgically prepared with catheters in the jugular vein to permit graded infusions of both a pressor agent, phenylephrine, and a depressor agent, sodium nitroprusside. A third catheter was fitted in the ventral tail artery through which recordings of mean arterial pressure and heart rate were obtained. Basal blood pressures were clearly higher in SS/Jr rats compared to SR/Jr rats. In contrast to previous reports of impaired baroreceptor sensitivity in the prehypertensive DS rat, no significant difference in the total range of the heart rate response to blood pressure change was observed in the adult hypertensive SS/Jr. Average gain of the baroreflex was in fact significantly greater in the SS/Jr rat, indicating slightly enhanced baroreceptor sensitivity over the range of heart rate change. The absence of baroreflex impairment in this model of hypertension may be a secondary effect of the development of hypertension and play a compensatory role in the presence of established elevations in blood pressure.

240.9

THE EFFECTS OF STRESS AND DIETARY COPPER DEFICIENCY ON BLOOD PRESSURE IN RATS. E.S. Halas and L.M. Klevay*. Dept. of Psychology, Univ. of North Dakota and USDA, ARS, Human Nutr. Res. Ctr., Grand Forks, ND 58202.

The etiology of most hypertension is unknown; stress is thought to elevate blood pressure. In two experiments, male weanling Sprague-Dawley rats were fed an adequate diet. Systolic blood pressure (BP) was measured weekly without anesthesia. After being matched by mean weight (c280g) and BP into 4 groups of 15, groups 1 and 2 received a diet without copper. After 24 days, rats in groups 2 and 4 were restrained for 45 min. daily for 23 days in a small cage. In Exp. 1, ten of 15 rats in Group 2 and one in each other Group died prematurely; there were no striking differences in mortality in Exp. 2. There was a progressive increase in mean BP for Groups 2, 3, and 4. In Exp. 1 mean BP were highest in Group 2 (131mm) and lowest in Group 3 (114mm). Both stress and copper deficiency independently caused some elevation of BP as shown by Groups 4 (123mm) and 1 (119mm). Results were similar in Exp. 2, but responses were delayed 1 week. Deficiency and stress caused small but significant increases in cardiac sodium and decreases in cardiac potassium, the latter only in Exp. 1. Stress and copper deficiency can cooperate to produce adverse effects on health.

240.10

CNS REGULATION OF THE HYPOTHALAMIC-PITUITARY-ADRENAL AXIS IN SHR RATS. S. Bhatnagar and M. J. Meaney. Douglas Hosp. Res. Ctr, Dept. Psychiatry, McGill Univ., Montreal, Quebec, H4H 1R3.

Hypothalamic-pituitary-adrenal (HPA) dysfunction has been implicated in the etiology of hypertension in the Spontaneously Hypertensive Rat (SHR). We sought to characterize the involvement of the HPA axis by examining AM and PM basal levels of ACTH in conscious adult SHRs (n=9) as well as their normotensive counterparts, the WKY rat (n=15). We found that SHRs had lower plasma levels of ACTH at both a.m. and p.m. samples (28.3 and 42.3 pg/ml, respectively), as compared to to WKYs (45.4 and 83.6 pg/ml, respectively), although ACTH levels increased for both groups in the p.m. samples. We found that SHR's (n=15) had significantly lower levels of CBG than did WKYs (n=15) at both a.m. and p.m. samples, suggesting more free corticosterone in circulation in SHRs than in WKYs.

Previous research has suggested an impaired negative feedback response in the HPA of SHRs. We, therefore, examined glucocorticoid receptor binding in the hippocampus, pituitary, and hypothalamus of 6 mo old SHRs and WKYs using the specific Type II, glucocorticoid receptor ligand [3H]RU-28362. Preliminary data suggests that hippocampal receptor concentrations were lower in the SHRs than in the WKYs (30% lower), while no such differences were found in either pituitary or hypothalamus. These results provide further evidence for impairment in HPA functioning in the SHR, and implicate hippocampal glucocorticoid receptors in this impairment.

EFFECTS OF CALCIUM CHLORIDE ON BLOOD PRESSURE AND VASOPRESSIN mRNA IN THE HYPOTHALAMUS OF SPONTANEOUSLY HYPERTENSIVE RATS. B. H. Hwang. Terre Haute Ctr. for Medical Education, Indiana Univ. Sch. of Med., Terre Haute, IN 47809.

Salt (sodium chloride) can cause hypertension. However, recent literature has also indicated that another kind of salt, calcium chloride can lower blood pressure. But it is unknown whether or not the vasopressin (VP) system in the hypothalamus is involved. Spontaneously hypertensive (SHR) rats and Wistar-Kyoto (WKY) rats at 4 weeks of age were used. The experiment consists of 4 groups of animals: (a) WKY-water group - allowed to drink deionized water; (b) WKY-$CaCl_2$ group - allowed to drink 0.15M $CaCl_2$; (c) SHR-water group; and (d) SHR-$CaCl_2$ group. The VP mRNAs were determined by quantitative autoradiography after in situ hybridization with ^{35}S-VP oligonucleotide probe. Results showed that $CaCl_2$ was able to lower blood pressure and prevent cardiac hypertrophy in SHR rats without altering VP mRNAs in the paraventricular hypothalamic nucleus (PVN) and supraoptic nucleus (SON). However, $CaCl_2$ did not change blood pressure significantly in WKY rats, whereas it greatly induced VP mRNA gene expressin in the PVN and SON of WKY rats. In conclusion, calcium chloride's ability to lower blood pressure in SHR rats is not closely associated with the hypothalamic VP system. (supported by NIH grant NS25087).

MEDIAL FRONTAL CORTEX LESIONS ELIMINATE CARDIAC BAROREFLEX GAIN CHANGES DURING STRESS IN THE RAT.
R.J. Frysztak & E.J. Neafsey, Department of Anatomy, Loyola Univ Med Ctr, 2160 S. First Ave, Maywood, IL 60153

Bilateral medial frontal cortex (MFC) lesions were made in 15 male Sprague-Dawley rats with .4 ul injections of N-Methyl-D-aspartate. Controls (N=15) received isotonic saline. Animals were conditioned to a 10 sec. tone paired with a mild footshock. During trials, the rat received the tone alone. Baroreflex gain was measured at 4 periods during the conditioned emotional response (CER): 1-rest, 2-during tone, 3-early post-tone, 4-late post-tone. Blood pressure was recorded via the brachial a. and activation of the cardiac baroreflex was produced via an intra-aortic balloon catheter (Fogarty-2F). Increases in BP produced by the balloon averaged 15 mm Hg, and lasted approximately 2 sec. Cardiac baroreflex gain was calculated by dividing the change in HR by the change in BP (Δbpm/ΔmmHg). Results are shown in the following table:

	PERIOD 1	PERIOD 2	PERIOD 3	PERIOD 4
CONTROL	-5.37	-2.33	-2.35	-4.31
MFC LESION	-2.54	-2.03	-2.27	-2.44

The gain at rest in controls was similar to that described by Verberne (BR 426,'87). Gain values during the CER (per 2,3,4) were significantly less then period 1 ($p<.05$). In MFC lesioned animals, the gain at rest was less than that of controls ($p<.01$), but no significant changes occurred during the CER (per. 2,3,4). (Supp by Loyola BRSG funds)

ACTIVATION OF A SPINO-MEDULLARY CHOLINERGIC PRESSOR PATHWAY DOES NOT INVOLVE MEDULLARY RESPIRATORY CENTERS. H. Takahashi* and J.J. Buccafusco. Dept. Pharmacology & Toxicology Medical College of Georgia & Veterans Administration, Medical Center, Augusta, GA 30912.

Intrathecal (IT) injection of neostigmine (NEO) produced a marked increase in blood pressure (BP) and heart rate (HR) in freely-moving rats (J Autonom Ner Sys 25:69, 1988). It was suggested that this spinal cholinergic system may play a role in the cardiovascular reflex response to a painful stimulus. It is known, however, that stimulation of sensory afferents produce hyperventilation as well as increases in BP and HR. The purpose of this study is to determine whether 1) the cholinergic system activated by NEO also affects respiration, and 2) this system is intrinsic or ascending to higher centers. NEO (10μg, IT) inhibited acetylcholinesterase activity of the thoracic and lumbar cord, but not the cervical cord or medulla, indicating a local site of action. In anesthetized spontaneously breathing rats, NEO increased BP and HR, but not tidal volume (TV) or respiratory rate (RR) and minute volume (MV). The increases in BP and HR were inhibited by IT pretreatment with 10μg atropine. Intracisternal (IC) injection of NEO also increased BP and HR, but in addition, it increased TV, and decreased RR and MV. In contrast to IT NEO, these responses to IC, NEO were not altered by IT pretreatment with atropine. The increases in BP and HR to IT NEO were observed in decerebrate but not in spinal C7-8 transected preparations. These results support the presence of an ascending cholinergic pressor pathway which terminates in the medulla and is independent of the medullary respiratory pathway. Suppted: NIH, HL&B and the Veterans Administration.

EXTRACELLULAR NOREPINEPHRINE (NE) IN SPECIFIC HYPOTHALAMIC NUCLEI AND MEAN ARTERIAL PRESSURE (MAP) ARE INCREASED BY SODIUM CHLORIDE (NaCl): APPLICATION OF SMALL-GAUGE MICRODIALYSIS PROBE IN AWAKE RATS. T. Nakata*,W. Berard*, E. Kogosov* and N. Alexander. (SPON:B.Newman). Departments of Med. and Anat. Univ. of So. Calif. Sch. of Med., Los Angeles CA 90033.

We compared the effect of NaCl on MAP and extracellular NE in 3 hypothalamic nuclei known to affect cardiovascular and metabolic function. Microdialysis probes were contructed with dialysis bags (1.0 mm long, 0.18 mm diam., 8000 mw cutoff) inserted into a 27 g. needle. The probe tip was inserted through a guide tube into lateral (LH), ventromedial (VMH) or posterior (PH) hypothalamus of awake, male, Wistar rats with a femoral artery catheter. Artificial CSF was perfused (2ul/min) through the probe and dialysate samples (10 ul) were collected for radioenzymatic assay of NE. Generally, rats rested or slept during perfusions. Baseline dialysate (extracellular) NE values were 54±8, 61±8 and 66±14 pg/ml for LH, VMH and PH. resp.; (not corrected for recovery). NaCl (3.2%) added to CSF perfusate produced similar changes in all 3 nuclei, namely, a 6-10 fold increase in dialysate NE and a 15% increase in MAP. Mannitol (20%), added to perfusate as an osmotic control, increased NE 3-6 fold in the 3 nuclei without changing MAP. We conclude that:1) NaCl added directly to LH, VMH or PH will produce a rise in MAP and increase local NE release and, 2) hypertonic perfusate may have a non-specific osmotic effect on dialysate NE independent of neuronal release.

ANTISTRESS EFFECT OF SUBSTANCE P (SP) ON THE CARDIOVASCULAR SYSTEM IN NON-HUMAN PRIMATES. M.Colditz+,G.Stechmesser+,G.Martin+ and C.Gurk+ Dept. of Neuroregulation Res., Central Institute for Cardiovascular Research and WHO Collaborat. Centre,Academy of Sciences of the G.D.R.,Berlin, G.D.R.

The hypothesis that only the peripheral application of the regulide SP,combined with a renewed activation of systemic mechanisms of psychoemotional stress, induces a long-term blood pressure decrease in individuals with manifest hypertension, caused by psychoemotional stress, was examined and confirmed in 36 primates (rhesus monkeys, baboons). A pilot study demonstrated that SP (2,5 µg/kg body weight x 4 days), intravenously injected under psychoemotional stress, reduced the prestimulus EEG frequency and abolished the disturbances of the evoked potentials related information processing in the frontal cortex, locus coeruleus and nucleus raphe, and reduced the heart rate compared with the respective stress reactions.

It might be suggested that under psychoemotional stress SP induces such frontocorticofugale mechanisms which increase the sympatho - inhibition and, thus, contribute to the discovered antihypertensive long-term effect of SP.

NEUROBLASTS EXPRESS GLIA-ASSOCIATED ANTIGENS DURING INSECT EMBRYONIC DEVELOPMENT. M.R. Meyer and J.S. Edwards, Dept. Zoology, University of Washington, Seattle, WA 98195.

Observations in a variety of developing insects suggest that some glial cells may arise from neuroblasts (NBs). This notion is supported here by results obtained with selective immunological probes which recognize distinct glia-related antigens in the cricket *Acheta domesticus* (Meyer et al., 1987, J. Neurosci. 7:512).

Antigen 3G6 is associated with glia which invest the adult CNS neuropil (but not central tracts). Early in development, 3G6 is expressed throughout ventral neuroepithelium, but NB labelling becomes progessively more pronounced; by later stages (ca. 50-60%) many NBs strongly express 3G6. NB expression then subsides as neuropil expression increases, but some late 3G6+ NB nests in brain persist. Similar NB-selective labelling occurs in larval Drosophila CNS. Striking reactivity is also associated with crystalline cone cells in the insect retina.

Antigen 5B12 is a glia-associated glycoprotein that delineates nerve tracts in the adult insect. In the early embryonic CNS, 5B12 is associated with basal lamina overlying developing neuropil. Later (ca.45-55%), antigen is expressed upon a discrete set of posteriolateral NBs and along subsets of commissural axon fascicles.

Two distinct glia-selective markers thus support the hypothesis that NBs are likely to be involved in producing glial elements as well as neurons in insects, with NB-related gliogenesis following neurogenesis. Supported by NIH #NS07778-20.

NEURONS AND GLIA ARISE FROM A COMMON PROGENITOR IN CHICK OPTIC TECTUM: DEMONSTRATION WITH TWO RETROVIRUSES AND CELL TYPE-SPECIFIC ANTIBODIES. D.S. Galileo*, G.E. Gray , G.C. Owens*, J. Majors[1] and J.R. Sanes, Departments of Anatomy & Neurobiology, and [1]Biochemistry, Washington University School of Medicine, St. Louis, Missouri 63110

We have been using a recombinant retrovirus to study cell lineage in the chick optic tectum. The virus inserts the lacZ (ß-galactosidase) gene into the genome of an infected cell; a histochemical stain fills the progeny of infected cells with a blue precipitate. By observing the shapes and positions of blue cells we found that individual clones frequently contain diverse neuronal types (Gray et al., PNAS 85: 7356, 1988). We next wanted to ask whether individual clones contain glia as well as neurons. However, identification of cells as glia by shape and size was often ambiguous, and identification by immunostaining was hampered by the blue precipitate. Furthermore, putative glia were sometimes dispersed, leading to occasional ambiguity in the definition of clonal boundaries.

To solve both of these problems, we constructed a new recombinant virus in which lacZ is fused to the nuclear localization signal of the SV40 T antigen. Cells infected with this virus are marked with blue nuclei instead of blue somata. Following infection of embryos with a mixture of the two retroviruses, individual clusters contained cells with only one type of label (nuclear or cytoplasmic), showing them to be clones. We were also able to immunostain the somata of cells that had blue nuclei, and thereby to show that neurons (neurofilament*) and glia (glutamine synthetase*) are found within a single clone. This demonstrates unambiguously that neurons and glia can develop from a common precursor in optic tectum. (Support: NIH, MS, and McKnight)

241.3

MIGRATORY PATTERNS OF CLONALLY RELATED CELLS DIFFER IN CHICKEN TECTUM AND FOREBRAIN. G.E. Gray and J.R. Sanes, Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, Missouri 63110

We previously used a retroviral tracing method to show that clonally related cells form radial arrays in chick optic tectum (Gray et al., PNAS, 85: 7356, 1988). Because the optic tectum has a radial functional organization, clonally related cells may frequently be functionally related. In the present study, we compared the spatial arrangement of clones in the tectum with clones in the forebrain, much of which has no known radial organization.

Recombinant virus bearing the lacZ gene (whose product can be marked histochemically in the progeny of infected cells) was injected into the neural tube on E3 (stage 17-19). Subsequently, brains were fixed, sectioned, and reacted for lacZ. Until E8, most clones in the forebrain were radial. However, by E10 many clones showed some dispersal, and by E19 most clones comprised loose clusters of cells, with little radial organization. One basis for these migratory differences might be that tectum and forebrain differ in the organization of their radial glia, which are thought to guide migration. To examine this possibility, we labeled tissue from the two areas either with an antibody to radial glia or with DiI. Both stains showed that radial glia remain present in the hatchling (E20) in the optic tectum (confirming Vanselow et al., Dev. Br. Res. 45:15, 1989), but largely disappear by ca. E12 in the forebrain. These experiments show 1) that the different arrangement of clonally related cells in tectum and forebrain reflects (and may influence) a difference in the functional organization of these two areas; and 2) that loss of radial glia is correlated with (and may underly) a loss of radial migratory constraint as the forebrain develops. (Support: NIH & McKnight)

Retroviral Vectors Reveal Compartment Specific Cell Lineages In The Developing Rat Forebrain. L.A. Krushel, J.G. Johnston, G. Fishell, and D. van der Kooy Neurobiology Research Group, Dept. of Anatomy, University of Toronto, Toronto, Ontario, Canada, M5S 1A8.

The two major structures of the rat forebrain, the cortex and striatum, are each developmentally and functionally compartmentalized. The cortex can be separated into deep and superficial layers, while the striatum can be divided into the patch and matrix compartments. Do these compartments arise from separate progenitor populations? To investigate the role of cell lineage in this compartmentalization of the forebrain, we injected a replicant-deficient retrovirus (containing a lac-Z marker gene) into the lateral ventricle of embryonic pups *in utero*. The virus was obtained from the supernatant of a psi 2 BAG alpha cell line (ATCC #CRL-9560). At birth, true blue was injected into the mesencephalon of the pups. This retrogradely labeled the striatal patch and deep layer corticospinal neurons. The pups were sacrificed at postnatal day 7 and processed histochemically for B-galactosidase. Embryonic day (E) 17 injections produced small neuronal clones (<3 cells) generally restricted to either the cortical superficial lamina or striatal matrix compartments. In contrast, E14 injections produced three classes of neuronal clones, 1) clones restricted to either the superficial cortical layers or matrix compartment, 2) single cell clones located in the deep layers, and 3) large clones (up to 11 cells) distributed across the deep and superficial layers. This suggests there may be three distinct neuronal progenitor populations, two of which give rise to cells that respect the boundaries of forebrain compartments, and thus may be directly involved in the formation of these compartments.

CELL LINEAGE IN THE MOUSE SOMATOSENSORY CORTEX: ANALYSIS OF CHIMERAS. K.Herrup and J.E. Crandall. E.K. Shriver Center, Waltham, MA 02254.

Experimental aggregation chimeric mice offer a perspective on cell lineage relationships complementary to that seen with recombinant retroviruses. Previous studies of cerebellar cortex in such chimeras indicate that there is a non-random spatial distribution of clonally related Purkinje cells (Herrup & Bower, *Neurosci. Abst.* **12**,769). Whereas the Purkinje cells are found topologically in only two dimensions, the cerebral cortex is a multilayered structure and the analysis of the spatial distribution of cell lineages must be approached in three dimensions. We have analyzed radial probes of somatosensory cortex in $Gus^{h}/Gus^{h} \leftrightarrow Gus^{b}/Gus^{b}$ chimeras. The position and genotype (determined with ß-glucuronidase) of all cortical cells were plotted. Preliminary analyses of the distribution of these cells indicate that there are significant differences in genotype ratios among: 1) adjacent radial probes in the tangential dimension and 2) cortical laminae. Retroviral studies indicate that different individual cortical cell clones are found in a variety of spatial distriburions ranging from predominantly radial to widely spread in the tangential plane. The chimera studies suggest a significant non-random spatial distribution of the entire set of cortical cell lineages.

LINEAGE ANALYSIS OF THE MOUSE CEREBRAL CORTEX USING RETROVIRUS VECTORS. C. Austin* and C. Cepko* (SPON: D. Fekete) Dept. of Genetics, Harvard Medical School, Boston, MA 02115.

The development of the cerebral cortex is being investigated using retrovirus vectors to introduce a stable, genetic marker into mitotic cells of the lateral ventricle of mice. Embryonic day 12 and 13 fetuses are infected with a small number of replication-incompetent retrovirus particles (BAG) which transduce and express the marker gene encoding E. coli ß-galactosidase (Price et al., PNAS 84:1345, 1987; Walsh and Cepko, Science 241:1342, 1988). Animals are then harvested after a variety of survival times, ranging from 2 days post infection to greater than 3 weeks. Xgal histochemistry is then performed on serial frozen sections to reveal the location of infected cells. By using a small number of particles to infect a large series of fetuses (over 200), we are able to reproducibly generate approximately 50-100 labelled cells distributed throughout the brain. Analysis of the distribution of labelled cells with respect to each other and with respect to defined anatomical structures is being pursued through 3-dimensional reconstruction of complete cortices. By using a series of harvest dates, patterns of migration and proliferation of labelled cells are being defined.

MIGRATING NEURONS OF THE MURINE CEREBRUM ASCEND IN PARALLEL TO RADIAL FIBERS: ANALYSIS BASED UPON DOUBLE-LABELING OF MIGRATING NEURONS AND RADIAL FIBERS. J.P.Misson*, C.Austin*, T.Takahashi*,C.Cepko*,V.S. Caviness Jr.,(SPON: J. Nathanson) Dept. Neurology, Mass. Gen. Hosp, & Dept. Genetics, Harvard Med. Sch., Boston, MA

We consider here the relationship of the pathway of neuron migration to the course of ascent of local Radial glial fibers(RGF) in the late embryonic cerebral wall. Migrating neurons, carrying a viral-inserted gene for E-Coli B-galactosidase, are identified histochemically at intervals of 3-8 days following intraventricular injection of the viral vector on E12-14 (Walsh et al, Science, 1988, 241, 1342). The entire population of RGF is delineated in the same histological preparation by immunostaining with RC2 antibody (Misson et al, Dev. Brain Res., 1988, 44,95). The majority of the migrating cells, as delineated, are simple in configuration: radially elongated with leading but no other processes. At all subcortical levels identified migrating cell is contacted by multiple fascicles of RGF and at cortical levels by at least one fascicle or single RGF. The long axis of migrating cell is invariably parallel to the path of ascent of adjacent RGF. Thus, in the dorsal convexity of the hemisphere where fiber ascent is radial, the migrating cell is radially aligned. Laterally in the hemisphere fiber alignment is more nearly tangential across the Intermediate Zone, becoming inflected sharply to radial alignment in its cortical span. Even in this circumstance migrating cell alignment is that of the adjacent fibers, tangential in crossing the IZ, but radial through cortical strata. The constant parallelism of alignment of migrating cells and adjacent fibers is consistent with the hypothesis that the fibers ' surface serves as a guide to migration. This parallel relationship holds for the presumed monoclonally derived single or paired migrating cells as well as for larger clusters of presumed polyclonally derived migrating cells arising from the same region in the Ventricular Zone.(supported by NIH grants NS12005 (V.S.C.) and NS23021 (C.C.) and by a C.A.King trust fellowship(J.-P.M.)

241.8

PROLIFERATIVE KINETICS OF CELLS IN THE SUBEPENDYMAL ZONE OF THE ADULT FOREBRAIN C.M. Morshead and D. van der Kooy. Neurobiology Research Group, Department of Anatomy, University of Toronto, Toronto, Ontario, Canada M5S 1A8

In the adult brain mitotic figures are rare, except in the subependymal layer which lines the lateral ventricles. Proliferation is most pronounced in the dorsolateral portion of this region where a single pulse of Brdu (a DNA synthesis marker) in the adult mouse labels 5% of the cells. In order to ask if the entire population in this region divides, Brdu was made continuously available for 3 days (injecting 165mg/kg every 8 hours). The population of labeled cells plateaued at 16% after 2 days. This suggests that only a minority of cells in the subependymal zone make up the proliferative population. Moreover, the plateau of Brdu labeled cells suggests that cell death is occurring in balance with continued proliferation. As an independent test of these suggestions, we injected a recombinant retrovirus into the lateral ventricle to mark clones of proliferating cells. Although multicell clones could be seen 1 and 2 days post-injection, we observed primarily single clones after survival times of 1 week. These results support the existence of a stem cell type of proliferation with survival of the self-renewing cell and death of the progeny. Additional experiments suggest some plasticity within this region as stress (exposure to anaesthetics) increases the number of dividing cells pulse labeled with a DNA synthesis marker. We are investigating whether stress decreases the cell cycle time of the stem cells or recruits cells from the non-dividing population.

241.9

FATE MAPS AND THE EARLY DETERMINATION OF THE FOREBRAIN IN ZEBRAFISH EMBRYOS. L.S. Ross, T.J. Parrett*, R.C. Marcus*, and S.S. Easter, Jr. Dept. of Biology, University of Michigan, Ann Arbor, MI 48109.

Lineage tracer molecules (HRP and fluorescent dextrans) were injected into single blastomeres at the animal pole of zebrafish embryos. At 24h postfertilization, the embryos were fixed and skinned, and their brains examined as whole mounts. Injections prior to 3h produced labeled cells, scattered throughout the brain, most concentrated in the forebrain. Injections at 3-4h gave a more restricted distribution, with large compact clones in the forebrain, most concentrated in the telencephalon. Injections after 4h (late blastula) produced small compact clones restricted to the telencephalon. We conclude that the dispersion of cells relative to their clonal neighbors ends quite early for those cells that will form the telencephalon.

In addition to mapping cell fates, we assessed differentiation by other methods. HNK immunoreactivity (MAb supplied by C. Stern) delineated the two major afferent pathways of the telencephalon as early as 20h. BRdU labeling indicated that the telencephalon has more postmitotic cells than other regions of the brain at 24h. Acetylcholinesterase staining showed differentiated cells concentrated in the telencephalon at 24h. These results support the idea that the telencephalon develops early relative to other regions of the brain.

PROGRESSIVE CHANGES IN CELL CYCLE AND DNA-SYNTHETIC PHASE LENGTHS DURING THE DEVELOPMENT OF THE DENTATE GYRUS OF C57Bl/6J MOUSE. R.R Gulay*, M.W. Miller and R.S. Nowakowski (Spon: N.L. Hayes). Dept. of Anatomy, UMDNJ-Robert Wood Johnson Medical School and School of Osteopathic Medicine, Piscataway, NJ 08854.

We have used a cumulative bromodeoxyuridine (BUdR) labeling technique (Nowakowski et al., J. Neurocytol., 1989) to determine the lengths of the cell cycle (T_C) and the DNA-synthetic phase (T_S) of proliferating cells in the developing hilus of the dentate gyrus. On postnatal days 0, 5, 10 and 20, C57BL/6J mice were injected with BUdR at two hour intervals for a total period of 10-12 hours. An iterative computer method was used to determine the lengths of T_C and T_S from counts of BUdR labelled and unlabelled cells.

The results (see Table) show that the lengths of T_C and T_S for the dentate gyrus change significantly during the postnatal period. Moreover, the ratio T_S/T_C increases progressively during development. Most widely used estimates of neuronal production based on single injections of ^{3}H-thymidine or BUdR have the implicit assumption that the T_S/T_C ratio is constant at different developmental stages. Consequently, previous studies should be re-evaluated in the context of the T_S/T_C ratio for each specified region and age analyzed.

	T_C	T_S	T_S/T_C

REGULATION OF NEURON NUMBERS IN THE VERTEBRATE CNS: A COMPUTER SIMULATION. Richard Wetts & Scott E. Fraser. Dept of Physiology & Biophysics and the Developmental Biology Center; Univ Calif, Irvine, 92717.

What parameter tells a neuroblast to become postmitotic? Analyses of cell numbers in chimeric mice suggest that small groups of progenitors are committed in the neurula (for example, 10 cells per side in C57BL/6 give rise to the cerebellar Purkinje cells); each progenitor gives rise to a specific number of descendants (9200 Purkinje cells; Range ± 3%). [Herrup & Sunter, 1986, *Dev Biol.* 117: 417.] Analyses of the terminal lineages (last 5 generations) in the frog retina suggest variability in the numbers of descendants that are produced by precursors labeled at the same developmental stage [Wetts & Fraser, 1988, *Science*, 239: 1142].

To understand which events are important for controlling the number of descendants in a clone, we compared these experimental observations to the output of a neural proliferation model. In this model, a single progenitor cell proliferates until all of its descendants become postmitotic; the decision to stop dividing is modeled as a stochastic process. We have examined the effects of making this probability a function of 1) Time, 2) total Cell Number in the population, or 3) Number of Generations. In each case, parameters can be specified such that the model replicates many of the experimental observations. The most realistic fit to the experimental data occurs when CNS neuroblasts use the number of divisions to decide when to stop dividing.

A CASE STUDY OF A +/LC CHIMERA WITH PURKINJE CELLS UNILATERALLY DISTRIBUTED IN THE LEFT CEREBELLAR HEMISPHERE. M.W. Vogel and K. Herrup. Maryland Psychiatric Research Center, Baltimore, MD 21228 and E.K. Shriver Center, Waltham, MA. 02254.

We recently discovered a +/*Lc* ↔ C3H chimera with its cerebellar Purkinje cells unilaterally distributed in the left hemisphere. Preliminary Purkinje cell counts indicate that this animal contains on the order of 7 to 10 thousand Purkinje cells, and of these, less than 5% are positioned in the right cerebellar hemisphere, all within 300 μm of the midline. Wetts and Herrup (1982, J. Neurosci.,2:1494) report a Purkinje cell clone size of 10,200 neurons for C3H mice. We have analyzed four additional +/*Lc* ↔ C3H chimeras, and the combined data is best fit by a clone size of 10,350 Purkinje cells. Our interpretation of the +/*Lc* chimera described here is that all of its Purkinje cells are descended from a single wild type progenitor cell. The unilateral distribution of Purkinje cells suggests that progenitor selection events on the right and left sides are independent and that there is little crossover of Purkinje cells between the right and left cerebellar hemispheres Furthermore, the ratio of granule to Purkinje cells is increased in +/*Lc* chimeras, and we have suggested that the deafferentation of wild type Purkinje cells is responsible for the increased granule cell survival. The granule cells of this chimera will be analyzed to determine if the increase in granule cell survival is a global property of +/*Lc* chimeras or due to local interactions. Qualitatively, the granule cell layer in the Purkinje cell-less hemisphere is greatly reduced in size favoring the later hypothesis.

241.13

LINEAGE OF MOTONEURONS IN CHICK SPINAL CORD STUDIED WITH A RETROVIRAL MARKER. S.M. Leber, S.M. Breedlove, and J.R. Sanes, Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, Missouri 63110

To define the range of cell types to which spinal motoneuron (MN) progenitors give rise, we injected replication-incompetent retroviruses into the neural tubes of stage (st.) 13-18 chick embryos. The progeny of infected cells expressed virally-encoded ß-galactosidase and were stained histochemically at st. 38-41 (E15). (MNs are born ~st. 15-23 and many die ~st. 29-36; V. Hamburger.) Isolated clusters of labeled cells were identified as clones by the methods of Gray et al. (PNAS 85: 7356, 1988) and Galileo et al. (see abstract). Cell types were identified by morphology, size, location, and the presence or absence of Nissl substance. Clones were usually radial or planar in shape, with rostro-caudal spread of <150 μm (a segment is ≥ 600 μm long at E15). As expected, injections at later stages gave rise to clones containing fewer MNs. Clonally related MNs were not restricted to a single column or motor pool, indicating that single progenitors can produce MNs that project to different muscles.

Multicellular clones containing only MNs were rare. Even after late (st. 17-18) injections, relatives of MNs were found in both the gray and white matter and included a variety of other neurons, as well as glia (probably both astrocytes and oligodendrocytes) and ventricular zone cells. Although most non-MNs in MN-containing clones were in the ventral part of the cord, some were found dorsally, and some were contralateral to the labeled MNs. We conclude that the close relatives of MNs are not necessarily other MNs, but include a variety of cell types. (Support: MDA, NIH, and McKnight)

241.14

CELL LINEAGE IN CHICK SENSORY GANGLIA STUDIED WITH A RETROVIRAL MARKER. E. Frank and J.R. Sanes[1], Dept. of Neurobiology, Anatomy and Cell Science, U. Pittsburgh School of Medicine, Pittsburgh, PA 15261, and [1]Dept. of Anatomy and Neurobiology, Washington U. School of Medicine, St. Louis, MO 63110

We have used retroviruses to trace the lineage of cells that populate dorsal root ganglia in chick embryos. Replication-deficient virions bearing the lacZ (ß-galactosidase) gene were injected into the neural tube at stages (St.) 13-18, when crest cells are migrating from the tube. At St. 35-49, embryos were fixed and reacted with X-gal to visualize individual labeled cells in sensory and sympathetic ganglia and their nerves. Many sensory ganglia bearing lacZ+ cells were isolated --i.e., adjacent and contralateral ganglia were lacZ-. Simultaneous injections with 2 different retroviruses (see abstract by Galileo et al.) indicated that labeled cells within such ganglia were likely to be clonal relatives: all labeled cells within each ganglion had a single viral phenotype. Individual clones sometimes contained labeled neurons, satellite cells, and Schwann cells, demonstrating that some ganglionic progenitors are pluripotent. Other clones contained sensory neurons or glia, but not both, suggesting that some crest cells are restricted in the range of cell types they normally produce. Clonally related sensory neurons were usually tightly clustered in a restricted part of the ganglion. In contrast, sensory neurons containing a specific peptide (e.g., CGRP) or projecting to a particular target (e.g., triceps muscles) were not obviously clustered. Thus, although neural crest cells may become committed in terms of major cell phenotypes (neurons or glia), single neuroblasts apparently produce a variety of sensory neuronal types. UPTAKE, STORAGE, SECRETION AND METABOLISM II

242.1

IDENTIFICATION OF THE HIGH-AFFINITY CHOLINE CARRIER IN RAT BRAIN SYNAPTOSOMAL MEMBRANES USING ^{3}H-CHOLINE MUSTARD. E.H. Colhoun* and R.J. Rylett. (SPON: T.E. Feasby) Depts. Physiology and Pharmacology, University of Western Ontario, London, Canada.

Choline used as substrate for acetylcholine synthesis is taken up into cholinergic nerve terminals by a sodium-dependent, hemicholinium-sensitive transporter. We reported previously that the choline analogue ^{3}H-choline mustard aziridinium ion (^{3}H-ChM Az) binds irreversibly to polypeptides of 40-42 and 58 kDa in presynaptic plasma membranes of Torpedo electromotor organ in the presence of sodium and absence of hemicholinium-3. The objective of the present study was to compare binding of this affinity ligand to choline transporters in rat brain synaptosomal membranes. Purified striatal synaptsomes from rat brain were incubated with ^{3}H-ChM Az, lysed and the washed presynaptic plasma membranes were solubilized and analyzed by SDS-polyacrylamide gel electrophoresis. Tritium-labelled polypeptides were observed with apparent molecular masses of about 42 and 56 kDa; a minor tritium-labelled polypeptide of Mr 33 kDa was also apparent, but could represent a proteolytic fragment. In contrast to results obtained with Torpedo presynaptic membranes, the predominantly labelled polypeptide in rat striatal membranes was that with Mr of about 56 kDa compared to the 42 kDa polypeptide. Binding of the affinity ligand was blocked by hemicholinium.

(Supported by Medical Research Council of Canada.)

242.2

HIGH AFFINITY CHOLINE CARRIER FROM SYNAPTOSOMAL MEMBRANES. H. Breer, M. Knipper*, C. Kahle*. Institute of Zoophysiology, Univ. Hohenheim 7000 Stuttgart 70, F.R.G.

The accumulation of choline via a specific high affinity uptake system is the rate-limiting step for the synthesis of acetylcholine. Using insect synaptosomal ghosts with artificially imposed ion gradients the energetics of choline translocation has been explored. The transport rate was found to be regulated via second messengers and specific protein kinases. Binding studies, using hemicholinium-3 as specific probe, suggest that the number of carrier increased upon kinase activation and that occult choline transporter may be recruited via phosphorylation. Towards an identification of the carrier constituents, monoclonal antibodies were produced which block the high affinity choline uptake. These antibodies labelled specific neuropil areas in immunocytochemical approaches and recognized a specific polypeptide band in Western blots. These putative carrier polypeptides were purified to homogeneity and functionally reconstituted in liposomes.

242.3

SYNTHESIS OF AN AFFINITY LABEL FOR THE ACETYLCHOLINE TRANSPORTER AND ITS USE IN REVERSIBLE AND IRREVERSIBLE STUDIES. Stanley M. Parsons and Gary A. Rogers.* Department of Chemistry, University of California, Santa Barbara, CA 93106

A structure-activity study of acetylcholine (ACh) elucidated structural features in ACh analogs giving potent, competitive inhibition of ACh active transport by synaptic vesicles purified from Torpedo electric organ. The analog Z-cyclohexylmethyl N-(4´-azidophenacyl)-N-methylisonipecotate was synthesized in unlabeled and tritium-labeled (10.8 Ci/mmol) forms. Unlabeled analog inhibited active transport of [^{3}H]ACh(K_m = 0.3 mM) with IC (0.85± 0.15) μM, and inhibited binding of [^{3}H]analog with K_i (1.0±0.6) μM. Unlabeled analog also was a competitive inhibitor of [^{3}H]vesamicol binding with K_i (0.46±0.06) μM. Vesamicol is a noncompetitive inhibitor of ACh active transport (K_i = 20 nM). Specifically bound [^{3}H]analog dissociated at a rate of (0.19±0.02) min^{-1} at 0°, which is slow enough to carry out filter-based binding studies. [^{3}H]ACh itself dissociates from the ACh transporter (AChT) much too quickly for such studies. Binding of [^{3}H]analog to synaptic vesicles exhibits a saturable component with K_d 0.4 μM and B_{max} 800 pmol/mg, and a large nonsaturable component. ACh partially displaced bound [^{3}H]analog with IC_{50} (3.2± 1.4) mM in the absence and presence of MgATP. Choline was less effective with IC_{50} (25± 13) mM. Vesicles trapped on a glass fiber filter and incubated with nonlabeled analog lost 90 percent of their ability to bind [^{3}H]vesamicol when photolyzed. Vesicles incubated with [^{3}H]analog, photolyzed and subjected to SDS slab gel electrophoresis and fluorography exhibited labeling of a species extending from 50,000 M_r to the top of the gel (M_r > 200,000). Labeling was completely inhibited by excess nonlabeled analog, 100 mM ACh or 1μM vesamicol, and partially inhibited by 3 mM ACh. We conclude that the AChT exhibits a very heterogeneous structure in SDS and a range of affinities for ACh, and it is intimately associated with the vesamicol binding site.

242.4

EFFECTS OF DM-9384, A NEW COGNITION-ENHANCING AGENT , ON GABA RELEASE AND CHOLINE UPTAKE IN RAT CORTEX. S. Watabe*, H. Yamaguchi* and S. Ashida* (SPON: M. Yoshii). Lab. of Pharmacol., Res. Insti., Daiichi Seiyaku Co. Ltd. Tokyo 134, JAPAN.

Previous reports have shown that N-(2,6-dimethylphenyl)-2-(2-oxo-1-pyrrolidinyl)acetamide(DM-9384) inhibits the amnesia induced by GABA and ACh antagonists(Nabeshima et al., Psychopharmacol., 96:Suppl. 305,1988). DM-9384 also potentiated learning acquisition and increased choline acetyltransferase(ChAT) activity in rat cortex. These results indicated that DM-9384 related to GABA and cholinergic system. In the present study, we performed on the effects of DM-9384 and aniracetam, an analogue of DM-9384, on the K^+-evoked efflux of ^{14}C-GABA from rat cortical slices and on the uptake of ^{3}H-choline in the cortical synaptosomes. The release and uptake experiments were carried out according to the procedures of Davies(1975), Atweh(1976), respectively. In high concentrations of DM-9384, the GABA release caused by the high K^+(40mM) was remarkably decreased by approximately 30%(10^{-3}M). On the contrary, the low concentration(10^{-6}M) of DM-9384 significantly increased by about 15%. On the other hand, aniracetam was no effect in all concentrations. The Na^+-dependent choline uptake slightly increased at 10^{-5}M of DM-9384. These results suggest that in GABA release, DM-9384 possesses two differential effects by different concentrations, and the GABAergic system is facilitated by the low concentrations of DM-9384. DM-9384 also accelerates the turnover in cholinergic system.

QUISQUALATE CAUSES GLYCOGEN DEPLETION AND INCREASED GLUCOSE UTILIZATION IN PRIMARY ASTROCYTE CULTURE. R.A. Swanson and F.R. Sharp Neurol. Dept., VAMC and UCSF, San Francisco, CA.

Previous studies have shown that incubation with L-glutamate (L-GLU) causes increased glycogen accumulation and decreased glucose utilization iin primary astrocyte culture. It has now been found that several analogues of L-GLU have effects opposite to these.

Primary astrocyte cultures were prepared from neonatal rat cortices as described by Hertz et al. and used after 4-5 weeks. L-GLU and analogues were added at initial media concentrations of 1mM. Glycogen was measured after 4 hr incubations by an amyloglucosidase linked flourometric procedure. Glucose utilization was assessed by adding (^{3}H)2-deoxyglucose for 45 min followed by 3 15 min washes in fresh media. The ^{3}H retained in the cells provided a relative index of the glucose utilization rates

L-GLU increased glycogen content 87±6% and reduced glucose utilization by 53±9%. In contrast, D-GLU, quisqualate, and L-α-aminoadipate each reduced glycogen content to less than 25% and increased glucose utilization to greater than 150% of controls. These effects on astrocyte metabolism may contribute to CNS toxicity.

242.6

GLUTAMATE UPTAKE SYSTEMS IN CELL CULTURES FROM RAT BRAIN. *B. Flott* and W. Seifert. (SPON: F.W. Schürmann) Max-Planck-Institut für biophys. Chem., Department of Neurobiology, Göttingen (F.R.G.)*

The neurotransmitter glutamate and the NMDA-receptor have become an important area of research on both synaptic plasticity and neurotoxicity in recent years. Most studies deal with the protection of glu-sensitive neurons by glu-receptor antagonists or other agents. An other approach is the investigation of glu-uptake as the physiological mechanism to stop glu-induced excitation. In addition to the well known Na^+ dependent glu-transport and the Cl^- dependent transport we have recently described a Ca^{++} dependent uptake in synaptic plasma membrane preparations which is active in the absence of Na^+ and Cl^- ions (Hollmann, Harnecker and Seifert, 1988, FEBS-Letters 228, 74-78.). In our studies we used cultured astrocytes and hippocampal neuronal cultures. We investigated the three different uptake systems including the Ca^{++} dependent system and the modulation of glu-uptake under various conditions and--as glu is probably involved in ischemic neuronal cell death--in the absence and presence of glucose. Our results show that, as documented for synaptosomes, physiological concentrations of Ca^{++} [2 mM] indeed induce Glu-uptake into cultured astrocytes significantly (1.5 times of the basal uptake). Cl^- gives an increase of about 8 times and Na^+ about 40 times of the control value. In addition, Ca^{++} enhances the Na^+ and Cl^- dependent transport.

242.7

AVERMECTIN ENHANCES DEPOLARIZATION-EVOKED ^{3}H-GABA RELEASE FROM RAT BRAIN SYNAPTOSOMES K.Subbarao*, T.J.Turner* and S.M.Goldin. Dept.of Biol. Chem.and Mol.Pharmacology, Harvard Medical School, Boston,MA 02115

Multiple components of Ca-dependent and Ca-independent ^{3}H-GABA release from rat brain synaptosomes have been resolved using a rapid superfusion method with a resolution time of ≈60 msec (Turner & Goldin [1989] Biochem. 28,586). 22,23-dihydro avermectin B_{1a} (AVM), a broad-spectrum anti-parasitic drug, selectively enhances the rate of K^+ depolarization-stimulated, Ca-independent GABA release 6-8 fold at [1μM]; 3-fold enhancement was observed at 100 nM [AVM]. The AVM enhanced release reaches a peak with a τ of 0.4 sec and decays exponentially (τ=1.6sec). AVM modestly increases basal GABA release but its major effect is seen only with depolarization. Bicuculline and picrotoxin block AVM enhanced release. The presence of Cl^- is a requirement for AVM to enhance GABA release. AVM enhanced GABA release was not blocked by nipecotate, an inhibitor of high-affinity GABA uptake carrier, suggesting that AVM enhanced GABA release is probably not mediated through the reversal of this carrier. AVM marginally enhanced the release of ^{3}H-dopamine but had no effect on ^{86}Rb release. These results indicate that AVM is mediating its effect through binding to the $GABA_A$ receptor, and requires Cl^- entry through its associated ion channel.

242.8

EXPRESSION OF GABA-TRANSPORTER mRNA IN XENOPUS OOCYTES. J. Guastella*, N. Davidson, H.A. Lester (SPON:W. Agnew). Division of Biology, 156-29, Caltech, Pasadena, CA, 91125.

We are using Xenopus oocytes as an expression system to characterize mRNA encoding the proteins responsible for the carrier-mediated transport of γ-aminobutyric acid (GABA). Microinjection of rat brain poly(A)$^+$ RNA into oocytes results in an 8 to 10-fold increase in the accumulation of ^{3}H-GABA above that seen in uninjected or water-injected controls. This increase is roughly linear with translation time up to about 96 hours, and is linear with incubation time up to 1 hour. Uptake is saturable, indicating that it is mediated by a carrier system, and is of high affinity, with a K_m of approximately 2 μM. The accumulation of ^{3}H-GABA is dependent on the presence of sodium ions, and is reduced 50-90% by 500 μM ß-alanine, nipecotic acid and 2,4-diaminobutyric acid. These results indicate that the GABA transporters being expressed share the properties of GABA transporters studied in more conventional preparations, such as brain slices, ganglia, and synaptosomes.

Fractionation of poly(A)$^+$ RNA on sucrose gradients resulted in a well-defined peak of activity corresponding to RNA's with lengths of about 3 to 6 kb. This fraction is currently being used to construct cDNA libraries enriched for GABA transporter cDNA. These libraries may also eventually prove useful for the isolation of cDNA's encoding other neurotransmitter transporters. (Supported by NIH Grants GM-10991 and GM-29836. JG is an NIH Postdoctoral Fellow).

242.9

REGION SPECIFIC REGULATION OF THE BRAIN SODIUM-DEPENDENT HIGH AFFINITY GLUTAMATE UPTAKE PROCESS BY HYPERAMMONEMIA. M.B. Robinson and M. Hunter-Ensor*. Depts. of Pediatrics and Pharmacology, University of Pennsylvania, Philadelphia, Pa, 19104.

Extracellular levels of excitatory amino acids, glutamate and aspartate, are primarily regulated by sodium-dependent high affinity uptake processes. The purpose of this investigation was to identify a condition that would lead to regulation of this uptake process. Hyperammonemia leads to increases in the level of brain glutamine (Gln), a putative precursor of releasable glutamate. Urease-containing mini-osmotic pumps were implanted intraperitoneally to develop prolonged hyperammonemia in rats with a 3.1-fold elevation of brain Gln. At 72 h post-implantation, we observed significant increases in the V_{max} for synaptosomal uptake of L-[^{3}H]-glutamate in cerebellum (45 %) and brainstem (28 %) with no changes observed in hippocampus, striatum, cortex and midbrain. The K_m did not change in any of these brain regions. Glutamate analogues were screened for inhibition of synaptosomal L-[^{3}H]-glutamate uptake. The IC_{50}'s are: (units = μM)

Compound	Cere	Brst	Hippo	Cor	Str	Mdbr
DL-*threo*-ß-hydroxyaspartate	3.2	2.4	1.2	2.3	1.4	1.5
L-Aspartate ß-hydroxamate	3.6	3.8	8.1	10	7.5	6.4
ß-Glutamate	1.9	1.5	2.8	3.6	4.1	2.8
L-Cysteine sulfinate	1.6	0.88	1.2	1.6	1.2	1.1
α-Aminoadipate	34	130	590	760	610	540
Dihydrokainate	>3000	440	150	120	81	150

These studies suggest that the region specific regulation may, in part, be due to heterogeneity of this uptake process. Supported by Pew to MBR.

FOREBRAIN AND CEREBELLAR mRNAS INDUCE PHARMACOLOGICALLY DISTINGUISHABLE L-GLUTAMATE TRANSPORTERS IN XENOPUS LAEVIS OOCYTES. R.D.Blakely and S.G.Amara. Section of Molecular Neurobiology, Howard Hughes Medical Institute, Yale Univ. Sch. Medicine, New Haven, CT 06510.

Previously, we have described the ability of poly(A)$^+$ RNA from different regions of the rat brain to induce the Na^+-dependent transport of neurotransmitters including L-glutamate (GLU), GABA, glycine, and dopamine (Blakely et al., PNAS 85, 9846-9850,1988). Transport of [^{3}H]GLU was found to be saturable (K_M =14μM), time- and temperature-dependent, and sensitive to competitive substrates of synaptosomal GLU carriers. These studies also determined that both GLU and GABA transporters are induced by 2.5-3.0 kb mRNAs. In the present study, we have sought to determine 1) if the mRNAs encoding forebrain GLU and GABA transporters are resolved by sucrose density gradients, 2) if forebrain and cerebellar mRNAs encoding these activities are similarly sized, and 3) if pharmacological distinctions could be made between forebrain and cerebellar mRNA carriers. Transport assays with fractions from a linear 10-31% sucrose density gradient with forebrain mRNA reveal comigrating peaks of [^{3}H]GLU and[^{3}H]GABA transport activity in the same size range as previously observed for cerebellar mRNAs. Consistent with synaptosomal studies by Ferkany et al. (J. Neurosci. Res. 16, 491-503, 1986), dihydrokainate (1mM) substantially inhibits forebrain (61±5%) and spinal cord (63±5%) mRNA-induced GLU transport while having only weak effects on transport induced by cerebellar (16±5%) mRNA. Thus, while mRNAs encoding forebrain and cerebellar Na^+-dependent GLU transporters appear of similar size, pharmacological heterogeneities persist after oocyte reconstitution suggesting the presence of distinct mRNAs encoding these activities.

242.11

BEHAVIORAL AND BIOCHEMICAL EFFECTS OF CHRONIC ADMINISTRATION OF GABA UPTAKE INHIBITORS IN MICE. W. Karbon*, M.Wyza*, S. Goode*, K. Naper*, J. Ferkany, S.J. Enna. (Sponsor: L. Steranka) Nova Pharmaceutical Corp., Baltimore, MD 21224-2788.

SKF 89976A and SKF 100330A are potent GABA uptake inhibitors with anticonvulsant properties in rodent models. Chronic (14 days, b.i.d., i.p) administration of 0.46 mg/kg SKF R-89976A did not produce a change in anticonvulsant activity, although a higher dose (8.9 mg/kg) caused a 2-fold increase in the ED_{50} (0.63 mg/kg vs. 1.23 mg/kg) for protection. Chronic administration of SKF 100330A (1.8 mg/kg, 13.6 mg/kg) did not influence the anticonvulsant potency of this compound. In contrast, the catalepsy observed in response to acute administration of the higher doses of each compound was markedly reduced in animals treated for as few as 4 days, and was accompanied by a significant increase in the cataleptic ED_{50} for SKF R-89976A (8.5 mg/kg vs. 36.5 mg/kg). [^{3}H]-GABA uptake measured in mouse forebrain synaptosomes was not altered by chronic drug administration, nor was [^{3}H]-$GABA_A$ or [^{3}H]-$GABA_B$ receptor binding. Likewise, [^{3}H]-sulpiride (D2) binding in mouse striatal membranes was unaffected by chronic drug treatment. These findings suggest that following chronic administration, the anticonvulsant effects of SKF R-89976A and SKF 100330A are influenced to a lesser extent than the cataleptic effects.

242.12

QUINOLINIC ACID AND KYNURENIC ACID SYNTHESIS BY HUMAN GLIOMA. [1]M.A. Stasi*, A. Vezzani[1], J.B.P. Gramsbergen, C. Speciale and R. Schwarcz (SPON: F. Du). [1]Istituto Di Ricerche Farmacologiche "Mario Negri", Milano (Italy) and Maryland Psychiatric Research Center, Baltimore, MD 21228.

In the rat brain, the enzymes responsible for the production of the neuroactive kynurenines quinolinic acid (QUIN) and kynurenic acid (KYNA) are localized in astrocytes. We have therefore examined human gliomas, obtained during neurosurgery, for their ability to synthesize QUIN and KYNA from their respective bioprecursors.

QUIN production was assessed in homogenates of glioma tissue after incubation with either kynurenine (KYN; 500 μM), 3-hydroxykynurenine (500 μM) or 3-hydroxyanthranilic acid (2.8 μM). In all cases (N=6), QUIN synthesis could be demonstrated. However, it appeared that kynurenine hydroxylase activity was very low and may constitute a rate-limiting step in QUIN production.

KYNA neosynthesis was assessed in 7 tumors according to the method of Turski et al.(J. Neurochem., 52:1629, 1989) in slices of human astrocytomas within 60 minutes after surgical removal of the tumor. The tissue was exposed to KYN, and KYNA was measured in the medium. Dose-dependent production of KYNA could be demonstrated.

It remains to be elaborated if and to what extent gliomas produce QUIN and KYNA in situ, and how glioma-derived kynurenines may play a role in pathophysiological conditions. Supported by USPHS grant NS 16102.

242.13

ROLE OF GLUTAMINE SYNTHETASE IN GLUTAMATE METABOLISM BY CULTURED ASTROCYTES. S.Farinelli*and W.J.Nicklas (SPON:E.T.Browning). Dept. of Neurology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854.

Glutamine synthetase (GS) catalyzes the amidation of glutamate (GLU) to glutamine (GLN). In the brain, GS has been shown to be localized within the astrocyte where it plays a pivotal role in maintaining the homeostasis of GLU. Previously we and others have shown that the major pathway of GLU metabolism in cultured rat astrocytes favors GLN synthesis and not oxidation. By treating cultures with methionine sulfoximine, an irreversible inhibitor of GS, and allowing the cells to resynthesize new GS enzyme for various periods up to one week, astrocyte cultures were generated with a range of GS activities (0-3.0 μmoles GLN formed/hr/mg protein). These cultures were subsequently used in the study of glutamate metabolism in which incorporation of label from [^{14}C(U)]-GLU into GLN, ASP and deaminated metabolites was quantified. The data suggests that the flux of GLU carbon into GLN is proportional to the amount of GS activity within the astrocyte. The level of GS activity also regulates the steady-state concentration of GLU inside the cell. The results further corroborate the importance of GS in the homeostatic regulation of astrocytic GLU metabolism.

242.14

ANALGESIC EFFECT OF THE GABA UPTAKE INHIBITOR NO-328 (N-(4,4-DI(3-METHYL-2-THIENYL)BUT-3-EN-1-YL)NIPECOTIC ACID). M.J.Sheardown,J.U.Weis,L.J. Knutsen,M.Swedberg and P.D. Suzdak. Dept. of CNS Pharmacology,NOVO Industries and Depts. of Neuropharm. and Behavioral Pharm., Ferrosan, Denmark.

NO-328 has previously been shown to be both a potent inhibitor of ^{3}H-GABA uptake in-vitro (IC_{50} =67 nM),and possess potent anticonvulsant effects in both mice (ED_{50} for inhibiting DMCM induced convulsions=0.8 mg/kg i.p.) and rats (ED_{50} for inhibiting PTZ induced convulsions=6 mg/kg i.p.). The present report examines the analgesic activity of NO-328. Following i.p. administration, NO-328 produced potent analgesic effects in acetic acid writhing (ED_{50}=0.18 mg/kg), hot-plate (ED_{50}= 3.7 mg/kg) and grid-shock tests (ED_{50}=1.75 mg/kg) in mice and Randall Selitto test in rats (ED_{50}= 12 mg/kg).NO-328 also showed analgesic activity following p.o. administration in mice.The analgesic activity of NO-328 was comparable to that of morphine,and superior to that of the GABA agonist THIP.NO-328 does not bind to central opiate receptors,and its analgesic activity is not blocked by naloxone.The analgesic activity of NO-328 in mice chronically treated with either NO-328 or morphine will also be discussed.These data suggest that NO-328 possesses a good analgesic profile in both mice and rats.

242.15

FUNCTIONAL RECONSTITUTION IN PROTEOLIPOSOMES OF PRESYNAPTIC VESICLE GLUTAMATE UPTAKE ACTIVITY P. R. Maycox*, T. Deckwerth* and R. Jahn. Dept. of Neurochem., Max Planck Institute for Psychiatry, Am Klopferspitz 18A, 8033 Planegg-Martinsried, FRG.

Glutamate uptake by presynaptic vesicles is a secondary active process and is dependent on the proton electrochemical potential generated by a Mg-dependent ATPase (NEM-sensitive vacuolar proton-pump) present in the vesicle membrane. The carrier is unique for synaptic vesicles and is clearly distinguishable from the carriers of the plasma membrane and mitochondria. A detailed study of the energy dependence has shown that glutamate uptake is totally dependent on the membrane potential, with no pH component involved. Recently we have reconstituted the ATP-dependent glutamate uptake activity in proteoliposomes. Highly pure synaptic vesicle membranes are dissolved with 1% sodium cholate and after the addition of exogenous lipids the system is reconstituted by dilution directly into the assay buffer. The reconstituted uptake shows all the characteristics of the endogenous system and represents at least 60% of the activity observed in native synaptic vesicles. We have also reconstituted glutamate uptake using the monomeric form of the light-driven bacterial proton-pump, bacteriorhodopsin (BR). The BR monomers are added to the reconstitution mixture, which is diluted into assay buffer lacking ATP. Glutamate uptake activity is detected only when the proteoliposomes are stimulated with light, indicating that BR generates the membrane potential required by the glutamate transporter. This system enables us to dissect the components involved in glutamate uptake and begin fractionation studies in order to purify the glutamate transporter.

242.16

[3H]-DIMETHYLSTAUROSPORINE: A LIGAND TO STUDY THE CATALYTIC DOMAIN OF PROTEIN KINASE C. W. F. Herblin, J. L. Gross*, U. H. Do* and S. Pounds* Medical Products and Dupont-NEN Products Departments, E. I. du Pont de Nemours & Company, Wilmington, DE and Boston, MA.

The microbial alkaloid staurosporine is the most potent and selective inhibitor of PKC thus far described. The interaction of [N,N-dimethyl-3H]staurosporine ([3H]DMS) with PKC was examined using an automated soluble binding assay. Total [3H]DMS binding to mouse brain PKC was stable over a broad pH range and was not dependent on calcium or phospholipid. The binding was high affinity (Kd=3.8 nM), reached equilibrium within 15 min. on ice, was reversible, with a t 1/2 of 69 min. and could be displaced by the PKC catalytic antagonists staurosporine, K252a, and the isoquinoline sulfonamide H-7. Staurosporine and dimethylstaurosporine were equipotent inhibitors of [3H]DMS binding to PKC and of PKC catalytic activity. [3H]DMS bound to the catalytic domain of PKC since high concentrations of phorbol dibutyrate had no inhibitory effect. In addition, rat brain PKC which had been proteolyzed to generate a phospholipid and calcium independent enzyme (PK-M), retained the ability to bind [3H]DMS but not [3H]phorbol dibutyrate. MgATP inhibited [3H]DMS binding to PKC, but only at high concentrations (2.5 mM). At concentrations of 12-50 uM, ATP partially reversed the inhibition of [3H]DMS binding by H-7, suggesting that ATP and H-7 compete with each other, but not at the [3H]DMS binding site. [3H]DMS is thus a useful ligand to study the mechanism of interaction of catalytic inhibitors with PKC.

242.17

ASCORBATE TRANSPORT BY RODENT ASTROGLIAL CELLS. J.X. Wilson*, A. Kulaga*, E.J. Jaworska* and S.J. Dixon* (SPON: J. Kraicer). Dept. of Physiol. and Div. of Oral Biol., Univ. of Western Ontario, London N6A 5C1, Canada.

Uptake of L-ascorbate (vitamin C) by astrocytes was studied in primary cultures prepared from the neopallium of newborn Swiss CD-1 mice or Sprague-Dawley rats. Exposure of cultures to dibutyryl cyclic AMP changed cell morphology from polygonal to stellate and stimulated ascorbate uptake, with the greatest stimulation occurring in mouse astrocytes. Uptake was specific for ascorbate since it was not diminished by the presence of other organic anions including acetate, formate, lactate, malonate, oxalate, p-aminohippurate, pyruvate and succinate. Astroglial ascorbate uptake was Na^+-dependent, but it did not have a specific requirement for external Cl^-. Ascorbate transport was rapidly ($\leq$1 min) and reversibly inhibited by the anion transport inhibitors furosemide, 4-acetamido-4'-isothiocyanostilbene-2,2'-disulfonic acid (SITS) and 4,4'-diisothiocyanostilbene-2,2'-disulfonic acid (DIDS). The rapid and reversible effects of the impermeant inhibitors are consistent with direct inhibition of Na^+-ascorbate cotransporters located in the astroglial plasma membrane.

242.18

CHARACTERIZATION OF THE ATPASES FROM SYNAPTIC VESICLES OF TORPEDO CALIFORNICA. Barry W. Hicks*, Stanley M. Parsons (SPON: R. Refinetti). Dept. of Chemistry, Neuroscience Research Program, Univ. of Calironia, Santa Barbara, CA 93106.

Cholinergic synaptic vesicles from the electric organ of Torpedo Californica contain a V-type and a P-type ATPase. The two ATPase activities can be distinguished by assaying in the absence and presence of vanadate. Using immunobeads coupled to SV2 monoclonal antibody both types of activity can be pelleted. Neither activity is significantly affected by common anions. The P-type has an absolute requirement for magnesium ion over calcium ion whereas the V-type is less specific. The P-type is slightly stimulated by sodium and potassium ions. Both types of activity were examined in the presence of the uncouplers FCCP, nigericin, valinomycin, gramicidin and A23187. Stimulation of the ATPase activities occurred, but at concentrations higher than required to inhibit active transport of acetylcholine. Tributyltin chloride inhibits both activities. Profiles of individual activities versus pH were generally bell shaped between pH 5 and 9 but also showed some heterogeneity. Lineweaver-Burke plots showed biphasicity for both activities. The P-type has an apparent subunit structure similiar to the sodium-potassium ATPase. Western blots of whole synaptic vesicles showed faint staining at 98K, but no cross reactivity with the vesicle P-type ATPase using polyclonal antibodies to sodium-potassium ATPase.

AN IMPROVED INVERTEBRATE SYNAPTOSOMAL PREPARATION WITH CHOLINERGIC PROPERTIES. C. Torrence - Campbell*, S. Sweet*, H. Gates* and J.G. Townsel. Department of Physiology, School of Medicine, Meharry Medical College, Nashville, TN 37208

Our laboratory has previously characterized a high affinity choline uptake system (HAChUS) in **Limulus** tissues (Maleque **et al., Biochem. Pharmac. 28**: 985-990, 1979; Ivy, M. and Townsel, J.G. **Comp. Biochem. Physiol.86(C)**:103-110, 1987) and synaptosomes (Newkirk, R.F. **et al., Comp. Biochem. Physiol. 70(C)**:177 - 184; 1981) We report here on the characterization of the HAChUS in synaptosomes prepared selectively from central nervous system tissues shown to be enriched for presumed cholinergic functions; namely the protocerebrum, corpora pedunculata and abdominal ganglia. Synaptosomes were prepared from these tissues by means of a modification of the subfractionation procedure developed by Dowdall and Whittaker (**J. Neurochem. 20**:921-935, 1973). In our modification, we harvested a PP_2L fraction exclusively from the S_2 fraction. Compared to the P_2L fraction, the PP_2L was approximately four times more efficient in (^3H) choline uptake and was significantly more sensitive to inhibition with micromolar concentrations of hemicholinium -3. The PP_2L fraction HAChUS was shown to have characteristics common to the HAChUS of identified cholinergic tissues. We also report on the kinetic isolation of the HAChUS from the low affinity transport of choline in these synaptosomes. (This project was supported in part by the Surdna Foundation, MBRS Grant RR08037 and the NSF/MRCE Grant 871485.)

PHOSPHATIDYLINOSITOL-SPECIFIC PHOSPHOLIPASE C SENSITIVITY OF ACETYLCHOLINESTERASE FROM THE CENTRAL NERVOUS SYSTEM OF MANDUCA SEXTA. D. J. Prescott* and C. G. MacLean*. (SPON: P. J. Stephens) Dept. of Bio., Bryn Mawr College, Bryn Mawr, PA 19010.

Acetylcholinesterase (AChE) can be extracted from central nervous system tissue of Manduca sexta by buffers containing detergent and 0.5 M NaCl. Approximately 20% of the enzyme is soluble in the absence of these agents, while 0.5 M NaCl alone releases 30 to 40% of total enzyme, and detergent (Triton X-100, 1%) releases 50% of the total enzyme in crude homogenates. Treatment of the crude brain homogenate with phosphatidylinositol-specific phospholipase C (PIPLC) from Bacillus thurengiensis results in substantial (70 to 80%) solubilization of AChE. Greatest response was achieved with PIPLC from Bacillus thurengiensis, while PIPLC from Bacillus cereus and from Trypanosoma brucei have the effectiveness of detergent, solubilizing about half the total AChE activity. Non-denaturing polyacrylamide gel electrophoresis indicates that detergent-isolated AChE, like the AChE which is natively soluble, occurs primarily in two molecular weight forms with residual large forms which do not enter 6% gels. AChE solubilized by B. thurengiensis PIPLC and by B. cereus PIPLC occurs only in one molecular form, corresponding to the lowest molecular weight form of detergent-isolated enzyme indicating that PIPLC treatment abolishes the ability of AChE to aggregate.

Preliminary studies indicate no evidence of autolysis. If an endogenous phospholipase is present either the amount is small or its activity somehow inhibited by tissue homogenization conditions.

The AChE in this invertebrate system demonstrates sensitivity to PIPLC similar to other invertebrate and vertebrate AChE's, thus joining a disparate, growing family of membrane-associated proteins attached to the membrane by covalent bonding to phosphatidylinositol.

ANALYSIS OF TREMOR WITH METHODS OF NONLINEAR DYNAMICS: ATTRACTOR DIMENSIONS. R.J. Elble. Southern Illinois Univ. School of Medicine, Springfield, IL 62794-9230.

Physiologic tremor and essential tremor exhibit irregularities in amplitude and frequency that could be attributed to stochastic noise or to nonlinear dynamics of the neural oscillators that are responsible for tremor. The spatial correlation method of Grassberger and Procaccia (Physica 1983; 9D:189-208) was used to estimate the functional nonlinear complexity (i.e., attractor dimension) of wrist tremor that was recorded from normal adult volunteers and from patients with essential tremor. The attractor dimension of essential tremor was 1.0-1.5 during times of greatest tremor and was 4-6 during times of relative tremor quiescence. Mild essential tremor and physiologic tremor exhibited large amplitude fluctuations, and the attractor dimension was often indeterminate (i.e., indistinguishable from infinity) for these forms of tremor. These results suggest that essential tremor fluctuates between chaotic and limit-cycle modes of oscillation and that essential tremor is most symptomatic when it behaves as a limit-cycle oscillator. By contrast, mild essential tremor and physiologic tremor tend to persist in either a chaotic, stochastic, or nonstationary mode of oscillation. These data are consistent with the notion that essential tremor results from a reduction in the functional degrees of freedom of the involved neural pathways. (Supported by NINDS NS20973).

FRACTALS IN KINESIOLOGY. JB Myklebust, BM Myklebust. Marquette University, College of Engineering, Laboratory of Sensory-Motor Performance, Zablocki VA Medical Center, Medical College of Wisconsin, Milwaukee, WI 53295.

Deviations of the center of pressure during quiet standing have been characterized for normal adults and in aging. These measurements have been used to assess neurological disorders of the vestibular and cerebellar systems, and lesions of the pyramidal and extrapyramidal tracts. The deviations have been quantified in terms of the area encompassed by the deviations of the center of pressure in the X-Y plane, as well as by spectral methods.

A method of characterizing planar curves which has had considerable success is the determination of the fractal dimension, D, of a curve[1]. In this context, D is a measure of the degree to which a curve fills the available space. D is calculated from the equation $D = \log(n)/[\log(n)+\log(d/L)]$; n is the number of connected line segments comprising the curve, d is the planar diameter of the curve (the largest distance between 2 points), and L is the cumulative length of the curve. A straight line has a dimension of 1; a curve which completely fills the space has a dimension of 2 (the Euclidean dimension). A curve which traces over itself multiple times could exceed 2.

Data was collected from 11 normal subjects in good general health ranging in age from 22 to 75 years and from 3 elderly patients with Alzheimer's disease with impairments of gait and stability, by clinical examination. The subjects were asked to stand quietly on a Kistler force plate for 1 minute with eyes open, followed by 1 minute with eyes closed. The 3 forces and 3 moments were sampled at 100 Hz and the positions of the center of pressure were computed. The middle 20 second period was analyzed for each trial. The mean value of D was 2.09 (sd=0.33) for the normal subjects and 1.67 (sd=0.11) for the Alzheimer's patients. These values were significantly different ($p<.03$); no statistical difference was observed between the 5 normal young adult subjects (22-40 yr) and the 6 healthy aging subjects (45-75 yr).

These preliminary studies suggest that measurement of the fractal dimension may be a simple and practical method to assess standing balance and characerize pathology.

SYNCHRONIZING HAND AND FOOT MOVEMENT IN A PROJECTIVE OR REACTIVE MODE: TWO CONTRASTING SCHEDULES OF MOTOR COMMAND. J.Paillard, CNRS-LNF2, Marseilles, C. Bard & M. Fleury, Human Motor Performance Lab., Laval Un., QC, Canada.

The accuracy with which the motor system may achieve temporal goal is surprisingly precise. Earlier study (Paillard 1948), however, showed contrasting motor commands schedules depending on whether the movement is triggered by an external or a self-induced signal. To further evaluate this hypothesis, two experimental conditions were presented. In a reactive condition, subjects were required to react simultaneously with the two hands or with the homolateral hand and foot to an auditive stimulus as quickly as possible. In a projective condition, subjects were instructed to simultaneously self-activate the two hands or the hand and foot. Seven subjects participated to the study. Temporal difference between the two limbs motor response was calculated on each trial (25 trials/condition). In the reactive condition, the hand significantly preceded foot by 30 ms. This delay corresponds to the difference observed in the reaction time of the two limbs when measured independently. Such a result reflects the observed difference in the efferent pathways conduction time assuming a quasi-simultaneous activation of the descending pathways at the central level. However, in the projective condition the serial order paradoxically inverted. Indeed, the foot preceded hand initiation by 20 ms, as if the temporal target used for scheduling the onset of the two motor commands was the synchronous return to the cortex of the reafferent information generated by each movement initiation. The results support the assumption that commands for goal-directed movement (temporal goal) are planned, organized and scheduled in accordance with the anticipated sensory consequences of the action. Fast reactions to an external signal, result from a direct synchronous motor commands coactivation.

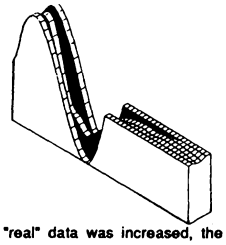
SENSORIMOTOR TRANSFORMATIONS FOR ARM MOVEMENTS: SERIAL AND PARALLEL PROCESSES. J.F.Soechting, M.Flanders and S.I.Tillery*. Department of Physiology, University of Minnesota, Minneapolis, MN 55455.

We have used errors in pointing movements to gain insight into the processes whereby visual information about target location is transformed into a representation of joint angles.

We asked subjects to make movements in the absence of possible visual corrections, that is to point to the remembered location of the target or to match the target's direction. Based on the results of a variety of such experiments we suggest that information about target location undergoes at least two serial transformations. Initially, target location is represented in a retinotopic frame of reference. It is then transformed into a shoulder-centered representation in terms of distance and direction of the target relative to the shoulder. A second transformation is used to compute orientation angles of the shoulder and elbow which would correspond to target location in shoulder-centered coordinates.

These two serial transformations also involve parallel processes. Target distance and direction (azimuth and elevation) appear to be represented separately. Target distance and elevation are used to compute joint elevation while, in parallel, target azimuth is used to compute the joints' yaw angles.

243.5



DONDER'S AND LISTING'S LAW FOR REACHING AND GRASPING ARM SYNERGIES. K. Hepp and M.-C. Hepp-Reymond, Physics Dept., ETHZ and Brain Research Institute, University of Zurich, Switzerland

In a large part of its workspace the arm has 4 rotatory degrees of freedom: 3 at the shoulder and 1 at the elbow joint. For pointing or grasping movements the grip (g) and elbow (e) vector from the shoulder defines as torsion (t) the rotation of the g-e plane around g. As for the eye, Donder's law requires t to depend only on g and Listing's law predicts that all rotations of the g-e plane from a forward reference position should have their axes in a fixed plane. We have investigated these hypotheses in 7 healthy humans. The subjects, lying on the floor to fixate the shoulder, had to reach or grasp targets in various positions of the workspace, in which scapula movements could be neglected. The starting position was varied systematically. For a fixed task Donder's law is violated in rapid unconstrained movements with a "hysteresis" which varies systematically in well-coordinated subjects. The influence of the starting position on the torsion of the arm can be "erased" by requiring a spiraling approach. In this case Donder's law holds with small fluctuations around a curved surface of rotation (quaternion) vectors through which a Listing plane can be fitted with an error of 5° to 10° standard deviation. This plane is tilted mostly downward up to 30° relative to the foreward position and varies for different subjects and experimental days. These arm synergies in repetitive pointing and grasping movements allow to interprete findings by Georgopoulos et al. (1988) of a directional representation in 3-D space in the firing patterns of motor cortical neuron populations.

IDENTIFYING MOVEMENT CORRECTIONS BY FORECASTING. A.M.Wing*, J.Wann*, I.Nimmo-Smith*, E.Miller* and B.Abernethy*, (SPON: D.Kennedy). MRC Applied Psychology Unit and Addenbrookes Hospital, Cambridge, CB2 2EF, UK and U Queensland, Australia.

To determine the nature of corrective adjustments during rapid positioning movements, a technique for identifying their presence and timing is required. We propose a method in which the time-course of a kinematic variable for an individual trial is evaluated using a forecasting approach. Data for hand movements to a target 20-cm in front of the body were obtained using an accelerometer. Acceleration waveforms for control trials were described by a mean and covariance matrix for the coefficients of a third-order polynomial consistent with a minimum jerk criterion. Illustrative data from a trial with an unexpected change in target position (that required the subject to increase movement amplitude) may be seen to diverge from flanking cubic polynomials. Cubic polynomials were fit to progressively increasing proportions of the acceleration waveform of individual trials. Fitting was constrained by using an estimate for the "missing" end portion based on control trial coefficients, ie a "forecast". As the proportion of "real" data was increased, the behaviour of the coefficients and of the residuals from the forecast was diagnostic of corrective adjustment to movement.

243.7

EFFECT OF IMPOSED AUDITORY RHYTHMS ON HUMAN INTERLIMB COORDINATION. Z. Beheshti and J.R. Higgins.* Teachers College, Columbia University, N.Y., N.Y. 10027.

We investigated the effect of imposed auditory rhythms on the coordination of rhythmic upper and lower limb movements. Seven seated subjects performed clapping and alternate foot tapping in 3 sessions. Data were collected on period, variability and phase-linkage of clap and foot tap cycles. In session 1 (control), when subjects performed at their preferred rate, 43% exhibited tight phase-linkage of the clap and foot tap cycles, while 57% manifested loose phase-linkage. In session 2, subjects foot tapped with the metronome (1, 2, 3 & 4Hz), while clapping at the preferred rate. In session 3, subjects clapped with the metronome and foot tapped at preferred rate. The results of sessions 2 and 3 indicated that both tight and loose phase-linked subjects retained their preferred rate phase-linkage, suggesting that externally-paced or self-paced rhythmic limb movements may be coordinated in a similar fashion. Our findings also suggest that interlimb coordination may be controlled in a manner similar to that of coupled oscillators.

243.8

DYNAMIC JOINT STIFFNESS VARIES SYSTEMATICALLY WITH THE PATTERN OF BIMANUAL COORDINATION DURING THE SAME MOTOR TASK. J. P. Scholz, School of Life & Health Sci., Univ. of Delaware, Newark, DE 19716.

A preliminary study of the neurophysiological correlates of differences in coordinative pattern stability, often associated with movement pattern transitions, is described. Dynamic stiffness of the second metacarpo-phalangeal joint (MCPJ) was measured to test the hypothesis that joint stiffness would be lower when moving in a more stable in-phase than in a less stable anti-phase coordination pattern (Kelso, J. A. S, et al., Physica Scr., 35:79, 1987). Subjects (N=3) placed their index fingers into two manipulanda and performed alternating in-phase or anti-phase flexion/extension movements. Movement frequency was increased from 1-2 Hz in 0.2 Hz steps using a metronome. A 75 Ncm torque was delivered randomly to extend the right MCPJ during flexion. Stiffness was estimated by dividing torque magnitude by the amplitude of finger displacement from torque onset to offset (50 ms). MCPJ stiffness was significantly ($p<.0001$) greater in the anti-phase (K=145.5 Ncm/rad) than in the in-phase (K=124 Ncm/rad) pattern for all frequencies studied. Results suggest that differences in coordinative pattern stability are associated with systematic differnces in the mechanical properties of the movement components.

IS HUMAN ARM TRAJECTORY FORMATION SIMPLIFIED BY VISCO-ELASTIC TUNING? S. A. Ellias* (SPON: H. B. Stanton). Mass. Gen. Hosp. & Dept. of Brain & Cognitive Sci., MIT, Cambridge, MA 02139.

A major issue in the study of human arm movements is how to generate multi-joint movements. Many investigators have suggested that multi-joint movements are obtained by using the net elastic (or stiffness) properties of the human arm, and not by solving the complete inverse dynamics problem. Experiments on multi-joint arm posture have demonstrated invariant spatial properties of the stiffness measured at the hand both at rest and under external loads (Mussa-Ivaldi, et al., 1985, 1987). Recently, a model assuming compliant motion about a *virtual* trajectory and incorporating these invariant stiffness properties has predicted the form of human planar arm movements (Flash, 1987).

The objective of the present computational study was to examine how the relationship between arm visco-elastic properties and inertia could influence trajectory formation. Simulations of planar arm movements were conducted using a model governed by visco-elastic properties and a *virtual* trajectory. The stiffness was systematically altered from the values measured in humans. The viscosity was either covariant or varied independently. The multi-joint arm inertia was computed along the arm paths.

The results of this study indicate that 1) visco-elastic values which mimic the invariant static stiffness properties measured in humans create better tracking of the *virtual* trajectory while using less stiffness; 2) these same values of stiffness appear to match inertial factors: i.e., they minimize some differences between the multi-joint inertia and stiffness when averaged over many paths in workspace. Thus, if particular visco-elastic properties during motion resemble those measured at rest, trajectory control is simpler. This suggests definite functional advantages of neuro-muscular visco-elastic tuning for the execution of movement. This work is supported by NIH Grants K07-NS00883 and NS09343.

PATTERN FORMATION IN A MULTISTABLE COORDINATIVE SYSTEM. J.J. Jeka and J.A.S. Kelso (SPON: A.J. Nash). Center for Complex Systems and Department of Psychology, Florida Atlantic University, Boca Raton, FL 33431.

We study the coordination among multiple, anatomically different components and their (multistable) patterns within the context of dynamic pattern theory which uses the concepts and tools of nonlinear dynamical systems (especially Haken's [1983] synergetics) as an operational framework for understanding coordinated behavior at several levels of description (e.g. Kelso, Schoner, Scholz and Haken, Physica Scripta, 35:79, 1987; Schoner and Kelso, Science, 239:1513, 1988).

An apparatus specifically designed for this purpose, allows us to measure the kinematics of (up to) four rhythmically moving limbs in the sagittal plane of a seated subject. Frequency of motion is increased by an auditory metronome to which the subject must synchronize his/her actions. Patterns are differentiated by qualitative changes in behavior, observed through the collective variable, relative phase. Several different phase transition phenomena were discovered in a set of four experiments: 1) When the system is prepared in the D mode (i.e., an arm and a leg cycling in Different directions) and frequency is increased, a spontaneous switch to the S mode (i.e., an arm and a leg cycling in the Same direction) occurs at a critical frequency. However, no such transition occurs when the system is prepared in the S mode; 2) At higher frequencies, further spontaneous transitions are observed to a variety of frequency- and phase-locked states, that can be quantitatively differentiated by their stability; 3) The time taken to *intentionally* switch from one 4-limb pattern to another is demonstrated to depend upon the relative stability of the different patterns, opening the way to experimentally explore switching routes among multiple attractors. These results may be understood in terms of dynamic pattern theory and its recent extensions to multi-component (>2) coordination.

243.11

SPATIALLY DEPENDENT PHASE TRANSITIONS IN SINGLE MULTI-JOINT LIMB MOVEMENTS. S.A. Wallace[1], J.J. Buchanan, and J.A.S. Kelso (SPON: I.B. Johanson). Program in Complex Systems and Brain Science, Center for Complex Systems, Florida Atlantic Univ., Boca Raton, FL 33431, and Department of Kinesiology, Univ. of Colorado-Boulder[1].

The coordination of multiple joints within a single limb was examined within the theoretical context of nonlinear dynamical systems. Six human subjects simultaneously flexed and extended the elbow and wrist joints of the right arm in synchrony with a metronome under the following conditions: 1) elbow flexion with wrist flexion and vice versa; and 2) elbow flexion with wrist extension and vice versa. Subjects began each trial with the forearm pronated or supinated under instructions to maintain synchrony among the joints for as long as comfortably possible as metronome frequency increased. With the forearm supinated, transitions from the elbow flexion-wrist extension pattern to the flexion-flexion pattern were observed as frequency of oscillation increased, accompanied by enhancement of fluctuations in the relative phasing between the joints. Fewer transitions in the pronated elbow flexion-wrist flexion pattern occurred, but phase fluctuations were greatly amplified relative to the pronated elbow flexion-wrist extension condition. To assess possible inertial contributions to these transitions, two subjects performed the supinated elbow flexion-wrist flexion and pronated elbow flexion-wrist extension patterns with a 'relaxed' wrist. Resultant kinematic and EMG data suggest that the transitions are neurally based and not due to inertial coupling alone. Switching between behavioral patterns within a single limb (as in multi-limb coordination) can be understood in detail as a nonequilibrium phase transition of the collective variable (relative phase). The stability of elbow and wrist joint patterns is dependent upon the spatial orientation of the forearm, and not upon the underlying muscle pairing across the relevant joints.

243.12

CYCLIC VOLUNTARY MOTION: KINEMATIC SMOOTHNESS. R. N. Stiles. Dept. Physiol. and Biophysics, Univ. Tenn., Memphis, Memphis, TN 38163.

While considered in terms of minimum-jerk, smoothness of rhythmic motion may be better considered in terms of compactness of its spectrum (Bracewell, R., The Fourier Transform and Its Applications. McGraw-Hill, 1965), with a single sinusoid being maximally smooth. On this basis, smoothness of self-paced, cyclic motion was analyzed in the frequency domain for hand, finger, forearm, and jaw. Each subject was asked to oscillate the body part in a smooth fashion without pauses, at a frequency between 1-7 Hz. Acceleration records were digitized at 64/s. For intended frequencies of 1-2 Hz, calculated displacement records appeared maximally smooth, while acceleration spectra indicated higher, usually odd, harmonics of the intended frequency, as well as a tremor. The tremor frequency typically was at, or near, one of the higher odd harmonics. Jaw motion was the least smooth, with several odd (and certain even) harmonics. Higher harmonics reflect biphasic acceleration pulses that followed brief pauses near the peak positions, indicating quick start-ups of this sinusoidal motion following such pauses.

243.13

ORGANIZING PRINCIPLES FOR SINGLE JOINT MOVEMENTS: THE SPEED-INSENSITIVE STRATEGY AS DEFAULT. D. M. Corcos, G.L.Gottlieb, G. C. Agarwal and M.L.Latash. University of Illinois at Chicago, IL 60680 and Rush-Presbyterian-St. Luke's Medical Center, Chicago, IL 60612.

The dual-strategy hypothesis of motor control suggests that certain classes of movement are controlled by regulating the duration of an "excitation pulse" to the motoneuron pool. The defining characteristic of such movements is that the task can be made at any speed and as such are "speed insensitive". Other classes of movements are generated by regulating the intensity of the excitation pulse and are classified as "speed sensitive". Examples of such movements are those that must be generated in a specific movement time. One interpretation of the speed-insensitive strategy is that it is a control strategy that is only employed for movements which are made at maximal performance levels and that duration increases because intensity is at a maximum. Another interpretation is that duration can be regulated across a wide variety of intensity values. To differentiate these two possible interpretations, human subjects made discrete elbow flexions in a horizontal plane over different distances, from a stationary initial position to a visually defined stationary target, 9° wide. We measured joint angle, acceleration and electromyograms from two agonist and two antagonist muscles. Subjects made movements over four different distances following one of four different instructions. The instructions produced a wide range of movement velocities. The initial rise of the inertial torque and consequently of the acceleration, as well as the initial slope of the agonist EMG, were all invariant over changes in the target distance for any single instruction. These results are interpreted to suggest that the speed-insensitive strategy chooses the intensity of motoneuron excitation and uses the duration of excitation as the primary control variable to adjust muscle forces to a level sufficient to accomplish the movement task. The results demonstrate that the uniform intensity of the excitation pulse is not a by-product of moving at maximal speed but is a selected feature of the pattern of movement control. (Supported by NIH grants AR 33189 and NS 23593)

243.14

EFFECT OF LOCALIZED FATIGUE ON COORDINATION PATTERN INVARIANCE AS DEFINED BY THE HOMOGENOUS ELEMENTS MODEL. T. B. Hoshizaki*, V. Vardaxis*, A. Matsuo*, and T. Fukunaga* (SPON:P Gardiner) Biomechanics Laboratory McGill University, Montreal, Quebec, Canada and University of Tokyo, Tokyo, Japan.

Movement pattern and underlying strategies employed for their optimization have been shown to be influenced by muscle properties or neural circuitry (Stein, Oguztoreli & Capaday, Human Muscle Power, 1982). While human movements may be consciously optimized the characteristics of the movements in part reflect the properties of the motors used and their limitations (Brady, Hollerback, Johnson, Lozano-Perez & Mason, MIT Press, 1982). Therefore the purpose of this study was to investigate changes in movement patterns in response to a muscle specific, fatigue stimulus. Five sprinters were required to perform a maximal velocity sprint under the following three conditions control (no fatigue), quadriceps fatigue and hamstring fatigue (60% of max.). Movement patterns were analyzed using inverse Newtonian equations to calculate power flow at the hip and knee joints during the recovery portions of the sprint stride (Robertson & Winter, J. of Biomech. 13: 845-854, 1980). This information was then used to develop a homogenous elements model for identification of the functional elements (Hoshizaki and Vardaxis, Proceedings Canadian Biomech. Society, 1988.) Analysis of the data identified five distinct phases at the hip and seven at the knee joint. The phase components remained invariant when comparing the three levels of the muscle condition supporting the existance of a generalized pattern. However significant differences were observed when the duration of each phase was compared across fatigue conditions.

243.15

HUMAN POSTURAL SYNERGIES: A GEOMETRIC ANALYSIS M.F. Gordon and F.E. Zajac. Rehab. Res. & Dev. Ctr. (153), VA Medical Center, Palo Alto, CA 94304, and Mechanical Engineering Dept., Design Division, Stanford University, Stanford, CA 94305-4021.

It is hypothesized that human upright posture is maintained using combinations of only a few stereotyped responses, called synergies. If the same synergy, appropriately scaled, were used for both strong and weak disturbances, CNS control could be further simplified. Therefore, we hypothesize that synergies activate muscles necessary for maximal acceleration of the body; thus, we propose that sub-maximal and maximal responses activate the same sets of muscles with a similar relative activation pattern. Our computational methodology finds all the maximal-acceleration synergies that correspond to a particular perturbation. We believe the identification of such synergies provides insight into the neural control of posture, and is also useful in the design of functional neuromuscular stimulation systems for paraplegics.

We modeled standing posture with sagittal-plane motion about the ankle and hip joints. For a given postural perturbation, possible body accelerations were points in the hip-ankle acceleration plane. Body acceleration was limited by finite muscle strengths, and by requirements that the feet remain flat and on the ground. When graphed in the hip-ankle plane, the feet constraints defined a V-shaped (open) region, and finite muscle strengths defined a closed polygon. Thus, possible body acceleration were those within the intersection of these regions. All synergies along the boundary of the muscle-strength polygon were identified. For any desired ratio of ankle and hip accelerations, a direction in the hip-ankle plane was specified. Maximal body acceleration and the corresponding synergy could then be determined graphically. Supported by the Veterans Administration and NIH grant NS 177662.

243.16

A SOLUTION FOR THE PROBLEM OF MULTI-JOINT MOVEMENT REDUNDANCY BY MINIMIZING JOINT ANGLE INCREMENTS. S.R.Gulman*, G.L.Gottlieb (SPON: G.Agarwal) Rush-Presbyterian-St. Luke's Medical Center, Chicago, IL 60612

The problem of redundancy of the motor control system requires imposing additional constraints for specifying parameters. Different constraints have been introduced in models of multi-joint movements, explicit (Mussa Ivaldi et al, *Biol. Cyber.* 1988) or implicit (Berkinblit et al, *Biofizika* 1986.). Here we suggest a solution for the redundancy problem by minimizing the sum of the joint angle increments during a movement. This leads to the following expression:

$$dp=J^*(JJ^*)^{-1}dx,$$

where J is a Jacobian matrix of the mapping of parametrical space W (with coordinates p, corresponding to joint angles) into the physical space V (with coordinates x).

In spite of the simplicity of this equation, the simulated behavior of the multi-joint limb demonstrates some features similar to those of real movements. This behavior has been modeled on a computer, using some additional assumptions concerning real movement tactics.

Computer simulation give the following results:

1. Postur and movement are both accompanied by oscillation of the working point resembling the tremor.
2. The working point of the limb can track any trajectory in V with some relative accuracy.
3. Cyclic reproduction of a given trajactory leads to variable actual trajectories in both the V and W with much higher variability in W.
4. Modifying the model parameters leads to movements of different accuracy and speed.
5. Joint fixation may not prevent a task execution although accuracy can suffer.

The study was supported in part by NIH grant AR 33189.

243.17

EXPLOITING DEGREES OF FREEDOM IN A BIARTICULAR PHASE-TRANSITION. P. V. McDonald*, and R. E. A. van Emmerik*. (SPON:E. Donchin). Department of Kinesiology, University of Illinois at Urbana-Champaign, Urbana, IL 61801

A phase-transition was examined occurring in a multi-segmental, bimanual drawing task. Although similar transitions have been modeled in terms of a 2nd order phase-transition (Haken, Kelso & Bunz, 1985) little attention has been paid to the exploitation of available degrees of freedom as the control parameter is varied. Subjects drew circular patterns with both limbs, starting in an out-of-phase mode involving nonhomologous muscle groups (both circles are drawn in the same direction). Increasing the frequency of movement resulted in a dramatic transition to an in-phase mode where one limb changed direction of movement, resulting in homologous muscle action. We report on the relationship between differences in the utilization of available degrees of freedom in the dominant and non-dominant limbs. Specifically, the impact this has on the order parameter (relative phase) dynamics before, during and after the phase transition. These results are considered in light of the physical theory of phase transitions in which common behavioral patterns are observed at many different scales of length as the critical point is approached (Wilson, 1971).

243.18

A MATHEMATICAL SIMULATION OF NEURAL CONTROL IN A MOTONEURON POOL. J.A.Hodgson*, A.Garfinkel*, R.R.Roy, R.G.Gregor and V.R.Edgerton. (SPON: R.F. Zernicke) Department of Kinesiology and Brain Research Institute, UCLA, Los Angeles, CA 90024.

A mathematical model of a motoneuron pool was created to investigate changes of motoneuron activity patterns in response to activity in Renshaw cells and in pathways found to reverse normal recruitment order (e.g. Rubrospinal pathway in cats). The input-output characteristics of the pool were tested by computer simulation. Results show that combinations of activities in several pathways generate a broader range of responses than is possible with activity in a single path. The results indicated mechanisms which may be responsible for the reduction of motor unit firing rate with increased recruitment and changes in the relative activities of slow and fast muscles in movements at different speeds. Renshaw cells may reduce the 'gain' of active neurons as excitation to the pool increases, limiting firing rates of excitable motoneurons by a mechanism intrinsic to the motoneuron pool. Pathways which in isolation reverse the normal order of motoneuron recruitment may be used to adjust threshold and gain of motoneurons, modifying their response to the Size Principle. Such pathways, peripheral or central may be used to 'set up' a motoneuron pool in preparation for activity in addition to modifying responses once activity begins. This provides a mechanism where properties of a motoneuron pool may be modified by other areas of the nervous system in anticipation of an activity rather than relying on mechanisms responding to motoneuron activity after movement has been initiated. SUPPORTED BY NIH GRANT NS 16333.

APPLICATION OF THE BACKPROPAGATION MODEL TO THE MUSCLE EMG TO TORQUE RELATION OF THE ANKLE JOINT UNDER ISOMETRIC, SUPINE CONDITION. L.M.Kent[1], A.Guez[2] and W. Freedman*[1,2] (SPON: J.P.Walsh). [1]Dept of Biomedical Engineering and [2]Dept of Electrical Engineering, Drexel University, Philadelphia, PA 19104.

The application of a neural network approach to solution of the muscle EMG -joint torque relation in the ankle joint under isometric, supine conditions is addressed in this study. The backpropagation neural network model (BEP) was used in this analysis. The experiment was performed at the FNS laboratory of the Philadelphia Unit of Shriners Hospitals. A KinCom Robotic Dynamometer, 6 surface electrodes, EMG amplifier system, and MicroVax II minicomputer were utilized. Six sites of muscle activity, monitoring the agonist/antagonist muscle activity about the ankle joint, were recorded on the subject's leg. The BEP was trained by being shown examples of the muscle EMG signals (full-wave rectified, bandpass filtered (100-1000 Hz)) and joint torque at many discrete torque levels (ranging from -1200 (plantarflexion) through +1000 (dorsiflexion) N-m)). The training signal was repeatedly presented to the network until the error between the calculated model torque and measured torque was minimized (<5%). The calculated and desired outputs were normalized between -0.9 and +0.9. The inputs were not scaled and ranged in value from 0 through 8.0 V. The architecture of the BEP, the learning rate and momentum were important parameters for prediction of torque. The relation between the muscle signals and joint torque is embedded within the trained network; i.e., within the hidden units and connections (weights). The muscle signals applied to the trained network may be considered the "intent" of the system, while the joint torque predicted is the "controlled" variable. It is expected that neural network models may be incorporated into controllers of intent recognition systems such as in functional electrical stimulators, myoelectric control of prosthetic devices, and robotic applications.

SIMULATION OF GOAL-DRIVEN BEHAVIOR LEARNED BY EXPERIENCE IN A NEURAL NETWORK MODELLING CEREBRUM AND CEREBELLUM, **A. de Callataÿ***, *IBM IEC, La Hulpe, B-1310 Belgium*

A computer simulation has shown the feasibility of a robot controller (brain model) learning to reach a target with an android arm. A sensation, e.g. a body position, is neurally *represented* when its activity in a CNS layer is created in another way. This representation is an *intention* (a problem) when the body movements needed to reproduce this sensation can be generated from it. The robot's behavior is controlled by two cognitivist formulas: *1) "stimulus & context → intention."* Any intention can be tried and the best ones are adaptively learned by perceptrons in basal ganglia. *2) "intention → action."* The action solving the goal is deduced from the most similar invariant rules (repeatable events) redundantly stored in the cerebral cortex after each action: *"a sensation S is followed by a sensation I* (a potential intention) *after an interval T (e.g. 260 ms) when a command M is applied."* The initial muscle contraction M is subsequently counteracted by a command of a fast servo-mechanism (located in the cerebellar internal nuclei) to prevent the vertebrate's serious risks of breaking joints or losing equilibrium. To offset the delay of the feedback signal, the cerebellar cortex predicts the limb position, using the rules redundantly stored, when known, after each event: *"when a command C is given with the limb in position A, it goes into a state B after a time V (e.g. 130ms)."* The neural mapping predicts unlikely physiological functions such as *"epilepsy as memory model"* (Goddard, 1969) and dendritic spine resorption (A. de Callataÿ, 1986, *Natural and Artificial Intelligence: Processor Systems Compared to the Human Brain*. North-Holland, Elsevier).

LESIONS OF THE RAT POSTSUBICULUM IMPAIR PERFORMANCE ON SPATIAL TASKS. J.S. Taube, J.P. Kesslak, and C.W. Cotman. Department of Psychobiology, University of California, Irvine, CA 92717.

Previous studies have identified a population of neurons in the post-subiculum which discharge as a function of the rat's head direction in the horizontal plane, independent of the animal's location and on-going behavior (Taube et al., Neurosci. Abstr. 13:1332). The directional selectivity of these cells suggests that they may be critical components of a neural network mediating spatial abilities. To assess the contribution of these cells to learning and memory, we tested male Long-Evans rats in a variety of spatial and non-spatial tasks following bilateral electrolytic lesions of the postsubiculum.

The performance of animals on an 8 arm radial maze was evaluated on the basis of the percentage of correct arms entered (number of arms correct/total arms entered). Compared to unlesioned control animals, lesioned animals were impaired on the 8 arm maze, although they improved over the course of the experiment. Animals were then evaluated in the Morris water maze task where the platform location was fixed and the animal's entry into the tank was randomly varied over 28 trials. Preliminary results suggest that animals with complete postsubicular lesions showed longer escape latencies compared to controls, although they showed improvement over the course of the experiment. Lesioned animals were unimpaired in a cued version of the water maze task when the platform was marked with a small flag and moved around to different locations. In a conditioned taste aversion paradigm, no difference was observed in the performance of lesioned animals compared to controls. All postsubicular lesioned animals showed significant hyperactivity in an open field apparatus throughout the series of experiments.

These results suggest that the postsubiculum may play a role in behavioral tasks involving the utilization of spatial information.
